(1910-1994)

# Preface

It is with great pleasure we offer the second edition of “Doppler Ultrasound in Obstetrics and Gynecology” to our readers. We remain deeply appreciative of the success of the first edition with its continuing enthusiastic reception from our readers.

Impressive advances have occurred in diagnostic Doppler sonography since the publication of the first edition of the book. With the ever-increasing emphasis on evidence-based medicine, the clinical applications of fetal Doppler ultrasound have become progressively more refined, although significant uncertainty still continues in many areas, providing opportunities for future investigations. Ultrasound technology and instrumentation have become increasingly more sophisticated and user friendly. Exciting technological innovations and breakthroughs, such as the emergence of real-time three-dimensional sonography, are offering huge potentials for Doppler assessment of the cardiovascular system. These advances have provided a powerful rationale for bringing the book up to date so that it may continue to serve our readers in the future. In this process, we have comprehensively and critically examined the information contained in the first edition, and revised and expanded it as deemed appropriate.

The second edition now boasts 40 chapters, expanded from 34 chapters in the previous edition. This results from the inclusion of eight new chapters and condensation of three gynecology chapters into one. In addition, there have been substantial revisions of the other preexisting chapters. To give the readers an overall sense of the contents, these changes are summarized here. The introductory chapters continue to deal with the basic principles of Doppler sonography, hemodynamics, fetal and maternal cardiovascular physiology, and biosafety and have been extensively revised. We have added two new chapters, one reviewing the venous hemodynamics and the other dealing with three-dimensional color and power Doppler ultrasound. The subsequent chapters have been significantly strengthened by the addition of with six new chapters dealing with the following topics: intrauterine blood flow; postnatal neurological development; clinical application of cerebral Doppler sonography; Doppler ultrasound examinations of the fetal coronary circulation, the umbilical venous flow, and the fetal pulmonary venous cir-

ulation; four-dimensional B-mode and color Doppler fetal echocardiography; and three-dimensional Doppler sonography in gynecology. The three previous separate chapters on Doppler ultrasound for benign gynecological disorders, ectopic pregnancy, and infertility have been combined into one single more cohesive and concise chapter. After implementation of these additions and revisions, the book now has 521 illustrations and 112 tables. Moreover, all the illustrations including the color plates are now incorporated in the text, which should significantly improve the ease of perusal for our readers.

In this complex and extensive endeavor, we have been greatly assisted by internationally recognized experts in the field who have generously and enthusiastically participated in this venture despite their enormous responsibilities and hectic schedules. I am truly obliged to my colleagues who were instrumental in making the first edition a success and who have updated their chapters for the second edition to reflect the changes that have developed in their areas of expertise. I am particularly indebted to those authors who, in addition to updating their chapters from the first edition, have kindly contributed new chapters. I take this opportunity to welcome the 23 new authors who have substantially contributed to enriching this edition. As well as those authors who have added new chapters to the book, several of the new authors have rewritten and updated chapters from the first edition. I am truly grateful to Dr. Ivica Zalud for his professional and editorial assistance in reorganizing and updating the chapters on gynecological Doppler ultrasound. I remain forever indebted to all my distinguished colleagues not only for their support in making this second edition a reality but also for their scholarly activities that continue to energize the progress in this field.

Finally, all our efforts will be worthwhile if our readers find this new edition of the book useful and stimulating for their education and clinical practice. It would be especially gratifying if the contents inspire and assist new investigations that make further progress in the development of Doppler sonography with the aim of improving women's health.

Summer 2005

Dev Maulik

# Acknowledgements

I would like to express my gratitude to Springer-Verlag GmbH & Co., Heidelberg, for the publication of this book, and in particular Dr. Ute Heilmann, Executive Editor Clinical Medicine at Springer-Verlag, for her enthusiastic support and for facilitating the completion of this second edition and Wilma McHugh, Medical Desk Editor, for her help in production work. I would also like to express my sincere thanks to Wendie Irving, my editorial assistant at Winthrop-

University Hospital, for her invaluable assistance and tireless dedication in the preparation of this book.

Finally, most of my activities related to this project occurred in the evenings and the weekends at home. I am deeply appreciative and thankful to my wife Shibani and our children, Devika and Daves, for their encouragement and support during this long process.

# Doppler Sonography: A Brief History

Dev Maulik

The origins of modern medical technology may be traced to nineteenth-century Europe, when the industrial revolution ushered in sweeping changes in every aspect of life. Of all the momentous discoveries and inventions of this period, there was one relatively obscure scientific event that laid the foundation for the subsequent development of Doppler technologies in the twentieth century – the discovery of a natural phenomenon that came to be known as the Doppler effect. Another critical event was the discovery of the piezoelectric phenomenon by Pierre Curie and Jacques Curie, which enabled the development of ultrasonic transducers many decades later. This chapter briefly describes the origin of the Doppler theory during the nineteenth century and traces the development of diagnostic Doppler ultrasound technology during the second half of the twentieth century to the present.

## Christian Andreas Doppler and the Doppler Theory

The *Doppler effect* is defined as the observed changes in the frequency of transmitted waves when relative motion exists between the source of the wave and an observer. The frequency increases when the source and the observer move closer and decreases when they move apart. The phenomenon bears the name of its discoverer, Christian Andreas Doppler, an Austrian mathematician and physicist (Fig. 1.1), born to Johann Evangelist and Therese Doppler on November 29, 1803 in Salzburg, Austria. The house in which he was born and raised still stands across the square from the family home of Wolfgang Amadeus Mozart in the Markart Platz. For nearly a century Doppler's Christian name has been consistently misquoted in the literature as Johann Christian. Doppler was baptized on the day of his birth at the Church of St. Andra, which was originally in close proximity of the Doppler home. Eden [1] conducted a thorough search for Doppler's birth and baptismal records and found them still preserved in the Church of St. Andra, which had moved to a new location in Salzburg in 1898. These documents conclusively established that Doppler had been christened Christian Andreas. It

appears, however, that Doppler never used his second name.

Doppler's father, a master stone mason, was a man of wealth and fame. Because of frail health Doppler was sent to school instead of joining the family trade. In 1822 Johann Doppler requested that Simon Stampfer, a professor at the local Lyceum, evaluate his son's aptitude. Stampfer was impressed with young Christian's scholastic abilities in mathematics and science,

**Fig. 1.1.** Christian Andreas Doppler. The oil painting was done by an unidentified artist probably at the time of Doppler's marriage in 1836. The original is in the Austrian Academy of Sciences to whom it was donated by Mathilda von Flugl, the great granddaughter of Christian Doppler. (Reprinted from [1], with permission)

**Fig. 1.2.** Title page of Christian Doppler's paper titled "On the Coloured Light of the Double Stars and Certain Other Stars of the Heavens." (Reprinted from [1], with permission)

and at his recommendation Doppler was sent to the Polytechnic Institute of Vienna for further education.

Doppler studied mathematics and physics in Vienna for 3 years and then returned to Salzburg where he concluded his education and eventually graduated in 1829. For 4 years he held the position of assistant in higher mathematics at the Vienna Polytechnic Institute. Following this assistantship he experienced difficulty finding an appropriate position, and in 1835 he seriously considered emigrating to the United States. At this point, however, he was offered and accepted the position of Professor of Elementary Mathematics and Commercial Accounting at the State Secondary School in Prague. The following year he was also appointed Supplementary Professor of Higher Mathematics at the Technical Institute in Prague. In 1841 Christian Doppler became a full Professor of Mathematics and Practical Geometry at the latter institution. One year later, on May 25, he presented his landmark paper on the Doppler effect at a meeting of the Natural Sciences Section of the Royal Bohemian

Society of Sciences in Prague. Ironically, there were only five people and a transcriber in the audience. The paper was entitled "On the Colored Light of the Double Stars and Certain Other Stars of the Heavens" (Fig. 1.2) and was published in 1843 in the Proceedings of the society [2]. Of 51 papers Doppler published, this one was destined to bring him lasting recognition.

Doppler's work was based on the theory of the aberration of light developed by Edmund Bradley, the eighteenth-century British Astronomer Royal. Doppler established the principle of frequency shift and developed the formula for calculating the velocity from the shift. For elucidating the theoretic background of the principle, Doppler used various analogies and examples primarily based on transmission of light and sound. Although his examples of sound transmission were correct, those involving light transmission were erroneous, as he presumed that all stars emitted only pure white light. He postulated that the color of a star was caused by the relative motions of the star and the

earth causing apparent spectral shifts of the emitted white light. The spectrum would shift toward blue if the star approached the earth; conversely, the spectrum would shift to red if the star receded away from the earth. When describing these phenomena Doppler did not take into account preexisting research on light transmission and spectrum. Herschel [3] had already discovered infrared radiation, and Ritter [4] had described ultraviolet radiation; but it appears that Doppler was unaware of these important developments.

## Verification of Doppler's Theory

As was to be expected, the paper generated critical responses. The most significant challenge came from a young Dutch scientist working at the University of Utrecht in Holland, Christoph Hendrik Diederik Buys Ballot (Fig. 1.3). In 1844 Buys Ballot proposed to refute the Doppler theory by designing an experiment involving sound transmission as his doctoral research project. Conveniently for him, a new railroad had just been established between Amsterdam and Utrecht, and the Dutch government gave him permission to use this railway system to verify the Doppler effect on sound transmission (Fig. 1.4). The first experiment was designed in February 1845. Two horn players who apparently had perfect pitch were chosen to participate in the experiment. The calibration was accomplished by one musician blowing a note and the other identifying the pitch of the tone. After this calibration was performed, one player was positioned on the train, and the other stood along the track. As the train passed, the stationary musician on the trackside perceived that the note blown by the musician on the train was half a note higher when the train approached him and half a note lower when it moved away. Unfortunately, a raging blizzard forced Buys Ballot to abandon his experiment and to reschedule it in a more temperate season. The results from the first experiment were published within less than a month in a music journal [5].

Buys Ballot conducted the experiment again in early June of the same year [6]. Three teams were stationed along the track. Each team was composed of a horn player, an observer, and a manager. A fourth team was on a flat car behind the locomotive. Buys Ballot positioned himself on the foot plate next to the engineer. This experiment was more sophisticated, but it also encountered environmental complications as the summer heat seriously interfered with the correct tuning of the musical instruments. The musicians originally tried to use one-sixteenth of a single note but failed, and the final experiment was done in eighths. The results were remarkable despite all the trials and tribulations. The study that set out to re-

**Fig. 1.3.** C.H.D. Buys Ballot (1817–1890). (From [40], with permission)

refute the Doppler theory ultimately confirmed it. Buys Ballot proved not only the existence of the Doppler effect in relation to sound transmission but its angle dependency as well. Incredibly, Buys Ballot still refused to accept the validity of the theory for the propagation of light and most of the scientific community of the nineteenth century did not acknowledge the validity of Doppler's theory because of his erroneous interpretation of astronomical phenomena.

As translated by Eden [1], Doppler's response was impressive in its foresight: "I still hold the trust – indeed, stronger than ever before – that in the course of time, this theory will serve astronomers as a welcome help to probe the happenings of the universe, at times when they feel deserted by all other methods" [7]. This statement was prophetic. Since the beginning of the twentieth century, the Doppler principle has been used extensively not only in astronomy but also in the immensely diverse fields of science and technology.

Doppler lived only 10 years after publishing his paper on the frequency shift; however, these few years brought him well-deserved recognition and honor. He

was elected to the membership of the Royal Bohemian Society of Sciences in 1843 and of the highly prestigious Imperial Academy of Sciences in Vienna in 1847. In 1850 he was appointed by Emperor Franz Josef of the Austro-Hungarian Empire to the coveted position of the Chair of Experimental Physics at the University of Vienna. Sadly, however, he was in poor health at this point because of the chronic respiratory disease which was presumed to be “consumption” or pulmonary tuberculosis and which he apparently had contracted in Prague years earlier. With the hope of recuperation he went to the warmer climate of Venice in the winter of 1852, where he died on March 17, 1853 at the age of only 49 in the arms of his wife Mathilde. He was given a grand funeral at the Parish Church of San Giovanni in Bragora and many academic and civil dignitaries were in attendance. A more comprehensive account of Doppler’s life is beyond the scope of this review. For those who are interested, I strongly recommend the excellent monograph written by Professor Alec Eden titled *The Search For Christian Doppler* [1].

### Technical Utilization of Doppler’s Principle

Initial applications of the Doppler principle were mostly for astronomic studies. Over the years the Doppler effect for light and radio waves has yielded information on a cosmic scale, from orbital velocity of planets and stars to galactic rotation and an ever-expanding universe. The principle still serves as a major tool for cosmologic research. With the beginning of the twentieth century, other applications

gradually emerged. The first sonar equipment for detecting submarines was developed by Paul Langevin of France, who also pioneered the use of piezoelectric crystals for transmitting and receiving ultrasound waves. This technology was used to detect submarines, initially during World War I and more extensively during World War II. The ensuing decades witnessed widespread application of the principle of the Doppler effect, from road-side radar speed detectors used by the police to the highly sophisticated military defense and weather forecasting Doppler radar systems. Doppler radio signals are used for navigation, surveying, monitoring animal migration, and estimating crop yields. The development of diagnostic Doppler ultrasound technology offers yet another example of the extensive use of the Doppler principle.

### Development of Spectral Doppler Ultrasonography

The first medical applications of Doppler sonography were initiated during the late 1950s, and impressive technologic innovations have been continuing ever since. Shigeo Satomura from the Institute of Scientific and Industrial Research of Osaka University in Japan developed the first Doppler ultrasound device for medical diagnostic purposes and reported the recording of various cardiac valvular movements [8]. Based on their experience, Satomura suggested the potential use of Doppler ultrasonography for percutaneous measurement of blood flow. In 1960 he and Kaneko were the first to report construction of an ultrasonic flowmeter [9]. A significant amount of the pioneering work occurred at the University of Washington in

Seattle in the United States. Major driving forces of this group included Robert Rushmer, a physician, and Dean Franklin, an engineer. They initiated the development of a prototype continuous-wave Doppler device in 1959 and reported blood flow assessment using the ultrasound Doppler frequency shift [10]. The Seattle team refined this instrument into a small portable device, and the earliest clinical trials were undertaken during the mid-1960s by Eugene Strandness, who at the time was undergoing training as a vascular surgeon [11].

The first pulsed-wave Doppler equipment was developed by the Seattle research team. Donald Baker, Dennis Watkins, and John Reid began working on this project in 1966 and produced one of the first pulsed Doppler devices [12]. Other pioneers of pulsed Doppler include Wells of the United Kingdom [13] and Peronneau of France [14]. The Seattle team also pioneered the construction of duplex Doppler instrumentation based on a mechanical sector scanning head in which a single transducer crystal performed both imaging and Doppler functions on a time-sharing basis. The duplex Doppler technique allowed the ultrasound operator to determine for the first time the target of Doppler insonation. This development is of critical importance in obstetric and gynecologic applications, as such range discrimination allows reliable Doppler interrogation of a deep-lying circulation, such as that of the fetus and of the maternal pelvic organs. It must be recognized that many others also have made immense pioneering contributions in the development and utilization of diagnostic Doppler sonography, a detailed discussion of which is beyond the scope of this chapter.

## **Development of Color Doppler Ultrasonography**

Spectral Doppler ultrasound interrogates along the single line of ultrasound beam transmission. The hemodynamic information thus generated is limited to unidimensional flow velocity characterization from the target area. This limitation provided the impetus to develop a method for depiction of flow in a two-dimensional plane in real time. Potential clinical utility of such an approach was obvious, particularly for cardiovascular applications to diagnose complex hemodynamic and structural abnormalities associated with acquired and congenital cardiac disease. However, the unidimensional spectral pulsed Doppler method was inadequate to cope with the processing needs of real-time two-dimensional Doppler ultrasonography, which involves analysis of an enormous number of signals derived from multiple sampling sites along multiple scan lines.

The initial attempts involved various invasive and noninvasive modifications of the existing echocardiographic approach, including the use of a sonocontrast agent to obtain information on blood flow patterns during two-dimensional echocardiographic imaging [15] and the development of multichannel duplex Doppler systems [16]. However, the spectral pulsed Doppler ultrasound used in these techniques could produce velocity information only along a single beam line. The development of real-time two-dimensional color Doppler ultrasonography therefore represents a major technologic breakthrough, which became possible because of the introduction of two critical pieces of technology for processing the Doppler ultrasound signal. First was the Doppler sonographic application by Angelsen and Kristofferson [17] of the sophisticated filtering technique of “the moving target indicator” used in radar systems. This filter allows removal of the high-amplitude/low-velocity clutter signals generated by the movement of tissue structures and vessel walls. The second was development of the autocorrelation technique by Namekawa et al. [18]. The autocorrelator is capable of processing mean Doppler phase shift data from the two-dimensional scan area in real time, so two-dimensional Doppler flow mapping is possible (see Chap. 5). In 1983 the Japanese group, which included Omoto, Namekawa, Kasai, and others, reported the use of a prototype device incorporating the new technology for visualizing intracardiac flow [19]. Extensive clinical evaluation of this new approach was carried on in the United States by Nanda and other investigators [20].

## **Introduction of Doppler Ultrasonography to Obstetrics and Gynecology**

The first obstetric application of Doppler ultrasonography consisted in detection of fetal heart movements [21]. Originally developed for fetal heart rate detection, the technique was further developed for noninvasive continuous electronic monitoring of the fetal heart rate. Currently, they constitute the most common uses of Doppler ultrasonography in obstetrics. The systems are based on utilizing relatively simple continuous-wave Doppler ultrasound to determine the fetal heart rate from the fetal cardiac wall or valvular motion. The first application of Doppler velocimetry in obstetrics was reported by FitzGerald and Drumm [22] from Dublin and MacCallum et al. [23] from Seattle. The former are recognized as the first group to publish a peer-reviewed article in this field. These publications were followed by an era of impres-

**Table 1.1.** Feasibility of Doppler velocimetry of fetal and uteroplacental circulations

sive research productivity during which various investigators [24–36] extended the use of Doppler sonography for assessing the fetal and the maternal circulation (Table 1.1).

In contrast to the prolific publications on the obstetric uses of Doppler sonography, reports on gynecologic applications of the technique did not begin to appear until the mid-1980s. Taylor and colleagues were the first to characterize Doppler waves from the ovarian and uterine arterial circulations utilizing pulsed duplex Doppler instrumentation [37]. This work was followed by reports of transvaginal color Doppler studies [38] and transvaginal duplex pulsed Doppler studies [39] of pelvic vessels. Through the late 1980s and early 1990s, Doppler sonographic research in gynecology steadily expanded.

## Conclusion

Discovery of the Doppler effect and its application to medical diagnostics after more than a century is a fascinating example of how our understanding and exploitation of natural phenomena can be translated into tangible advances in medicine. This is also relevant for obstetrics and gynecology as Doppler sonography has enabled us to explore and understand human fetal hemodynamics, which was virtually inaccessible before. As we continue to advance our knowledge, it is important to pause and acknowledge the immense contributions of the pioneers who made it all happen.

# Physical Principles of Doppler Ultrasonography

Dev Maulik

This chapter presents the basic concepts of sound and ultrasound propagation and discusses the physical principles of the Doppler effect and Doppler sonography, which are essential for understanding their diagnostic uses. Although this book focuses primarily on clinical utilization of the diagnostic Doppler technology, developing an understanding of the basic principles is imperative for its proficient use. The following is a brief introduction and is not intended to be a comprehensive treatise on the subject. For a more in-depth discussion, there are several excellent textbooks that comprehensively examine the physics of Doppler ultrasonography [1-4].

## Propagation of Sound

Sound is a form of mechanical energy that travels through solid or liquid media as pressure waves (Fig. 2.1). Sound waves are generated when an object vibrates in a medium. For example, percussion causes a drum membrane to vibrate and to generate sound waves in the air. During vibration the forward movement of the sound source causes a pressure rise in

the adjacent medium, so the molecules of the medium become crowded. As the source moves backward there is a pressure drop in the medium, so the molecules now move apart. This phenomenon of alternating molecular compression and rarefaction accompanies the waves of sound energy as they propagate along the medium (Fig. 2.2). Although the molecules vibrate, they remain in their original location and are not displaced. Sound travels faster in solids than in liquids and faster in liquids than in gases.

Although usually considered in a unidimensional plane, in reality sound is transmitted in a three-dimensional space. Sound waves from a vibratory source or from a reflector are moving surfaces of high and low pressures. These surfaces are called *waveforms*. The shape of a waveform depends on the shape of the source or the interface. Thus a plane waveform emanates from a flat source and a spherical waveform from a spherical source. With Doppler ultrasonics, the scattered waveform is spherical, as red blood cells (RBCs) behave as spherical sources during the scattering of an incident beam.

**Fig. 2.1 A, B.** Propagation of sound. **A** Passage of a sound pulse through point "A" in the medium. **B** Consequent changes in the pressure at that point

**Fig. 2.2.** Propagation of sound. Compression and rarefaction of the molecules in a medium associated with the propagation of a pressure wave related to sound or ultrasound transmission. *Horizontal axis* represents the distance; *vertical axis* represents the magnitude of pressure wave deflections around the baseline. Upward deflection represents the positive pressure changes and downward deflection the negative pressure changes

## Propagation Speed of Sound

The *propagation speed* of sound in a medium is the rate of change of position of the sound wave in unit time in that medium. It is called *velocity* when the direction of motion is also specified. The speed of ultrasound propagation in a medium is directly related to the bulk modulus of elasticity and density of the medium. A change in transmitting frequency within the range of clinical usage does not alter the speed. Although speed of sound is affected by temperature, no appreciable effects are known in clinical applications. With diagnostic ultrasonography, the propagation speed information is used to compute the depth distance from the echo return time. It is also a component of the Doppler equation that allows determination of speed of the scatterer from the Doppler frequency shift. The average propagation speed of ultrasound in soft tissues is approximately 1,540 meters per second (m/s).

## Wavelength, Frequency, Pulse

The *wavelength* of sound is comprised of one cycle of compression and rarefaction. Therefore it is the distance between a pair of consecutive peaks or troughs of adjacent pressure waves (Fig. 2.3). The *frequency* of sound is the number of such cycles occurring in 1 s. One *cycle* is called a hertz (Hz). Wavelength and frequency are inversely related:

$$\lambda = c/f$$

where  $\lambda$  represents the wavelength,  $c$  the speed of sound, and  $f$  the frequency. As the propagation speed

**Fig. 2.3.** Wavelength of sound. *Horizontal axis* represents the distance and the *vertical axis* the magnitude of pressure wave deflections around the baseline. The peak-to-peak distance ( $\lambda$ ) between the consecutive pressure waves is one wavelength

of sound in tissue is known and is relatively constant, one can determine the frequency from the wavelength and vice versa (Table 2.1). The duration of one cycle, or wavelength, of sound is called its *period* (Fig. 2.4). Period is measured in seconds and microseconds. It is inversely related to the frequency:

$$T = 1/f$$

where  $T$  is the period, and  $f$  is the frequency of sound.

Pulsed Doppler (both spectral and color flow mapping) and pulse echo imaging systems transmit ultrasound waves in pulses. The number of such pulses transmitted per second is known as the *pulse repetition frequency* (PRF) (Fig. 2.5). The length of one ultrasound pulse is known as the *spatial pulse length* (Fig. 2.6). Pulse length varies according to the mode of ultrasound. With pulsed Doppler ultrasound, the pulse length ranges from 5 to 30 cycles. In contrast, the length is much shorter for pulsed echo imaging system, as they generate two to three cycles per pulse.

**Table 2.1.** Frequency and corresponding wavelength of commonly used Doppler transducers in obstetrics

Frequency (MHz)	Wavelength ( $\mu\text{m}$ )
2.0	770
2.5	616

3.5	440
4.0	385
4.5	342
5.0	308
5.5	280
6.0	257
6.5	236
7.0	220
7.5	205

**Fig. 2.4.** Period of sound. The duration of one wavelength of sound is its period. *Horizontal axis* represents the time and the *vertical axis* the magnitude of pressure wave deflections around the baseline

**Fig. 2.5.** Concept of pulse repetition frequency (PRF). The illustration shows a PRF of 1 KHz (1,000 pulses per second)

**Fig. 2.6.** Pulse length, which is the distance in space occupied by one ultrasound pulse. *Horizontal axis* represents the distance and the *vertical axis* the pressure amplitude

For pulsed Doppler applications, the PFR limits the highest velocity that can be measured without creating the artifact known as aliasing. This subject is further discussed in Chap. 3.

## Amplitude, Power, Intensity

The maximum variation in pressure generated in a medium by a propagating sound wave is called *pressure amplitude* (Fig. 2.7). Pressure amplitude is directly related to the amount of sound energy emanating from a vibratory source. It is therefore a measure of the strength of sound radiation. The rate of flow of ultrasonic energy through the cross-sectional area of the beam is expressed as its *power*. The *intensity* of a

**Fig. 2.7.** Pressure amplitude of a sound wave. *Horizontal axis* depicts distance or time. *Vertical axis* represents variations in the acoustic pressure. The *plus* and *minus signs* indicate the positive and negative fluctuations of the pressure, respectively. *P*, the amplitude that is the maximum change in the pressure above or below the baseline value represented by the *horizontal line*

sound wave at a location is the rate of flow of energy per unit of cross-sectional area of the beam at that location. It is therefore power divided by beam cross-sectional area. Pressure amplitude is measured using a device called a hydrophone. Intensity (*I*) is derived from the pressure amplitude (*p*) as they are directly related:

$$I = p^2/c$$

Intensity is expressed by several descriptor parameters based on its peak and average values.

For continuous-wave Doppler ultrasound, intensity is measured as the spatial peak value ( $I_{sp}$ ) and the spatial average value ( $I_{sa}$ ). The former is measured usually at the focal point of the beam, the latter at the cross-sectional location of the beam. For pulsed Doppler ultrasound it is necessary to consider both the spatial and the temporal intensity values. Both peak and average values are measured in various combinations, as follows: spatial peak temporal peak ( $I_{sptp}$ ), spatial peak temporal average ( $I_{spta}$ ), spatial average temporal peak ( $I_{satp}$ ), and spatial average temporal average ( $I_{sata}$ ). Additional descriptors of pulsed ultrasound intensity include the spatial peak pulse average intensity ( $I_{sppa}$ ), which is the intensity at the spatial peak averaged over the pulse length. These measures of sound energy of a transmitted Doppler ultrasound beam are important for biosafety considerations and are discussed in Chap. 6.

## Ultrasound and Piezoelectric Effect

Audible sound frequency ranges from approximately 10 Hz to 20 KHz. Sound with a frequency of more than 20 KHz is inaudible to the human ear and is

known as *ultrasound*. With Doppler ultrasound used for medical diagnostics, the commonly employed frequency range is 2–10 MHz. The frequency range for obstetric transducers is 2–5 MHz. To produce vibrations or oscillations at the rate of millions of cycles per second, special materials with piezoelectric properties are used. These piezoelectric elements are solid, nonconducting substances that demonstrate physical properties whose measurements are different along different axes (anisotropic). When compressed in certain directions, these elements undergo electrical polarization, and a corresponding voltage is generated that is proportional to the pressure. Conversely, when such an element is subjected to an electric field it exhibits mechanical distortion by an amount proportional to the applied field. This phenomenon is known as the *piezoelectric effect* (Fig. 2.8). The piezoelectric effect allows interconversion between sound and electricity and forms the basis for the construction of Doppler and other types of ultrasound transducer. The naturally occurring piezoelectric elements include crystals such as quartz, tourmaline, and rochelle salt. Synthetic ceramic elements employed in the construction of Doppler and other ultrasound transducers are polycrystalline substances consisting of tetravalent metal ions such as zirconium or titanium embedded in a lattice of bigger divalent metal ions such as lead or barium, and oxygen. The most common piezoelectric ceramics include barium titanium trioxide and lead zirconium trioxide. More recently, synthetic single crystals are being developed which include lead zirconate niobate/lead titanate, barium titanate trioxide, and lithium niobate trioxide. These newer single elements demonstrate much greater strain, which is directly related to their performance.

**Fig. 2.8 A, B.** Piezoelectric effect. **A** Conversion of the electrical energy to sound energy. **B** Conversion of sound to electrical energy

## Characteristics of Sound Transmission in a Medium

The resistance offered by a medium to sound transmission is known as its *acoustic impedance*. The acoustic impedance of a medium is the product of its density and the velocity of sound, and it is measured in rayl units. Most soft tissues demonstrate only minor variations in their acoustic impedance [5]. For example, the impedance rayl values for blood, brain, kidney, and muscle are  $1.61 \times 10^5$ ,  $1.58 \times 10^5$ ,  $1.62 \times 10^5$ , and  $1.70 \times 10^5$ , respectively. In contrast, bones possess a significantly higher acoustic impedance ( $7.8 \times 10^5$ ). The significance of acoustic impedance lies in the fact that it is the impedance inhomogeneities in tissues that give rise to echoes, which form the basis for ultrasonic imaging and Doppler velocimetry. The boundary between adjacent media with differing acoustic impedance values is called an *acoustic interface*. The characteristics of sound transmission change at the interface. Such changes include reflection and refraction. The amplitude of reflection is directly proportional to the magnitude of impedance difference at the interface. However, even minor differences in acoustic impedance generate echoes. When impedance inhomogeneity exists across an acoustic interface, a variable portion of an ultrasound beam is reflected. At most soft tissue interfaces it involves only a small portion of the ultrasound energy, with the rest being transmitted and reaching the medium beyond the interface (Fig. 2.9). In contrast, thick bone offers a large acoustic mismatch in relation to the surrounding soft tissue medium, so a major portion of the ultrasound energy is reflected. This situation inevitably results in markedly diminished transmission of the beam, and the resultant “acoustic

**Fig. 2.9.** Reflection and transmission of sound at the interface acoustically mismatched in medium 1 and medium 2. In this example the beam strikes the interface perpendicularly

shadow” affects optimal imaging of structures lying posterior to the bone. At most tissue interfaces, an incident beam is echoed in different directions, a process known as *diffuse reflection*. In relation to Doppler ultrasonic reflections, however, an entirely different phenomenon occurs, known as *scattering*. This phenomenon is discussed below.

When an ultrasound beam travels with an oblique angle of incidence across an interface, the beam path deviates and the angle of transmission differs from the angle of incidence (Fig. 2.10). The phenomenon is similar to refraction of light. Refractive deviation in the beam path may compromise image quality. For pulsed Doppler duplex applications, where two-dimensional gray-scale imaging is used for placing the Doppler sample volume in deep vascular locations, refraction may lead to error. However, the propagation speed of sound does not vary appreciably in most soft tissues; therefore only minimal refraction occurs at most tissue interfaces. For example, an ultrasound beam passing through a muscle-blood interface at an incident angle of  $30^\circ$  undergoes only a  $0^\circ 47'$  refractive deviation [2].

Progressive decline in the pressure amplitude and intensity of a propagating ultrasonic wave is known as *attenuation*. Attenuation is caused by many factors, including absorption, scattering, reflection, and wavefront divergence. *Absorption* is the phenomenon whereby sound energy is converted to heat and is therefore responsible for thermal bioeffects. Attenuation is also affected by the transmitting frequency of a transducer: the higher the frequency, the greater the attenuation. It limits the use of high-frequency transducers for Doppler interrogation of deep vascu-

lar structures. These considerations influence the choice of a transducer for a specific use. Thus for Doppler examinations of fetal circulation, a 5-MHz transducer may be less efficient for obtaining adequate signals than a 2-MHz transducer.

## Doppler Effect

The Doppler effect is the phenomenon of observed changes in the frequency of energy wave transmission when relative motion occurs between the source of wave transmission and the observer. The change in the frequency is known as the Doppler frequency shift, or simply the Doppler shift:

$$f_d = f_t - f_r$$

where  $f_d$  is the Doppler shift frequency,  $f_t$  is the transmitted frequency, and  $f_r$  is the received frequency. When the source and the observer move closer, the wavelength decreases and the frequency increases. Conversely, when the source and the observer move apart, the wavelength increases and the frequency decreases. The Doppler effect is observed irrespective of whether the source or the observer moves (Fig. 2.11). The principle is applicable to all forms of wave propagation. The utility of the Doppler effect originates from the fact that the shift in frequency is proportional to the speed of movement between the source and the receiver and therefore can be used to assess this speed. The Doppler effect is observed irrespective of whether the source or the observer moves.

**Fig. 2.10.** Reflection, refraction, and transmission of sound. The beam, in this example, is encountering the acoustic interface obliquely. A portion of the incident sound is reflected back, and the rest is transmitted. The angle of reflection ( $\phi_r$ ) equals the angle of incidence ( $\phi_i$ ). The transmitted sound is refracted. The angle of refraction ( $\phi_t$ ) depends on the angle of incidence and the propagation speeds of sound in medium 1 and medium 2

## Doppler Ultrasound

For sound transmission, the Doppler shift sound is of a higher frequency when the source and the receiver move closer and of a lower frequency when they re-

**Fig. 2.11.** Graphic depiction of the Doppler shift when a source of sound transmission moves away or toward a stationary observer

**Fig. 2.12.** Doppler effect when an ultrasound beam interrogates circulating blood.  $f_d$  Doppler shift,  $f_t$  transmitted beam,  $V$  velocity of blood flow,  $c$  speed sound propagation in tissue,  $\theta$  angle of incidence between the ultrasound beam and the direction of blood flow

cede. The phenomenon of the Doppler effect is also observed when an ultrasound beam encounters blood flow (Fig. 2.12). With blood circulation, millions of red blood cells (RBCs) act as moving scatterers of the incident ultrasound. In this circumstance the erythrocytes act first as moving receivers and then as moving sources [6], forming the basis for the Doppler equation:

$$f_d = 2f_t v/c$$

where  $f_d$  represents the Doppler frequency shift,  $f_t$  the frequency of the incident beam (transducer frequency),  $v$  the velocity of the scatterer in a given direction, and  $c$  the propagation speed of sound in the medium. Note that the transmitted ultrasound undergoes double Doppler shift before returning to the receiving transducer, the scatterer acting first as a receiver and then as a transmitter. This phenomenon accounts for the factor of 2 in the above equation.

If the direction of the incident beam is at an angle ( $\theta$ ) to the direction of blood flow, the  $v$  in the Doppler equation is replaced by the component of the velocity in the direction of the flow (obtained by the cosine of the angle,  $\cos \theta$ ):

$$f_d = 2f_t \cdot \cos \theta \cdot v/c$$

To determine the velocity of the scatterer, the equation can be rewritten as follows:

$$v = f_d \cdot c / 2f_t \cdot \cos \theta$$

Thus if the angle of beam incidence and the Doppler shift are known, the velocity of blood flow is also known, assuming that the transducer frequency and the velocity of sound in tissue remain relatively constant (Fig. 2.12). The above equation forms the basis for clinical application of the Doppler principle.

## Backscattering

We briefly alluded to a special category of sound reflection called scattering. The process of ultrasonic scattering is analogous to scattering of light by gas molecules and is known as *Rayleigh scattering* [7, 8]. Light so reflected is called Tyndall light and is responsible for the blue sky. Interestingly, it was inquiry into the cause of blue sky at the turn of the century by a group of scientists, including Lord Rayleigh and Tyndall, that led to our understanding of this phenomenon [9]. Rayleigh scattering occurs when energy waves traveling through a medium encounter reflectors whose size is much smaller than the wavelength of the propagating energy; a portion of the energy is then reflected in all directions. The scattered energy wave is spherical in shape irrespective of the shape of the scatterer.

One characteristic of Rayleigh scattering is that the power, or intensity, of the scattered energy ( $I$ ) is proportional to the fourth power of the frequency ( $f$ ).

$$I \sim f^4$$

The frequency dependence of scattering power has important consequences for selecting the appropriate transducer frequency for Doppler applications. Increasing the incident ultrasonic frequency immensely amplifies the power of the reflected echoes. Thus raising the transducer frequency from 3 MHz to 4 MHz leads to fivefold augmentation of the scattered echo intensity. Ironically, this increase also limits the ability of the transducer to sample deep-lying circulations, as a higher frequency leads to greater attenuation. Obviously, one must balance these contrary effects when selecting the optimal frequency for a specific application. For example, for most fetal Doppler insonations via the maternal abdomen, transducers with a frequency range of 2–4 MHz are commonly used to reach the deep-lying vascular targets in the fetus. In contrast, with a transvaginal approach, where the transducer lies in close proximity to pelvic structures, such as the uterine or ovarian arteries, the use of a higher frequency (e.g., 5 MHz) increases the Doppler sensitivity without significant attenuation of the beam.

When a propagating ultrasonic wave encounters an acoustic interface, reflection occurs. Scattering takes

place when the size of the interface is smaller than the incident sound wavelength. Such an interface is known as a *point target*. In regard to Doppler shift, the scatterer is significantly smaller than the wavelength and is in motion. The Doppler-shifted ultrasound reflecting from such a moving scatter propagates in all directions (Fig. 2.13). Obviously, it also reaches any receiving transducer at the source of transmission. The process of scattered ultrasound returning to the source-receiver is called *backscattering*.

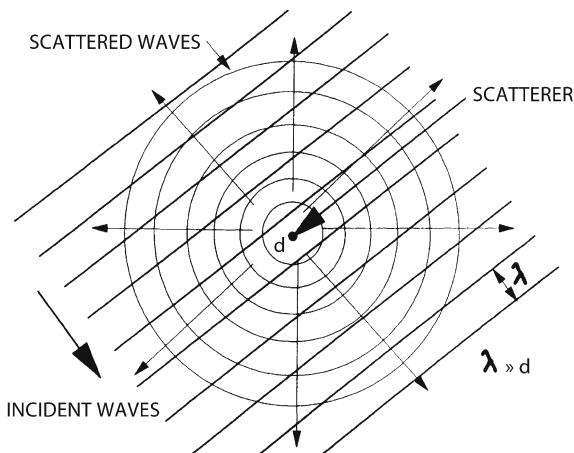

It is well accepted that the primary sources of scattering in blood are the circulating RBCs [10]. These cells are so numerous that the contribution of the other formed elements of blood, such as white blood cells and platelets, to scattering ultrasound is inconsequential. An RBC has a biconcave discoid shape with a mean diameter of  $7.2\ \mu\text{m}$  and a mean thickness of  $2.2\ \mu\text{m}$ . In comparison, the wavelength of Doppler ultrasound for diagnostic applications varies from  $1540\ \mu\text{m}$  to  $154\ \mu\text{m}$ , corresponding to 1–10 MHz transducer frequency. As is apparent, the RBCs are several magnitudes smaller than the wavelengths, so they can be regarded as point targets. In reality, however, circulating erythrocytes do not act as discrete scatterers but as volumes of randomly distributed point targets. The number of RBCs in such a scattering volume fluctuates around a mean value and causes fluctuations in the scattering power. Turbulent blood flow increases fluctuations in the RBC concentration and is therefore associated with increases in the scattering power and consequently the power of the Doppler shift signal [10]. In regard to whole blood, it has been experimentally demonstrated that

the scattering power becomes maximum at a hematocrit range of 25%–30% [10]. At higher hematocrit values, the scattering behavior of blood becomes more complex as the RBCs become too crowded and can no longer be treated as randomly distributed scatterers.

In addition to hematocrit, scattering is also affected by the state of red cell aggregation. Spatial variations in the flow field can result in changes in the variance of red cell packing and backscattering cross section which will influence the Doppler power at a given frequency [11]. In this circumstance, the mean Doppler frequency will not necessarily be proportional to the mean flow through the sample volume and may affect volumetric flow quantification and the power mode display of color Doppler. Scattering is also dependent on certain characteristics of the transmitted ultrasound including the frequency and the angle of insonation [12]. The phenomenon is a complex subject and a comprehensive review is beyond the scope of this chapter.

## Magnitude of Doppler Shift

Relative velocities of the sound and the scatterers are important determinants of the magnitude of the Doppler frequency shift. In regard to blood flow, the speed of RBCs is significantly less than the speed of sound in a biologic medium. Consequently, the Doppler shift is much smaller than the incident ultrasonic frequency. Assuming a sound propagation speed of  $1,540\ \text{m/s}$  in soft tissues, the Doppler shift for a given blood flow speed and the transducer frequency can be calculated from the Doppler equation. This exercise is illustrated in Table 2.2, which lists the Doppler frequency shifts for most obstetric transducer frequencies (2–7 MHz) at blood flow speeds of 25, 50, and 75 cm/s. As is evident, the frequency shifts are approximately 1/1,000 their corresponding transducer frequencies. Furthermore, the Doppler shifted sound

**Fig. 2.13.** Phenomenon of scattering.  $d$  Scatter,  $\lambda$  wavelength of the incident beam. The large arrow shows the direction of propagation of the incident ultrasound. The smaller arrows radiating from  $d$  indicate the directions of scattering. Note that scattering occurs when the wavelength is much greater than the size of the reflector ( $\lambda \gg d$ )

**Table 2.2.** Doppler frequency shifts for various transducer frequencies at three blood flow velocities and an insonation angle of  $0^\circ$

Transducer frequency (MHz)	Doppler shift at three flow velocities (KHz)		
	at 25 cm/s	at 50 cm/s	at 75 cm/s
2	1.3	0.7	1.9
3	1.9	1.0	2.9
4	2.6	1.3	3.9
5	3.2	1.6	4.9
6	3.9	1.9	5.8
7	4.6	2.3	6.8

is well within the limits of human hearing as its frequency is in the kilohertz range.

## Angle Dependence of Doppler Shift

It is evident from the Doppler equation that the greatest frequency shift occurs when the transmitted ultrasound beam is parallel to the flow axis; and when the beam intersects the vessel, it is the component or the vector of the RBC velocity along the beam path that contributes to the Doppler effect. This vector is determined from the cosine of the beam-vessel angle and is incorporated into the Doppler equation (see above). As the angle increases, the frequency shift proportionately decreases. When the angle exceeds  $60^\circ$ , the fall in the Doppler shifted frequency exceeds 50%. When the angle reaches  $90^\circ$ , the Doppler shift is virtually nonexistent. However, minimal Doppler signals may still be generated because of beam divergence and nonuniform flow in the vessel.

As the angle of insonation decreases, the frequency shift increases; and maximum Doppler shift is obtained, at least in theory, when the angle becomes zero with the ultrasound beam being parallel to the flow axis. In reality, however, as the angle drops below  $30^\circ$ , significant reflection of the incident beam

occurs at the interface between blood and the vessel wall, and the Doppler sensitivity becomes seriously compromised. Thus the lower limit of the angle for desirable Doppler interrogation is  $30^\circ$ . In contrast to general vascular applications, the phenomenon of loss of sensitivity with a low angle is not observed in cardiac Doppler insonations. With fetal and postnatal Doppler echocardiography, optimal Doppler waveforms are obtained when the incident beam is aligned with the vessel axis in pulmonic or aortic outflow tracts. Apparently, complex cardiac anatomy does not reflect the incident beam the same way as do peripheral vessel walls.

As is apparent from the Doppler equation, the estimation of blood flow speed from the Doppler shift requires a reliable measurement of the angle of insonation. Although the Doppler shift is angle-dependent, flow speed calculated from the Doppler shift is not affected, in theory, by the magnitude of the angle. This situation, however, assumes ideal circumstances – such as insonation of a uniform flow in a straight vessel of uniform diameter – which one does not encounter often in reality. Therefore the desirable angle range for flow speed estimation remains, as indicated above,  $30^\circ$ – $60^\circ$ . Measurement of the angle in a duplex Doppler device is usually accomplished with apparent ease. The operator uses the two-dimensional image to

**Fig. 2.14.** Duplex Doppler interrogation. *Top:* Two-dimensional Doppler flow image of the fetal ductus arteriosus. The *oblique vertical line* is the cursor representing the beam path. The Doppler sample volume (*two short horizontal lines*) is placed at the ductal site, which shows high-speed blood flow. The *small oblique line* at the sample volume is the angle indicator. *Bottom:* Angle-corrected Doppler shifts from the ductus. The *right margin* of the panel shows the frequency scale in kilohertz. The *left margin* of the panel shows the blood flow velocity scale in centimeters per second

align an angle indicator cursor with the vessel axis (the presumed flow axis) and determines the angle it incurs with the beam path indicator cursor (Fig. 2.14). The device computes this angle and produces the velocity information in real time. The procedure is subjective, and the precision of the measurement obviously depends on operator skill.

Determination of the flow velocity may be clinically useful during fetal echocardiographic examination, as abnormal flow velocities in the pulmonary artery, aorta, or ductus arteriosus may assist in identifying structural or functional abnormalities. A reliable measurement of the Doppler angle is also a requirement for measuring volumetric blood flow and inaccuracies in measuring the angle can introduce significant errors in this measurement. Finally, an optimal angle is important for an appropriate interpretation of Doppler waveforms from the arteries that demonstrate continuing forward flow during the end-diastolic phase, as a large angle may artificially reduce the magnitude of the end-diastolic frequency shift. This point is of critical importance when assessing an umbilical arterial circulation in which a reduced or absent end-diastolic frequency shift may indicate fetal jeopardy. The challenge of the angle of insonation in Doppler sonography has prompted significant research on the development of angle-independent ultrasound technology for circulatory investigations; this is further discussed in Chap. 4.

# Spectral Doppler: Basic Principles and Instrumentation

Dev Maulik

Spectral Doppler ultrasound velocimetry involves systematic analysis of the spectrum of frequencies that constitute the Doppler signal. This chapter presents a general perspective on Doppler signal analyses and describes the spectral Doppler ultrasound devices commercially available for clinical use. They include continuous-wave (CW) Doppler, pulsed-wave (PW) Doppler, and duplex Doppler devices. Within the realm of obstetric usage, the application needs are diverse and require various choices of equipment. For example, fetal Doppler echocardiography requires advanced duplex ultrasound instrumentation, which combines the capabilities of high-resolution two-dimensional imaging with the PW Doppler mode and an acoustic power output appropriate for fetal application. For umbilical arterial hemodynamic assessment, simpler, substantially less expensive CW Doppler equipment with a spectral analyzer may be sufficient. It is essential therefore that one develop a basic understanding of the implementation of Doppler ultrasound technology.

## Doppler Signal Processing

As discussed in Chap. 2, the Doppler frequency shift signal represents the summation of multiple Doppler frequency shifts backscattered by millions of red blood cells (RBCs). The RBCs travel at different speeds, and the number of cells traveling at these speeds varies as well. As the speed of the scatterers determines the magnitude of the frequency shift and the quantity of the amplitude, the Doppler signal is composed of a range of frequencies with varying amplitude content. Moreover, the total received Doppler signal contains low-frequency and high-amplitude signals generated by tissue movements and high-frequency noise generated by the instrumentation. Obviously, systematic processing is necessary before the Doppler shifted frequencies can be used clinically. The Doppler signal is processed in sequential steps (Fig. 3.1), consisting of reception and amplification, demodulation and determination of directionality of flow, and spectral processing.

Fig. 3.1. Sequential steps of Doppler signal processing

## Reception-Amplification

The returning signals are first received and amplified by a radiofrequency (RF) receiving device. Amplification is necessary, as the Doppler frequency shift generates weak electrical voltage at the receiving transducer.

## Demodulation

The total received and amplified echoes contain not only the Doppler-shifted frequencies but also the carrier frequency, which is the frequency of the incident beam. During the next step, the Doppler-shifted frequencies are extracted from the carrier frequency. This process is known as *demodulation*. There are various methods of demodulation [1], among which the coherent phase quadrature procedure is commonly employed. Phase quadrature implies that one signal is one-fourth of a cycle out of phase or delayed compared to the other. With this technique the incoming signals are mixed with the direct and the

one-fourth of a cycle ( $90^\circ$ ) phase-shifted reference electrical signals. With coherent demodulation, the reference signal is supplied by the master oscillator, which is a voltage generator whose primary function is to produce the driving frequency for the source transducer. Demodulation results in generation of a direct and a quadrature output. When the flow is toward the transducer, the direct signal lags the quadrature signal by one-fourth of a cycle. When the flow is away from the transducer, the direct signal leads the quadrature signal by one-fourth of a cycle.

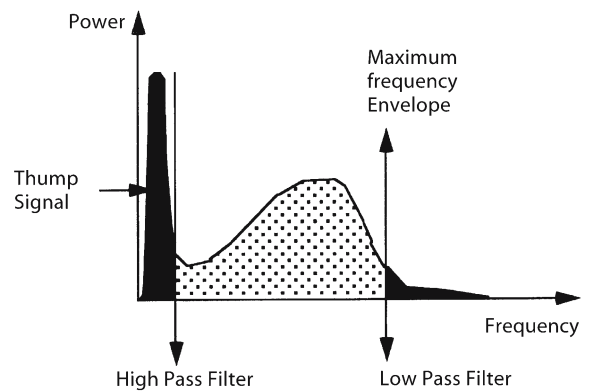

### Direction Discrimination

The resulting directional separation of the flow, however, is not complete and requires additional processing. The latter is achieved by frequency domain processing in which the demodulator outputs are mixed with the direct and quadrature (phase shifted by one-fourth of a cycle) outputs of a voltage generator. The resultant single-channel output separates the forward and reverse flow signals. With the pilot frequency of the quadrature oscillator providing the baseline, or zero frequency, the flow toward the transducer is presented as the positive Doppler shift and the flow away as the negative Doppler shift. The next step is comprised of removing the undesirable frequency components from the demodulated Doppler signal by digital filtration.

### High-Pass and Low-Pass Filters

The total signal input of a Doppler system is comprised of not only Doppler frequency shift signals from the target vessel but also low-frequency/high-amplitude signals originating from moving adjacent structures such as vessel walls and cardiac valves. It also contains high-frequency noise contributions from within the instrumentation. Obviously the frequencies from the extraneous sources represent error components of the total signal, and their reduction or elimination improves the signal quality. Electronic digital filters are used to accomplish this objective. By and large, two types of filter are used: a high-pass filter and a low-pass filter.

The purpose of a high-pass filtering system is to eliminate the extrinsic low-frequency components of Doppler signals, which arise predominantly from the vessel walls or other adjacent slow-moving structures (Fig. 3.2). For peripheral vascular applications this type of processing often improves the signal quality. Such low-frequency signals may also originate from the slow-moving boundary layer of blood flow adjoining the vascular wall. Moreover, with low-impedance circulations where forward flow continues through the end of the diastolic phase, the important end-dia-

**Fig. 3.2.** Doppler amplitude-frequency (power) spectrum illustrating the concept of high- and low-pass filtering. *Vertical axis* represents the amplitude or the power of the spectrum. *Horizontal axis* represents the frequency scale. The *left dark area* of the spectrum indicates signals arising from slow-moving tissue structures such as the vessel wall (thump signal). The *right dark area* shows high-frequency noise in the spectrum. The *vertical downward arrows* indicate the frequency cutoff levels of the high- and low-pass filters

stolic velocity information is lost, which may lead to the erroneous inference of compromised or absent end-diastolic velocity. The importance of this situation can be appreciated from the fact that absent or reverse end-diastolic flow is associated with high perinatal mortality and morbidity. Obviously, for most fetal applications the high-pass filter should be either turned off or kept at the lowest setting, preferably at 50 Hz and not exceeding 100 Hz. With most Doppler instruments the high-pass filter is adjustable.

A low-pass filter allows frequencies only below a certain threshold to pass, thereby removing any frequencies higher than that level (Fig. 2). This threshold is set higher than the maximum frequency shifts expected in a circulation. Such low-pass filters, in general, improve the signal-to-noise ratio. However, if the low-pass filter is set at an inappropriately low level, it may eliminate valuable high-frequency information from a high-velocity circulation, which in turn leads to underestimation of the maximum and mean frequency shifts.

### Doppler Spectral Analysis

The steps described above generate demodulated and filtered Doppler frequency shift signals displayed as a complex, uninterpretable waveform consisting of variations of amplitude over time (Fig. 3.3). Spectral analysis converts this waveform to an orderly array of constituent frequencies and corresponding amplitudes of the signal. The amplitude approximately represents the

**Fig. 3.3.** Demodulated Doppler signal prior to spectral processing. The signal was derived from the umbilical arteries

number of scatterers traveling at a given speed and is known as the *power of the spectrum*. A full spectral processing that provides comprehensive information on both the frequency and its average power content is called the *power-spectrum analysis*. As circulation is a pulsatile phenomenon, the speed of flow varies with time, as does the Doppler frequency shift generated by the flow. Spectral processing must therefore estimate temporal changes in the Doppler power spectrum.

Of the various approaches for spectral processing, Fourier analysis and autoregression techniques are commonly used at present. The Fourier-based approaches are usually used for Doppler spectral analysis, whereas autoregression techniques are usually employed for two-dimensional Doppler flow mapping.

### Fourier Transform Spectral Analysis

Fourier transform is a powerful mathematic technique for spectral analysis of constantly repeating cyclic phenomena, such as alternating electrical current,

sound waves, or electromagnetic waves. Baron Jean Baptiste Joseph Fourier, a French mathematician of the Napoleonic era, first described this approach in 1807. The process breaks down a complex periodic signal or waveform into its constituent frequencies of specific amplitudes and phases (Fig. 3.4). The spectrum of a periodic signal, such as that obtained from Doppler insonation, consists not of discrete values but of a continuous function distributed over the range of the constituent frequencies. For practical implementation, however, samples are drawn so a finite, or discrete, series of frequency points are chosen for analysis. It is called the *discrete* Fourier transform. The *fast* Fourier transform (FFT) is a computer programming sequence for rapid digital implementation of the discrete Fourier transform [2]. FFT processing significantly reduces computational need and is a highly effective tool for power spectral analysis of the Doppler signal [3, 4]. FFT-based Doppler analysis has been used extensively for assessing various circulatory system, including the carotid [5] and umbilical

**Fig. 3.4.** Principle of Fourier transform analysis. The complex flow waveform (A) is transformed into its constituent sine waves of different frequencies and phases (a1, a2, a3, a4, a5). Vertical axis shows the flow magnitude, and horizontal axis shows time. The process converts a time domain phenomenon into a frequency domain phenomenon

arterial [6] hemodynamics; and it is the current industry standard for Doppler ultrasound devices used for medical diagnostic applications. The number of discrete frequency components usually analyzed varies between 64 and 512. Maulik et al. described a 256-point FFT analysis for umbilical arterial velocimetry yielding a frequency resolution of 31.25 Hz (1.23 cm/s) [7]. For most perinatal applications, a 64-point FFT analysis is adequate. The initial step involves sampling the demodulated signal at given intervals and then digitizing the sampled signals, converting them to numeric values. It is achieved by an analog-to-digital converter. For the next step, the digitized data are processed by the FFT processor, which determines the power spectrum of the sample. Each spectrum is computed over a time window, and a number of consecutive overlapping time windows are averaged to prevent spectral loss. This procedure, regrettably, also compromises the spectral resolution. It should be appreciated that the FFT-derived power spectrum is an approximation of the true spectrum, is relatively noisy, and demonstrates a considerable amount of variance. The latter can be reduced to

some extent by various windowing and averaging techniques. Figure 3.5 shows a three-dimensional display of the Doppler power spectrum from the umbilical artery generated by FFT processing.

### Limitations of FFT Spectral Analysis

There are basic limitations of the FFT approach for spectral processing of the Doppler signal. They include spectral variance and intrinsic spectral broadening.

#### *Spectral Variance*

The Doppler frequency spectrum from an arterial circulation varies with the changing hemodynamics of the cardiac cycle. Therefore the duration of the Doppler signal sample for FFT analysis during which the flow condition, and therefore the power spectrum, can be considered unchanging is limited. For an arterial circulation it is usually 10–20 ms. In the fetus the assumption of the spectral nonvariance may be valid for only 5 ms because the faster fetal heart rate pro-

**Fig. 3.5.** Three-dimensional plot of Doppler power spectrum generated by fast Fourier transform analysis. The spectrum was obtained from the umbilical circulation

duces faster temporal changes in the blood flow speed and in the power spectral density. A shorter temporal length of the sample ensures spectral nonvariance. However, the shorter the duration of the Doppler data segment, the worse is the frequency resolution. A signal segment of 5 ms gives a resolution of only 200 Hz, whereas increasing the duration to 20 ms improves the resolution to 50 Hz. Prolonging the duration, however, introduces uncertainty regarding the constancy of the power spectrum density. Under this circumstance, FFT processing does not function reliably, as it is based implicitly on the assumption of spectral constancy for the duration of the sample.

### Intrinsic Spectral Broadening

When a single scatterer moves at a constant speed across an ultrasound beam of limited width, the resultant Doppler spectrum has a range of frequencies instead of a single frequency. Because the phenomenon of broadening the Doppler spectrum is caused by the inherent properties of the measurement system, it is known as *intrinsic spectral broadening* (also *transit time broadening*). Spectral broadening mostly encompasses the following phenomena: (1) transit time broadening caused by the inhomogeneity of the ultrasound field causing amplitude fluctuations of the returning echo; this produces a range of frequencies distributed around the centroid Doppler shift frequency; (2) geometric broadening which results from the changing angles of insonation incurred by the scatterer as it moves across the beam; (3) non-stationary broadening caused by the changes in velocity during the sampling time; and (4) velocity gradient broadening originating from the changes in velocity within the sampling volume [8]. The problem of spectral broadening is compounded by the contribution from multiple moving RBCs traversing the ultrasound beam. The RBCs do not act as discrete scatterers but as volumes of randomly distributed scatterers. The number of RBCs in such a scattering volume in an ultrasonic field varies continually and randomly around a mean value, which causes swings in the scattering power. The consequences are similar to the spectral broadening of the Doppler signal observed with a single moving scatterer.

Spectral broadening is affected by the beam width, pulse length, and angle of insonation. Wider and more homogeneous beams, longer pulses, and smaller angles of insonation narrow the spectral spread. Obviously, the situation is worse with the short-gate pulsed Doppler ultrasound applications, where a scatterer can traverse only a part of the beam of a transmitted short pulse. The consequent transit time broadening effect generates a significant degree of ambiguity regarding the true distribution of velocity

Spectrum without Intrinsic Spectral Broadening

Spectrum with Intrinsic Spectral Broadening

**Fig. 3.6.** Amplitude-frequency spectrum from a circulation with a parabolic flow velocity profile. *Top:* Ideal spectrum with an even distribution of amplitudes (scattering power) at various frequencies, indicating erythrocytes traveling at various speeds. *Bottom:* Effect of spectral broadening on the maximum frequency definition of the same spectrum. *ISB* intrinsic spectral broadening

in the sample volume. The main clinical significance of spectral broadening is that it potentially compromises the precision of the maximum frequency shift envelope (Fig. 3.6). The mean frequency definition, however, is not affected, as the distribution of the frequencies around the mean shift is symmetric.

### Analog Fourier Spectral Analysis

Analog Fourier spectral analysis allows fast spectral processing of the Doppler signals utilizing analog techniques as opposed to the digital approach of FFT. One such implementation, known as Chirp Z analysis, is also a discrete Fourier transform-based method and requires less computing power and offers a wide dynamic signal processing range.

### Autoregression Analysis

Although Fourier-based methods dominate, alternative approaches for Doppler spectral processing are available. These methods are theoretically capable of eliminating many of the inherent disadvantages of the FFT method. Kay and Marple comprehensively described the autoregressive approach for spectral analysis [9]. Such procedures have been widely used for spectral analysis of speech and other periodic phe-

nomena. The autoregression method acts as a digital filter and assumes the signal at a given time to be the sum of the previous samples. In contrast to power quantification of the discrete frequencies in the FFT analysis, autoregression allows power quantification of all the frequencies of the spectrum. Moreover, it produces cleaner spectra and better frequency resolution than those generated by FFT processing.

We have evaluated autoregressive (AR), moving average (MA), and autoregressive moving average (ARMA)-based spectral processing approaches as possible alternatives to the FFT analysis [10]. Compared to the FFT processing, these parametric techniques produce cleaner spectra. The AR model estimates maximum frequency well, and the MA model indicates velocities at which most scatterers (erythrocytes) travel. The ARMA shows the potential of producing superior spectral analysis by combining the advantages of the AR and MA models. These parametric methods depend on appropriate system identification of the data.

## Continuous-Wave Doppler Ultrasonography

A continuous-wave (CW) Doppler transducer continuously transmits and receives ultrasonic signals. A CW Doppler system essentially consists of a double element transducer for both emitting and receiving signals, a radiofrequency receiver amplifier for the acquisition and amplification of the electrical voltage signals from the receiving transducer, a voltage generator that provides the driving frequency of the emitting transducer and the reference frequency for the demodulator, a demodulator that extracts the Doppler shifted frequencies from the total echo signals, and a direction detector that completely separates the signals of the forward flow from those of the backward flow. Details of these components of Doppler signal analyses and subsequent spectral processing are described at the outset of this chapter. The transducer assembly encases two piezoelectric elements; one continuously emits ultrasound and the other continuously receives the backscattered echoes (Fig. 3.7). For most transducers, the emitting and receiving elements are either rectangular or half-circle in shape. There may also be a concentric arrangement with a central circular element surrounded by a ring element. The elements are positioned in such a manner that their faces sustain a suitable angle to each other, and consequently there is an overlap between the transmitted ultrasound field generated by the emitting element and the sensitive zone for the receiving element.

A CW Doppler setup does not have range discrimination, and any movement within the sensitive re-

Fig. 3.7. Continuous-wave Doppler transducer

gion causes backscattering and consequently Doppler shift of the incident beam. If the beam interrogates more than one vessel, the Doppler signals from all the vessels merge to form a composite display. The only discrimination that exists is that the signals from a deep location are more attenuated because of the longer transmission path through tissues. A CW system is sensitive also to the movements of nonhemodynamic objects in its path, such as pulsating vascular walls or moving cardiac structures. These sources of Doppler shift produce high-amplitude/low-frequency signals, which may overwhelm a receiver-amplifier of limited dynamic range. This situation leads to loss of important hemodynamic signals. The problem can be resolved by ensuring an extended dynamic range of the receiver and by use of an appropriate high-pass filter, as described above.

Continuous-wave Doppler ultrasound instruments are used extensively in obstetrics for nonvelocimetric applications, such as fetal heart rate detection and external electronic fetal heart rate monitoring. For velocimetric applications, CW devices with a spectral analyzer are used for insonation of the umbilical arteries and often the uterine arteries. Despite the inherent absence of range discrimination, Doppler signals from the umbilical or uterine arteries can be obtained with relative ease. Moreover, the equipment is substantially less expensive than the duplex pulsed Doppler devices and requires less expertise to operate. However, CW Doppler instruments are infrequently used at present for fetal surveillance.

## Pulsed-Wave Doppler Ultrasonography

With the PW Doppler setup, a single transducer crystal emits pulses of short bursts of ultrasound energy (Fig. 3.8). Between the pulses the same crystal acts as the receiving transducer. As the velocity of sound in soft tissues is virtually constant, the time interval between transmission and reception of the ultrasound beam determines the distance, or range, of the target area from the transducer. Thus the location of the target area can be selected by varying this time delay. This process is known as *range gating*.

A simplified description of the pulsed Doppler ultrasound system is presented: As mentioned above, the same transducer crystal acts as both the transmitter and the receiver of ultrasound signals. A master oscillator generates a reference signal at the resonant frequency of the transducer. An electronic gate controls the transmission of the signal to the transducer, so a pulse of only a few cycles reaches it. The rate at which the pulses are generated (pulse repetition frequency) is determined by an electronic device called the pulse repetition frequency generator. The generator also controls the delay gate, which in turn controls the range gate and therefore the time interval between the ultrasonic transmission and reception. As described above, a demodulating system extracts the Doppler frequency shifts from the carrier frequency. The Doppler signals thus produced are stored, integrated, and updated with the signals from the next pulse. After appropriate filtering, the signals are now ready for audio output and spectral analysis. A more complete review of the pulsed Doppler system has been presented by Evans and associates [1].

Fig. 3.8. Pulsed-wave Doppler transducer

## Doppler Sample Volume

The three-dimensional region in the path of the transmitted ultrasound beam from which the frequency shift signals are obtained is called the Doppler *sample volume* (DSV). For the CW Doppler system, the totality of the superimposed region represents the DSV and is therefore of no relevance. For the PW Doppler system, the range-gated zone from which the backscattered echoes are received constitutes the sample volume. The DSV is an important consideration for PW Doppler applications because its location and axial dimension can be controlled by the examiner. The examiner therefore has the ability to interrogate a target area of appropriate location and size and to obtain more precise spatial velocity information. This subject is discussed further below.

The length of the DSV along the ultrasonic beam axis is known as its axial dimension. The lateral measurable limits of the beam, perpendicular to the beam axis, define its transverse dimension, or width. The shape resembles a pear or a teardrop (Fig. 3.9). The axial dimension is determined by the pulse length or duration as sensed by the receiving transducer and is therefore dependent on the duration of the transmitted ultrasonic pulse and the time window during which the receiver gate is open. As the last two factors are amenable to controlled variations, the axial dimension of the DSV can be altered by the operator. Many current duplex systems allow sample length variations, from 1.5 to 25.0 mm.

The transverse dimension of the DSV is determined by the ultrasonic beam width, which approximates the diameter of the transducer face in the near field. In the

Fig. 3.9. Doppler sample volume and the factors controlling its dimensions

far field the beam progressively diverges. In this circumstance, the angle of beam divergence, which depends on the wavelength and the transducer radius, dictates the transverse dimension of the DSV. Obviously, the width of the DSV is better defined in the near field than in the far field. Consequently, operating in the near field ensures greater certainty of velocity assessment. In contrast to the sample length, the sample width is not amenable to ready manipulation. However, owing to progress in transducer technology, including acoustic focusing, a few instruments allow controlled variations of the beam width in the far field and therefore of the transverse dimension of the DSV.

The dimensions of the sample volume can significantly affect the accuracy of velocity assessment. A sample volume that is large in relation to the dimensions of the target vessel can significantly compromise the range resolution of the measured velocities and lower the signal-to-noise ratio [11]. Conversely, a sample size smaller than the vascular dimension can diminish the sensitivity of the system. Moreover, depending on its relative size and location in the lumen of a large vessel, the assessed velocity profile can be significantly distorted. This subject is further discussed in Chap. 4.

## Artifacts of Spectral Doppler Sonography

Limitations of Fourier-based spectral analysis have been described in a previous section of this chapter. There are additional device-dependent false representations of the Doppler information that may compromise interpretive clarity. These artifacts are discussed herein.

## Nyquist Limit

A major problem of the PW Doppler system is its inherent limitation in accurately representing Doppler shifts from circulations with high-speed flow. A PW Doppler is essentially a sampling tool for a cyclic phenomenon. The sampling rate is the pulse repetition frequency of the Doppler system; the cyclic phenomenon is the Doppler shift frequencies generated by blood flow. The relation between the pulse repetition frequency and appropriate measurement of the maximum frequency shift is dictated by Shannon's theorem on sampling, which states that for unambiguous measurement of a periodic phenomenon the maximum frequency must not exceed half the sampling rate [12], which amounts to a minimum of two samples per cycle of the highest frequency. This maximum frequency threshold is known as the *Nyquist frequency* or *Nyquist limit*. The relation is expressed in the following equation:

$$f_{\max} = f_{pr}/2$$

where  $f_{\max}$  is the maximum frequency measurable without ambiguity (Nyquist limit), and  $f_{pr}$  is the sampling rate or the pulse repetition frequency.

Ambiguity in frequency resolution occurs when the PW Doppler beam interrogates a vessel with such a high blood flow velocity that the maximum frequency content of the Doppler signal exceeds the Nyquist limit. In this circumstance, the frequency cannot be estimated precisely. The frequency component in excess of the limit is subtracted from the Nyquist frequency and is negatively expressed (Fig. 3.10). This phenomenon is known as the *Nyquist effect*. It is also

**Fig. 3.10.** Example of aliasing and its correction. *Top* Aliased waveforms. Note the abrupt termination of the peak portion of the waveforms and the display of these peaks in the lower part of the panel below the baseline (*horizontal arrowheads*). *Bottom:* Correction of aliasing of the waveforms by increased pulse repetition frequency

known as *aliasing*, as it produces a representation of the frequency shift that is false in terms of magnitude and direction.

Aliasing does not pose a problem with most fetal PW Doppler measurements, particularly those involving the umbilical and cerebral circulations. However, the phenomenon may be observed when a high-velocity flow is encountered in fetal intracardiac and aortic circulations.

### Implications of Aliasing

Aliasing distorts the spectral display with an abrupt discontinuity at the Nyquist limit. The aliased part of the signal is displaced into the opposite frequency range of the display (Fig. 3.10). Such distortion also affects the audio output of the Doppler signal. The problem can be corrected in a number of ways.

1. The Nyquist limit can be raised by increasing the pulse repetition frequency, thereby resolving aliasing. However, this measure may introduce range ambiguity, as the Doppler signals from varying depths may be received at the same time.

2. Shifting the baseline resolves the problem by increasing the positive frequency range and decreasing the negative frequency range in the display. It effectively extends the maximum velocity limit, and the spectra are displayed in the same direction without ambiguity.

3. As the operating frequency of the transducer is directly proportional to the magnitude of the Doppler shift, reducing the former may lower the maximum frequency enough for the elimination of aliasing without changing the sampling rate.

4. Increasing the angle of insonation between the Doppler beam and the flow axis reduces the maximum Doppler shift, which may eliminate aliasing.

If these measures are inadequate for resolving aliasing, one may use a CW Doppler setup, which is not limited by the Nyquist frequency and does not produce aliasing, although range resolution is lost with this approach.

### Range-Velocity Resolution

The maximum range, or depth, at which the velocity of blood flow can be measured accurately by a PW Doppler system is limited. As the distance on the target from the transducer increases, more total time is required for a transmitted ultrasound pulse to travel to the target and the backscattered echo to return to the source. The device must wait this period of time before transmitting the next pulse. If more than one pulse propagates in the target at the same time, the PW Doppler system is incapable of determining the

spatial origins of the different returning echoes, resulting in range ambiguity. To avoid this problem, the interpulse interval must be increased with the greater depth of the target vessels. Obviously, the maximum depth at which PW Doppler measurement can be performed without range confusion is limited by the interpulse interval. This relation is shown in the following equation:

$$D_{\max} = c \cdot T_p / 2$$

where  $D_{\max}$  indicates the maximum depth of the target vessel,  $c$  is the velocity of sound in soft tissue, and  $T_p$  is the interpulse interval. As the pulse repetition frequency ( $f_{pr}$ ) is the reciprocal of the interpulse interval, the equation can be expressed as:

$$D_{\max} = c / 2f_{pr}$$

The pulse repetition frequency also determines the maximum allowable Doppler frequency shift and therefore the blood flow velocity that can be measured without producing aliasing. It follows therefore that the deeper the PW Doppler sampling location, the lower the maximum measurable velocity.

For the above consideration, it has been assumed that the frequency of the transmitted ultrasound is fixed. However, another variable comes into play when the ultrasound frequency can be changed. The lower the ultrasonic frequency, the lower the attenuation and the greater the maximum depth at which the Doppler measurement can be made. Given a maximum sampling depth, an upper limit is established for the pulse repetition frequency and correspondingly for the Nyquist frequency. It follows therefore that for a given sampling depth and pulse repetition frequency, higher flow velocities can be measured using lower transmitted frequencies. For most obstetric applications, a transducer frequency of 3–4 MHz provides the best Doppler output.

It is interesting to consider the CW Doppler operation as a special case of the pulsed mode, where the pulses are transmitted at an exceedingly high speed, theoretically, at an infinite pulse repetition frequency. Obviously, no range information is available for the received pulses, as it becomes impossible to relate a given reflection to any particular pulse. However, because of the theoretically infinite pulse repetition frequency, the Nyquist limit for the Doppler frequency shift is also infinite. With the DW Doppler system, then, there are no limits on the maximum measurable velocity.

## Mirror Imaging

With the artifact of mirror imaging a Doppler device falsely represents unidirectional flow as bidirectional flow. The artifactual flow is depicted as a mirror image of the true flow on the opposite side of the baseline (Fig. 3.11). The problem afflicts both CW and PW Doppler systems and is caused by leakage of the Doppler signal from one directional quadrature channel to the other (quadrature channel cross-talk), so the signals are duplicated. Although there is directional ambiguity, there is no subtraction and relocation of Doppler spectral information as encountered with the Nyquist effect. Quadrature cross-talk can occur with high-velocity flows, excessive gain setting, preponderance of high-amplitude Doppler signals, and paradoxically also with low-velocity flows.

The mirror imaging artifact may be eliminated by decreasing the gain, which reduces the quadrature cross-talk. Increasing the high-pass filter may also improve the problem by removing the high-amplitude/low-frequency signals and decreasing the signal leakage in the quadrature channels. Increasing the angle of insonation may also effectively prevent quadrature leakage while interrogating high-speed circulations. Finally, prior knowledge of the target circulation should prevent erroneous interpretation of the Doppler tracing.

False depiction of a unidirectional flow as bidirectional due to system limitation should be distinguished from the situation where the Doppler beam

insonates a true bidirectional flow system and consequently the Doppler waveforms appear on both sides of the baseline. For example, a Doppler beam with a sufficiently long sample volume interrogating the umbilical cord may encounter flows in the adjacent loops of the umbilical arteries in opposite directions relative to the transducer, and the Doppler waveform is correctly depicted on either side of the baseline. Similar nonartifactual mirror imaging may also occur when a focused pulsed Doppler beam intersects the flow axis at a right angle, and the same unidirectional flow is toward the transducer in one part of the beam and away from the transducer in the other part. The Doppler tracing in this situation is correctly bidirectional in relation to the transducer and is depicted as such.

## Duplex System

### Principles of the Duplex Doppler System

A duplex ultrasound system combines the modality of a real-time two-dimensional pulse-echo imaging of anatomic structures with that of a Doppler ultrasound system. Although the inherent range resolution feature of a PW Doppler system potentially allows collection of Doppler signals from a specific vascular target, this capability is hardly useful unless a method exists for placing the Doppler sample volume at the desired vascular location. A duplex system resolves this problem. The imaging mode offers the

**Fig. 3.11.** Example of mirror imaging of the Doppler waveform obtained from the uterine artery. *Top:* Two-dimensional image shows placement of the Doppler sample volume (horizontal bars). *Bottom:* Doppler frequency shift waveforms. The mirror image is seen on the lower side of the baseline

anatomic information so the Doppler sample volume can be placed at the target from which the Doppler frequency shift or velocity information can be obtained. It is achieved by employing a technique similar to that used for M-mode echocardiography. An electronically produced cursor line can be directed across any targeted component of the two-dimensional real-time cross-sectional image (Fig. 3.12). The cursor line indicates the Doppler beam path. The location of the Doppler sample volume is indicated on the cursor line by a marker, which can be an arrow, a small variably sized solid rectangle, or other shape. This location can be moved along the cursor line. Moreover, the axial dimension of the sample volume can be varied in most duplex instruments.

Experience with fetal Doppler echodiagraphy illustrates the significant advantages of duplex Doppler for fetal circulatory assessment [13]. A two-dimensional echocardiographic scan allows pulsed Doppler interrogation of complex intracardiac flow channels and outflow tracts. Similarly, it would be impossible to perform reliable Doppler assessment of fetal aortic or middle cerebral circulations without the guidance of two-dimensional imaging. Doppler evaluation of these vascular systems is based entirely on duplex technology, which offers the only choice for interrogating most circulatory targets of the fetus. The only exception is the umbilical artery, which can be readily insonated with CW Doppler without duplex imaging guidance. Most duplex ultrasound instruments include the additional modalities of CW Doppler and M-mode ultrasound; and high-end duplex instru-

ments also include two-dimensional Doppler color flow mapping.

### Optimal Configuration of a Duplex System: Imaging Versus Doppler System

One of the major challenges of configuring a duplex ultrasound system lies in reconciling the conflicting needs of optimally performed imaging and the Doppler scanning components. For imaging, spatial resolution is of basic importance. System features (e.g., short pulses, well-damped transducers, and wide-band receivers) contribute significantly to improving the image resolution. These factors are therefore important considerations for pulsed echo imaging. However, because of the low amplitude of the backscattered Doppler signals, the optimal performance of a Doppler system is mostly dependent on its sensitivity, not on spatial resolution. In contrast to the imaging needs, the sensitivity of a Doppler system is enhanced by longer pulses, which by interrogating larger clusters of RBCs increase the amplitude of returning signals and improve the sensitivity. The sensitivity is increased by reducing the transducer damping and using narrow-band receivers.

It is obvious that the optimal configuration of a transducer system for duplex application is a trade-off between the conflicting needs of imaging and Doppler sonography. For the latter, lower frequencies are preferred as they ensure adequate depth penetration and minimize the changes of producing range-velocity ambiguity. Higher frequencies, on the other

**Fig. 3.12.** Typical example of a duplex Doppler display. *Top:* Two-dimensional gray-scale image. The spectral Doppler beam path is indicated by the dotted cursor line. The Doppler sample volume is indicated by two white lines. *Bottom:* Spectral Doppler frequency shift waveforms from the sampled umbilical arterial location

hand, compromise Doppler sensitivity. In contrast, low frequencies reduce spatial resolution, which is of central importance for imaging. These factors are important considerations when choosing appropriate transducers for fetal Doppler applications where deep-lying small vascular structures demand both sufficient spatial resolution and adequate Doppler sensitivity. Obviously, depending on the specific use of a duplex system, varying degrees of compromise are needed between these competing needs.

### Duplex Implementation

Efficient integration of imaging and Doppler functions in a duplex transducer assembly offers a significant challenge for engineering innovation. Any comprehensive description of the current state of duplex Doppler transducer technology is beyond the scope of this chapter. Therefore only a brief account of the Doppler implementation of the duplex probes is presented in this section. These transducers can be classified into two broad categories according to the mechanism of scanning and focusing: (1) mechanical sector scanners, and (2) electronic array scanners, in which electronic means are employed for scanning and focusing.

Mechanical sector scanners use electric motors to rotate or oscillate the active transducer elements for sweeping the ultrasound beam to scan the tissue plane. Alternatively, a mirror may be used to sweep the beam, while the transducer element remains stationary. For duplex function, most mechanical systems use the same transducer elements for both imaging and Doppler scanning. In a mechanical sector system, the comparatively greater dimension of the transducer crystals and acoustic focusing favor improved image resolution and Doppler sensitivity. The inherent disadvantage of a mechanical system where the same elements are used for both imaging and Doppler scanning is the discontinuity between these two functions. Thus, during the actual Doppler recording, the fetus may move, so that the Doppler sample volume may no longer be at the desired target. Mechanical sector transducers are no longer used in obstetrical duplex Doppler applications, which now invariably involve electronic array transducers.

### Electronic Array Scanner

In contrast to the mechanical scanners, electronic array transducers contain multiple piezoelectric elements (128 or more), and the ultrasonic scanning beam is formed by electronically controlled firing of these elements [4-17]. Over the years these transducers have evolved in terms of the complexity of their construction and the sophistication of their opera-

tion. The beam formation, steering, focusing, and aperture control are electronically implemented. Currently, several varieties of electronic array transducers are available. They are classified according to the arrangement of the piezoelectric elements in the transducer assembly and the electronic mechanism of beam formation. The elements may be arranged in the transducer assembly: (1) in a straight line, which constitutes a linear array transducer (Fig. 3.13); (2) in a convex arc, in which case the assembly is labeled as a convex array transducer, (3) in concentric rings, called the annular array (Fig. 3.14); and (4) in a two-dimensional rectangular space for three-dimensional sonography, usually termed a two-dimensional array or matrix array. The last one is discussed further in Chap. 34. According to the electronic mechanism of producing the scanning beam, there are two types of array transducer: (1) the sequenced array, which op-

**Fig. 3.13.** Linear sequenced array transducer. The Doppler cursor line is shown to be electronically steered across the rectangular field of imaging

**Fig. 3.14.** Annular array transducer

erates by sequentially triggering batches of piezoelectric elements for scanning the beam; and (2) the phased array, which electronically triggers all or most of the piezoelectric elements as a group during a given pulse. Time delays (known as *phasing*) are used in consecutive pulses to form the scanning beam. For both of these arrays, the beam is focused by appropriate phasing, or time delay, of the piezoelectric elements. A specific transducer may have mixed features; for example, a linear sequenced array has phasic operation for focusing, or an annular array focuses electronically but scans mechanically. Currently, the following electronic array transducers are most frequently used in obstetric applications.

1. *Convex sequenced array* (Fig. 3.15). The piezoelectric elements are arranged in a convex arc and are fired sequentially in small groups as with the previous two categories. They are also known as curvilinear, curved, or radial array transducers (Fig. 3.15). The field of image is sectorshaped. This design allows a small transducer footprint with a wide field of imaging at depth – a combination of features particularly useful for obstetric scanning. Furthermore, the wide field of view is achieved without the grating lobe problem of the linear phased array. With the phased convex sequenced array, the focusing is achieved by phasing of the firing sequence. Doppler insonation is performed by a batch of phased elements that can be steered in the sector field of exposure.

2. *Linear phased array*. This configuration is also known as the phased or electronic sector array. As the name implies, the piezoelectric elements are arranged in a straight line, and the beam is formed by the simultaneous phased firing of all the elements. Focusing and steering is accomplished electronically by the phased triggering of the elements. The field of image created by a linear phased array is sector-shape. Although these transducers do not often provide optimal imaging for general obstetric applications, they are useful for fetal cardiac imaging. The Doppler ultrasonic beam is produced by a batch of elements that are phased and can be steered within the scanned image area to interrogate the target vessel.

### Integration of the Doppler and Imaging Functions in Array Transducer

We referred earlier in the chapter to the conflicting needs of optimal transducer frequency for imaging and Doppler sonography. In many current duplex systems the problem has been addressed by providing dual-frequency transducers, a higher operating frequency for imaging, and a lower frequency for Doppler ultrasound. The latter improves the Doppler sensitivity and sets a higher Nyquist limit, whereas the former improves spatial resolution for imaging. For example, the transducer has 3.5 MHz for imaging function and 2.5 MHz for Doppler insonation. Such an arrangement has been possible only since the ad-

**Fig. 3.15.** Convex sequenced array transducers. *Left panel:* Example. *Middle panel:* Color flow image of the umbilical circulation demonstrating placement of the Doppler sample volume. The Doppler parameters are noted in the left

*lower corner. Right panel:* Doppler frequency shift waveforms of the umbilical artery. The vertical cursors in this panel define one cardiac cycle

vent of broad bandwidth electronic array transducers and advanced processing capability.

In contrast to mechanical scanners, electronic transducer array scanners are capable of seemingly simultaneous execution of imaging and Doppler functions. The simultaneous operation, which is only apparent and not real, can be achieved by several methods. With one such technique, alternate pulses are shared between the two-dimensional imaging mode and Doppler sonography. This technique is similar to that used when performing simultaneous imaging and M-mode scanning. However, it reduces the Doppler pulse repetition frequency and therefore the Nyquist limit, which results in significant restriction in the maximum velocity that can be measured without aliasing. The two-dimensional imaging, frame rate is also slowed. To address the aliasing problem, a modified time-sharing approach limits the time for imaging in favor of the time for Doppler scanning. However, this method produces slow, sweeping images, which restrict the utility of the imaging guidance and are visually disconcerting for the operator [18].

A more efficient solution, used with the current generation of devices, consists in devoting more scanning time to imaging than to Doppler sonography, so a single but full image frame can be formed. The Doppler data lost during this interval is simulated from the preceding recorded spectrum by an interpolation algorithm, known as the missing signal estimator. Although it still reduces the imaging frame rate, the results are superior to those of other alternatives for approximating simultaneity. In a typical scenario,

the Doppler scan is performed for 10 ms, followed by pulse echo imaging for 20 ms. During the 20-ms interruption, the missing Doppler spectrum is interpolated from the immediate prior recording and is displayed without discontinuity. The system performs this routine with great swiftness many times a second, which allows Doppler shift assessment along with the imaging guidance to continuously verify the source of Doppler signals [19]. Obviously, this level of system performance is possible only in an electronic array with powerful processors and efficient algorithms.

### Multiple-Gate and Multiple-Sample Doppler Systems

With a multiple-gate Doppler system, the standard PW Doppler system is enhanced so multiple receiver channels are range-gated sequentially. It allows multiple-point velocity assessment along the beam path. This technique, however, still does not provide comprehensive velocity information encompassing the scanned plane. With a multiple-sample Doppler system, the above approach is extended so multiple lines are sampled at several gate levels in a sequence. The process is complex, requires intensive computing, and its use has been mostly experimental. Relatively recently, a multigated, multisample spectral Doppler system has been reported [20]. The system rapidly acquires multiline, multigated Doppler waveforms from the region of interest as determined by the operator and automatically analyzes the spectral data to

**Fig. 3.16.** Multigated simultaneous spectral Doppler imaging. *Upper panel* depicts color-coded pulsatility index (PI) map from the umbilical cord. Each pixel represents a PI value at the sampled site on the anatomic image. *Lower panel* displays selected spectra from which the color pixels originated. (Courtesy of Dr. S. Haberman)

determine the maximum frequency shift envelopes. Various Doppler indices are determined automatically and displayed either spatially as color-coded superimpositions over the gray-scale two-dimensional anatomical image or as a statistical distribution histogram of the indices in the scanned area (Fig. 3.16). Although the reproducibility of the new modality has been confirmed in relation to the umbilical artery, its utility remains to be confirmed.

## Doppler Display

During operation, the Doppler information is displayed on a monitor screen. The details of the display vary according to the type of instrumentation and manufacturer. The CW Doppler instruments obviously have simpler displays (Fig. 3.11) in comparison with duplex Doppler systems (Fig. 3.12). During real-time Doppler interrogation, the spectral display scrolls from the right of the screen to the left with time, as progressively newer spectral information is added to the display. In addition to the spectral waveform, a CW Doppler display also includes the zero line, the frequency (or velocity) scale in the vertical axis, and the time scale in the horizontal axis. The spectral display area also includes the cursor lines for measuring the peak systolic or end-diastolic fre-

quency shifts. Additional information is shown outside the spectral display window but within the screen area. It may include measures of the frequency shift including the peak systolic and end-diastolic components, Doppler indices, and various indicators of the system function.

A duplex Doppler system display is complex because of its extended function, encompassing both imaging and Doppler modes. Moreover, M-mode capability and both CW and PW Doppler modes are integrated into these systems. With more advanced systems, color Doppler flow mapping is also included. Compared with the imaging and M-mode instruments, these devices must convey to the operator a far greater amount of information. To maintain user-friendliness, the devices employ a software menu approach to their system control, which is usually reflected in the control panel display and the monitor display, so the operator is guided through the multiplicity of functions with relative ease. In the Doppler mode the monitor screen should display not only the spectra, the data of examination, and the patient's identity but comprehensive Doppler information as well, including transducer frequency, mode of Doppler, depth and size of the sample volume, angle of insonation, frequency or velocity mode, pulse repetition frequency, and Nyquist limit. It is imperative to indicate the filter and gain settings and to offer some meaningful information on the power output of the transducer. The latter is needed to ensure that the fetus is not exposed to a high level of ultrasonic energy when a lower output is sufficient to yield the desired information. Most current instruments include real-time energy output displays, the thermal index and the mechanical index, which indicate to the operator the potential for producing any biological effects in soft tissue. This is discussed in Chap. 8. Both manufacturers and users must be cognizant of these biosafety considerations. A number of options are available for archival storage of the Doppler information, including video recording and hardcopy prints, thermal printouts, photographic recording, and computer storage. When choosing the appropriate storage modality, many factors should be considered, including the needs of an individual practice, cost-benefit issues, archival integrity, and the ease of retrieval.

The indices (S/D, D/A) are also shown

## Summary

The backscattered echo signals from a vascular source consist of the carrier and the Doppler shifted frequencies along with noise generated from various sources. To obtain clinically useful information, it is necessary to generate Doppler waveforms by systematically processing these signals. The steps involve re-

ception and amplification of the returning signals, separation of the Doppler-shifted frequencies and determination of the directionality of flow in relation to the transducer, and spectral processing, which sorts the frequencies of the signal and determines their amplitude content. In addition, appropriate filtering is performed to eliminate the low-frequency/high-amplitude signals from tissue-sources and the high-frequency noise signals from the device. Doppler interrogation is performed by either CW Doppler transducers, which do not have range resolution, or PW transducers, which are capable of sampling a specific vascular location. Each approach has significant advantages and limitations. However, CW Doppler devices are seldom used at present for fetal investigation. Duplex Doppler ultrasonography combines two-dimensional imaging with the Doppler modality that allows image-guided interrogation of vascular targets. This capability is particularly useful for fetal investigation. Of the various types of duplex transducers, the convex sequenced array and the linear phased array are commonly used for obstetrics and gynecology.

# Spectral Doppler Sonography: Waveform Analysis and Hemodynamic Interpretation

Dev Maulik

The spectral Doppler power waveform contains an immense amount of hemodynamic information from the sampled circulation. As we saw in Chap. 3, the spectral information consists of three fundamental variables: frequency, amplitude, and time. Spectral frequency reflects the speed of blood flow. The amplitude approximately represents the number of scatterers traveling at a given speed and is also known as the power of the spectrum. Amplitude depends on the quantity of moving red blood cells (RBCs) in the sample and therefore reflects the volume of blood flow. The time over which the frequency and amplitude vary is the third variable. A comprehensive depiction of the Doppler spectrum is therefore three-dimensional (see Chap. 3). Such a display is complex, however, and not particularly useful for clinical application. Fortunately, there are alternative approaches

for effectively characterizing the spectral waveform, including two-dimensional sonograms and various frequency envelope waveforms. These approaches can be utilized to evaluate various aspects of hemodynamics of flow, ranging from the presence and directionality of flow to downstream impedance. This chapter discusses these subjects and other related issues.

## Spectral Doppler Sonogram

A typical two-dimensional sonographic display of Doppler frequency shift waveforms from the umbilical circulation is shown in Fig. 4.1. Each spectrum of the Doppler shift is depicted in a vertical line whose vertical dimension represents the magnitude of the

**Fig. 4.1.** Spectral Doppler waveform from the umbilical arteries. *Vertical axis* represents the magnitude of the Doppler frequency shift. *Horizontal axis* represents time. Brightness of the tracing indicates the amplitude of the Doppler spectrum. Note that the recording is scrolled from right to left as new information is continuously added to the right end of the spectral display

frequency; the image intensity or brightness represents the amplitude. Each successive spectrum is added to the right of the previous spectrum as the display is scrolled from right to left. Thus the horizontal axis indicates the temporal dimension of the Doppler recording. When sampled from an arterial circulation, a Doppler waveform depicts one cardiac cycle. The left limit of the wave corresponds with the onset of systole, the zenith of the wave with peak systole, and the right limit with the end of diastole. In a two-dimensional Doppler sonogram, only the frequency and time are quantitatively depicted, whereas the amplitude, or power of the spectrum, is expressed only qualitatively. The directionality is depicted in terms of whether the flow is toward or away from the transducer. The flow toward the transducer is shown as an upward deflection from the baseline and flow away as a downward deflection; this configuration may be reversed in the display. The hemodynamic interpretation and utilization of the various characteristics of the Doppler wave sonogram are discussed later in this chapter.

### Doppler Frequency Shift Envelopes

Although the full power spectral display of the Doppler signal as described above provides a comprehensive account of the dynamics of flow velocity, often more limited and focused spectral information based on the various envelope definitions of the Doppler frequency shift waveform is used (Fig. 4.2). Of the various envelopes, the maximum and mean frequency shift waveforms are most commonly used for clinical applications. These envelopes and an additional one, the first moment, are discussed here.

#### Maximum Frequency Shift Envelope

The maximum frequency shift envelope may be derived manually by outlining the spectral waveform or electronically by analog or digital techniques. Many devices allow superimposition of the maximum frequency envelope over the spectral display waveform. It should be noted that most Doppler descriptor indices are based on the maximum frequency shift values (see below), although most indices are usually determined without defining the total envelope. This envelope is not significantly affected by uneven insonation so long as the ultrasound beam includes the fastest flow within the lumen. It is also resistant to the flow velocity profile of the circulation, the attenuation variation between blood and soft tissue, the signal-to-noise ratio, and the high-pass filter. The maximum frequency envelope is susceptible to spectral broadening as the definition of maximum frequency in relation to the spectral power becomes im-

**Fig. 4.2.** Descriptor envelopes of the Doppler frequency shift waveform. (Reprinted from [2] with permission)

precise, and the maximum frequency values form a gradual slope at the various cutoff levels of peak power (see Fig. 3.6).

#### Mean Frequency Shift Envelope

Under the ideal circumstances of complete and uniform insonation of the target vessel, the mean frequency provides an indirect estimate of mean flow velocity; corrected for angle of insonation, it yields actual velocity values. The accuracy of the mean frequency depends on the velocity profile and is compromised when a vessel is incompletely insonated. The envelope is affected by the differential attenuation of sound between blood and tissue, which favors transmission of Doppler signals from the center of the vascular lumen; it results in false elevation of the mean frequency. It is also susceptible to high-pass filtering, which increases the mean frequency estimate by eliminating low-frequency signals along with the tissue-derived clutter signals. The mean frequency has the advantage of being unaffected by spectral broadening because of the symmetric nature of the spectral spread.

### First Moment Envelope

Of the additional definitions of the Doppler envelope, the first moment of the Doppler power spectrum is of particular interest. The Doppler-shifted frequency is proportional to the speed of the backscattering erythrocytes, and the power of a Doppler spectrum is proportional to the density of erythrocytes moving at a corresponding speed. On this theoretic basis, Saini and associates [1] proposed that being a summation of the power-frequency product the first moment represents the integrated cell count-velocity product within the sample volume and is therefore indicative of instantaneous volumetric flow. Maulik and colleagues [2] investigated the potential of the first moment-derived Doppler waveform from the umbilical artery and observed that the first moment-based pulsatility index was twice that derived by the maximum frequency shift envelope. This phenomenon may be explained by the relative flattening of the velocity profile during early systole and by changes in the arterial diameter.

The utility of first moment remains uncertain. Although this approach contains more hemodynamic information, its practical application is limited by the impracticality of ensuring uniform insonation. Moreover, as pointed out by Evans and coinvestigators [3], the total power of the Doppler spectrum may be affected by many factors other than the vascular cross-sectional dimension.

## Hemodynamic Information from Doppler Sonography

The Doppler frequency shift estimates, but does not directly measure, blood velocity. Doppler ultrasound can generate a wide range of hemodynamic information, including the presence of flow, directionality of flow, flow velocity profile, quantity of flow, and the state of down-stream flow impedance.

### Flow Detection

Identification of the presence of blood flow is one of the common uses of Doppler ultrasound. Pulsed duplex Doppler insonation, especially with the two-dimensional color flow mapping mode, is capable of identifying flow that has multiple utilities in clinical practice. For example, color Doppler insonation is used to identify loops of umbilical cord in the amniotic cavity, especially when gray-scale imaging is inconclusive (Fig. 4.3). This information is useful for conducting invasive procedures, such as amniocentesis or cordocentesis, and for evaluating the amniotic fluid volume. In the human fetus, detection of anom-

**Fig. 4.3.** Color Doppler identification of umbilical vessels. *Left:* Gray-scale imaging shows apparently cord-free amniotic fluid space. *Right:* Color Doppler interrogation shows the presence of the umbilical cord in this space

alous flow using pulsed Doppler echocardiography may significantly supplement the two-dimensional echocardiographic technique for diagnosing cardiac abnormalities (see Chap. 33). For example, Doppler ultrasound detection of flow in an echo-deficient area adjacent to the main pulmonary artery of the fetus was noted to assist the diagnosis of congenital aneurysm [4].

A major application of duplex Doppler flow identification is the diagnosis of proximal vein thrombosis. An absent or anomalous flow in a proximal vein suggests complete or partial occlusion. The technique has been used to assess peripheral vascular competence with varying degrees of success. However, caution should be exercised when interpreting failure to detect Doppler shift because in this circumstance the flow may be present but not within the sensitivity of the Doppler device. The maternal and fetal placental circulation offer prime examples of this problem. Although these circulations carry an immense amount of blood flow, Doppler interrogation fails to produce any recognizable Doppler shifts from most of the placental mass. Recent introduction of the power mode of color Doppler ultrasound has significantly improved the capability of recognizing slow- and low-flow states. This subject is further discussed in Chap. 6.

### Flow Direction

The demodulation technique allows determination of the directionality of flow; forward and reverse flows are displayed on the opposite sides of the baseline. Flow directionality provides basic hemodynamic information that can be of significant clinical utility. For perinatal applications, flow directionality allows assessment of the status of continuing forward flow during end-diastole in umbilical and uteroplacental circulations. Absence or reversal of this end-diastolic forward flow is of ominous prognostic significance and is further discussed in Chap. 25. Depiction of

flow directionality during echocardiographic assessment may assist in recognizing pathology. For example, atrioventricular valvular incompetence may be diagnosed from the demonstration of reverse flow during systole at the tricuspid or mitral orifice.

### Flow Velocity Profile

Doppler shift spectral range may reflect the velocity profile of blood flow in the insonated vessel. When the spectral range is wide it is called *spectral broadening*, and when it is slim it is known as *spectral narrowing*.

Spectral narrowing usually indicates a flat or plug flow velocity profile in which most RBCs are moving at a similar speed; it is usually seen in large vessels. For obstetric applications, this flow profile is encountered in fetal ventricular outflows (Fig. 4.4). Spectral narrowing is seen during the early systolic phase (from the outset to peak systole) in a great vessel as the ventricular ejection force at its prime imparts similar speeds of flow to the RBCs; however, such an appearance may be artifactual because of the steepness of the trace [5]. Spectral narrowing is also observed when the sample volume size is smaller than the lumen, and it is placed in the center of the lumen where the flow speed is fastest.

Spectral broadening is seen with a parabolic flow where the RBCs travel at a wide range of speeds and produce a wide range of Doppler-shifted frequencies. In a parabolic velocity profile, the RBCs travel at

varying speeds, with the cells at the center of the vessel traveling at the highest velocity and those near the vascular wall at the lowest velocity because of the viscous drag. Such a wide distribution of RBC velocities provides uniform broadening of the Doppler spectral display, which is usually encountered in small vessels, such as the uterine and ovarian arteries. Figure 4.5 shows an example of spectral broadening of the Doppler waveform. In obstetrics, blunted parabolic flow is seen in the umbilical arteries. It is also encountered in a turbulent flow characterized by a wide distribution of RBC speed across the vascular lumen. Finally, as noted with spectral narrowing, partial insonation of an artery may also lead to spectral broadening. If a small sample volume is placed near the wall of a large vessel, spectral broadening occurs as the flow layers toward the vessel wall show wider speed distribution.

### Doppler Flow Quantification

Measurement of volumetric blood flow remains a parameter of fundamental hemodynamic importance. There are various noninvasive sonographic methods for quantifying flow. Of these, Doppler ultrasound velocimetry still remains the standard modality. There are also non-Doppler-based ultrasound technologies for measuring volumetric blood flow without some of the limitations of the Doppler technique. These approaches are discussed below.

**Fig. 4.4.** Spectral narrowing. *Top:* Two-dimensional image of the fetal heart with the Doppler sample volume placed at the left ventricular outflow. *Bottom:* Doppler waveforms. Note the spectral narrowing of the waveforms

**Fig. 4.5.** Spectral broadening. Top: Flow-guided placement of the Doppler sample volume in the uterine artery. Note the spectral broadening of the waveform

### Principle of Doppler Flowmetry

The Doppler flowmetric technique has been used to measure umbilical venous flow [6], descending aortic flow [7], and fetal right and left ventricular outputs [8]. The theoretical basis of Doppler flow quantification is as follows (Fig. 4.6). The volumetric flow in a given instant ( $Q$ ) is the product of the spatial mean velocity across the vascular lumen at that instant ( $\bar{v}(t)$ ) multiplied by the vascular cross-sectional area at that instant ( $A(t)$ ):

$$Q(t) = \bar{v}(t)A(t) \quad (1)$$

The mean velocity is estimated from the mean Doppler frequency shift ( $\bar{f}_d$ ) by Doppler velocimetry provided the angle of insonation ( $\theta$ ) is also known:

$$\bar{v}(t) = \bar{f}_d(t)c/2f_t \cos \theta \quad (2)$$

where  $f_t$  is the transducer frequency and  $c$  is the speed of sound in blood. The equation (1) can now be rewritten as follows:

$$Q(t) = (\bar{f}_d(t)c/2f_t \cos \theta)A(t) \quad (3)$$

**Fig. 4.6.** Doppler sonographic volumetric quantification. Graphic depiction of the principle of even insonation technique.  $Q$  volumetric flow in a given instant,  $\bar{v}(t)$  spatial mean velocity across the vascular lumen at that instant,  $A(t)$  vascular cross-sectional area at that instant

Arterial circulation is pulsatile. Therefore the volumetric flow passing through the arterial tree fluctuates through the cardiac cycle. The temporal average flow over the cardiac cycle is obtained from the temporal average product of the instantaneous mean velocity (mean frequency shift) and the vascular cross-sectional area.

## Doppler Velocity Measurement

There are several sonographic approaches to Doppler measurement of blood flow velocity. These include the uniform insonation method and the assumed velocity profile method.

### *Uniform Insonation Method*

In this approach, a duplex Doppler ultrasound device is used to insonate uniformly and completely the lumen of the target vessel, and to determine the instantaneous mean frequency shift, the cross-sectional area of the vessel, and the angle of insonation. The Doppler sample volume needs to be large enough to encompass the entire vascular cross-sectional area but not to include the surrounding structures. It is also assumed that the angle of insonation is constant over the entire sample volume.

Error in estimating mean frequency shift can be due to uneven insonation, intrinsic spectral broadening, blood-tissue attenuation difference, high-pass filter, and poor signal-to-noise ratio. Of these, uneven insonation is potentially the most significant contributor. For example, partial insonation of a vessel in the periphery of the lumen will underestimate the mean frequency, whereas similar insonation in the center of the lumen will overestimate it. Most duplex Doppler devices available at present utilize a narrow beam for Doppler insonation and therefore may not be able to uniformly insonate the whole vessel even in the fetus.

### *Assumed Velocity Profile Method*

A modification of the uniform insonation, the assumed velocity profile technique attempts to address the problem related to the mean frequency measurement by estimating the mean velocity from the time-averaged maximum frequency shift value. In this approach, the velocity profile across the flow cross-sectional area is assumed rather than measured, and maximum frequency shift data from a point target are translated into mean frequency shift values. The mean velocity is estimated by multiplying the angle-corrected instantaneous maximum frequency shift with an arbitrary calibration factor and is based on the assumption that the flow velocity profile is either flat or parabolic. In case of a flat profile, the calibration factor has a value of 1 as the mean and maximum velocities are theoretically the same. However, when the profile is parabolic, the mean velocity is half of the maximum velocity and the calibration factor has a value of only 0.5. Although this technique obviates to some extent the problem of mean velocity determination, the underlying assumptions regarding the flow velocity profile often do not exist in reality

and the technique still suffers from the other limitations of the uniform insonation method. An example of the use of this technique which describes the measurement of fetal cardiac output is given in Chap. 32. This approach may introduce inaccuracies in quantifying flow. These errors are related to measuring of the mean frequency shifts, the vascular luminal cross-sectional area and the angle of insonation.

## Determination of Vascular Luminal Area

The cross-sectional area of the vessel lumen may be measured from the two-dimensional image or from the M-mode tracing of the vessel. The radius, which is half the diameter of the luminal cross section is measured first and the area is estimated according to the equation:

$$A = \pi r^2 \quad (4)$$

where  $A$  is the cross-sectional area and  $r$  is the radius. This equation assumes that the vascular cross section is circular in shape. This assumption, however, is erroneous as the shape of the vascular lumen is more ellipsoidal than circular, and the shape and the dimensions of the arterial cross section are known to vary during the cardiac cycle. The problem is confounded by the fact that any error in measuring the vessel diameter is significantly amplified in the volumetric flow value. Because of these limitations, measurement of the vascular cross-sectional area is the most significant source of error for Doppler sonographic estimation of volume flow. This is especially relevant for deep-lying smaller fetal vessels. However, the error may be minimized by averaging several measurements of the diameter. Temporal averaging of the diameter during the cardiac cycle is especially important for arterial circulations. Magnification of the digital image of the vessel off line in a computer may also improve the accuracy and has been reported [9]. Simultaneous measurement of the vascular cross section and the mean velocity remains technically challenging. The best sonographic approach for imaging and measuring vascular dimension may not often be optimal for Doppler insonation.

## Determination of the Angle of Insonation

Finally, the angle of insonation is an important source of inaccuracy for volumetric flow quantification as the cosine value of the angle ascertains the component of blood flow velocity reflected in the Doppler shift. The higher the angle of insonation, the greater the error of measurement. This is discussed in greater depth in Chap. 2.

## Alternative Methods of Doppler Flowmetry

### Measured Instantaneous Velocity Profile

#### Method – The Multigated Doppler

In this technique, the individual velocity components across the vascular lumen are measured using multigated pulse-wave Doppler. As in the previous technique, it is also necessary to measure the beam-vessel angle in order to transform the Doppler frequency shift information into velocity data. The summation of these velocity components constitutes the volumetric flow. An advanced implementation of this approach (Cardiosonix, Neoprobe Ltd, Dublin, Ohio, USA) has been reported in which two ultrasound beams set at a fixed known angle are used and numerous small (<200 mm length) sample volumes at successive depths are collected and analyzed by fast Fourier transform in real time [10] (Fig. 4.7). The angle of insonation and the flow diameter are automatically computed allowing measurement of volumetric flow in real time. This technique is at present limited to assessing superficial vessels such as the carotid arteries and is not available for maternal or fetal applications.

#### Vector Doppler – Multiple Beam Insonation

Doppler methods as described above measure the component of flow velocity parallel to the vascular axis but not the velocity components from the secondary flows resulting from vessel curvatures, bifurcations, and pulsatility. One of the techniques that at-

**Fig. 4.7.** Multigated angle-independent Doppler flow measurement as implemented in a commercial system. Schematic representation of the FlowGuard technology. The ADBF technology uses 2 ultrasound beams (*L1* and *L2*) crossing the vessel lumen with a known angle ( $\theta$ ) between them and allows the simultaneous acquisition of hundreds of small sample volumes (*small dots*) of less than 200  $\mu\text{m}$  in depth (*D*) along *L1* and *L2*. This in turn authorizes accurate determination of the flow velocity profile, vessel diameter, and insonation angle ( $\theta$ ). (With permission from [10])

tempts to resolve this limitation utilizes multiple transducers to measure multiple velocity vectors in a circulation and is also known as vector Doppler. Systems utilizing a single transmitter and two or more receivers to measure the various velocity vector components have been described [11, 12]. Experiments using a dual-beam vector Doppler system based on a modified linear array show that this system has low dependence on angle and similar reproducibility to that of single-beam systems [13]. These devices are not available yet for clinical use in obstetrics.

### Non-Doppler Flowmetry – Time Domain Processing Velocity Measurement

Time domain processing is an emerging field with a tremendous potential for offering a viable alternative to Doppler sonography. The basic implementations of time domain processing for measuring velocity and volume flow are briefly discussed below. Most of these still remain experimental in nature.

#### Ultrasound B-Flow

As the name implies, this innovative technology is based on B-mode ultrasound and allows imaging of blood flow. It utilizes digital ultrasound which allows encoding of the signals on transmission and decoding of the returning echoes into separate tissue and blood signals. As the echogenicity of blood is substantially lower than that of tissue, the returning signals are processed and equalized to enhance blood flow signals over those from the tissue. Whereas color Doppler duplex ultrasound imaging requires separate activation of the transducer elements for the Doppler

**Fig. 4.8.** Ultrasound B flow imaging of blood flow in the umbilical vessels. The flow image is simultaneously derived along with B imaging and not superimposed. (With permission from General Electric Health Care System, Milwaukee, WI)

and for the B-mode imaging (see Chap. 6), B-flow approach utilizes the same B-mode scan for both the tissue and the flow imaging. This allows B-flow to achieve high-resolution images at high frame rates without the constraints of Doppler sonography such as aliasing, angle dependence, wall filtering, and the need for complex controls. The safety concerns are also minimized because the acoustic intensity of B-mode ultrasound is lower than that of Doppler. This new modality holds immense potential for clinical application in the perinatal field. An example B-flow image of the umbilical vessels is shown in Fig. 4.8.

### Time Domain A-Line Echo Tracking

One of the first commercial implementations of time domain processing, called color velocity imaging (CVI), measured blood flow velocity by determining the distance traveled by a group of RBCs during a known time period (Fig. 4.9) [14–16]. The method is based on cross-correlating the consecutive returning A-line echo signals from an RBC group moving in the beam path. As the interval between the pulses is very short, the cells in the group maintain the same spatial inter-relationship so that their echo signatures remain approximately identical. This allows determination of the distance traveled by the RBC cluster in a given time and therefore the velocity. Volumetric flow is obtained by measuring the spatial average velocity across the vascular lumen and multiplying this value by the cross-sectional area of the functional vascular lumen derived from M-mode tracking of the vessel (Fig. 4.10). The technique was employed also to generate real-time color flow mapping. In vitro and in vivo (animal) validation studies of the technique have confirmed the precision and accuracy of the

technique in measuring velocity and volumetric flow [17]. For velocimetry, both CVI and Doppler methods showed low variance, low intrarater variability (0.03% and 0.09% respectively), high reliability coefficients (97% and 96%, respectively), and a significant correlation ( $r=0.96$ ;  $p<0.001$ ). For in vitro flow quantification, CVI and graduated cylinder methods showed low variance, low intrarater variability (0.09% and 0.01% respectively), high reliability coefficients (99.60% and 99.96%, respectively), and a significant correlation ( $r=0.98$ ,  $p<0.001$ ). For in vivo flow quantification, CVI and transit time flowmeter showed a significant correlation ( $r=0.96$ ,  $p<0.001$ ). Within the limits of the in vitro and in vivo experimental conditions, this study provided the validity of the time domain processing ultrasound technique for measuring peak flow velocity and volumetric flow. In spite of the significant advantages of angle independence and absence of aliasing, the initial promises of this approach have not been realized in clinical use.

### Time Domain Speckle Tracking

More recently, time domain processing of blood flow velocity has utilized speckle tracking techniques. Speckle is the manifestation of the variations in the amplitude of the backscattered ultrasound signals from randomly distributed subresolution scatterers. Speckle literally means small spots and gives the mottled appearance to the B-mode ultrasound images resulting from the amplitude fluctuations over time. In Doppler sonography, speckle appears as variations in the Doppler signal amplitude. Speckle degrades the spatial and the contrast resolutions of sonographic images which may be improved by the removal of speckle. However, methods for tracking speckle

**Fig. 4.9.** Principle of time domain processing velocity measurement. (Reprinted from [17] with permission)

**Fig. 4.10.** Flow quantification by time domain processing. *Top:* Velocity waves. *Bottom:* M-mode imaging of the flow and the outlining of effective flow lumen. Maximum velocity, minimum velocity, and average flow are measured for one cardiac cycle as defined by the cursors 1 and 2

movement are being investigated as a non-Doppler sonographic technique for measuring velocity and therefore blood flow. Speckle patterns remain mostly stable between B-mode image frames and tracking their frame-to-frame displacement allows velocity measurement in a flow (Fig. 4.11) [18]. Theoretically, the technique is capable of measuring both the axial and the lateral flow velocity vectors unencumbered by the angle of insonation, aliasing, or range ambiguities. However, the accuracy of speckle tracking is less for the lateral vectors than for the axial vector aligned with the beam path and several techniques exist for improving the lateral tracking [19]. The speckle tracking principles may also be applied for measuring volumetric flow in the emerging three- or four-dimensional sonography [20]. This approach holds exciting possibilities for real-time flow and perfusion assessment in clinical settings. Speckle tracking technology is not yet commercially available.

## Doppler Waveform Analysis and Doppler Indices

Because of the problems related to volumetric flow assessment, there has been a need to seek alternative ways to investigate vascular flow dynamics using the Doppler method. The maximum Doppler frequency shift waveform represents the temporal changes in the peak velocity of RBC movement during the cardiac cycle. It is therefore under the influence of both

**Fig. 4.11.** Graphic depiction of speckle tracking velocimetry. The best match of a speckle target region in successive frames determines the distance traveled in unit time. This forms the basis of measuring the velocity and therefore the flow

upstream and downstream circulatory factors [21]. The objective has been to obtain information specifically on distal circulatory hemodynamics. Techniques have been developed for analyzing this waveform in an angle-independent manner. Most of these analytic techniques involve deriving Doppler indices or ratios from the various combinations of the peak systolic, end-diastolic, and temporal mean values of the maximum frequency shift envelope (Fig. 4.12). Because these parameters are obtained from the same cardiac

**Fig. 4.12.** Doppler indices derived from the maximum frequency shift envelope. *S* peak systolic frequency shift, *D* end-diastolic frequency shift, *A* temporal average frequency shift over one cardiac cycle. (Reprinted from [30] with permission)

cycle, the ratios are virtually independent of the angle of insonation.

A unique feature of the uteroplacental, umbilical, and fetal cerebral circulations is the continuing forward flow during diastole so the perfusion of vital organs is uninterrupted throughout the cardiac cycle. This feature develops progressively in the fetoplacental circulation. The essential effects of this phenomenon include not only a progressive increase in the end-diastolic component of the flow velocity but also a concomitant decrease in the pulsatility, which is the difference between the maximum systolic and end-diastolic components (Fig. 4.13). The pulsatility of the flow velocity was originally investigated using Doppler ultrasonography in the peripheral vascular system.

Gosling and King were the first to develop the pulsatility index (PI) as a measure of the systolic-diastolic differential of the velocity pulse [22]. The PI was first derived from Fourier transform data and is

**Fig. 4.13.** Concept of pulsatility of an arterial velocity waveform. Vertical axis represents the velocity magnitude. Horizontal axis represents the time

known as the Fourier PI. Subsequently, a simpler version, the peak-to-peak PI (Fig. 4.12), was introduced based on the peak systolic frequency shift (*S*), the end-diastolic frequency shift (*D*), and the temporal mean of the maximum frequency shift over one cardiac cycle (*A*):

$$PI = \frac{S - D}{A} \quad (5)$$

Almost at the same time, Pourcelot reported a similar index, called the resistance index (RI) [23]. It also gave an angle-independent measure of pulsatility:

$$RI = \frac{S - D}{S} \quad (6)$$

where *S* represents the peak systolic and *D* the end-diastolic frequency shift. Stuart and associates [24] described a simpler index for pulsatility in which the numerator is the peak systolic frequency and the denominator is the end-diastolic frequency shift:

$$S/D \quad (7)$$

where *S* represents the peak systolic, and *D* represents the end-diastolic maximum frequency shift. (Originally, it was called the A/B ratio). Because the variations in the end-diastolic frequency shift appear to be the most relevant component of the waveform, Maulik and associates [8] suggested the direct use of this parameter normalized by the mean value of the maximum frequency shift envelope over the cardiac cycle:

$$D/A \quad (8)$$

There has been a proliferation of indices over the years. Most of them refer to the pulsatility of the maximum frequency shift envelope of the Doppler waveform, but some reflect various hemodynamic parameters, such as transit time broadening. For obstetric applications, assessment of the pulsatility and the end-diastolic frequency shift is of clinical importance.

## Comprehensive Waveform Analysis

Attempts have also been made to analyze the Doppler waveform in a more comprehensive manner. Maulik and colleagues [2] described a comprehensive feature characterization of a coherently averaged Doppler waveform from the umbilical artery (Fig. 4.14). The measured parameters included the PI and the normalized systolic slope and end-diastolic velocity. In 1983 Campbell and colleagues [25] reported a technique for normalization of the whole waveform, called the frequency index profile. Thompson and as-

**Fig. 4.14.** Reference points in a typical velocity envelope waveform obtained from the umbilical arteries. 1 trough, 2–3 ascending slope, 4 peak, 5–6 initial descending slope, 7–8 final descending slope, 9–10 trough. (Reprinted from [2] with permission)

sociates [26] described yet another technique of comprehensive waveform analysis that involved a four-parameter curve-fitting analysis of an averaged waveform. More recently, Mařál reported use of a classification system based on the PI value and end-diastolic flow characteristics [27]. This classification system was superior to other measures of the waveform for predicting fetal distress and operative delivery due to fetal distress. Most of these techniques have not been thoroughly evaluated, and currently there is no evidence that they offer any advantages over the simpler Doppler indices.

## Choice of Indices

Of the various indices, the systolic/diastolic (S/D) ratio, RI, and PI have been used most extensively in obstetric practice. Of these, the S/D ratio and RI, being based on the same set of Doppler parameters (peak systolic and end-diastolic frequency shifts), are related to each other as shown in Eq. (8) and Fig. 4.15:

$$RI = 1 - \frac{S}{D} \quad (9)$$

As the end-diastolic frequency shift declines the S/D ratio rises exponentially; and when the end-diastolic flow disappears the value of the index becomes infinity. Hence the S/D ratio value becomes meaningless beyond a certain point as the fetoplacental flow impedance continues to rise. This behavior of the S/D ratio

**Fig. 4.15.** Correlation between the resistance index (RI) and the systolic/diastolic (S/D) ratio

is inherent in its formation and is reflected in its distribution characteristics [28] (Fig. 4.16) and its total variance (Fig. 4.17). Despite these limitations, this index is used extensively in obstetrics, particularly in the United States. The RI values, on the other hand, have defined limits with a minimum value of 0 and a maximum value of 1.0. Unlike the S/D, the RI shows gaussian distribution and is therefore amenable to parametric statistical analyses (Fig. 4.18). The limitation of RI is due to its inability to reflect impedance increases with the reversal of end-diastolic flow. Theoretically, the PI provides more hemodynamic information than the RI and S/D ratio, as it includes data on the whole cardiac cycle in the form of its denominator, which is the time-averaged value of the maximum frequency shift envelope over one cardiac cycle. Furthermore, it expresses hemodynamic alterations associated with absent or reversed end-diastolic flow. In practice, however, computation of the time-averaged value is not as precise as determination of the peak systolic or end-

**Fig. 4.16.** Distribution of the umbilical arterial systolic/diastolic ratio in the study population. Note its nongaussian distribution. (Based on data from [28])

**Fig. 4.17.** Total variance values (percentage) of the various Doppler indices. *S/D* systolic/diastolic ratio, *PI* pulsatility index, *D/A* diastolic/average ratio, *RI* resistance index. Note that the *S/D* ratio varies the most and the *RI* the least under the same hemodynamic conditions

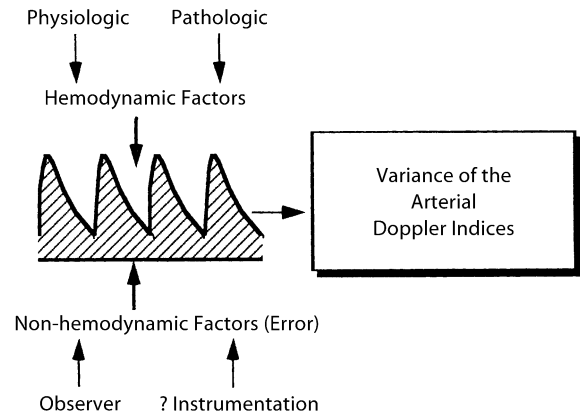

**Fig. 4.18.** Gaussian distribution of the umbilical arterial resistance index. (Based on data from [29])

diastolic frequency shifts. There has been a paucity of data regarding the relative diagnostic merits of these indices. In a prospective blinded study, Maulik and associates [29] showed that the *RI* had the best and *PI* the worst discriminatory performance. This subject is further discussed in Chap. 10.

### Sources of Variance of the Doppler Indices

The configuration of an arterial Doppler waveform is modulated by hemodynamic and nonhemodynamic factors [30] (Fig. 4.19). The hemodynamic modulators may be short term or long-term in nature. Examples of short-term factors include any acute changes in the impedance or heart rate; examples of long-term changes in the impedance include those encountered in the umbilical or uterine circulation with the progression of pregnancy. The nonhemodynamic modulators are those related to the examiners and devices,

**Fig. 4.19.** Factors affecting the variance of Doppler indices

and they constitute the error component of the variance in the Doppler indices. Interobserver and intraobserver variations are the main examples of such errors. The error component of the variance may be systematic or random. The former remains relatively constant from examination to examination. This relative constancy permits it to be considered as predictable when interpreting results. In contrast, random errors are unpredictable and significantly compromise the clinical utility of a test. As an example of the hemodynamic modulation of Doppler waveforms from a circulation, we may briefly consider the sources of variance of the umbilical arterial Doppler indices. Of the various vascular systems of the fetus, the umbilical circulation has been most widely investigated in this regard. The sources of variance that influence the indices through direct or indirect hemodynamic mechanisms include gestational age-related changes in fetoplacental vascular impedance, the site of examination in the cord, fetal breathing, and fetal heart rate. The sources of variance that are not related to any hemodynamic phenomenon and constitute error consist of inter- and intraobserver variations, and interdevice variations. The latter constitute a systematic error. A detailed discussion of the sources of variance of umbilical arterial circulation may be found in Chap. 10.

### Hemodynamic Basis of Doppler Waveform Analysis

Studies on the hemodynamic basis of Doppler waveform analysis have, in general, looked for any correlation between the commonly used Doppler indices and independently measured parameters of central and peripheral hemodynamics. The latter included the heart rate, peripheral resistance, and components of arterial input impedance. In addition, the association

between placental angiomorphologic changes and the Doppler indices has been investigated by several workers. This section summarizes these findings and presents a brief description of basic hemodynamic concepts relevant for Doppler validation studies.

### Experimental Approaches to Hemodynamic Validation of Doppler Indices

Experimental procedures to validate Doppler indices hemodynamically often require not only the direct measurement of relevant hemodynamic parameters, such as pressure and flow, but also controlled alterations of the circulatory state. Such interventions are too invasive to be performed in relation to human pregnancy because of risks to the mother and fetus. This limitation has led to the utilization of physical and animal models. In vitro circulatory simulation exemplifies the physical model and has been used widely to investigate complex hemodynamic phenomena. Nonbiologic materials are used for prototyping circulatory systems for this type of simulation. In an intact organism it may be difficult to perform comprehensive hemodynamic measurements without profoundly altering the physiologic state of the preparation. Indeed, it may be impossible to conduct certain hemodynamic experiments in vivo because of the inherent complexities of modeling. It is also well recognized that the fundamental hydrodynamics principles are equally applicable to explaining circulatory phenomena in a physical simulation and in a biologic system. The principles of in vitro simulation for hemodynamic studies have been comprehensively reviewed by Hwang [31]. More specifically, hemodynamic parameters for designing an in vitro circulatory system for validation the Doppler indices have been reviewed by Maulik and Yarlagadda [32]. Regarding animal models, lamb fetuses and newborns have been used in both acute and chronic preparations. These models have been utilized traditionally to elucidate the circulatory phenomenon in human fetuses.

### Arterial Input Impedance: Basic Concepts and Relevance to Doppler Waveform Analysis

The relevant aspects of peripheral circulatory dynamics are briefly reviewed here. Specifically, the basic principle of arterial input impedance and its relevance to Doppler waveform analysis are discussed. Traditionally, opposition to flow has been expressed in terms of peripheral resistance ( $Z_{pr}$ ), which is the ratio of mean pressure ( $P_m$ ) to mean flow ( $Q_m$ ):

$$Z_{pr} = P_m/Q_m \quad (10)$$

Although peripheral resistance has been the prevalent concept for describing the opposition to flow, it is applicable only to steady, nonpulsatile flow conditions. Flow of blood in the arterial system, however, is a pulsatile phenomenon driven by myocardial contractions with periodic rise and fall of pressure and flow associated with systole and diastole of the ventricles. The pressure and flow pulses, thus generated, are profoundly affected by the downstream circulatory conditions, specifically the opposition to flow offered by the rest of the arterial tree distal to the measurement point in the peripheral vascular bed. The idea of vascular impedance provides the foundation for understanding this complex phenomenon in a pulsatile circulation. Vascular impedance is analogous to electrical impedance in an alternating current system. Womersley [33] showed that the equations dealing with electrical impedance are applicable to solving the problems of vascular impedance. It should be noted in this context that the idea of vascular resistance is analogous to the principle of electrical resistance in direct-current electrical transmissions.

Closely related to impedance is the phenomenon of wave reflection in a vascular tree. The shape of pressure and flow waves at a specific vascular location results from the interaction of the forward propagating (orthograde) waves with the reflected backward propagating (retrograde) waves [34, 35].

$$P_m = P_o + P_r \quad (11)$$

$$Q_m = Q_o + Q_r \quad (12)$$

where  $P$  is pressure,  $Q$  is flow,  $m$  is the measured wave,  $o$  is the orthograde wave, and  $r$  is the retrograde wave. The presence of reflected pressure and flow waves in the arterial circulation has long been recognized by hemodynamics experts. Comprehensive analysis and understanding of the phenomenon was facilitated by using the analogy of the theory of electrical current transmission. The existence of wave reflections in the circulatory system is evident from the observation that as one obtains samples along the arterial tree from the heart to the periphery the pulsatility of pressure waves progressively increases and that of the flow or flow velocity waves declines. Consequently, pressure and flow waves acquire distinctly differing configurations as they propagate down the arterial tree. The phenomenon has been analyzed mathematically by separating the observed pressure and flow waves into their constituent orthograde and retrograde components [35]. It should be noted that the forward propagating waves of pressure and flow demonstrate the same configuration. When wave reflection occurs, the retrograde flow waves are

inverted, but not the retrograde pressure waves. Consequently, the observed pressure waves, which are produced by the summation of orthograde and retrograde waves, show an “additive” effect; in contrast, the observed flow (or flow velocity) waves demonstrate a “subtractive” effect (Fig. 4.20). In the absence of wave reflection, the two waves would have the same shape. Wave reflections arise whenever there is a significant alteration or mismatching of vascular impedance in a circulation. Current evidence suggests that the arterial-arteriolar junctions serve as the main source of wave reflections in an arterial system. Vasodilation decreases impedance and wave reflection. In contrast, vasoconstriction increases impedance and wave reflection. As the Doppler wave represents the flow velocity wave, it is apparent that downstream impedance and wave reflection play a central part in modulating the configuration of this waveform and therefore the descriptor indices. An in-depth discussion of arterial impedance and wave reflection is beyond the scope of this review, although relevant impedance parameters are briefly described below.

The input impedance of an arterial system [32] at a specific vascular site is the ratio of the pulsatile pressure and the pulsatile flow at that location. As the pressure and flow waves are complex in shape, they are first converted by Fourier analysis to their constituent sinusoidal harmonic components. Two parameters are generated: the modulus and the phase (Fig. 4.21). The modulus is the magnitude of the

**Fig. 4.20.** Influence of pulse-wave reflections on ascending aortic pressure (*P*) and flow (*Q*) waveforms. Incident or forward (*f*) and backward or reflected (*r*) pressure and flow waves are summed to yield measured (*m*) pressure and flow waveforms. The forward pressure and flow waves are identical, as are the reflected waves, except that the reflected flow wave is inverted with an impact on the reflected pressure wave. (From [55] with permission)

**Fig. 4.21.** Input impedance modulus (top) and phase (bottom) as functions of frequency

pressure/flow harmonic ratios as a function of frequency; the units of measurement for the modulus are dynes·s·cm<sup>-3</sup> for velocity and dynes·s·cm<sup>-5</sup> for volumetric flow. The *impedance* phase expresses the phase relation between the pressure and the flow waves as a function of frequency. The phase is measured in negative or positive radians. The descriptors of vascular impedance include the following:

1. *Input impedance* is the opposition to pulsatile flow in an arterial system. Impedance at zero frequency is the peripheral resistance, which represents the steady, nonpulsatile component of vascular impedance.
2. *Characteristic impedance* reflects the properties or characteristics of the arterial system, such as the cross-sectional area, wall thickness, and vasculo-

elasticity. Any discontinuity or change in these properties gives rise to reflections of pressure and flow waves.

3. *Reflection coefficient* expresses the magnitude of the phenomenon of wave reflection in an arterial tree.

These well-established hemodynamic concepts provide the bases for hemodynamic interpretation of fetal Doppler waveforms in various physiologic and pathologic states. As the arterial Doppler wave represents the arterial flow velocity wave, it is apparent that down-stream impedance and wave reflection are among the principal modulators of the waveform and therefore of the descriptor indices. As gestation progresses, umbilical arterial Doppler waveforms demonstrate a continuing increase in the end-diastolic frequency shifts (see Fig. 10.5), which is attributable to a progressive decline in fetoplacental vascular impedance. The latter is necessarily associated with diminished wave reflections, although it has not been feasible to study the phenomenon directly.

### Doppler Indices and Peripheral Resistance

Investigations in this field were aimed at establishing a hemodynamic foundation for the Doppler indices in terms of peripheral vascular resistance. In vitro and in vivo models were used. The experimental approach essentially consisted of increasing the circulatory resistance and analyzing the changes in the indices.

Spencer and coinvestigators [36] used an in vitro flow model to validate the Doppler indices in terms of peripheral resistance (mean pressure/mean flow). The flow was reduced in a stepwise fashion using a clamp. The decline in flow led to increases in RI, PI, and S/D ratio. The pressure and pressure waveform remained unchanged. The authors noted that rises in the Doppler indices reflected an increasing peripheral resistance; the RI and PI had a mostly linear increase, whereas the S/D ratio demonstrated an exponential increase. Maulik and colleagues [37] investigated the relation between the various umbilical arterial Doppler indices and umbilical arterial resistance in fetal lambs. The hemodynamic perturbation was induced by mechanical constriction of the umbilical artery, which resulted in declines in flow by 74%–89% and increases in pressure by 8%–23%. The correlation between the Doppler indices and the hemodynamic parameters is shown in Table 4.1, which indicates that with a well-defined obstruction to the downstream flow the indices correlate highly with the downstream hemodynamic parameters, including the peripheral resistance ( $p < 0.005$ ).

Trudinger and associates [38] studied the effects of chronic embolization of the umbilical circulation on

**Table 4.1.** Correlation coefficients, Doppler indices versus hemodynamic parameters: constriction experiments (from [37] with permission)

Parameter	S/D	PI	RI
Peripheral resistance	0.95	0.89	0.88
Volumetric flow	-0.91	-0.96	-0.97
Pressure	0.81	0.84	0.82

S/D, systolic/diastolic ratio; PI, Pulsatility index; RI, resistance index. All significant at  $p < 0.005$ .

the umbilical arterial S/D ratio and umbilical circulatory resistance in fetal lambs. Chronic embolization resulted in: (1) increased fetoplacental vascular resistance ( $0.25\text{--}0.35\text{ mmHg}\cdot\text{ml}^{-1}\cdot\text{min}^{-1}$ ); (2) increased umbilical arterial S/D ratios; (3) significant ( $p < 0.05$ ) declines in the umbilical total flow and the umbilical/splanchnic flow ratio (from 3.36 to 1.53). The authors concluded that the umbilical artery flow velocity waveform S/D ratio measures the reflection coefficient at the peripheral vascular bed of the placenta. It should be noted, however, that the reflection coefficient, which has a precise hemodynamic definition (see above), was not measured in these experiments; and no correlations were performed between the hemodynamic parameters and the indices. Nevertheless, the study established a relation between chronic circulatory alteration and the umbilical arterial Doppler waveform. The above findings were corroborated by Morrow and colleagues [39], who observed progressive increases in the umbilical arterial pulsatility consequent to fetoplacental arterial embolization. In this study involving chronically catheterized sheep fetuses, the umbilical arterial S/D ratio correlated significantly ( $r = 0.76$ ,  $p = 0.001$ ) with placental resistance derived from the aortic-inferior vena caval pressure gradient and mean peak velocity.

One of the limitations of these studies was that resistance, rather than impedance, was used to assess the peripheral circulatory state in a pulsatile flow system. Vascular input impedance, however, is the hemodynamic parameter of choice when assessing the opposition to flow in a pulsatile circulation. In contrast, peripheral resistance is applicable only to the nonpulsatile component of a circulation and as such constitutes one of the parameters of arterial impedance.

### Doppler Indices and Input Impedance

There have been a few studies investigating the relation between the Doppler indices and vascular impedance using an in vitro model and a neonatal lamb model [40–43].

Maulik and Yarlagadda [40] used an in vitro circulatory simulation system for hydrodynamic validation of the Doppler indices. The in vitro system consisted

of a ventricular pump, an “arterial” line, a proximal “arterial” compliance unit, a “fetal placental vascular” branching model, a systemic bypass circuit, and a “venous” line for return of the perfusate into an “atrial” reservoir, which was connected to the pump. The impedance to flow was increased progressively by sequentially occluding the vessels of the branching model. All the indices correlated significantly ( $p < 0.01$ ) with the peripheral resistance and reflection coefficient, indicating that changes in the peripheral resistance and the wave reflections from the downstream circulation are expressed by changes in the Doppler waveform as described by the indices. This study indicated that, within the general confines of a hydrodynamic model characterized by an increasing downstream opposition to a pulsatile flow and by a constant pump function, the descriptor indices of the Doppler waveform are capable of reflecting the state of the downstream flow impedance.

The correlation between vascular impedance and Doppler indices was also investigated in *in vivo* models. Downing and associates [41] developed a phar-

macologic model of hemodynamic alteration using chronic term neonatal lamb preparations (Fig. 4.22). General anesthesia was used for the initial surgical preparation, which allowed *in situ* placement of a 4-MHz continuous-wave Doppler transducer and a transit time flow transducer on the infrarenal descending aorta. A pressure transducer was introduced retrogradely up to the level of the flow probe by the left femoral artery. Each animal was allowed to recover for 4 days, following which experimental intervention was initiated. After baseline recording of the blood pressure, heart rate, aortic flow rate, and Doppler waveforms, either vasodilation or vasoconstriction was produced with the administration of hydralazine or norepinephrine, respectively. The following parameters were measured: peripheral vascular resistance, characteristic impedance, reflection coefficient, and PI. The basic hemodynamic changes are shown in Table 4.2. Evidently, vasodilation led to tachycardia, hyperperfusion, and hypotension. Opposite changes were noted with vasoconstriction. Significant increases in the PI, peripheral vascular resistance, char-

**Fig. 4.22.** Experimental model. Newborn lambs were instrumented with indwelling pressure transducers, volumetric flow probes, and continuous-wave Doppler flow probes around the infrarenal descending aorta. Probe wires were externalized to a flank pouch. During monitoring per-

iods, data were collected via the use of a computerized data acquisition system, which permitted conversion of on-line recording of Doppler frequency shift signals, continuous aortic blood pressure, and volumetric blood flow. (Reprinted from [43] with permission)

**Table 4.2.** Alterations of circulatory parameters in response to vasodilation and vasoconstriction (from [41] with permission)

Parameter	Baseline	Hydralazine	Norepinephrine
Heart rate (bpm)	132±15	164±14	82±10*
Mean arterial blood pressure (mmHg)	78±5	55±5*	122±8*
Mean volumetric flow, descending aorta (ml/min)	319±21	405±28*	138±22*

Data are means±SEM. \* Significant difference from baseline parameter ( $p<0.005$ ).

acteristic impedance, and reflection coefficient were seen in response to the administration of norepinephrine, and decreases in PI were noted with the administration of hydralazine. Figure 4.23 depicts the changes in the PI and reflection coefficient and Fig. 4.24 the changes in the input impedance moduli and phase. As is evident, the impedance modulus curve showed distinct changes with vasoconstriction and vasodilation. Further analysis of the data showed a statistically significant correlation between the PI and peripheral resistance. However, changes in the PI did not significantly correlate with the changes in characteristic impedance and reflection coefficient.

The next study investigated this issue [42]. The experimental model was the same as in the previous study. The experimental protocol, however, ensured that the heart rate changes due to vasoactive interventions were pharmacologically suppressed by trimethopran during vasodilation or atropine methylbromide during vasoconstriction. The results are presented in Table 4.3. In response to both vasodilation and vasoconstriction without controlling the reflex heart rate responses, the aortic PI was highly and positively correlated with peripheral resistance ( $r=0.78$ ,  $p<0.001$ ) but not with characteristic im-

pedance. However, when the reflex heart rate responses were inhibited, the changes in PI correlated well with peripheral resistance and characteristic impedance ( $r=0.92$ ,  $0.95$ ;  $p<0.001$ ). It is reasonable to conclude from these findings that the Doppler indices of pulsatility reflect the state of downstream circulation independent of the changes in the heart rate. However, the heart rate does influence the pulsatility and should therefore be taken into consideration. This subject is further discussed below.

**Fig. 4.23.** Responses of the pulsatility index (PI) and the reflection coefficient (Rc) to vasodilation with hydralazine and vasoconstriction with norepinephrine. PI and Rc increased significantly from baseline in response to hydralazine, but Rc was not significantly affected. (From [56] with permission)

**Fig. 4.24.** Impedance moduli and phase angle during baseline, vasodilation, and vasoconstriction with hydralazine and norepinephrine, respectively. Each curve represents the mean±SEM impedance moduli for all study animals. (From [56] with permission)

**Table 4.3.** Hemodynamic parameters and Doppler indices in drug-induced vasodilation and vasoconstriction with and without heart rate changes (from [43], with permission)

Parameters	Control	Hydralazine	Hydralazine, trimethopan	Phenylephrine	Phenylephrine, atropine MB

## Doppler Indices and Central Circulation

Central circulation potentially influences the Doppler waveform and should be an important consideration when interpreting the changes in Doppler indices. The clinical significance of fetal heart rate effect on the indices has been somewhat controversial. Although earlier studies found no significant effect of the heart rate on the Doppler indices [44], several subsequent reports refuted these findings [45, 46]. There is no evidence at present to indicate that correcting the indices for fetal heart rate improves their diagnostic efficacy when the baseline heart rate remains within the normal range. The mechanism of the heart rate effect on the Doppler indices has been well studied in animal and in vitro models. It is well recognized in clinical practice that when the heart rate drops the diastolic phase of the cardiac cycle is prolonged, which results in a decrease in the end-diastolic frequency shift (Fig. 4.25). This condition obviously increases the pulsatility of the waveform,

which is reflected in the descriptor indices, such as the PI or the S/D ratio.

This phenomenon was clearly demonstrated in fetal ovine models in which fetal bradycardia was experimentally induced by either acute uteroplacental flow occlusion [47] or maternal hypoxia [48]. The Doppler indices measured were the RI, S/D ratio, and PI. The duration of the cardiac cycle and its systolic and diastolic times were approximated from the Doppler waveform. In the uteroplacental flow insufficiency model, transient occlusion of the maternal common uterine artery produced statistically significant ( $p < 0.005$ ) increases in the Doppler indices and cardiac cycle time. The increases in the Doppler indices disappeared ( $p > 0.05$ ) when the latter were corrected for changes in the cardiac cycle time (Fig. 4.26). As expected, the diastolic time was noted to be the principal contributor to the changes in heart rate (Fig. 4.27). The effect of heart rate was also investigated in a chronic ovine model in which changes in the umbilical arterial Doppler waveform

**Fig. 4.25.** Comparison of the umbilical arterial Doppler waveforms with normal heart rate (125 bpm) and bradycardia (77 bpm). Vertical axis represents the magnitude of Doppler frequency shift. Horizontal axis represents the time

**Fig. 4.26.** Effect of variations in the cardiac cycle time correction on the resistance index ( $RI$ ). The three divisions in this figure correspond to baseline, measured peak, and corrected values, respectively. Please note that the differences between the baseline and the measured peak values (all significant at  $p < 0.005$ ) disappeared when corrected for fetal heart rate (none significant at  $p < 0.005$ ). (From [47] with permission)

in response to acute maternal hypoxemia were assessed. During the periods of maternal hypoxemia, the fetal heart rate decreased (to  $< 80$  bpm) and umbilical arterial Doppler indices increased ( $p < 0.001$ ). Furthermore, the Doppler indices were highly but negatively correlated with alterations in the fetal heart rate ( $p < 0.001$ ). Analysis of the Doppler waveform phase intervals revealed nearly constant systolic intervals, whereas diastolic intervals varied inversely with the heart rate alterations. Moreover, the umbilical arterial Doppler indices, when corrected for the fetal heart rate changes, were relatively unchanged from

baseline measurements. Both studies confirmed that the fetal cardiac cycle, and therefore the fetal heart rate, plays an important role in shaping the umbilical arterial Doppler waveform. Furthermore, this effect is mediated predominantly via changes in the diastolic phase of the cardiac cycle. There is also evidence that the fetal heart rate may affect the ability of the Doppler waveform analysis to reflect completely the changes in downstream impedance [49]. It should be noted that there is a paucity of information on the central circulatory factors, other than heart rate, that influence the Doppler waveform.

Legarath and Thorup [49, 50] utilized an in vitro model of circulation in which they studied the influence of central and peripheral circulations on the Doppler waveform. The in vitro model allowed independent control over pulse rate, volumetric flow, stroke volume, pressure, and peripheral resistance. The authors observed that the velocity indices changed with the pulse rate, although flow and peripheral resistance were constant. They also noted that the rising slope of the Doppler waveform did not correlate with cardiac contractility as measured by the changes in pressure (the first maximum derivative of the intraventricular pressure:  $dP/dt$ ).

This finding is intriguing and deserves further investigation. Regarding the effect of resistance on the rising slope, the two parameters did not correlate when the flow was kept constant, but when the pressure was kept constant the rising slope increased significantly with resistance.

These studies emphasize the relative importance of the central circulatory changes to alterations in the Doppler waveform.

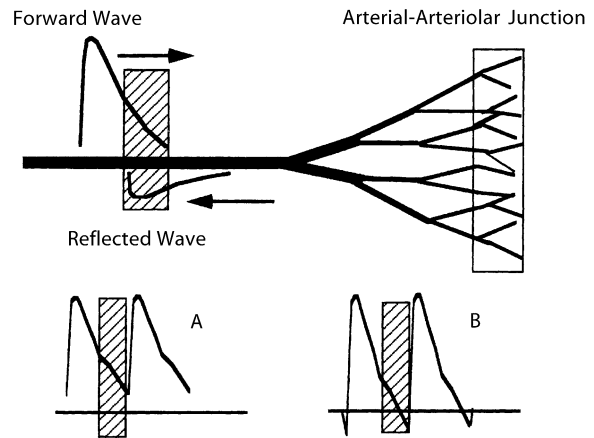

**Fig. 4.27.** Correlation between systolic and diastolic components of the Doppler waveform and the fetal heart rate ( $FHR$ ), which is the reciprocal of the cardiac cycle time. Note that the slope of the diastolic time versus  $FHR$  is approximately 9 times greater than the slope of the systolic time versus  $FHR$ . (Based on data from [47])

## Placental Vascular Changes and Abnormal Doppler Waveforms

The dependence of arterial Doppler waveform on downstream circulatory impedance is also reflected in the pathology of the distal vascular bed. Various investigators reported fetoplacental morphological changes in relation to umbilical arterial velocimetry and pregnancy complications including fetal growth compromise. Giles and coinvestigators [51] correlated fetoplacental histopathological changes with umbilical arterial S/D ratio in women with normal and complicated pregnancies. A statistically significant decrease ( $p < 0.01$ ) in the modal small arterial count (arteries in the tertiary stem villi measuring less than  $90 \mu\text{m}$  in diameter) was observed in abnormal pregnancies with an abnormal Doppler index. The authors suggested fetoplacental vaso-obliterative pathologic processes as the underlying cause of an abnormal Doppler waveform. Subsequently, Krebs and coinvestigators [52] demonstrated that in preterm intrauterine growth restriction pregnancies with umbilical arterial absent end-diastolic flow velocity, the capillary loops were sparse in number and significantly longer, and had significantly less branching and coiling than in the control cases. These findings are more reflective of villous maldevelopment rather than a vaso-obliterative process. This was further corroborated by Todros and associates [53] who demonstrated that, compared with those with positive end-diastolic flow in the umbilical artery, the placentas from growth-restricted fetuses with absent or reverse end-diastolic flow showed a normal pattern of stem artery development, accompanied by significantly decreased capillary angiogenesis and terminal villous development. The authors speculated that these findings suggested fetoplacental adaptive response in the presence of uteroplacental ischemia.

A similar observation has been reported in relation to angiomorphological pathology of the uteroplacental vascular bed and the uteroplacental Doppler waveform. Voigt and Baker [54] performed placental bed biopsies in pregnancies complicated by preeclampsia or otherwise presumed fetal growth restriction delivered by cesarean section. Similar biopsies were also performed in a control group of healthy pregnancies delivered by cesarean section for labor dysfunction or malpresentation. The uteroplacental PI predicted abnormal uteroplacental angiomorphology with significant accuracy.

Based on these observations, the following vascular and hemodynamic mechanism may be suggested for abnormal umbilical arterial Doppler waveforms in pregnancies complicated with fetal growth restriction and highly abnormal umbilical arterial Doppler indices. Abnormal uteroplacental angiogenesis and consequent ischemia leads to fetoplacental villous malde-

**Fig. 4.28.** Effect of wave reflection on umbilical arterial Doppler waveforms. Note that as the pulse wave propagation velocity in the fetus is slower than in the adults, retrograde waves affect forward propagating waves during late diastole (cross-hatched box). (A) Normal waveforms with minimal wave reflection because of low impedance in the fetoplacental arterial circulation. (B) Effect of significant wave reflection when fetoplacental impedance becomes high, resulting in the absence or reversal of end-diastolic frequency shift

velopment and deficient angiogenesis and vascularity. These changes result in an increase in the arterial impedance, which is necessarily associated with enhanced pressure and flow velocity wave reflections. The reflected flow velocity waves propagating backward will change the shape of arterial flow velocity waves. A graphic depiction of this concept in relation to umbilical arterial Doppler waveforms is presented in Fig. 4.28.

## Summary

Doppler velocimetry offers a wide range of hemodynamic information. Although the technique permits volumetric flow quantification, there are critical concerns regarding the precision of this approach. Assessment of the downstream hemodynamic state is of importance for perinatal application. It is achieved by Doppler waveform analysis, which generates indices describing the pulsatility of the wave. These analytic techniques are based on accepted hemodynamic principles and are supported by experimental evidence on hemodynamic validation of the Doppler indices. As summarized above, the Doppler indices can reflect impedance to flow downstream from the measurement point, although the effect of fetal heart rate changes on the diastolic phase of the cardiac cycle may confound this ability of the indices. In addition, there is angiomorphologic evidence that links abnormal Doppler indices to both the fetoplacental and the uteroplacental vascular pathology.

# Venous Hemodynamics

Torvid Kiserud

In recent years evaluation of the venous system has become a compulsory part of the haemodynamic assessment of the fetus, but the underlying mechanisms of our Doppler recordings are still incompletely understood. The present chapter is not intended to solve all that, but rather to address important hemodynamic issues from a clinical point of view to help clinicians use and interpret venous Doppler recordings. For the interested reader more extensive discussions of blood flow dynamics are available in the literature [1–5].

## Velocity Profile in Veins

### Parabolic Blood Velocity Profile and Flow Calculation

In a straight section of the umbilical vein with a steady velocity, the distribution of the velocity across the cross-sectional area of the vessel is assumed to be parabolic with the highest velocity ( $V_{\max}$ ) in the center of the cross section (Fig. 5.1). The ratio of the average velocity across the vessel ( $V_{\text{mean}}$ ) and the  $V_{\max}$  characterizes the velocity profile. For parabolic flow, the ratio  $V_{\text{mean}}/V_{\max}$  is 0.5.

**Fig. 5.1.** The velocity profile represents the velocity distribution across the vessel and is characterized by the  $V_{\text{mean}}/V_{\max}$  ratio. The steady blood flow in the umbilical vein has a parabolic velocity profile (i.e. ratio 0.5). The accelerated blood at the ductus venosus inlet has a partially blunted velocity profile corresponding to a ratio of 0.7, while at the cardiac outlets the profile is even more blunted (e.g. ratio 0.97). (From [17])

For calculating volume flow we need the averaged velocity across the vessel area. We can derive that by tracing the weighted mean velocity ( $V_{w,\text{mean}}$ ) of the Doppler recording. Ideally, with a strictly parabolic flow, the relation would be  $V_{w,\text{mean}} = V_{\text{mean}} = 0.5 V_{\max}$ . This is particularly useful since the intensity-weighted mean velocity ( $V_{w,\text{mean}}$ ) derived from the Doppler shift is easily influenced by low-velocity signals from the vessel wall or neighboring vessels, or from loss of low-velocity recordings due to filters, or loss of the weakest signals when travelling through the tissues. Secondly, the  $V_{w,\text{mean}}$  represents the average of the velocities recorded in the sample volume (Doppler gate), which is not identical to the vessel cross-section. The sample volume may cover the vessel incompletely or asymmetrically. The low velocities at the periphery of the vessel are more likely to be under-represented than the high axial velocities of the center. In short, we have two ways of calculating blood flow:

$$\pi(D/2)^2 V_{w,\text{mean}}$$

and

$$\pi(D/2)^2 0.5 V_{\max}$$

the latter being the more robust, provided the velocity actually is parabolic.

That may not always be the case. For example, the velocity profile is found to be more blunted the first few centimetres after the umbilical vein has left the placenta [6]. During acceleration or retardation the velocity profile changes, and variation in geometry, branching and curvature alter the velocity profile (Fig. 5.2). These changes are further determined by the viscosity of the blood and dimension of the vessel expressed in the Reynold's number [1]. These facts favor the use of  $V_{w,\text{mean}}$ , which is not dependent on a known profile factor; thus, it has not been determined which method is the best, and the literature has examples of both methods [7–14].

**Fig. 5.2.** The impact of geometry on the velocity profile. The profile changes from a parabolic shape to a more blunted (flat) shape at converging vessel lumen (*upper panel*). A funnel-shaped geometry with increasing diameter is associated with reduced velocities at the periphery and a more or less maintained axial velocity resulting in a pointed velocity profile (*lower panel*). (From [2])

### Factors Modifying the Velocity Profile

The acceleration of blood, as seen in the isthmus of the ductus venosus, also represents a transition of the velocity profile from the parabolic ( $V_{\text{mean}}/V_{\text{max}}=0.5$ ) to a more blunted profile (Fig. 5.1). There is now theoretical and experimental proof that the blood velocity profile at the ductus venosus inlet is partially blunted with  $V_{\text{mean}}/V_{\text{max}}=0.7$  [15–17], which has been used when calculating volume flow in the ductus venosus [12, 13]. This value of the ratio is applicable with the high ductus venosus velocities seen during the second half of pregnancy. It is less certain that it applies to the low velocities of early pregnancy.

Curvature, bifurcation or other changes in blood flow direction cause changes in the velocity profile. The blood starts spiralling along the wall of the curvature and the velocity profile is commonly dislodged towards the periphery of the vessel cross section. Depending on the geometrical details, dimensions and viscosity (i.e. Reynold's number), and the magnitude of the velocity, the velocity profile may show a proportion of negative (reversed) velocity (Fig. 5.3).

It is also worth noting that the velocity and its profile starts to change before the blood has reached the narrow section of a constriction, and gradually returns to parabolic or more pointed velocity profile on the other side of the constriction, again depending on geometrical details (Fig. 5.4). An example would be the physiological constriction of the umbilical vein at the abdominal inlet. The abrupt expansion of the umbilical vein diameter after the constriction at the abdominal wall makes the blood slow down and re-

**Fig. 5.3.** Two-dimensional velocity profile in the ductus venosus predicted by computer modelling (**a**). Note the skewed profile and the small negative velocity component estimated by using the present geometrical details. (From [16])

gain parabolic flow within a short distance. In some cases this expansion is extensive and permits vortex formation (whirls) and may be misinterpreted as an aneurysm instead of a “post-stenotic dilatation”. In contrast, the tapering geometry of the ductus venosus central to the isthmic inlet maintains the high axial velocity for a longer distance (Fig. 5.4).

During pulsation the velocity profile is continuously changing. That is of particular interest in early pregnancy when the Doppler recording of the ductus venosus is used to identify risk groups of chromosomal aberration. During atrial contraction the velocity may retard to reach the zero line or beyond. Commonly, there may be both positive and negative velocities at the same time (Fig. 5.5, left). Apart from interference of signals from neighboring vessels (umbilical vein or liver), both the negative and positive recordings could be genuine ductus venosus signals representing a transitional change of the velocity profile containing both negative and positive velocities at the same time (Fig. 5.5, right). The degree of such changes depends on the velocity, vessel diameter, viscosity and pulse frequency, and can be predicted by using the Womersley equation [1]; thus, the results of the studies in early pregnancy using the zero or reversed velocity in the ductus venosus recorded during atrial contraction depend on how the velocity is

**Fig. 5.4.** Estimated spatial velocity distribution at the umbilical vein–ductus venosus junction based on a computer model. The velocity increases before the blood has reached the narrow entrance of the ductus venosus. The high axial velocity is maintained for a longer distance compared with the peripheral velocities that are reduced with the growing cross section along the vessel (see also Figs. 5.2, 5.3). (From [32])

**Fig. 5.5.** Blood velocity recorded at the isthmus of the ductus venosus at 12 weeks of gestation (*left*). During atrial contraction the velocity shows a deflection below the zero line (*a*), but at the same time retaining some antegrade velocity (*arrow*). The reason could be that the velocity profile across the vessel cross section at this moment is transformed and contains both antegrade and retrograde velocities (*right*)

traced and what is actually defined as the minimum velocity during atrial contraction.

### Pulsation in Veins

Venous pulsation observed during ultrasound Doppler recording is commonly used for diagnostic purposes. It is a regularly repeated velocity increment or inflection; however, it is worthwhile to keep in mind

that the velocity pulsation of the Doppler recording incompletely describes the pulse wave, excluding such information as variation in volume or cross section, pressure, pulse velocity and direction.

### Cardiac Function and Waveform

The waveform of the venous pulse is determined by the function of the heart. Usually there is a systolic peak (during ventricular systole), a diastolic peak (during passive filling of the ventricles) and a diastolic nadir (reflecting the atrial contraction; Fig. 5.6). The more energy put into the pulse, the further out in the system it will reach. That is particularly obvious during atrial contraction. The Frank-Starling mechanism causes an augmented contraction in a distended atrium during fetal bradycardia, and the wave propagating along the veins reflects that. A particularly strong atrial wave is seen in cases of arrhythmia when atria and ventricles happen to beat simultaneously. An augmented atrial wave is also seen in cases with increased afterload and adrenergic drive during hypoxemia [18–23]. Although the atrial contraction wave is the most commonly used sign for cardiac function, there is additional information hidden in the waveform [24, 25].

The smooth systolic peak of the wave of a precordial vein also reflects a normal compliance of the heart. External constricting processes (e.g. high-pressure pleural effusion; Fig. 5.6), particularly a stiffer and less compliant myocardium (e.g. hypoxia, acidosis, cardiomyopathy), gives a quick rise in pressure during systolic filling of the atrium, and a corresponding steep downstroke of velocity resulting in the more pointed systolic peak velocity (Fig. 5.6) [26, 27]. A quick rise in atrial pressure is sometimes caused by a significant tricuspid regurgitation leading to a similar but less acute downstroke during systole.

Reduced compliance of the myocardium is not only reflected in the acute downstroke of the systolic peak but also in the dissociation of the systolic and diastolic peak (Fig. 5.6). The dissociation between the systolic and diastolic peak seems to be a late and ominous sign of myocardial compromise [27, 28].

### Transmission Lines

The pulse generated in the heart is not transmitted equally well in all tissues. It travels better along transmission lines, and arteries and veins connected to the heart constitute such transmission lines.

A discontinuation of the transmission line affects the pulse propagation and deprives the venous waveform of its usual details [27, 29]. If the pulmonary vein is not connected to the left atrium but to the portal system, the pulse recorded in the vein no longer reflects

**Fig. 5.6.** Effect of cardiac compliance on the venous waveform in the ductus venosus. Although a stiff myocardium due to acidosis or hypoxia is the most common cause, in this case it was the fetal pleural effusion (*PI*) at 30 weeks of gestation (*upper panel*) that had a constrictive effect on the heart. The reduced compliance was reflected in the rapid downstroke of the peak velocity during ventricular systole (*S*) causing the dissociation between *S* and the diastolic peak (*D*; *middle panel*). Doppler recording 2 min after the pleural effusion has been drained off (*lower panel*) showed an instantaneous improvement in myocardial compliance (less pointed *S* and reduced dissociation between *S* and *D*), and the end-diastolic pressure was less, signified by the less pronounced atrial contraction wave (*a*)

details of the cardiac events, but rather the general pressure variation of the fetal chest (Fig. 5.7). The Doppler recording thus supports the diagnosis.

Another important transmission line is formed by the inferior vena cava (IVC), ductus venosus and um-

**Fig. 5.7.** The pressure variation of the left atrium is reflected in the velocity recording of the pulmonary veins (*upper panel*). With the loss of connection the pressure variation is not transmitted into the vein and the velocity pattern reflects instead the general pressure variation in the chest (typical for anomalous pulmonary venous drainage; *lower panel*). *A* atrial contraction wave, *D* diastolic peak, *S* systolic peak. (From [27])

bilical vein (Fig. 5.8a) [30, 31]. Agenesis of the ductus venosus has been shown to interrupt the transmission of the cardiac wave to the umbilical vein [29]. The wave propagating along this line reflects the changes in both the left and the right atrium since the IVC is connected to the left atrium through the foramen ovale in addition to the connection to the right atrium. Conversely, the pulmonary veins reflect predominantly the left atrium, and to some extent the right atrium, depending on the size of the foramen ovale [27].

## Wave Reflections

The pulse wave travelling along the transmission line is modified according to the local physical conditions [6, 15, 16, 27, 30, 32–35]. Pulsation at the ductus venosus outlet is more pronounced than at the inlet [36]. The stiffness of the vessel wall is different at the ductus venosus outlet, ductus venosus inlet and intra-abdominal umbilical vein, and so are cross-section and compliance [37]. The single most important mechanism for changing the propagating pulse in the veins is reflections. In much the same fashion as light is reflected or transmitted when the beam encounters a medium with a different density, the pulse wave in the veins is reflected and transmitted when it hits a change in impedance (Fig. 5.8b) [30, 31, 38]. Vascular junctions often represent a significant change in cross section (and thus impedance). The junction between the ductus venosus inlet and the umbilical vein is of great diagnostic interest and has been particularly well examined. During the second half of pregnancy

**Fig. 5.8.** The same veins that direct blood towards the heart (a) act as transmission lines for pulse waves generated in the heart. The most studied transmission line is formed by the proximal portion of the inferior vena cava, ductus venosus (DV) and the umbilical vein (b). The wave is partially reflected at the junctions according to the difference in impedance above and below the junction. Due to the large difference in impedance between the ductus venosus inlet and the intra-abdominal umbilical vein, most of the wave is reflected at this junction. The small wave energy transmitted into the umbilical vein is usually not enough to cause visible velocity pulsation at this site. (From [31], [55])

pulsation is regularly observed at the ductus venosus inlet, but on the other side of the junction, millimeters away, there is no pulsation in the umbilical vein. The reason is reflections [34]. The Reflex coefficient ( $R_c$ ) determines the degree of reflection and depends on the impedance of the two sections of veins (e.g.  $Z_{DV}$  ductus venosus, and  $Z_{UV}$  umbilical vein):

$$R_c = \frac{\text{Reflected wave}}{\text{Incident wave}} = \frac{Z_{UV} - Z_{DV}}{Z_{UV} + Z_{DV}}$$

In this case,  $Z_{UV}$  represents the terminal (distal) impedance in fluid dynamic terms, whereas  $Z_{DV}$  represents the characteristic impedance. From a practical point a view, the single most important determinant for impedance is the cross section of the vessel (A):

$$Z = \rho c / A$$

( $\rho$ =density, and  $c$ =wave velocity). In the case of the ductus venosus–umbilical vein junction, there is an extraordinary difference in cross section, and thus impedance; the ratio of the diameter of the umbilical vein and the ductus venosus being 4 (95% CI 2; 6) [30]. Correspondingly, most of the wave will be reflected and little energy transmitted further down. The small proportion of the energy transmitted to the umbilical vein is not sufficient to cause visible pulsation. In extreme conditions, such as during hypoxia, the ductus venosus distends [39, 40], and the difference in vessel area between the two sections is reduced, and less wave is reflected and more transmitted (Fig. 5.9a); thus, a larger proportion of the wave arrives in the umbilical vein and may induce pulsation, particularly if the a-wave was augmented in the first place.

In 3% of all recordings there is no pulsation in the ductus venosus, which is a normal phenomenon [41]. The pattern is in many cases caused by the position of the fetus bending forward and thus squeezing the IVC and ductus venosus outlet (Figs. 5.9b, 5.10) [30]. The extensively reduced cross section causes a total reflection of wave at the level of the IVC–ductus venosus junction and hardly any pulse is transmitted further down until the squeeze has been released. A similar effect can probably be obtained by the spontaneous variation in cross section sometimes seen in the proximal portion of the IVC.

### Compliance and Reservoir Function of the Umbilical Vein

Another determinant affecting pulsation is the reservoir effect [34]. Whether a pulse that arrives in the umbilical vein induces velocity pulsation depends on the local compliance. The umbilical vein is a sizeable

**Fig. 5.9.** A distension of the ductus venosus (DV) inlet and increased tone in the umbilical vein with reduced diameter reduce the difference of impedance between the two sections. Correspondingly, less reflection and more transmission increase the likelihood that velocity pulsations are observed in the umbilical vein (a). When the DV is squeezed right up to the outlet, a larger proportion of the wave is reflected at the level of outlet (b) leaving little wave energy to be transmitted further down the transmission line. No pulsation may then be observed at the DV inlet. (From [31])

vessel and acts as a reservoir. The larger and more compliant the reservoir is, the higher wave energy is required to induce a visible pulsation of the blood velocity (Fig. 5.11). Accordingly, pulsation should be

**Fig. 5.10.** Doppler recording of the ductus venosus blood velocity without pulsation (a) due to the fetal position bending forward and squeezing the ductus venosus outlet. The wave has been completely reflected at the junction with the inferior vena cava (see Fig. 9b). Seconds later, a change in fetal position restores the dimension of the vessel and the pulsatile flow pattern (b). (From [31])

a rare event in late pregnancy, whereas the small vascular dimensions in early pregnancy predispose for pulsation. Pulsation in the umbilical vein is a normal phenomenon particularly before 13 weeks of gestation [56]. It follows that an increased tone of the vessel wall (e.g. adrenergic drive, venous congestion) and reduced diameter (e.g. hypovolaemia in fetal hemorrhage) may be accompanied by pulsation in the umbilical vein.

The effect of compliance is particularly well illustrated by the physiological stricture of the umbilical vein at the entrance through the abdominal wall. Once the period of physiological umbilical herniation has been completed at 12 weeks of gestation, there is an increasing tightening of the umbilical ring causing a constricting impact on the vein in quite a few fetuses during the following weeks and months [42–44]. The stricture causes a high velocity, which, interestingly, often pulsates (Fig. 5.12) [45]. Although the pulsation may be a velocity inflection caused by the a-wave, probably a more common waveform would be a smooth increment of velocity caused by the neighboring umbilical arteries. The same phenomenon can be traced in the umbilical cord with increased turgor, angulation or extreme twisting [46]. Another example is the pulsation commonly traced in the left branch

**Fig. 5.11.** Mathematical model showing how umbilical venous pulsation changes with wall stiffness ( $\beta_{UV}$ ), a determinant for compliance. Index of pulsation for the pressure wave (IP=pulse amplitude divided by time-averaged pressure) increases with stiffness. The model also demonstrates the effect of increased diameter ratio between the umbilical vein and ductus venosus ( $D_{UV}/D_{DV}=g$ ) on pressure transmission to the umbilical vein. Increased ratio is associated with less pulsation in the umbilical vein due to increased degree of reflections at the junction. (From [34])

of the fetal portal vein [47, 48]. Compared with the umbilical vein, the left portal branch has a smaller diameter (i.e. compliance), which increases the likelihood for visible pulsation [49].

### Direction of Pulse and Blood Velocity

A short velocity deflection of the umbilical venous flow is commonly recognized as the atrial contraction wave; however, pulsations may appear differently and have various causes. Recent research has addressed this part of physiology. One important determinant is the direction of the pulse wave compared with the direction of the blood flow. The concept of wave intensity was introduced to explain the wave in arteries [50], but the concept is equally valid for veins [27, 28, 38]. When the pressure wave travels in the opposite direction of the blood velocity (Fig. 5.13), the pressure wave causes a deflection in the velocity (e.g. atrial contraction wave in the hepatic veins, ductus venosus and umbilical vein); however, if the pressure wave and blood velocity travel in the same direction, the pressure wave will impose a velocity increase (e.g. umbilical artery waveform), an effect also seen in the venous system (e.g. left portal vein; Fig. 5.13).

A particularly instructive example is found at the junction between the ductus venosus and the umbilical vein/portal system (Fig. 5.14) [49]. The pressure wave travels down the ductus venosus in the opposite direction of the blood flow (atrial contraction wave is negative). When the pressure wave enters the umbili-

**Fig. 5.12.** Upper panel: The physiological constriction of the umbilical vein at the abdominal inlet (b) represents a reduction in compliance compared with the section in the cord (a) or intra-abdominal portion (c; from [43]). Lower panel: High velocity is recorded at the constriction (b) compared with outside (a) or inside (c) the abdominal wall. The pulsation from the neighboring umbilical artery induces velocity pulsation in the vein at the constriction area but not in the neighboring sections where the compliance is higher (a and c). (From [45])

cal vein it propagates in two directions: down the umbilical vein, or up the left portal vein. In the former case the velocity wave is negative, in the latter it is positive (Figs. 5.13, 5.15). In the compromised fetal circulation the left portal vein also acts as a watershed area between the left and right part of the liver [49]; thus, blood in this section may pendulate or reverse. Depending on the direction of flow in this section, the waveform will turn the same way or be inverted when compared with the umbilical vein pulse.

**Fig. 5.13.** *Upper panel:* When the pressure pulse and velocity travel in *opposite* directions, the resulting velocity change during the pulse will be a deflection. A common example is the atrial contraction wave recorded in the umbilical vein (A). *Lower panel:* When the pressure pulse and

velocity travel in the *same* direction, the resulting velocity change during the pulse will be an increase. Accordingly, the atrial contraction wave recorded in the left portal vein is recognized as a peak (A). For further explanation see Fig. 5.14 and 5.15. (From [28], [49])

**Source of Pulse**

Whenever a pulse is generated it will be transmitted into the neighboring structures modified by the local physical conditions. Although the pulse wave commonly carries the “fingerprint” of its source (e.g. cardiac cycle) [20, 21, 51], at some distance such characteristics may have disappeared making the identification of the source less certain. Pulsation in the umbilical vein is of clinical interest if it signifies an augmented atrial contraction that has reached that far out [23, 46, 52–54]; however, the velocity pulse could have been transmitted locally from the umbilical artery, or could have been caused by rapid fetal respiratory movements or any other rhythmic fetal activity.

**Fig. 5.14.** The pressure pulse emitted from the heart travels along the veins as transmission lines. When the pulse reaches the junction between the ductus venosus inlet and the umbilical vein, the pulse wave continues in two directions: it continues along the umbilical vein *against* the flow direction, or follows the left portal branch (LPV) into the liver *with* the flow direction. FOV foramen ovale valve, IVC inferior vena cava, LA left atrium, MPS main portal stem, RA right atrium, RPV right portal branch. (From [49])

**Fig. 5.15.** Doppler recording in the ductus venosus (a) and the left portal branch (b) in a fetus of 25 weeks gestation with placental compromise. For anatomical references see also Fig. 5.14. The ductus venosus recording shows an augmented atrial contraction wave (A) reaching the zero line (pulse wave and blood flow have opposite directions). The same wave recorded in the left portal branch is a peak (A in b) since pulse wave now has the same direction as the blood flow; thus, the entire waveform during the cardiac cycle is found to be reciprocal (mirror image) at the two sites. D diastolic peak, S systolic peak. (From [49])

**Fig. 5.16.** Vortex formation (whirls) recorded as velocity variation, which mimics pulsation, in the umbilical vein. Such whirls tend to occur in large bore vessels with steady velocity, particularly if there is a diameter variation, curvature or bifurcation. The velocity usually does not fit with the heart rate. (From [29])

The vibration of the heart is also transmitted into the liver tissue and beyond and may have impact on the venous flow. Vortices, like whirls in a river, may occur in large veins and cause velocity variation recorded in the Doppler shift (Fig. 5.16). In some cases, infor-

mation on pulse-wave direction, time of the pulse and details of its form does permit the discrimination between sources.

It follows from what is presented in this section that pulsatile venous flow, both in precordial veins and in peripheral veins, such as the umbilical vein and intracranial veins, is determined by cardiac function *and* the local physical properties of the vasculature. All determinants vary with gestational age. Unless these facts are taken into account, we shall not be able to use the diagnostic techniques of venous Doppler recordings to their full potential, but face a commonly occurring risk of misinterpretation.

# Sonographic Color Flow Mapping: Basic Principles

Dev Maulik

Color flow mapping consists of real-time depiction of two-dimensional flow patterns superimposed on cross-sectional pulse echo images of anatomic structures [1–3]. The flow patterns are color-coded to present a variety of hemodynamic information. Doppler color flow mapping is based on the estimation of mean Doppler-shifted frequency and does not provide information on peak frequency shift or actual flow. Furthermore, the hemodynamic information provided is qualitative rather than quantitative. Nevertheless, color flow mapping has proved useful for elucidating structural and functional abnormalities of the circulatory system. The technique was first introduced in cardiology practice and has revolutionized noninvasive diagnosis of cardiac pathology. The use of this method has since been extended to other medical disciplines. In obstetrics and gynecology, color flow mapping has been used to investigate fetal and maternal hemodynamics during pregnancy and pelvic vessels in non-pregnant women. Color flow has been found to be useful for elucidating complex cardiac malformations of the fetus, directing spectral Doppler interrogation of fetal cerebral, renal, and other circulations, diagnosing ectopic pregnancy, and assessing pelvic tumor vascularity. It should be recognized, however, that the information generated by Doppler color flow mapping is significantly influenced by the instrumental setting and characteristics. The reliability of the method thus depends on the appropriate use of the device by the operator, who should have a clear understanding of the basic principles of Doppler color flow mapping and its implementation.

In this chapter we describe the basic principles, instrumentation, and limitations of Doppler color flow mapping and present practical guidelines for its use. We also discuss an alternative sonographic color flow mapping technique based on the time domain processing analysis.

## Principles of Doppler Color Flow Mapping

### Multigated Doppler Interrogation

Doppler color flow mapping is based on multigated sampling of multiple scan lines using bursts of short pulses of ultrasound (Fig. 6.1). Many range-gated samples are obtained for each emitted pulse of ultrasound along a single scan line by opening the receiving gate sequentially to the echo signals arriving from various depths along the scan line. The time needed for the return journey of the echo is used to determine the spatial origin of the returning echoes. Assuming a sound propagation speed of 1,540 m/s in tissue, the echo return time for an emitted sound pulse in 13 ms/cm of tissue depth. Thus a signal from a depth of 5 cm takes 65 ms from the moment of transmission to its return to the transducer. If the second sample is to be obtained from a depth of 10 cm, the range gate is opened at 65 ms after reception of the first sample (130 ms after transmission of the pulse). In reality, many samples are collected, and the consecutive sampling of the signals along the

**Fig. 6.1.** Doppler color flow mapping. Multigated sampling of multiple scan lines sweeping across the field of color Doppler interrogation

scan line is timed according to the depth of the sampling location.

Each returning echo is referenced to its range gate, which identifies it with the spatial location of its origin, and is electronically stored using delay circuitry. After all the echoes from the first pulse are received, a second pulse in phase with the first pulse is sent along the same scan line. Appropriate timing of the pulse repetition is a critical consideration for pulsed Doppler, as transmission of a pulse before the return of the echoes from the previous pulse causes range ambiguity (see Chap. 3). With two-dimensional Doppler color flow mapping, range ambiguity is not permissible. The backscattered echo signals of the second pulse are collected from range locations identical to those of the first pulse and are referenced to their respective range gates. To determine the mean Doppler shift, each echo signal from each pulse sampled from a given range gate is compared with that from the previous pulse sampled from the same gate. Because an enormous amount of samples are collected, the comprehensive spectral processing techniques (see Chap. 3) cannot be implemented in Doppler color flow mapping. Instead, the autocorrelation technique is utilized to obtain the mean Doppler phase shift (see below).

Each scan line is repeatedly sampled using multiple pulses. The latter ranges from 3 to 32, although usually 8–10 pulses are used. The signals from the identical range gates are collected and compared to obtain mean Doppler shifts, which are averaged for each gate. The number of pulses per scan line is called the *ensemble length* (Fig. 6.2). There are several reasons for this repeated sampling of a single scan line. The most important is the fact that blood flow is a continuously changing phenomenon, and the duration of each pulse in Doppler color flow mapping is too short (<2 ms) to provide an acceptable mean

value. As the number of pulses per scan line is increased, the quality of flow information improves in terms of reliability and completeness. Another distinct advantage of increasing the samples is the enhancement of Doppler sensitivity to detect low-velocity circulations. This ability may be useful for gynecologic applications, specifically for detecting ovarian, uterine, or tumor blood flow, where it is more important to detect flow than to be concerned with the temporal resolution. Moreover, as the samples are repeated and averaged against a constant background of noise, the signal-to-noise ratio improves. Multiple sampling also contributes to stabilization of the high-pass filter.

Once sampling of a scan line is completed, the next scan line is interrogated in the same manner as described above. The color flow map is completed by multiple scan lines sweeping across the imaging field (Fig. 6.1).

### Color Doppler Signal Analysis

Multigated sampling of multiple scan lines of the color flow imaging field generates an enormous amount of data. Color flow mapping requires real-time processing and display of these data. The demands of processing such a vast flow of information cannot be met by the currently available comprehensive spectral analytic techniques, such as fast Fourier transform (see Chap. 3). For example, during the time the Fourier spectral analyzer processes signals from one sample volume, thousands of samples must be processed for color flow mapping. Obviously, color flow mapping requires an alternative approach for Doppler signal analyses [4, 5], which is usually achieved by the autocorrelation technique (Fig. 6.3), which generates mean Doppler shift information, rather than the comprehensive power spectral data generated by full spectral processing. It is important to note that the autocorrelation method does not estimate the peak frequency shift.

The mean Doppler shift is based on phase differences between the echoes generated from consecutive sound pulses transmitted in the same direction and sampled from the same location. *Phase* is defined in physics as a specific degree of progression of a cyclic phenomenon. When two waves are in step, they are in phase. The movement of the scatterer during the elapsed time between the two consecutive pulses causes the resulting echoes to be out of step or phase. The autocorrelator measures this phase difference by multiplying the successive signals. The mean Doppler shift is related to the phase difference, as shown in the following equation:

$$\phi = 360^\circ \times MF_d / PRF$$

Fig. 6.2. Concept of ensemble length

**Fig. 6.3.** Principle of two-dimensional Doppler signal analysis. During the first ultrasound transmission, the stationary tissue objects and the moving erythrocytes generated echoes (A1 and B1, respectively). During the second transmission echoes are produced again (A2 and B2, respectively). Note that the echoes from the stationary objects remain the same (A1 and A2), whereas those originating from the moving objects (B1 and B2) differ. Correlating the first echo with the next echo cancels the signals from the stationary targets and identifies the signals from the moving scatters (C). This process is repeated with the successive echoes from moving targets to estimate the mean Doppler frequency shift in real time

where  $\varphi$  is the phase angle,  $MF_d$  is the mean Doppler frequency shift, and  $PRF$  is the pulse repetition frequency. The autocorrelation is achieved by electronically delaying an echo signal, which is then processed with the subsequent echo signal (see above).

### Instrumentation

The instrumentation for two-dimensional Doppler color mapping consists of multiplex systems that combine multiple ultrasound modalities, providing a comprehensive array of sophisticated diagnostic tools (Table 6.1). It is not surprising that the technology employed in these devices is highly complex, especially in the Doppler color mode. In addition, commercially available devices not only demonstrate a fair degree of diversity in the engineering implementation of the Doppler technology they also differ in the organization and the choice of system controls they offer to the operator. Although a comprehensive discussion is beyond the scope of this chapter, we present here the basic principles of Doppler color flow instrumentation.

### Color Flow Processor

The basic components of a color flow signal processing system consist of the following (Fig. 6.4):

**Fig. 6.4.** Doppler color flow signal processing system

1. Transducer for transmitting the ultrasound beam and receiving the echoes for both imaging and Doppler analysis.

2. Receiver, which receives and amplifies the incoming signals from the transducer for further processing for gray-scale tissue imaging and for Doppler color flow mapping.

3. Echo information for tissue imaging is processed and converted to digital format. It is stored in the digital scan converter for subsequent integration with color flow mapping.

4. Backscattered echoes for Doppler processing are first converted from analog (electrical voltage variations) data to numeric or digital data.

5. Digitized signals are then subjected to filtering to remove noise generated by stationary and slow-moving tissue structures. The filter is known as the moving target indicator.

6. Filtered data are then analyzed by the autocorrelator to determine the Doppler phase shift. The autocorrelator output consists of three types of information: Doppler mean frequency shift, variance, and Doppler amplitude (power or energy). These data are fed to the digital scan converter, where they are integrated with the tissue image information.

7. Doppler-related data are color-coded by the color processor and the combined gray-scale tissue image, and the Doppler color map is sent to the video display via digital-to-analog conversion.

The above description is only a general outline. The implementation of color Doppler sonography involves highly complex technology and proprietary engineering innovations – information not accessible in the public domain.

### Transducers for Doppler Color Flow Mapping

The various types of duplex transducer are discussed in Chap. 3. Among them electronic array systems are used in most devices for color flow mapping. Mechanical transducers do not offer as optimal a platform for Doppler color flow implementation as does simultaneous tissue imaging and Doppler interrogation; and other advanced features, such as beam steering cannot be performed with these transducers. With these devices one must freeze the tissue image before using the Doppler mode. These limitations preclude their use for obstetric Doppler sonography.

Color Doppler flow mapping has been implemented using linear sequenced array, convex sequenced array, linear phased array, and annular phased array transducers. In a linear sequenced array transducer, the scan lines are perpendicular along the length of the transducer face, producing a rectangular field.

Although this configuration provides the optimal imaging approach, it is not optimal for Doppler imaging of vessels or flow channels located across the beam path. This problem can be mitigated by the hybrid sequenced and phased systems in which the Doppler beam can be steered independent of the direction of the imaging beam, producing a more favorable angle of insonation. As all scan lines are parallel to one another, they incur the same angle with a given flow axis. Beam steering reduces the effective aperture and increases the beam thickness; it may compromise the sensitivity and lateral resolution. These transducers are advantageous for peripheral vascular imaging, but they are not particularly useful for obstetric or gynecologic applications.

A modification of the linear sequence design, the convex sequenced array offers distinct advantages over the previous design for obstetric scanning because of its smaller footprint. It also offers a wider field of imaging at depth, and the wider field of view is achieved without the grating lobe problem of the linear phased array. The angle of Doppler insonation is better achieved in the convex than in the linear array despite some of the disadvantages of the former, as previously discussed.

The linear phased array offers a sector-shaped field of image and is useful for cardiologic applications. These transducers, however, are not optimal for fetal imaging applications. They do not provide the wide angle of view at depth and may produce side lobe problems, resulting in spurious flow depiction. Annular array transducers are seldom used for color flow obstetric applications.

## Color Mapping

Color flow mapping is based on color-encoding each pixel representing the averaged mean Doppler shift. The color is used to represent the direction, magnitude, and flow characteristics of the sampled circulation. These parameters are qualitative rather than quantitative. The color scheme is based on color classification, which is derived from the fundamental properties of light perception composed of hue, luminance, and saturation.

### Color Classification

*Hue* is the property of light by which the color of an object is classified as the primary colors of red, blue, green, or yellow in reference to the light spectrum. The basic classification is based on the presence or absence of hue. Those colors with hue are termed chromatic colors and include red, orange, yellow, green, blue, and so on. Those without hue are called

achromatic colors and include black, gray, and white. The chromatic colors are further classified into groups according to their hue. All hues of red are grouped together, all blues are together, and so on, resulting in a continuous circle of overlapping hues. The human eye is incapable of differentiating between two superimposed primary hues, which led to the discovery that it was possible to produce any given color using a combination of three primary colors. The selection of the three primary hues is arbitrary. Red, blue, and green colors are used in color video displays, including color flow mapping, whereas artists use red, blue, and yellow pigments as their three primary colors.

The next characteristic of light for color classification is *luminance*, which is the brightness: Some of the chromatic colors of a single hue are darker or lighter than others, analogous to the degrees of gray of the achromatic colors. This classification is known as luminance or brightness.

The third property for color grouping is *saturation*, which indicates the combination of a hue of particular brilliance with an achromatic color of the same brightness. The consequent light stimulus depends on the relative amount of the chromatic and achromatic components in which the latter has 0 saturation and the former has a saturation value between 0 and 1.0.

### Color Perception

Color is the perception generated by the stimulus of light falling on the retina of the human eye. The eye can distinguish a wide range of gradations of hue and saturation. In contrast, the ability to differentiate various grades of luminance is relatively limited. Therefore refined appreciation of color maps is achieved better with hue and saturation than with luminance. Hues with higher luminance are better perceived by older observers.

In regard to the impact of color blindness on a diagnostician's ability to assess color flow mapping, it should be recognized that about 8.0% of men and fewer than 0.5% of women suffer from varying degrees of deficiency of color perception. Total absence of color vision is rare. Anomalopia is partial color blindness, in which both red and green are poorly recognized. Most color-blind persons find it easier to recognize saturation characteristics of a color flow map because saturation involves mixing of achromatic colors with chromatic hues.

### Color Encoding of Doppler Flow Signals

Hemodynamic attributes of the interrogated blood flow are expressed by color encoding of the mean

Doppler shift signals. These attributes are the direction of flow in relation to the transducer, the magnitude of velocity, variance of the measured mean parameter (mean Doppler shift), and the amount of scattering power (the amplitude or energy or power of the Doppler shift).

### Color Mapping of Direction of Flow

The directionality of flow in relation to the transducer is depicted in the primary colors of red and blue. With most Doppler color flow systems, the default mode depicts the flow toward the transducer as red and the flow away as blue.

### Color Mapping of Velocity and the Color Bar

The magnitude of the flow velocity is qualitatively expressed by assigning levels of luminance to the primary hue. The highest velocity flow is depicted by the most luminance and the lowest velocity by the least luminance or black. The highest measurable velocity toward the transducer is shown in the most brilliant red, and the highest measurable velocity away from the transducer in the most brilliant blue. The highest limit of the velocity unambiguously measurable by a Doppler color flow mapping system, based on the pulse Doppler interrogation, is the *Nyquist limit*. As noted before (see Chap. 3), this limit depends on pulse repetition frequency and the depth of Doppler interrogation. The lowest measurable velocity in a color flow mapping device depends on a multiplicity of factors and varies from device to device.

The calibration of the velocity magnitude as a function of luminance gradation is displayed graphically on the video screen as a color bar or circle (Fig. 6.5). It is customary to display the magnitude of the Doppler shift on the vertical axis and the variance (see below) on the horizontal axis. The Doppler shift may be displayed as either frequency or velocity. The velocity information is merely an approximation, as the Doppler angle of insonation is not measurable in color flow mapping. For color flow mapping, it is usually assumed that this angle is zero. The scales are not quantitative, and a particular level of luminance does not reflect a specific single value of Doppler shift but, rather, a range of values. In addition, the color bars of the devices do not have any uniformity of scale for depicting the magnitude of Doppler shift, as the corresponding levels of brightness are assigned arbitrarily and on a nonlinear scale. The baseline, which indicates zero frequency shift, divides the color bar into positive and negative frequency shifts. The baseline is indicated as a black band on the color bar,

**Fig. 6.5.** Examples of color indicators from three ultrasound devices (A, B, C). The first two panels show the color velocity information in the form of a color bar. The flow toward the transducer is encoded in red, and flow away from the transducer is encoded in blue. The baseline is the black band between the two colors. Its vertical dimension varies with the magnitude of the wall filter. The magnitude of velocity is indicated by the brightness of colors, which progressively increases toward the upper and lower ends of the color bar. The magnitude of the velocity is indicated either as Doppler frequency shift (kilohertz) or as velocity (centimeters per second). The third panel (C) represents the Doppler information as a color circle, with the color flow directionality indicated by arrows. The color coding in this example is the same as that in the previous examples. The variance information is indicated by the additional mixing of color in the horizontal axis. Examples B and C also include indicators for gray-scale imaging priority

and its location can be adjusted to vary the proportion of positive or negative shifts. The vertical measure of the baseline is variable and reflects the magnitude of the wall filter.

Despite its qualitative nature, the velocity information provided by color flow mapping is of significant clinical utility. Identification of different vessels traversing in close proximity may be facilitated by the luminance and hue of the color display, with the former indicating velocity magnitude and the latter providing directional information. For example, with fetal echocardiography ascending aortic and pulmonary trunk systems can be distinguished and their “crossover” spatial relationship confidently established with the assistance of color flow mapping (see Chap. 32). This information helps to exclude various outflow tract malformations, such as the transposition of great vessels or the common outflow tract. Although this diagnostic information may be obtained through two-dimensional gray-scale imaging alone, addition of color flow mapping significantly augments the diagnostic efficacy. Similarly, the technique eases iden-

tification of the ductus arteriosus, noting the directionality of flow in conjunction with brightness of color because of a high ductal flow velocity. Often the ductal flow velocity exceeds the Nyquist limit so aliasing can be observed, which also assists the process of identification.

### Color Mapping of Variance

Variance is statistically defined as a measure of dispersion of the values around the mean. As discussed above, color flow mapping is based on the estimation of mean Doppler shift calculated by autocorrelation from the phase difference between consecutive echo signals. Variance in color flow mapping is the spread of the mean Doppler shift value and is determined statistically by the autocorrelator. Variance information is displayed only when the value exceeds a certain threshold and is achieved by changing the hue. With most devices this change consists in adding green to the primary color. If the flow is toward the transducer, mixing of green with red results in yellow. If the flow is away, addition of green to blue results in cyan color. In either situation, the brightness of the mixed color is determined by the luminance of the primary hue.

The presence of variance above the threshold value may indicate spectral broadening caused by flow turbulence. However, the variance display may also be activated in a nonturbulent flow by variations in the flow velocity. In addition, if the flow velocity exceeds the Nyquist threshold, consequent aliasing may produce mosaic patterns in the color display that may be misinterpreted as turbulent flow.

### Formation of a Color Frame

A color frame is a single complete cross-sectional display of a two-dimensional color flow map superimposed on a gray-scale image of the tissue structures produced by one complete sweep of the ultrasound beam. Obviously, there are two primary components of such a frame: the color flow map and the gray-scale image.

### Two-Dimensional Color Frame Formation

The color flow map is generated by the multigated interrogation of multiple scan lines sweeping across the target field as discussed above. A two-dimensional B-scan tissue image is formed by pulse echo interrogation of the same scan lines. There are various procedures for achieving this image:

1. Imaging and flow information are sampled from each scan line synchronously and collated in the digi-

tal scan converter. When both imaging and flow mapping fields are completely scanned, the completed frame is displayed with the flow image superimposed on the tissue image.

2. Imaging and flow data are synchronously sampled for each line similar to the previous approach but are displayed sequentially as each line is interrogated rather than when a complete frame is formed.

3. Scanning for tissue imaging is performed first followed by scanning for flow. Flow information is then superimposed on the tissue image.

The composite image frames generated by the above methods are remarkably similar, although there are differences related to the superimposition technique that may compromise the ease of visual perception or interpretation of the hemodynamic information. For example, separate frame formations for the tissue and color flow images may produce a hemodynamically incoherent appearance. Similarly, line-by-line sequential image formation may lead to mixing of consecutive individual frame components, which is seen during frame-by-frame review of the images stored in the memory.

It should be noted that whereas only one pulse per scan line is sufficient for tissue imaging, 3–32 pulses are needed for color Doppler imaging – which is therefore a more time-consuming process. One way to minimize the demand on time is to restrict Doppler flow sampling to an area smaller than the total available field. This color window is superimposed on the gray-scale tissue image, and its size can be manipulated by the operator. A small color window improves Doppler sensitivity and temporal resolution. Therefore it is advisable to restrict the size of this window to the area of interest for Doppler interrogation.

## Persistence

Interpolation algorithms may be used to produce temporal averaging of color Doppler information. The process of averaging is known as *persistence*, as it allows more prolonged display or lingering of the color image. It produces a smoother color Doppler image at the cost of losing some detail. Most devices allow selection of different degrees of averaging or persistence. As the color Doppler image remains displayed longer with a higher persistence setting, areas of circulation with a lower flow velocity become more visible in the color map. The application of persistence control may therefore be useful when color mapping such slow-flow conditions as are encountered in the ovarian, placental, and fetal splanchnic circulations. Similarly, as the blood flow velocity declines near the vessel wall because of viscous drag, persistence may produce a more complete outline of a vascular image.

## Frame Rate

*Frame rate* is the number of image frames produced per second. For Doppler color flow mapping, the rate varies from 10 to 60 frames per second. As discussed above, Doppler color flow interrogation places great demand on time. The frame rate (FR) is directly affected by the pulse repetition frequency (PRF); it is inversely influenced by the scan line density (SLD) in the color field and the number of pulses per scan line or the ensemble length (EL):

$$FR = PRF / (SLD \cdot EL)$$

Therefore the frame rate of color imaging can be changed by manipulating these factors, which, however, alters other imaging parameters due to their interdependence. For example, a higher frame rate can be achieved by increasing the PRF, which also limits the depth of interrogation. Similarly, a reduction in the line density not only increases the frame rate, it compromises the spatial resolution; a decline in the number of samples per line also reduces the Doppler sensitivity. These trade-offs should be taken into consideration when ensuring optimal color imaging for a given situation. Thus a low frame rate improves image quality by producing better sensitivity and spatial resolution. Slow flows are better detected with a low frame rate. The latter also allows more effective high-pass filtering, which results in more effective elimination of motion artifacts, such as ghosting. A low frame rate decreases temporal resolution, however, so asynchronous events may be displayed in the same frame. As expected, the problem becomes worse with a high heart rate, as observed in the fetus. A high frame rate improves the temporal resolution, provided the line density and number of pulses per scan line remain adequate to maintain an acceptable spatial resolution and Doppler sensitivity, respectively.

## M-Mode Color Frame Formation

In Doppler color M-mode, multigated Doppler sampling is performed on a single scan line sampled 1,000 times per second. The unidimensional tissue and color flow images are scrolled (usually from right to left on the video screen) and therefore are displayed as a function of time (Fig. 6.6). In the time-motion format, the vertical axis represents tissue depth, and the horizontal axis represents time. As with gray-scale M-mode insonation, the spatial location of the beam path is ascertained using two-dimensional color flow imaging. Because of the high sampling rate from a single line, color M-mode insonation provides high Doppler sensitivity and temporal resolution, and it allows reliable timing of the flow

**Fig. 6.6.** Color M-mode sonogram. *Top:* Two-dimensional color Doppler echocardiogram of the fetal heart (four-chamber view). M-mode cursor is indicated by the *dotted line*. *Bottom:* Color M-mode tracing of flow from the right atrium (RA) to the right ventricle (RV) across the tricuspid orifice. The movement of the tricuspid valve (TV) is visible in the *middle* of the panel. As the flow is toward the transducer, it is coded *red*. Note the aliasing at the tricuspid orifice level (*blue and yellow*)

with the events of the cardiac cycle. For this reason, color M-mode sonography is a useful tool for fetal echocardiographic examination.

## Operational Considerations

### Transducer Frequency

The operating frequency of the transducer is an important contributor to the functional efficacy of the system. A high carrier frequency results in better spatial resolution of the image but reduces the depth of penetration. The Doppler mode is more vulnerable to depth limitation than gray-scale tissue imaging. For most obstetric applications, a frequency of 2–4 MHz provides adequate penetration and resolution and is usually preferred. For transvaginal applications, a higher frequency (5–12 MHz) is used, as penetration is not a problem. Currently, piezoelectric elements capable of resonating at more than one frequency are available, so a single transducer can operate at multiple frequencies. This capability offers a unique advantage for color flow mapping, as a low frequency may be used for the combined tissue imaging and color Doppler mode, and one may then default to a high frequency for tissue imaging to ensure a higher gray-scale resolution.

### Pulse Repetition Frequency

Doppler color flow mapping is based on pulsed Doppler insonation. The magnitude of the frequency shift in color flow Doppler sonography therefore depends on the PRF of the transmitted ultrasound. The PRF is

**Fig. 6.7a–c.** Effect of pulse repetition frequency (PRF) on the color flow map. The images show atrioventricular flow on the oblique apical four-chamber view of the heart. **a** Low PRF setting resulting in severe aliasing with mosaic patterns and spatial overrepresentation of flow. **b** Effect of a modest increase in the PRF is partially improved image quality. Overrepresentation of flow and mosaic appearance are still present. **c** More appropriate color flow depiction with another substantial increase in the PRF. Note the presence of aliasing across the tricuspid orifice. RA right atrium, RV right ventricle, LA left atrium, LV left ventricle

adjustable and should be optimized for specific applications. As the PRF is changed, the range of Doppler shifts for a given PRF is shown in the color bar. The displayed range is a qualitative approximation and cannot be used as quantitative information. The PRF setting should be manipulated to accommodate a changing velocity pattern (Fig. 6.7). A low PRF in the presence of a high-velocity flow results in aliasing of the displayed frequencies. A high PRF, on the other hand, reduces the sensitivity so a low-velocity flow may not be identified. The location of the baseline can be changed to depict optimally the entire range of frequencies encountered in a target vessel in the appropriate direction. As indicated in the previous section, the PRF is related to the frame rate and affects the depth of imaging. These factors should be taken into consideration for increasing the efficiency of color flow imaging.

### Doppler Color Flow Gain

The gain control deals with signal amplification. Most color flow devices offer separate gain controls for pulse echo imaging, spectral Doppler, and Doppler color mapping functions. The greater the gain, the more sensitive the Doppler procedure. Appropriate color gain adjustment is essential for generating reliable hemodynamic information. A higher gain setting improves the sensitivity of color Doppler sonography for identifying low-velocity flow states. However, increased gain also amplifies the noise component of the signal (Fig. 6.8), which causes display of misleading information, including the appearance of random color speckles in the color window, overflow of color outside vascular areas, and semblance of mosaic patterns. The latter falsely suggests the presence of turbulence when the flow is nonturbulent. The optimal gain setting should therefore be tailored to the specific examination. As a practical guideline, the gain should be initially increased until random color speckles start to appear; the gain is then reduced until the speckles disappear. Further manipulation should take into account other attributes of the color image and the characteristics of the flow.

### High-Pass Filter (Wall Filter)

A high-pass filter eliminates high-amplitude/low-frequency Doppler shift signals generated by movement of the vascular wall, cardiac structures, or surrounding tissues (Fig. 6.8). Such signals, because of their high-power content, obfuscate Doppler signals generated by blood flow. This filter is called *high pass* because it allows high frequencies to pass through for further processing. As discussed in Chap. 4, high-pass filters are an essential part of signal processing in

spectral Doppler ultrasonography. They are also an integral part of Doppler color flow mapping. The technique, however, is relatively more complex in this application, as an immense amount of Doppler data must be processed in real time. A filter that simply eliminates low-frequency signals also removes low-velocity blood flow signals with consequent loss of important hemodynamic information. For obstetric and gynecologic applications, low-speed flow is encountered in ovarian and tumor vessels, placental circulation, and fetal splanchnic vessels. The technique used for Doppler color flow application has its origins in radar engineering and is also known as a moving target indicator. The filters can be implemented at various levels of high-pass threshold. The thresholds are defined in terms of either frequency values or predesignated levels optimized for specific applications. The threshold may change automatically as the PRF is increased. With many devices a minimum level of filtering operates at all times.

For proper use of the high-pass filter, the circumstances of its application must be taken into account. Thus investigation of such low-flow systems as are encountered in the ovaries involves little or no filtering. Moreover, unlike the Doppler interrogation of the cardiac circulation, which may be associated with significant high-amplitude/low-velocity signals because of the movement of cardiac structures and surrounding tissues, such clutter signals are not a significant problem during interrogation of the pelvic vessels. The need for the use of high-pass filters in this situation is less compelling. In contrast, careful use of graded high-pass filters may be necessary during fetal echocardiography, as significant tissue movement is often encountered because of a fast fetal heart rate. For optimal use of the filter, one must also take into account other system parameters, especially the frame rate. A high frame rate decreases the processing time and Doppler sensitivity. Therefore a high-pass filter setting should not be used along with a high frame rate, as this combination leads to loss of low-velocity flow signals. As a rule of thumb, a low-level filter should be used for imaging ovarian, pelvic tumor, fetal splanchnic, intrauterine, and placental vessels; a medium level is useful for imaging umbilical or fetal venous flow; and a high level is recommended for fetal intracardiac flow or pelvic vessels such as the internal iliac or uterine arteries.

Although the exact algorithm of filtering is proprietary and varies according to the vendor, the current generation of high-pass filters use multivariate techniques capable of discriminating between low-velocity blood flow and wall motion. Introduction of such filtering techniques has led to the recent resurgence of interest in Doppler amplitude mode (also known as power Doppler or energy Doppler) for col-

**Fig. 6.8a–d.** Doppler color gain and wall filter. The examples illustrate the effect of variations in color gain and wall filter on color flow imaging of the fetal heart. The gain, wall filter, and other settings of the image are displayed at the *left upper margin*. **a** Echogram at 74% color gain and medium level of wall filter. **b** Image at 86% color gain and

or flow mapping, which may be helpful for identifying slow-flow circulations (see below).

## Limitations of Doppler Color Flow Mapping

Despite the impressive technologic innovations of Doppler color flow ultrasonography that have revolutionized noninvasive cardiovascular diagnosis, there are important limitations of the method that should be considered. These limitations are inherent in the physical principles and the engineering implementation of the method. They are also responsible for various artifacts that one may encounter during use of this technique. An understanding of these limitations and artifacts is essential for the appropriate use and interpretation of Doppler color flow mapping. The following section discusses these factors, which

include aliasing, range ambiguity, temporal ambiguity, problems related to the angle of insonation, tissue ghost signals, and mirror imaging.

## Aliasing

As color flow mapping is based on pulsed Doppler insonation, its ability to measure the maximum frequency shift without ambiguity is limited by the PRF rate of the system. The threshold level of Doppler shift beyond which the measurement becomes ambiguous is called the Nyquist limit, and the phenomenon of Doppler shift ambiguity beyond the Nyquist limit is called the Nyquist effect, or *aliasing*. This phenomenon is known as aliasing because it falsely depicts the frequency shift in terms of both magnitude and direction. Aliasing in spectral pulsed Doppler sonography is discussed in detail in Chap. 3.

Aliasing in a color flow system is shown in a spatial two-dimensional plane in which the aliased flow

is depicted in reversed color surrounded by the non-aliased flow (Fig. 6.9). This pattern mimics the color flow appearance of separate streams in differing directions. The two patterns, however, are clearly distinguishable. In an aliased flow, the higher velocity generates a higher Doppler shifted frequency, which is depicted with greater brightness: the higher the frequency shift, the brighter the color. The brightest level in the color calibration bar (the uppermost for the flow toward the transducer and lowermost for the flow away from the transducer) represents the Nyquist limit. As the velocity, and therefore the frequency shift, exceeds this limit, the color wraps around the calibration bar and appears at the other end as the most luminous color of the opposite direction (Fig. 6.10). For example, flow toward the transducer with an increasing velocity is depicted with an increasingly bright red color changing to yellow (Fig. 6.9). As the Nyquist limit is reached, the color flow shows brightest yellow in the color bar; and as the limit is exceeded, flow is shown in the brightest blue. Thus in an aliased flow, the bright or pale color of one direction is juxtaposed against the bright color of the opposite direction. In contrast, with genuine flow separation the distinct flow streams are depicted in the directionally appropriate colors separated by a dark margin (Fig. 6.11). Note that the hue that demarcates an aliased flow depends on the choice of the color mapping scheme.

When demonstrating aliasing, an apparent contradiction may be seen between the spectral Doppler and the Doppler color flow interrogations. Doppler color flow mapping may show a nonaliased flow pat-

**Fig. 6.9.** Color Doppler Nyquist effect. The image shows Doppler color flow mapping of the left ventricular outflow. Note the change of color from red to yellow and then from bright blue to dark blue. With the declining velocity, blue changes first to yellow and then to red. LVOT left ventricular outflow tract

**Fig. 6.10.** Color Doppler Nyquist effect. The image shows Doppler color flow mapping of the left ventricular outflow. Note the change of color from red to yellow and then from bright blue to dark blue. With the declining velocity, blue changes first to yellow and then to red. LVOT left ventricular outflow tract

**Fig. 6.11.** Doppler color flow depiction of change in the direction of flow. The image shows Doppler color mapping of flow through the ascending aorta (AA) and the arch of the aorta. In the ascending aorta the flow is toward the transducer and is therefore depicted as red according to the color bar setting. As the direction of flow changes, the color becomes blue with a dark line separating the two hues. LV left ventricle

tern when aliasing is observed with the spectral Doppler waveform. This phenomenon is explained by the fact that the mean frequency is less than the peak frequency, and Doppler color flow depiction is based on the use of mean frequency, so the Nyquist limit is not reached as readily as with the peak frequency depiction by the spectral Doppler method.

Color Doppler aliasing can be eliminated by elevating the Nyquist limit, which can be achieved by either increasing the PRF or decreasing the transducer frequency. However, an increasing PRF may eventually result in such shortening of the interpulse in-

terval as to cause range ambiguity of the returning echoes – unless the depth of interrogation is reduced so all the echoes from one pulse are received at the transducer before the next pulse is transmitted. As Doppler color flow mapping technology critically depends on identifying the spatial origin of an echo, color Doppler devices are preset to prevent range ambiguity by automatically reducing the color imaging depth.

### Range Ambiguity

The occurrence of range ambiguity in regard to pulsed spectral Doppler sonography is discussed in Chap. 3. Range ambiguity arises when the interpulse interval is short in relation to the depth of the field of insonation, so echoes from deeper sampling locations do not reach the transducer before transmission of the next pulse. These Doppler signals are then treated as the early returning echoes of the second pulse being reflected from a superficial location and are displayed as such. Consequently, spurious color flow is shown in areas devoid of any vascularity. In practise, however, most Doppler color flow devices prevent this problem by automatically reducing the depth when the PRF is increased to the threshold of range ambiguity.

### Temporal Ambiguity

Temporal ambiguity occurs when Doppler color flow mapping fails to depict hemodynamic events with temporal accuracy. Specifically, such a situation arises when the frame rate for color flow is too slow relative to the circulatory dynamics. As discussed earlier, the basic unit of color flow depiction is a single frame that, when completed, shows the average mean frequency shifts color-coded and superimposed on the gray-scale tissue image. The flow dynamics are therefore summarized for the duration of one frame. As we noted above, the frame rate is inversely proportional to the number of scan lines and the number of samples per scan line. The slower the frame rate, the better the color image quality in terms of both spatial resolution and Doppler sensitivity. Herein lies the paradox, as a slower rate means longer duration of a frame. As the frame duration increases, there is progressive loss of the ability to recognize discrete hemodynamic events.

This decline in the temporal relevance of the flow map is accentuated by hyperdynamic circulatory states with the rapidly changing hemodynamic phenomena. One may encounter such a situation in the fetal circulation, which is driven by a fast heart rate, normally 120–160 bpm. A faster rate means a shorter cardiac cycle. The shorter the cardiac cycle, the lower

**Table 6.2.** Relation between frame rate, completed frames per cardiac cycle, and fetal heart rate

Frames per second	Duration of a frame (ms)	Complete frames per cardiac cycle	
		FHR 120 bpm	FHR 160 bpm
10	100	5	3
15	66	7	5
30	33	15	11

FHR, fetal heart rate.

the number of complete frames available for depicting each cardiac cycle (Table 6.2) and the greater the risk of temporal ambiguity. This artifact may be apparent in the simultaneous depiction of temporally sequential circulatory phenomena. For example, with fetal echocardiography one may see in the same frame atrioventricular flow across the mitral orifice and left ventricular outflow into the aortic root. The former is related to ventricular diastole and the latter to ventricular systole. One may also experience temporal ambiguity in color flow devices that form gray-scale and color flow images separately in a frame that may depict discordance between the gray-scale depiction and the color flow mapping of the cardiac events.

### Angle of Insonation

Angle dependence of the Doppler shifted frequencies, discussed in Chap. 2 in relation to spectral Doppler sonography, is a critical factor in color flow mapping. With sector scanning, multiple scan lines spread out from the transducer in a fan-like manner. When the sector scanner is used to interrogate a circulatory system in which the direction of flow is across these scan lines in a color window, the angle of insonation between the flow axis and the ultrasound beam changes (Fig. 6.12). The angle is smallest when the flow stream enters in the sector field and progressively rises to 90° as the flow approaches the center of the field. Concurrently, the Doppler-shifted frequencies progressively decline and may become undetectable at the center of the color field (Fig. 6.13).

A sector scanner may also create apparently contradictory directional information in a vessel traversing the color field. As the flow approaches the midline of the field, the flow is depicted in color encoding for flow toward the transducer, which usually is red; as the flow moves away, it is encoded blue. Thus the same vessel shows bidirectional flow (Fig. 6.13). This paradox highlights the basic concept of representation of flow directionality by any Doppler system. The latter does not depict the actual flow direction, merely the vector of flow toward the transducer.

**Fig. 6.12.** Progressive increase in the angle of insonation and change in color coding of flow as a vessel traverses a sector field

**Fig. 6.13.** Color Doppler sonogram of the fetal thoraco-abdominal aorta demonstrating the effect of varying angles of insonation in a sector field. Although the flow in reality is unidirectional, the color coding of flow changes as the vessel traverses across the sector field giving a false impression of bidirectional flow. Note also the absence of color flow at the center of the color field as the beam intersects the vessel at a right angle

### Wall Motion Ghost Signals

Spurious color flow signals may be generated by movements of the cardiac structures or vascular walls. These signals may be easily distinguished from the blood flow-related color map, as they are of lower frequency, are usually displayed outside the intracardiac or intravascular space, and may be asynchronous with the cardiac or vascular hemodynamic events (Fig. 6.14). These signals are seen more frequently with hyperdynamic circulations with high-speed wall movements. They may also be noted with deep cardiovascular structures whose motion generates Doppler signals; these signals reverberate at various structures and become more visible as the real blood

**Fig. 6.14.** Example of tissue motion-generated color signals unrelated to flow (*horizontal arrow*). The echogram depicts a fetal thoracic cross section at the level of the heart

flow signals are attenuated because of the depth. With obstetric applications, this artifact is of relevance mostly in relation to fetal echocardiography. Ghost signals may be reduced by elevating the high-pass filtering threshold, by increasing the PRF (which raises the minimum detectable velocity), or by the reject function (which cuts off low frequencies).

### Mirroring

Mirror images of color flow are produced by reflection of the Doppler signal at a vessel wall or other structures so it takes longer to return to the transducer. The system recognizes and depicts the signal as originating from a deeper location than its real source.

### Color Mapping of Doppler Amplitude (Doppler Power or Doppler Energy)

The Doppler signal amplitude implies the intensity of the signal and is also referred to as Doppler power or energy. As discussed in Chaps. 3 and 4, Doppler flow signals have three dimensions: (1) frequency, which is proportional to the speed of red blood cell (RBC) movement; (2) amplitude, or intensity, of the signal, which is proportional to the number of RBCs scattering the transmitted ultrasound beam; and (3) time, during which the above two parameters change. Whereas the frequency information and its temporal changes form the basis for clinical application of the Doppler technique, the amplitude data remain largely unutilized. However, amplitude reflects the scattering power and therefore may prove useful in clinical applications. During Doppler color flow processing, the autocorrelator measures the amplitude from the

**Table 6.3.** Advantages and disadvantages of the Doppler power or energy mode

Advantages	
Increased sensitivity for detecting low-velocity circulatory systems as encountered in splanchnic, placental, or tumor vessels	
Virtual independence of the angle of insonation	
May allow better delineation of flow in vascular channels	
Absence of Nyquist effect	
Disadvantages	
Does not provide information on the directionality of flow	
Depth-dependent, so the greater the depth of the vessel, the less available amplitude flow information	

phase analysis of the returning echoes. Although it was theoretically possible to produce two-dimensional Doppler color flow mapping based on the intensity of the Doppler signal, it is only recently that the systems have seriously attempted to resolve the technical challenge of producing an amplitude-based map that would be independent of Doppler-shifted frequency. The advantages and disadvantages of the amplitude mode are summarized in Table 6.3 and are discussed further below.

With spectral Doppler analysis the amplitude information is generated by the spectral analysis, which provides complete information on the Doppler power spectrum. It is depicted in the so-called Z axis as brightness of the waveforms. With color flow processing, which is based on phase-difference analysis, the amplitude of the Doppler signal is estimated by the autocorrelator. The output is color-coded and is displayed along with the gray-scale tissue images. The Doppler energy or power display, however, does not indicate directionality of flow in relation to the transducer. In contrast to the frequency mode, which as is apparent from the Doppler equation is angle-dependent, the amplitude mode is virtually unaffected by the angle of insonation.

The amplitude output is affected by the wall (high-pass) filter as it removes high-amplitude/low-frequency Doppler signals generated by tissue movements. If the filter setting were identical to the frequency-based color flow mapping, the amplitude map would offer no more flow information than the former. Current filter algorithms, particularly those utilizing the multivariate approach, have substantially minimized this problem. An appropriate filter setting is essential for optimal color Doppler amplitude imaging (Fig. 6.15). A low threshold of wall filter is needed for identifying low-flow states. Doppler power, or energy, imaging is also affected by the gain

(Fig. 6.15). A high gain results in increased sensitivity for detecting slow-velocity circulations but also in the extension of color flow areas beyond the vascular margin and the depiction of tissue or wall movements. Other factors that interdependently or independently affect the power or energy mode display include the transmitted acoustic power, depth, color sensitivity, preponderance of gray scale (write priority), and persistence. The implementation of these controls and the resultant changes in the amplitude color maps vary from device to device.

Amplitude mapping may be helpful for identifying blood flows of low volume or low velocity. Doppler mean frequency shift based on color mapping may not be sensitive enough to detect such a flow system. Examples of such potential uses in obstetrics include fetal echocardiography and demonstration of splanchnic flow in fetal lungs and placenta. In gynecologic practice, amplitude may optimize our ability to detect flow in pelvic organs such as the ovaries (Fig. 6.16), especially in postmenopausal women. The extent of its clinical utility is still being explored, particularly in assessing tumor vascularity. Three-dimensional reconstruction of the vascular channels has been accomplished utilizing the Doppler amplitude mode. This feature may have potentially promising clinical application. Applications of power Doppler sonography are discussed in Chaps. 7, 39, and 40.

**Fig. 6.15 a–e.** The effects of wall filter and gain on color Doppler amplitude imaging of fetal renal flow. **a** A reasonable amplitude image of renal flow. **b, c** The effect of low- and high-wall filter setting, respectively. **d, e** The effects of low and high gain, respectively

## Summary

The introduction of Doppler color flow mapping has ushered in an exciting era for diagnostic sonographic imaging. As discussed in the relevant chapters of this book, application of this technique to obstetric and gynecologic imaging has proved highly useful. A prerequisite for optimal utilization of this technique is an in-depth knowledge of its principles and limita-

tions. Furthermore, it is important to appreciate that the appearance of color flow images is influenced by the operational setting of the equipment, which must be taken into account for reliable interpretation. Finally, there are even newer modalities of flow imaging that present exciting possibilities for the future of noninvasive hemodynamic investigation in clinical practice.

# Three-dimensional Color and Power Doppler Ultrasonography of the Fetal Cardiovascular System

Rabih Chaoui, Karim D. Kalache

## Introduction

The recent development of fast processors has enabled ultra-rapid calculation and rendering of 3D images and the advent of real-time 3D (also called 4D) ultrasonography. Moreover, using newer systems, fetal structures can now be visualized in different modes including the surface-, the maximum-, the minimum-, and the “X-ray” mode. The fetal vascular anatomy can be examined by using color Doppler and power Doppler ultrasound, power Doppler being superior to color Doppler in visualizing small vessels with low flow; however, the spatial course of the vessels in the human body is best evaluated using 3D ultrasonography. By combining power Doppler and 3D techniques it is possible to study the fetal and placental vessels in relation to surrounding anatomic structures.

Potential fields of application in obstetrics have been reported in the past several years either as single case reports [1–5] or small series [6, 7]. This chapter reviews the technical background and potential fields of application in obstetrical ultrasound.

## Technical Background

### Equipment

The few commercially available 3D systems have an integrated 3D power Doppler ultrasonography (3D PDU) feature as well, but there are also external workstations adaptable to the different ultrasound systems, offering offline postprocessing analysis and evaluation. Most of our expertise we report in this chapter was acquired by using the Voluson 730 Expert system (General Electrics-Kretztechnik, Zipf, Austria) with an integrated on-line evaluation of volume rendering. Broadband curvilinear transducers with frequencies ranging between 4–8 MHz for the abdominal probe and 5–9 MHz for the vaginal probe were used.

## Advantages of Power Doppler for 3D Rendering

Both color and power Doppler ultrasonography are applied in vessel visualization, and practically both can be used for 3D visualization. Power Doppler has, however, various advantages over conventional color Doppler [8, 9] that make it optimal for the 3D mode:

1. Sensitivity in flow detection: amplitude of Doppler signals instead of their frequency shift is analyzed in power Doppler and this was shown to be three to five times more sensitive than conventional color Doppler in visualizing small vessels and low flows [8].
2. Improved noise differentiation: in power Doppler, noise signals are encoded in a uniform color; hence, it is possible to turn the gain all the way up, which fills the entire image with noise, and the vascular signal will still be distinguishable.
3. Better edge definition: power Doppler has a better edge definition in displaying flow. This is because color samples which extend partially beyond the edges are shown in a different color due to the lower signal amplitude.
4. Detection of flow orthogonal to beam: power Doppler is able to detect flow at right angles to the beam. The amplitudes of the positive and negative components of the flow tend to add up, resulting in a powerful signal.

## Principle of Data Acquisition, Image Rendering, and Display

The two main aspects which have to be considered when using a 3D imaging system are given below.

### *Volume Data Acquisition, Image Rendering, and Display*

1. During volume data acquisition the information is stored within a volume of interest. The acquired volume is a sequence of a pre-defined number of 2D slices (Fig. 7.1). The system assesses the spatial information of the structures in relation to each other in the different 2D images and allows a 3D

**Fig. 7.1.** Several longitudinal views are necessary to visualize the different vessels in the upper abdomen such as the hepatic veins (HV), inferior vena cava (IVC), umbilical vein

(UV) with ductus venosus (DV), and the descending aorta (Ao). Compare with Fig. 7.2

**Fig. 7.2.** Longitudinal view of thorax and upper abdomen. Three-dimensional power Doppler rendering allows visualization of all vessels described in Fig. 7.1 and their relationship to one another

sufficient knowledge about how vessels are best visualized using power Doppler is a prerequisite to obtaining a good-quality 3D power Doppler image. Even if the method is very sensitive and allows the imaging of small vessels, the optimization of pulse repetition frequency (PRF), filter, insonation angle, and persistence are of major importance. The PRF and filter have to be set as high as necessary in order to visualize only the vessels of interest, since superimposed vessels may lead to confusion and complicates orientation within the 3D volume. Neighboring vessels or noise signals interfering with the region of interest can be erased during off-line reconstruction; however, good quality of the original volume is essential for an optimal rendering.

2. Image rendering is the process of creating a 3D representation of the parameters of interest. Generally, the principle used is the “planar geometric projection” of the 3D image, i.e. a 2D image representing the 3D data as seen in the figures of this chapter. The virtual impression of the third dimension is generally given by the on-line rotation of the image on the screen and by different shadowing of anterior and posterior structures. Different color maps can be used as well as various post-processing features

rendering (Fig. 7.2). Detailed gray-scale information is often not essential and lowers the quality of the rendered 3D power Doppler image; therefore,

**Fig. 7.3.** Combined solid and 3D PDU mode with increasing transparency from left to right in a fetus with ascites

such as changing the brightness, threshold, or transparency of color. The examiner can further decide whether only vessels of interest are to be visualized or if it is important to have the information of the surrounding structures as well (so-called glass-body rendering). The system allows the examiner to switch progressively between surface and transparent mode, which gives the impression that the vascular tree shines through the surrounding structures (Fig. 7.3).

### Limitations of 3D Power Doppler in Prenatal Ultrasound

Similar to other 3D modes, fetal movements are a major cause of artifacts. Other limitations specific to the method are related to the regions of interest and neighboring vessel. In most cases the examiner is choosing a compromise between the vessels of interest with their ramifications and the overlapping from neighboring vessels. Most limitations are still at the level of the heart, where overlapping of color from adjacent structures can limit the understanding of the image. Pulsations of the heart during data acquisition are still difficult to overcome, but the use of a quick sweep by reducing image quality and increasing persistence can reduce these artifacts [3].

### Clinical Application

Conventional color Doppler and power Doppler ultrasound are both useful in the assessment of fetal abnormalities involving the cardiovascular system [12]. Application of color Doppler is not only of benefit in the assessment of fetal cardiac anomalies [13, 14], but also for completing diagnosis in many extracardiac conditions [12]. The 3D PDU technique allows spatial analysis of fetal vessels in relationship to their surrounding anatomic structures. In a recent study [6] we examined the application of 3D PDU in prenatal

diagnosis, by comparing 45 normal fetuses and 87 abnormal pregnancies with vascular abnormalities. In the study we used a prototype system (HDI-3000, Philips-ATL, Bothell, Wash.) and satisfactory image information was obtained in only 64% (56 of 87) of the abnormal cases. The following eight anatomical regions were, however, found to be of interest:

1. Placenta
2. Umbilical cord
3. Abdomen
4. Kidneys
5. Lung
6. Brain
7. Fetal tumors
8. Heart and great vessels

The following section summarizes possible applications of 3D color and power Doppler ultrasonography in these different regions.

### Umbilical Cord and Placenta

Placental vessels are best visualized in relation to the umbilical cord insertion. The intraplacental vascular tree can be visualized with this method [15]. The umbilical cord can be rendered from its placental (Figs. 7.4, 7.5) to its abdominal insertion including the free loop (Figs. 7.6, 7.7) [6]. From our experience it is the easiest structure to assess using 3D PDU throughout pregnancy. Conditions in which 3D power Doppler might be of some benefit are listed in Table 7.1.

### Intraabdominal Vessels

Examination of the intraabdominal structures using 3D Power Doppler is best achieved when examining the abdomen in a longitudinal plane. This approach allows the visualization of the intraabdominal portion of the umbilical arteries (Figs. 7.8, 7.9) and vein with the ductus venosus (Figs. 7.2, 7.3), the portal system, the hepatic veins, the splenic vessels, the inferior vena

**Fig. 7.9.** In the same view as Fig. 7.8, 3D PDU demonstrates in this case an agenesis of the left umbilical artery. Only one (dilated right) artery can be seen in its course to the umbilical ring

cava, and the abdominal aorta. Using this technique it is also possible to display the normal course of umbilical arteries around the urinary bladder (Fig. 7.8). Since Doppler studies of the ductus venosus in growth-restricted fetuses is becoming an important field in prenatal medicine, abnormalities of the intrahepatic venous system are frequently detected (Fig. 7.10) [16]. This anatomical region is, however, complex, and it has been shown that 3D Power Doppler can help in the differentiation between anomalies (Table 7.2).

**Table 7.2.** Conditions for potential 3D power Doppler application in the abdominal region

Abnormal course of vessels in isomerism, i.e., interruption of inferior vena cava with azygous continuity
Single umbilical artery and abnormalities in lower abdomen

### Renal Vessels

The renal vascular tree is best visualized in a coronal plane (Fig. 7.11). Depending on velocity scale setting, vessels can be seen from the main artery with some ramifications to the peripheral cortical vessels including arteries and veins. The visualization of renal vessels is known to increase the accuracy of diagnosis of kidney malformations in the fetus. The examiner should be, however, aware of pitfalls such as the visualization of the ventrally situated abdominal arteries (inferior mesenteric artery and vessels from celiac trunk) that can be misinterpreted as renal arteries. Conditions in which 3D PDU could be of diagnostic value are listed in Table 7.3.

**Fig. 7.10.** Abnormal course of the intraabdominal umbilical vein and ductus venosus in a fetus with early hydrops at 13 weeks

**Fig. 7.11.** A dorsal view to the fetus in 3D showing the spine and both kidneys. The progressive visualization of power Doppler demonstrates the descending aorta (Ao)

and the bifurcation of both renal arteries. Ductus venosus is connected directly to the IVC

approach enables the visualization of the pericallosal artery with its ramifications (Fig. 7.13) [17]. By selecting a lower velocity scale it is possible to obtain impressive images of the cerebral veins and the sagittal sinus. Conditions with possible benefit of 3D power Doppler, such as vein of Galen aneurysm (Fig. 7.14) and others, are listed in Table 7.4.

**Intracranial Vessels**

As with color Doppler two main vascular regions can be examined in 3D mode depending on the insonation plane. A transversal insonation allows easy reconstruction of the circle of Willis (Fig. 7.12), whereas a sagittal

**Fig. 7.13.** Sagittal approach insonation of the brain enables the demonstration of the pericallosal artery arising from the anterior cerebral artery

**Lung Vessels**

Proximal and peripheral lung arteries and veins can be seen from their origin to the peripheral pulmonary segments. Especially the right lung can be as-

sessed even by a less experienced examiner. Potential fields of interest include the analysis of the 3D vessel architecture in cystic lung malformations, congenital diaphragmatic hernia, and in bronchopulmonary sequestration. In the latter condition 3D power Doppler facilitates the visualization of the abnormal systemic vessel that feeds the sequester. Application fields are listed in Table 7.5.

**Fetal Tumors or Aberrant Vessels**

Aberrant vessels can be visualized in the presence of several malformations such as choriangioma, lymphangioma sacrococcygeal teratoma (Fig. 7.15), and acardiac twin. The visualization of the vascular pattern of fetal tumors is not only interesting because of

**Fig. 7.17.** Three-dimensional PDU of a four-chamber view in a fetus with a hypoplastic left heart syndrome. Blood flow enters from the right atrium (RA) into the right ventricle (RV), but no flow is seen within the left ventricle (LV). LA left atrium

their risk of cardiac failure due to the presence of arteriovenous fistulae, but also to assess compression or shifting of neighboring organs. Table 7.6 gives a summary of these fields of interest.

### Heart and Great Vessels

The 3D rendering of the heart and the great vessels is still a challenge to fetal ultrasound. Reliable volumes are still difficult to obtain under routine scan condi-

**Fig. 7.18.** Aortic arch with the origin of the cephalic vessels: the innominate (brachiocephalic) artery; the left common carotid artery (LCC); and the left subclavian artery (LS)

tions. According to our experience we think that 3D PDU can be helpful in fetal cardiology in the near future and might facilitate the assessment of spatial arrangement of the heart chambers including their size and shape (Figs. 7.16, 7.17) as we demonstrate in some of the figures in this chapter. Another possible application field is an easier assessment of the course of the great vessels (Fig. 7.18). Crossing of vessels vs parallel course (Fig. 7.19), abnormal course as seen in double aortic arch, right arch with a sling, or simply tortuous hypoplastic aorta or pulmonary artery

**Fig. 7.19.** Great vessels of a normal fetus (*left*) and a fetus with transposition of the great arteries (*right*). In the left image the crossing of the vessels is recognized with the course of the aorta under the pulmonary trunk (*TP*) and

the connection of the ductus arteriosus (*DA*) at the level of the isthmus (*ISTH*). In transposition both vessels are parallel and the aorta is on the right side of the pulmonary trunk

**Fig. 7.20.** A normal fetus (*left*) compared with a fetus with left isomerism (polysplenia; *right*): On the left the inferior vena cava is seen entering the heart and on the right side of the aorta the tiny azygos vein is recognized connecting with the superior vena cava. In left isomerism there is an

interruption of the inferior vena cava (*star*), which is absent on 3D PDU. Venous blood from the inferior part of the body returns via the azygos vein, which is dilated and seen side by side near the aorta

**Table 7.7.** Conditions for potential 3D power and color Doppler application in fetal echocardiography

Anomalies of the four chambers
Abnormal atrioventricular connection
Malformations of the great arteries in conotruncal malformations such as transposition
Severe tricuspid regurgitation

# Biological Safety of Diagnostic Sonography

Dev Maulik

## Introduction

Diagnostic insonation is generally considered to be safe during pregnancy as cumulative experience and epidemiological investigations have failed to demonstrate any causally related adverse effects in the exposed population since its introduction over 40 years ago. Over the decades prenatal utilization of diagnostic ultrasonography has continued to expand [1]. According to the National Vital Statistics, approximately 2.7 million mothers comprising 68% of those who had live births were exposed to diagnostic ultrasound in 2002 in the United States [2]. This represents a 42% increase since 1989 when about 50% of the mothers with live births underwent sonographic scanning. Such a magnitude of exposure requires continuing concern regarding its safety as it has long been recognized that ultrasound exposure can affect biological systems under certain circumstances.

The conventional wisdom has held until recently that the intensity and other acoustic features of diagnostic insonation are insufficient to trigger the known physical mechanisms for bioeffects. This contention has been challenged by theoretical considerations and experimental findings which suggest that such exposure may potentially exert bioeffects, especially tissue heating which may possibly lead to deleterious consequences. In 1997, further concerns were raised when regulatory changes in the United States allowed the Food and Drug Administration (FDA) to give market approval for obstetrical diagnostic ultrasound devices with significantly increased overall upper limits of acoustic energy output (spatial peak temporal average intensity of  $720 \text{ mW/cm}^2$ ) provided that these devices incorporated an acoustic power output display (see below). Even this limit can be surpassed under certain operational conditions, especially during Doppler color flow imaging [3, 4]. Moreover, unlike the United States, most countries do not regulate acoustic output of diagnostic ultrasound instruments which therefore can be equipped with unrestrained acoustic power. This relaxed regulatory policy significantly shifts the responsibility for the safe use of diagnostic ultrasound to sonographers and sonologists who are obliged to respond to this

challenge by careful practice and through continuing education. The scientific community remains divided on the issue of continuing the current upper limits of acoustic power output imposed by the FDA as exemplified by the recent educational debate organized by the American Institute of Ultrasound in Medicine (AIUM) where arguments in favor of removing the limits were counterbalanced by continuing concerns and uncertainties regarding safety [5].

Any absolute assurance on the safety of embryonic and fetal exposure to diagnostic ultrasound remains unattainable because of the continuing possibility that a rare or as yet unknown risk may be present from prenatal exposure. However, if biosafety implies the absence of any recognizable adverse effects, then diagnostic ultrasound can surely be considered safe. Furthermore, the theoretical question of hazards from any potential bioeffects must be considered against the benefits that this diagnostic modality offers for optimizing patient care and the risks related to refraining from indicated use.

Extensively updated to address these complex issues, this chapter presents a concise review of the safe use of Doppler sonography in pregnancy and includes the following: the acoustic output of diagnostic ultrasound devices and its regulation; the known physical mechanisms of interaction between ultrasound and biological systems; the bioeffects observed under experimental circumstances; and the current epidemiological evidence regarding its safety. The chapter also recommends guidelines for the safe use of Doppler ultrasound drawing liberally from the current reports and guidelines developed by the various societies and agencies including the following: the National Council on Radiation Protection and Measurements (NCRP) [6], the American Institute of Ultrasound in Medicine (AIUM) [7], the International Perinatal Doppler Society (IPDS) [8], the European Federation of Societies for Ultrasound in Medicine and Biology (EFSUMB) [9], and the World Federation of Societies for Ultrasound in Medicine and Biology (WFSUMB) [10].

## Acoustic Output of Diagnostic Ultrasound Devices and Its Regulation

A central issue in the safe use of diagnostic ultrasound is the power output of the instruments. By enacting the Medical Devices Amendment to the US Food, Drug and Cosmetic Act on May 28, 1976, the United States Congress empowered the FDA to control the output limits to the devices through the mandatory premarketing approval process. The approval was based on the manufacturers' ability to demonstrate substantial equivalence of each new device in safety and efficacy to diagnostic ultrasound devices on the market prior to the enactment date. The principle of substantial equivalence in safety was based on the assumption that the pre-enactment devices were safe and was supported by the available scientific data which provided no evidence of independently confirmed adverse significant biological effects in mammalian tissue exposed in vivo to  $I_{SPTA}$  below 100 mW/cm<sup>2</sup> [11]. In 1985, the FDA introduced the application specific output standards of substantial equivalence covering four areas of use: cardiac, peripheral vascular, fetal imaging and other, and ophthalmic. In the early 1990s, based on an NCRP technical report called the Output Display Standard (ODS) [12], the AIUM and the National Electrical Manufacturers Association (NEMA) led an initiative to increase the intensity in exchange for on-screen labeling which resulted in a modification of the existing regulation by the FDA. The track 3 option allows devices to increase the overall maximum output limit to 720 mW/cm<sup>2</sup> provided they incorporate the ODS [13]. Equipments used in ophthalmology were exempted. The track 3 devices can have a substantial increase in the power output and it is the responsibility of the sonographer to use the display to limit the intensity of fetal exposure. Given the potential for adverse effects, the need for user education and training in this area can not be overstressed. This provides a compelling rationale for this chapter.

The ODS consists of two risk indicators, a thermal index (TI) for thermal bioeffects, and a mechanical index (MI) for nonthermal bioeffects [12]. The TI was further refined in 1998 adding three tissue-specific TI models [14]. These are further described below:

- The TI is the ratio of total acoustic power to the acoustic power that would be required to raise temperature by 1 °C for a specific tissue model. As a ratio it is dimensionless and provides an estimate of maximum temperature rise rather than the actual increase. Thus a TI of 2 indicates a higher temperature elevation than a TI of 1, but does not

imply an actual rise of 2 °C in the insonated tissue. There are three tissue-specific thermal indices:

- TIS=Thermal index for soft tissue is concerned with temperature rise within homogeneous soft tissue.
- TIB=Thermal index bone is related to temperature elevation in bone at or near the focus of the beam.
- TIC=Thermal index cranial bone indicates temperature increase of bone at or near the surface, such as during a cranial examination.
- The MI is also a dimensionless quantity and is derived from the peak rarefactional pressure at the point of the maximal intensity divided by the square root of the center frequency of the pulse bandwidth. It is an indicator of potential nonthermal bioeffects, especially those that are cavitation-related. According to the FDA, the MI may range up to 1.9 except for ophthalmic usage. The higher the value of MI, the higher the risk of a mechanical effect.

The relevance and practical utilization of the indices for safe use of diagnostic sonography are further discussed later.

## Mechanisms of Bioeffects

Any review of bioeffects of ultrasound must include considerations of the known mechanisms by which propagating ultrasound reacts with biological systems. The following effects are currently recognized:

1. Thermal effects which are mediated by insonation-induced tissue heating
2. Nonthermal or mechanical effects which include those not related to heat generation.

The thermal and the mechanical effects of diagnostic acoustic exposure and their relevance for the safety of Doppler ultrasound usage are further discussed below.

## Thermal Effects

As a beam of ultrasound propagates through a tissue medium, a portion of its energy is absorbed and converted to heat because the frictional forces in the medium oppose the ultrasound-related molecular oscillations. The rate of temperature elevation in the insonated tissue is determined by the balance between the rates of heat production and of heat dissipation. The rate of heat generation depends on the characteristics of the transmitted ultrasound and the tissue medium [15].

## Acoustic Characteristics

Generation of heat in the insonated tissue depends essentially on the power and intensity of the ultrasound. Several acoustic features are involved in this process including the following:

- a. **Acoustic power:** The most relevant power parameter for thermal bioeffect is the spatial-peak temporal-average intensity ( $I_{SPTA}$ ) which, as discussed in Chap. 2, is the highest time-averaged acoustic intensity at any point in the field. The output intensity varies with the application-specific default settings such as fetal, cardiac, or peripheral vascular investigations. The operator can supersede such regulations in choosing the mode. Most devices provide a control for altering the power output. Caution must be exercised in increasing the power indiscriminately as most obstetrical ultrasound examinations can be performed efficiently with the acoustic power set well below the regulatory limits. These issues will be discussed again.
- b. **Focus:** The  $I_{SPTA}$  increases with focusing, which concentrates the power in a small area, causing higher intensities and increasing the potential for heating. Most diagnostic instruments employ a focused beam in order to enhance lateral resolution and directionality.
- c. **Scanning vs stationary beam:** The  $I_{SPTA}$  intensity is affected by whether the ultrasound device utilizes a scanning or a stationary beam. In the scanning ultrasound modes, which include B-mode and color flow Doppler imaging, the moving beam temporally distributes the acoustic energy over a wide volume of tissue in the scanned area and thus minimizes the risk of tissue heating. In the stationary ultrasound modes, which include spectral Doppler and M-mode, the acoustic power is concentrated linearly along the static ultrasound beam axis, depositing acoustic energy in a significantly smaller volume of tissue for the duration of exposure. In this scenario, the highest elevation of temperature is encountered along the beam axis between the surface and proximal to the focal point, and its location is near the surface if the focal length is long and adjacent to the focal point if the focal length is short.
- d. **Pulse repetition frequency (PRF):** The higher the PRF, the greater the temporal average intensity. The PRF is under the user control, but can change automatically interactively with other controls such as the focal range. Increasing the focal range may automatically elevate the PRF. In spectral pulsed Doppler and color Doppler modes, the PRF is increased to eliminate aliasing which can result in increased  $I_{SPTA}$ .
- e. **Pulse length (also known as the pulse duration or burst length):** This directly affects  $I_{SPTA}$ . This is relevant for using the pulsed Doppler mode, as a larger Doppler sample volume will increase pulse duration which will increase the intensity. The pulse length is also greater in color flow Doppler than in B-mode imaging.
- f. **Dwell time:** This refers to the duration of ultrasound exposure. The longer the dwell time, the greater the thermal effect. During most fetal examinations the operator moves the transducer around, thereby reducing the duration of exposure in a given location. In using unscanned modes such as spectral Doppler interrogation of the middle cerebral artery, one needs to reduce the scan time deliberately because of the greater risk of thermal effect in this specific instance.
- g. **Write zoom:** In this function, where the image is magnified by rescanning a smaller area of interest in the image plane with more scan lines, the insonated tissue is exposed to a higher concentration of acoustic intensity. Moreover, using the write zoom box at a greater depth will lead to an even higher intensity as this requires a larger aperture involving more transducer elements emitting more power. This is especially applicable to the color flow Doppler color box function where a narrower and deeper color box will increase the intensity and the risk of temperature elevation. This risk is enhanced when color flow Doppler is used along with spectral pulsed Doppler in the duplex mode.
- h. **Transducer frequency:** Higher frequency ultrasound is more avidly absorbed by tissues, increasing the risk of heating. As higher frequency limits the depth of penetration, heating is restricted to the superficial tissues close to the transducer. Moreover, suboptimal depth resolution in this case may prompt the user to increase the power output, which may contribute to tissue heating.
- i. **The nonlinearity of ultrasound propagation:** In ultrasound pulses, especially the high amplitude waves, the compression in the wave propagates faster than the rarefaction, resulting in distortion in the waveform so that the peak of the wave follows the trough very closely. With the compression following the rarefaction very quickly, shock and harmonic components of higher frequencies are generated. This phenomenon is impeded in tissue with higher attenuation such as bone and is facilitated in tissue with lower attenuation such as amniotic fluid or even neural tissue. The higher frequency may lead to significant absorption of energy and conversion to heat. Although such thermal effects have not been demonstrated in the fetus, the potential exists, especially when ultrasound of higher amplitudes propagating through a

fluid media develops shock waves with high-frequency harmonics before entering soft-tissue media.

### Tissue Characteristics for Thermal Effect

Ultrasound-induced tissue heating is determined by the balance between heat generation and heat loss (Fig. 8.1). The ultrasound-induced temperature increase in biological tissue depends on the inherent acoustic properties of the tissue that determine heat generation. These include its acoustic impedance and the attenuation and absorption of the sound in the tissue which leads to conversion of sound energy to thermal energy. The degree of ultrasound-induced temperature is directly related to the absorption coefficient of the tissue [16, 17]. The actual temperature elevation is also dependent on the factors that control dissipation of heat in the tissue and include tissue perfusion and thermal conduction and diffusion. The impact of tissue heating depends on the mechanisms that control cellular response to heating, the specific types of tissue, and the anatomic configuration, such as proximity to bone. These are discussed below.

### Cellular Response to Heating, Acoustic Power, and Temporal Threshold

The cellular and tissue response to hyperthermia has been extensively investigated in relation to cancer therapy. Cells and tissues differ in their response to heat. Nonlethal temperature elevation induces cells to mobilize defensive mechanisms constituting what is known as the heat-shock response. The response essentially involves induction of genes that encode a spectrum of protective proteins known as heat-shock proteins (HSP) [18]. The dominant group in eukaryotic cells is the HSP70 family although other HSP families are also involved. Nonlethal temperature elevations above the normal induce synthesis of the HSPs which then act as molecular chaperones and prevent protein denaturation or aggregation. These protective mechanisms, however, become rapidly ineffective if the tissue temperature exceeds 43°C. Beyond this threshold the duration and the magnitude of temperature elevation determine the thermal injury, with each degree of temperature elevation reduc-

ing the temporal threshold for thermal effect by a factor of 2 [19]. As discussed by Duck [20], these considerations, especially the exponentially decreasing temporal threshold for producing thermal injury with the increasing acoustic power, assist in defining the safe upper limits of power. For example, if insonation with an acoustic power equivalent to a TI of 6.0 raises tissue temperature to 43°C, and thermal injury occurs after 30 min of such exposure, doubling that acoustic power will markedly reduce the time threshold to only 30 s. This theoretical scenario is based on the available experimental evidence and theoretical analyses. The practical implications are further considered below. As many currently marketed devices are capable of producing a TI of 6.0 [21], great caution should be exercised in using such instruments.

### Experimental Evidence of Thermal Effects

Because of the importance of thermal injury in any consideration of ultrasound biosafety and the potential of temperature elevation from the current generation of ultrasound diagnostic devices especially with spectral pulsed Doppler applications, thermal effects have been extensively investigated. Animal studies have demonstrated that embryonic and fetal tissues are more prone to thermal injury during organogenesis with rapidly replicating and differentiating cells [22]. Furthermore, germ cells in the fetal gonads, especially the testes, continue to be vulnerable to temperature elevation; this may compromise future fertility. Hyperthermia is a proven teratogen and thermal teratogenesis is threshold dependent [23]. The spectrum of thermal teratogenic effects include abortion, neural tube defects, decreased brain growth, anophthalmia, cataracts, cleft lip and cleft palate, and heart, skeletal, spinal, vertebral, and dental defects [17].

However, extrapolating experimental findings to clinical situations remains challenging. It is difficult to justify that experimental conditions such as whole-body heating are applicable to the circumstances of clinical diagnostic ultrasound. Nevertheless, these data help to define boundary conditions of safe use. For exposures lasting up to 50 h, no significant biological effects have been observed when temperature

elevation does not exceed  $1.5^{\circ}\text{C}$  above the normal core temperature. Most evidence shows that developmental injury requires a temperature rise of at least  $1.5^{\circ}\text{C}$ . Above this threshold, teratogenic effects are determined by the magnitude of the temperature rise and its duration. For temperature increases of  $4^{\circ}\text{C}$  and  $6^{\circ}\text{C}$  above normal, the respective limits for the duration are 16 min and 1 min. The lowest temperature value for consistent teratogenesis in mammals has been reported to be  $41.5^{\circ}\text{C}$  [24].

### Acoustic Heating of Fetal Bones

Mineralized bone has the highest coefficient,  $10\text{ dB/cm}\cdot\text{MHz}$ , and therefore the highest likelihood of thermal effect. Mineralization and ossification of fetal bones begins in the 12th week of pregnancy and progresses with advancing gestation. Drewniak and associates [25] studied the effect of progressive ossification with advancing gestation on ultrasound-induced heat generation in human fetal femur ex utero. By 15 weeks of pregnancy, the rate of temperature rise in the bone was 30 times greater than that in the soft tissue.

### Acoustic Heating of Fetal Brain

The average absorption coefficient for neural tissue is  $0.2\text{ dB/cm}\cdot\text{MHz}$ . Despite its low absorption coefficient, the fetal central nervous system being enclosed in the skull and the spinal canal vertebrae is vulnerable to bone-related heating. Similar risks may also exist for other structures lying close to bone, such as the pituitary gland or the hypothalamus. However, there is conflicting evidence on the actual risk of brain heating from insonation.

Bosward et al. [26] noted in fresh and formalin-fixed fetal guinea-pig brains a mean temperature elevation of  $5.2^{\circ}\text{C}$  following a 2-min insonation with  $I_{\text{SPTA}}$  of  $2.9\text{ W/cm}^2$  with a stationary beam in a tank containing water at  $38^{\circ}\text{C}$ . The greatest temperature rise in brain tissue occurred close to the bone and correlated with both gestational age and progression in bone development. Barnett [27] has recently reviewed the experimental evidence regarding brain temperature elevation and concluded that insonation-induced intracranial heating increases with gestational age concomitant with progressive fetal bone development. Pulsed spectral Doppler ultrasound can produce a biologically significant temperature rise in the fetal brain with approximately 75% of the maximum heating occurring within 30 s. Brain blood flow does not significantly impact heating induced by exposure to a narrow focused ultrasound beam. An insonation-induced temperature rise of  $4^{\circ}\text{C}$  sustained for 5 min leads to irreversible injury to the fetal

brain, whereas a temperature increase of up to  $1.5^{\circ}\text{C}$  for 120 s does not elicit measurable electrophysiological responses in the fetal brain.

In contrast to the above findings, others have failed to note any significant temperature elevation in animal models. Stone and associates [28] conducted investigations on the heating effects of pulsed Doppler ultrasound on fetal brain tissue in dead and live animals. Whereas tissue heating was observed at the skull bone-to-brain interface in the dead lamb brain, minimal or no temperature elevation was observed in live lambs. Tarantal and colleagues [24] investigated in vivo temperature elevations in gravid primates (macaques) measured intracranially or at the muscle-bone interface consequent to imaging and pulsed Doppler ultrasonic exposure. This study is one of the very few reports on pulsed Doppler exposure. Utilizing a commercial ultrasound instrument and with varying duration of insonation involving the imaging and the pulsed Doppler mode, the highest temperature elevation observed was  $0.6^{\circ}\text{C}$ . Both the reports suggest that the presence of tissue perfusion in a living animal may play a protective role by dissipating the heat.

A rare report involving direct thermocouple recording of intracranial temperature in a neurosurgical patient during color transcranial Doppler ultrasound for 30 min failed to demonstrate any temperature elevation either in the brain parenchyma or at the bone/soft tissue interface [29]. A 2.5-MHz transducer was used with the Doppler mode power settings at SPTA of  $2,132\text{ mW/cm}^2$  and a maximum power of 149.3 mW. The ipsilateral tympanic temperature rose by  $0.06^{\circ}\text{C}$ , indicating an overall increase in brain temperature.

### Clinical Significance of the Ultrasound Thermal Effects

Although ultrasound exposure carries the potential for tissue heating, there is no clinical evidence of thermal injury to the human fetus from diagnostic insonation. However, as theoretical risks exist, one must exercise caution especially in using spectral pulsed Doppler ultrasound. The ability of the human body to tolerate limited temperature elevations without any harm is well known. In healthy humans, variations in the body temperature occur under different physiological circumstances such as during physical exercise. However, febrile illnesses may increase the risk enough for extra caution. The fetus is dependent on the mother for heat dissipation mostly through the placental circulation and to some extent across the fetal skin and amniotic fluid to maternal tissues and circulation [30]. The fetus is warmer than the mother [31]. Fetal skin temperature has been shown

on average  $0.23^{\circ}\text{C}$  above the temperature of the uterine wall [32] and fetal core temperature is  $0.75^{\circ}\text{C}$  above its skin temperature [33].

Miller and Ziskin [23] suggested that the probability of any measurable bioeffects from diagnostic insonation is minimal or nonexistent if the maximum temperature rise remains  $2^{\circ}\text{C}$  or less in an afebrile subject. Temperature elevations not exceeding  $39^{\circ}\text{C}$  are most unlikely to induce any fetal abnormalities. However, at higher temperatures, the duration of ultrasound exposure becomes a significant factor. Indeed, as shown in Fig. 8.2, these authors have defined a boundary line based on the temperature rise and exposure duration; below this line, risks of thermal bioeffects are virtually nonexistent. The authors recommended that an ultrasound examination need not be restricted if the combination of temperature elevation and exposure duration remains below this boundary line.

In obstetrical ultrasonography, fetal developmental issues require additional considerations. Fetal vulnerability in the worst case scenario demands prudent practice while not depriving the patient of the benefits of diagnostic ultrasonography. This issue has been discussed extensively by the various international societies who have issued official statements on thermal effects and the safe use of diagnostic insonation.

The WFSUMB endorsed the following recommendations regarding Doppler in 1997:

“It has been demonstrated in experiments with unperfused tissue that some Doppler diagnostic

equipment has the potential to produce biologically significant temperature rises, specifically at bone/soft tissue interfaces. The effects of elevated temperatures may be minimised by keeping the time for which the beam passes through any one point in tissue as short as possible. Where output power can be controlled, the lowest available power level consistent with obtaining the desired diagnostic information should be used. Although the data on humans are sparse, it is clear from animal studies that exposures resulting in temperatures less than  $38.5^{\circ}\text{C}$  can be used without reservation on thermal grounds. This includes obstetric applications” [10].

The 1997 AIUM position on temperature elevation and exposure duration is as follows [7]:

- “For exposure duration up to 50 hours, there have been no significant biological effects observed due to temperature increases less than or equal to  $2^{\circ}\text{C}$  above normal.
- For temperature increases greater than  $2^{\circ}\text{C}$  above normal, there have been no significant biological effects observed due to temperature increases less than or equal to  $6 - (\log_{10} t/0.6)$ , where  $t$  is the exposure duration ranging from 1 to 250 min. For example, for temperature increases of  $4^{\circ}\text{C}$  and  $6^{\circ}\text{C}$ , the corresponding limits for the exposure duration  $t$  are 16 min and 1 min respectively.
- In general, adult tissues are more tolerant of temperature increases than fetal and neonatal tissues.

**Fig. 8.2.** Thermal bioeffects. A plot of thermally produced biological effects that have been reported in the literature in which the temperature elevation and exposure durations are provided. Each data point represents either the lowest temperature reported for any duration or the shortest

duration for any temperature reported for a given effect. The *solid lines* link multiple data points relating to the same bioeffect. The *dashed line* represents a lower boundary ( $t_{43}=1$ ) for observed, thermally induced biological effects. (With permission from [23])

Therefore, higher temperatures and/or longer exposure durations would be required for thermal damage.”

The position of the International Perinatal Doppler Society, which draws extensively from the existing evidence as well as the deliberations of the other learned societies, published in 2001, is reflected in the following statement:

“In general, Doppler applications (excluding fetal monitoring) present the highest risk of inducing biological effects that are thermally mediated. This follows from the use of longer pulses and higher pulse repetition rates than those used in B-mode gray scale scanned imaging modes. The current FDA regulatory limit for diagnostic ultrasound devices used in the USA for obstetric ultrasound applications is  $720 \text{ mW/cm}^2$  intensity ( $I_{\text{SPTA}}$ ) at the tissue of interest, i.e. attenuated according to the beam path length in tissue. For this intensity, the maximum temperature increase in the conceptus may exceed  $2^\circ\text{C}$ . Data from animal experiments have shown that some Doppler equipment can produce a biologically significant temperature rise ( $>4^\circ\text{C}$ ), especially at bone/soft tissue interfaces such as in fetal examinations in the 2<sup>nd</sup> and 3<sup>rd</sup> trimester. Scientific data on effects of whole body hyperthermia show that adverse effects on embryo and fetal development can result from exposure to temperature increases of  $2^\circ\text{C}$  or more above normal body temperature. The risk of adverse effects resulting from a given level of heating increases with duration of exposure” [8].

## Mechanical Effects

These bioeffects of ultrasound exposure encompass nonthermal mechanisms, primarily those related to acoustic cavitation phenomena involving expansion and collapse of gas bubbles in tissues. Nonthermal effects also include nonthermal and noncavitation phenomena such as acoustic radiation pressure, force, and torque and acoustic streaming; these will not be discussed in this chapter as their significance in producing biological effects remains unclear.

### Cavitation

Cavitation is the formation and growth of bubbles in a liquid. Under certain circumstances the bubbles undergo inertial collapse. Acoustic cavitation relates to cavitation phenomena caused by propagating sound waves on preexisting gaseous nuclei or microbubbles in the exposed medium [34–37]. Two types of cavitation phenomena are recognized: inertial cavitation and stable cavitation.

In inertial cavitation, the rarefaction and compression cycle of propagating ultrasound waves induce expansion and contraction of gaseous micronuclei of appropriate resonant size [38]. At lower ultrasound intensities, as used in diagnostic ultrasound devices, the size of the bubble is bigger during the expansion than during the contraction. This results in gradually increasing dimensions of the bubble until it starts to resonate when it readily absorbs acoustic energy and rapidly expands. A critical threshold is reached when the bubble can no longer absorb energy sufficient enough to maintain its expansion. During the compression, the surrounding fluid rushes into the bubble at a very high speed and the momentum of the fluid jet causes rapid collapse of the bubble. In the final phase of collapse, the energy content of the cavity will be liberated in an extremely minute space, generating intense heat and pressure. The temperatures of a collapsing bubble may exceed  $5,000^\circ\text{C}$  with pressures of hundreds to thousands of atmospheres. The heat and the pressure rapidly dissipate as the phenomenon is very localized, microscopic in size, and less than a microsecond in duration. This phenomenon of nonlinear oscillation and eventual collapse of a resonating bubble in an acoustic field is known as inertial cavitation (Fig. 8.3). In the past, the phenomenon has also been known as transient or collapse cavitation.

If the acoustic pressure amplitude remains less than the initial radius of the bubble, the oscillations are relatively stable. This is known as stable cavitation. Such an oscillating bubble absorbs energy from the incident ultrasonic beam and converts this into heat and spherical waves. These waves then re-radiate from the bubble. The oscillatory motion of a cavity often shows asymmetry because of the distortions produced by an adjacent solid boundary or by surface waves at the bubble-liquid interface. In the adjacent

**Fig. 8.3.** A high-speed flash photomicrograph of an imploding cavity. The asymmetry of implosion is caused by the solid surface near the bubble (depicted by the *straight line*). (With permission from [123])

liquid, the oscillatory motion generates a steady eddy flow, often of high velocity; this phenomenon is known as microstreaming. Intracellular microstreaming can also occur from a vibrating cell membrane close to an asymmetrically oscillating cavity. That stable cavitation can induce bioeffects under experimental conditions has been demonstrated by various investigators [39, 40]. However this type of cavitation has not been shown to be of any significance in bioeffects considerations.

Cavitation phenomenon in a medium related to ultrasound exposure is controlled by many factors including acoustic characteristics of field, ambient factors, and cavitation potential of the medium. These are elaborated below.

### Acoustic Characteristics for Cavitation

The critical acoustic factors responsible for producing inertial collapse of a resonating bubble are the maximum rarefaction and compressional pressures. The greater the rarefactional or negative pressure, the more the bubble expands preceding collapse. The greater the compressional or positive pressure, the more intense is the inertial pressure of the collapse. Both factors determine the intensity of the bubble collapse and the consequent severe local disruption. However, positive or negative pressure spikes of very short duration ( $<0.01 \mu\text{s}$ ) are not of significance. With pulsed ultrasound, the pulse length, duty cycle and frequency affect cavitation. Shorter pulses and lower pulse repetition frequency increase the cavitation intensity threshold. Indeed, it has been suggested that cavitation may probably be prevented if the pulse duration is sufficiently reduced [41], which has led to the general assumption that with medical diagnostic pulsed echo ultrasound, the pulse duration is too short to produce any cavitation activity. However, it has been demonstrated that microsecond-length pulses used in diagnostic pulsed-echo equipment may cause inertial cavitation if gas nuclei of suitable size are present in the medium and if the acoustic parameters of the ultrasound are appropriate. Moreover, the intensity threshold for producing inertial cavitation has been shown to be  $1\text{--}10 \text{ W/cm}^2$  for microsecond-length pulses [42]. Temporal maximum intensity far exceeding this level can occur in diagnostic ultrasound imaging. The risk is potentially greater with some pulsed Doppler systems because of the higher pulse repetition frequency and intensity.

### Ambient Pressure and Temperature

Ambient pressure and cavitation activity are inversely related, so an increase in the former increases the threshold intensities for cavitation. Conversely,

higher temperature facilitates cavitation by decreasing the solubility of gas in the medium which will lead to microbubbles that serve as nuclei for cavitation to occur.

### Tissue Characteristics for Cavitation

Prerequisites for cavitation activity are the quantity and size of the gas nuclei present in the medium. As mentioned earlier, even microsecond-length pulses have the potential to induce inertial cavitation, depending on the presence of micronuclei of sufficient size. Unfortunately, gaseous micronuclei are not easily detected. Although it has been disputed in the past, there is ample evidence that strongly suggests the presence of such nuclei in mammalian tissues. Such evidence includes studies on decompression syndrome in humans, experiments with lithotripter in dogs [43], and the observation in mice that application of hydrostatic pressure increased the threshold for sonar-related tissue damage [44]. The presence of such nuclei and insonation-related cavitation has been demonstrated in mammals by Lee and Frizzell [45] who observed hydrostatic pressure and temperature-dependent neonatal mouse hind limb paralysis due to ultrasound exposure. Aerated lung tissue with its blood – gas interface is particularly susceptible to the presence of gas nuclei. This is further discussed below.

### Biological Effects of Inertial Cavitation

A collapsing cavity can result in cell lysis, dissociation of water vapor, and generation of free radicals. The mechanism by which inertial cavitation causes cell destruction involves generation of intense local heat and pressure and the generation of shear forces by the bubble implosion [14, 46]. Furthermore, it has recently been suggested that such implosions may occur within the cell; such an event may not lyse the cells but may give rise to free radicals. Continuous-wave high-intensity ultrasound has been shown to produce free radicals in aqueous biological medium by inertial cavitation [47]. The free radicals may affect macromolecules. Thymine base alteration, chromosomal agglomeration, and mutation have been observed in insonated but intact cells. Irreversible deterioration of the enzyme A-chymotrypsin has been reported following production of radicals from insonation-induced cavitation [48]. Similarly, other toxic products such as hydrogen peroxide may induce adverse effects in a biological system. It should be emphasized that these phenomena have been noted mostly during *in vitro* experiments and never in relation to any human exposure.

Animal experiments have demonstrated lung, kidney, and other organ injuries due to nonthermal effects of ultrasound exposure. Especially relevant is the demonstration of pulmonary capillary hemorrhage and cardiac arrhythmia in nonmammalian and mammalian species from exposure to ultrasound. *Drosophila* larvae are highly susceptible to injury from exposure to high peak intensity (50–100 W/cm<sup>2</sup>) pulsed ultrasound only shortly before hatching when they have air in the respiratory system, suggesting a cavitation effect [49]. The mouse lung exposed to pulsed ultrasound demonstrates threshold-dependent hemorrhagic lesions [50]. More relevantly, a primate study corroborates these findings [51]. Appropriately controlled studies were performed in monkeys using a clinical diagnostic ultrasound instrument with combined imaging, and color and pulsed Doppler modes creating maximum power output conditions with peak rarefactional pressure of 3.7 MPa at 4 MHz representing an MI of approximately 1.8. The exposure resulted in multiple well-demarcated circular hemorrhagic focal lesions (0.1–1.0 cm) in the study groups but not in the control groups. Recently, acoustic cavitation as the mechanism for insonation-induced lung hemorrhage has been questioned. It has been suggested relatively recently that lung hemorrhage in the absence of the contrast agents may not be related to acoustic cavitation [52]. It has also been demonstrated recently in a rat model that lung hemorrhage correlates better with in situ (at the lung surface) pulse intensity integral than with in situ peak rarefactional pressure, suggesting a mechanism other than cavitation [53]. Insonation-induced reductions in aortic pressure and ventricular arrhythmia have been reported in the frog and murine hearts [54, 55]. It appears that the former effect may be related to radiation force. No lesions were noted in the cardiac tissues. Comprehensive reviews of these studies are available elsewhere [6, 56].

In a rare study involving humans, ultrasonically induced lung hemorrhage was investigated in 50 patients following routine intraoperative transesophageal echocardiography [57]. The left lung was observed directly by the surgeon. The ultrasound characteristics were: maximum derated intensity in the sound field of 186 W/cm<sup>2</sup>, maximum derated rarefactional acoustic pressure of 2.4 MPa, maximum mechanical index of 1.3, and lowest frequency of 3.5 MHz. These criteria are greater than the threshold found for gross lung surface hemorrhage seen in laboratory animals. No lung surface hemorrhage was observed on gross examination. The authors concluded that clinical transesophageal echocardiography, even above the threshold levels for lung hemorrhage in experimental animals, did not cause surface lung hemorrhage apparent on gross observation.

Most of the above and similar evidence is more relevant for neonatal and adult than fetal diagnostic ultrasound. No gas bodies have been shown to exist in the fetus. Although lung tissue, because of its blood–air interface, may be particularly susceptible to cavitation effects, this clearly is not applicable to fetal lung tissue. There are no reported studies demonstrating any cavitation effects in the fetus.

The use of contrast agents, however, presents a different scenario. Contrast agents are encapsulated gas microbubbles that are used to enhance the ultrasound backscattering in echocardiography and vascular imaging. When exposed to ultrasound, the contrast agent gas bodies are activated, destabilize, and form cavitation nuclei, and thus provide the potential for inertial cavitation. Such activation has been implicated in causing hemolysis in whole blood [58], membrane damage in cells in monolayer culture [59], increased cardiac microvascular permeability, petechial hemorrhage, and premature ventricular contractions in rats [60]. There is an ever-increasing body of evidence on the bioeffects of contrast agents and a comprehensive review is beyond the scope of this chapter.

### Clinical Significance of Acoustic Cavitation

Although the question of inertial or stable cavitation occurring from diagnostic insonation is entirely speculative, a theoretical possibility exists, as the presence of gaseous nuclei in mammalian tissues has been demonstrated and some diagnostic ultrasound instruments may generate temporal maximum intensities in excess of the cavitation threshold. Even if cavitation phenomena occur, the consequent loss of a few cells, in all probability, may not be significant for most clinical situations. However, even this scant theoretical risk of cavitation should be considered in order to restrict the maximum intensity output of diagnostic imaging especially for the Doppler mode. Consistent with the principles of prudent practice, one should be guided by the MI, which is the best indicator of cavitation potential currently available. An MI value of 1 or lower, considered to be safe for adult and pediatric applications, should also suffice for fetal applications where the risks of cavitation remain very remote. However, the safety concerns are substantially different with regard to the use of contrast agents in obstetrics and their use is clearly contraindicated in obstetrical imaging.

The IPDS recommendation for the prenatal use of Doppler use is as follows: “To avoid cavitation-related biological effects it is important to reduce the peak amplitude, or to use a lower value for MI on equipment that has an ODS. The presence of contrast agents should be taken into account when consider-

ing the risk/benefit ratio of an ultrasound examination” [8].

## Experimentally Induced Developmental Bioeffects

Although Mackintosh and Davey [61] reported low-intensity ultrasound-induced chromosomal aberrations in human leukocyte culture, subsequent investigators, including Mackintosh and coworkers, did not succeed in reproducing these results, even when the intensities were raised to cavitation threshold [62–64]. Increased sister chromatid exchange in human lymphocytes was reported to occur from experimental ultrasound exposure [65]. The significance of this finding can be appreciated from the fact that such an increase in sister chromatid exchange is regarded as an indicator of chromosomal damage. However, numerous subsequent reports failed to corroborate this. In an *in vitro* model utilizing fresh human placentas, Ehlinger et al. [66] observed increased sister chromatid exchange in fetal lymphocytes using a clinical diagnostic linear array unit. However, a subsequent investigation [67] and a subsequent review by Miller [68] failed to verify this. It can be reasonably concluded from the available evidence that clinical diagnostic ultrasound exerts no appreciable damaging effects on chromosomes.

Consequences of prenatal insonation on embryonic and fetal development were extensively investigated in animals. Most of the reports demonstrated conflicting

outcomes, and thus contributed little to elucidating the risks of prenatal ultrasound exposure. In their excellent review on this subject, Carstensen and Gates [69] observed that more than half the reported investigations failed to demonstrate any developmental bioeffects. Moreover, multigeneration studies have failed to demonstrate any consistent adverse effects in the offsprings of animals exposed to ultrasound *in utero* [70, 71]. The adverse effects, when noted, included fetal growth restriction [72, 73], increased perinatal loss [74–76], fetal malformations [77, 78], and behavioral teratogenesis, including delayed maturation of grasp reflex. In contrast, there are studies that failed to show fetal growth compromise [79–81], increased malformation [82], increased perinatal mortality [83], and behavioral alterations in the neonate [84].

## Epidemiological Evidence of Developmental Bioeffects

It is well known that embryos and fetuses of all mammalian species are highly sensitive to environmental insults. This makes them more vulnerable than adults to the risks of ultrasound-induced bioeffects. Although a number of investigations have been carried out in humans on the developmental effects of ultrasound, the dearth of well-controlled studies dedicated to safety is remarkable. This is understandable because of formidable logistics and financial challenges of such investigations. Furthermore, acoustic specifications of the diagnostic equipment should

**Table 8.1.** Summary of epidemiological evidence of biological effects of diagnostic ultrasound

Outcome	Study type	Ultrasound	Results	References
General development and neonatal outcome	Observational and randomized trial	Ultrasound and B-mode	No effects	87–94
Fetal movements	Observational	CW Doppler FHR monitor	One study noted increased movements. Other studies did not confirm	95–98
Fetal and infant growth	Observational and randomized trial	Doppler and B-mode imaging	One study showed increased low birth weight. Follow up showed no difference at 1 year. All other studies showed no adverse effect on fetal and infant growth	94, 99–107
Pediatric malignancies	Observational	B-mode imaging	No increased risk in any of the studies	109–113
Neurodevelopment, learning, speech	Observational and randomized trial	B-mode imaging	One study showed higher incidence of delayed speech. Rest of the studies did not confirm this	94, 114–117
Neurodevelopment, sinistrality	Randomized trials and cohort	B-mode imaging	Not increased in general. Increased left handedness in boys by subgroup analysis	118–120

remain comparable during the study period in order to ensure uniformity of exposure conditions, which is unlikely with the rapid evolution of ultrasound technology. Despite these challenges, a substantial body of evidence exists which has been extensively reviewed [85, 86]. A review of human bioeffects is presented below according to selected outcome categories and further summarized in Table 8.1.

## General Outcome

It is noteworthy that almost all human epidemiological studies fail to show any demonstrable adverse outcome in the fetus, the neonate, and the infant [87–94]. In 1972, Ziskin [90] reported a survey of clinical applications of diagnostic insonation involving over 121,000 examinations and noted no recognizable adverse effects. The data indicate that the probability of occurrence of a known adverse effect is less than 1 in 400,000 examinations. In the largest study reported [92], the Health Protection Branch of the Canadian Environmental Health Directorate conducted a nation-wide survey of diagnostic ultrasound usage during 1977. This report, which involved 340,000 patients and 1.2 million exposures, failed to identify any adverse effect clearly attributable to insonation. Hellman et al. investigated the risk of insonation-related developmental anomalies in 3,297 exposed mothers, of whom only 1,114 patients were included in the analysis [88]. Mothers were exposed to pulsed or continuous-wave ultrasound between 10 and 40 weeks of pregnancy. The investigators reported no greater frequency of congenital abnormalities in the insonated group than in the general population.

## Fetal Movement

Following a report by David and associates that continuous-wave Doppler ultrasound exposure as used in electronic fetal heart rate monitoring increased the mean fetal activity by 90% as measured by fetal movement count [95], several studies failed to confirm such an association [96–98]. Murrills and coinvestigators performed a randomized double-blind controlled trial involving 100 mothers in the study group and 50 in the control group and found no evidence supporting such an effect. The authors attributed the initial reported observation to mechanisms unrelated to continuous-wave Doppler ultrasound exposure.

## Birth Weight

The relationship between prenatal diagnostic ultrasound exposure and fetal growth has been investigated primarily or secondarily by several investigators [94, 99–107]. Moore and associates [101] conducted a

retrospective cohort study that compared the birth weights of 1,598 exposed and 944 unexposed single live births. Confounding variables associated with both exposure status and birth weight outcome were included in multivariate analysis. Although the frequency of ultrasound scanning and the first exposure during the third trimester were associated with a reduction in birth weight, the most consistent effect on the birth weight appeared to be the indication for an ultrasound examination. The relationship of ultrasound exposure and reduced birth weight appeared to be due to shared common risk factors, which lead to both exposure and a reduction in birth weight. Waldenstrom and associates performed a randomized trial in 4,997 pregnant women of whom 2,482 received routine ultrasound screening at 15 weeks of pregnancy and the 2,515 received the usual prenatal care [102]. In the study group, the frequency of birth weight less than 2,500 g was significantly reduced (59 vs 95,  $p=0.005$ ) and the mean birth weight was significantly higher (42 g,  $p=0.008$ ). The authors speculated that the effect may be attributable to reduced smoking in screened women in response to watching their fetus on the scan. Ewigman and coinvestigators performed a randomized clinical trial of prenatal ultrasound involving more than 15,000 pregnancies and did not observe any effect of ultrasound exposure on the birth weight [104]. Newnham and associates investigated the beneficial effects of frequent prenatal ultrasound, both imaging and Doppler, in a randomized trial involving 2,834 women (study group 1,415, control group 1,419) with singleton pregnancies. Sonographic investigations were carried out at 18, 24, 28, 34 and 38 weeks [103]. The only outcome difference noted between the two groups was significantly higher intrauterine growth restriction in the ultrasound group (birth weight 10th centile: relative risk 1.35, 95% confidence interval 1.09–1.67,  $p=0.006$ ; and birth weight 3rd centile: relative risk 1.65, 95% confidence intervals 1.09–2.49,  $p=0.020$ ). The primary objective of the study was not to test the effect of ultrasound on fetal growth. Subsequent follow-up of these infants demonstrated no growth differences between the groups at 1 year of age [107]. The issue was studied by Grisso and associates [106] utilizing a case-control approach involving more than 13,000 pregnancies. This retrospective investigation specifically examined the association between prenatal ultrasound exposure and the risk of low birth weight. No adverse effects of ultrasound were noted. The most recent Cochrane Review reported a meta-analysis of nine published trials of ultrasound. Six trials provided information on the incidence of low birth weight (<2,500 g ms) and the systematic review of the data did not demonstrate any significant effect of prenatal ultrasound on the frequency of low birth

weight (Peto odds ratio 0.96, 95% confidence interval 0.82–1.12) [108].

### **Pediatric Malignancy**

The risks of childhood malignancies following prenatal diagnostic ultrasound exposure have been studied by several investigators. The malignant conditions investigated included lymphatic leukemia, myeloid leukemia, and solid tumors. The earlier studies found no association between in utero ultrasound exposure and childhood leukemia or solid tumors [109–112]. More recently, a prospective population-based case-control study from Sweden investigated the relationship between fetal exposure to ultrasound and development of childhood leukemia [113]. The study failed to demonstrate any significant association between single or repeated prenatal insonation and lymphatic or myeloid leukemia developing in infancy and childhood. The respective odds ratios were 0.85 (95% confidence interval 0.62–1.17) and 1.0 (95% confidence interval 0.42–2.40). Corrections for potential confounding variables, such as maternal age, high birth weight, and twin pregnancies, did not influence the results.

### **Neurodevelopment – General**

Investigations in this field have so far yielded assuring results [99, 114–117]. Stark and coinvestigators followed up 425 infants exposed to diagnostic insonation in utero and a control group of 381 unexposed infants for various outcome parameters including neurological outcomes at 7 and 12 years of age [99]. The tests included conductive and nerve measurements of hearing, visual acuity and color vision, cognitive function, behavior, and a complete and detailed neurologic assessment. No significant differences were noted between the study and the control groups. Salvesen and associates [114] examined any association between routine ultrasonography in utero and subsequent brain development in 8- and 9-year-old children of 2,161 women who took part in two randomized, controlled trials of routine ultrasonography during pregnancy. No clear differences were found between the groups with regard to deficits in attention, motor control, and perception or neurological development during the first year of life. The results are very assuring as no association with impaired neurological development was found. The same group [116] also investigated any possible association between routine ultrasonography in utero and reading and writing skills among 8- or 9-year-old children in primary school. The population base was the same as the previous report [114]. Of 2,428 singletons eligible for follow-up, the school performance of 2,011 children (83%) was assessed by their teachers, who were

unaware of ultrasound exposure status. A subgroup of 603 children were also tested for dyslexia. There were no statistically significant differences between children screened with ultrasound and controls in the teacher-reported school performance (scores for reading, spelling, arithmetic, or overall performance). Results showed no differences between screened children and controls in reading, reading comprehension, spelling, arithmetic, overall performance, and dyslexia. Kieler et al. [117] investigated the association between ultrasound exposure in early fetal life and impaired neurologic development in childhood in 3,265 children age 8–9 years whose mothers participated in a randomized controlled trial of ultrasound screening during pregnancy in Sweden during 1985–1987. No significant difference in impaired neurologic development between ultrasound-exposed and -unexposed children was found in this study. A Cochrane systematic review of ultrasound in early pregnancy reanalyzed the results of the Scandinavian trials and showed no long-term adverse outcome related to school performance, neurobehavioural function, vision, or hearing as a consequence of prenatal exposure to ultrasound [108].

### **Neurodevelopment – Sinistrality**

Salvesen and colleagues observed a significant increase in non-right handedness among the children in the study group than among those in the control group (odds ratio 1.32; 95% confidence interval 1.02–1.71) [118]. Kieler and associates also studied a possible association between ultrasound screening in early pregnancy and altered cerebral dominance measured by the prevalence of non-right handedness among children, particularly boys [119]. A significant association was found between ultrasound exposure and non-right handedness among boys (odds ratio 1.33; 95% confidence interval 1.02–1.74). The association was, however, confined to analyses comparing exposed and nonexposed boys and no associations were found when the comparisons were performed according to the randomized groups. This study was unable to exclude a possible association between non-right handedness among boys and sonographic exposure in early fetal life. In a subsequent cohort study, the same group of investigators found a significant association between ultrasound exposure and non-right handedness among boys (odds ratio 1.32; 95% confidence interval 1.16–1.51) when ultrasound was offered more widely (1976–78), whereas no such association was found during the initial phase of routine screening with ultrasound (1973–75) (odds ratio 1.03; 95% confidence interval 0.91–1.17) [120]. The effect was estimated as an extra three left-handers among 100 male births.

The most recent Cochrane Review of the trials observed that although fewer of the ultrasound exposed children were right-handed, this was not confirmed by analysis of long-term follow-up data [108]. However, the possibility of such an effect may exist if exposure of male children to early ultrasound is considered separately regardless of the actual group of assignment in the study. The reviewers concluded that this finding may have been “a chance observation that emanated from the large number of outcome measures assessed, or from the method of ascertainment; alternatively, if it was a real consequence of ultrasound exposure, then it could imply that the effect of diagnostic ultrasound on the developing brain may alter developmental pathways. No firm conclusion can be reached from available data, and there is a need to study these children formally rather than to rely on a limited number of questionnaire responses obtained from the parents”.

### Clinical Significance

The evidence as discussed above is overwhelmingly reassuring. The position of the AIUM is as follows [121]: “Based on the epidemiologic evidence to date and on current knowledge of interactive mechanisms, there is insufficient justification to warrant a conclusion that there is a causal relationship between diagnostic ultrasound and adverse effects.” However, there is a limitation to the current epidemiological evidence of safety, which has been summarized in the International Perinatal Doppler Society Guidelines [8]. The current epidemiological data are based on the use of diagnostic ultrasound devices from the pre-amendment period. However, as discussed at the outset of this chapter, an amendment in the regulatory policy in the USA has enabled the use of substantially increased acoustic outputs, including applications in obstetrics. There are no data from the substantial acoustic exposures delivered by modern ultrasound equipment or from exposures in the early first trimester. This should prompt prudent use of diagnostic ultrasound, especially in the pulsed Doppler mode in a pregnant patient. This is further elaborated in the next section.

### Guidelines for Clinical Application

It is assuring that even after years of use, there has not been a single known instance of any identifiable perinatal injury from diagnostic ultrasound usage. This must be recognized as an impressive record of safety. The benefits of diagnostic ultrasound, on the other hand, are remarkable. The technique has extended the scope and precision of diagnostic medi-

cine, and thus has promoted better patient care. This assessment holds true for a wide spectrum of clinical disciplines ranging from cardiology to obstetrics and gynecology.

In spite of this excellent record, the need for continuing vigilance for biosafety is well recognized. That insonation can produce bioeffects is well known, although much of this information is not very relevant for assessing the risks of diagnostic exposure. The epidemiological evidence is very assuring. However, there has been no comprehensive well-controlled, large-scale human study investigating the possibility of subtle, long-term, or cumulative adverse effects of Doppler ultrasound. A matter of recent concern is the increased acoustic power output of the diagnostic ultrasound devices following the changes in FDA regulations [122]. This has renewed the need for caution for pulsed Doppler ultrasound exposure at high intensity and for prolonged periods near fetal bone such as the fetal cranium as would be required for cerebral arterial Doppler interrogation. Similar caution should be exercised for transvaginal Doppler scanning in early pregnancy because close proximity of the transducer to the target tissue and, therefore, reduced attenuation will increase the acoustic energy delivered to the tissue. These risk potentials, although theoretical, should guide us to use diagnostic ultrasound with prudence and clinical judgment. Diagnostic Doppler ultrasound should be used in pregnancy when a medical benefit is expected. Furthermore, as suggested in this chapter, the acoustic exposure conditions should be kept within the limits for obtaining adequate diagnostic information and be guided by the display indicators (MI and TI). Practical guidelines and recommendations have been forwarded by various organizations in this regard. A compilation of the IPDS recommendations are summarized here to serve as guidelines for use of Doppler sonography in obstetrical practice [8]:

1. Care should be taken to ensure that all examinations are performed with the minimum level of acoustic output and dwell time necessary to obtain the required diagnostic information, i.e., use the ALARA (As Low As Reasonably Achievable) principle.
2. Where equipment provides a form of output display, users are encouraged to utilize this feature to help apply the ALARA principle.
3. Users of equipment with an output display should be aware that it is capable of producing far greater intensities in obstetric examinations than equipment that has no output display (i.e., approved through FDA-regulated application-specific limits).
4. Users should take notice of exposure information provided by the manufacturer and minimize exposures to tissue structures containing bone and/or gas.

5. Due to the possible influence of potentiating factors, duplex/Doppler ultrasound in febrile patients might present an additional embryonic and fetal risk.
6. The use of Doppler ultrasound in the first trimester of pregnancy should be restricted to medically indicated diagnostic purposes when there is a reasonable expectation of beneficial outcome.
7. Given the absence of any evidence of beneficial outcome, the use of Doppler ultrasound in low-risk screening applications may be inadvisable in clinical practice outside a study protocol.

As long as these general principles and guidelines are observed, there should be no inhibition in using diagnostic ultrasound when a benefit is expected, nor should any future research for expanding its diagnostic applications be restricted provided it is conducted with appropriate approval, counseling, and consent.

# Fetal and Maternal Cardiovascular Physiology

Joseph Itskovitz-Eldor, Israel Thaler

Pregnancy is a high-flow, low-resistance state of cardiovascular homeostasis associated with remarkable hemodynamic changes. In the human and most other mammalian species, cardiac output increases during early pregnancy, reaching a peak of 30%–50% above nonpregnant values at 20–24 weeks' gestation. It remains unchanged or falls slightly thereafter [1, 2]. This increment in maternal cardiac output is accounted for by the dramatic increase in uterine blood flow needed to satisfy the metabolic demands of the conceptus and by the significant increase in blood flow to certain nonreproductive organs that are involved in the physiologic adjustments to pregnancy (e.g., kidneys, skin, gastrointestinal tract) [3]. There is also a 20% increase in maternal heart rate, a slight fall in mean arterial pressure, and a significant decrease in systemic vascular resistance – hence the need for the 40% expansion in maternal blood volume during normal pregnancy [4].

In addition to these alterations, there is the development of attenuated pressor responses to several vasoactive agents during normal pregnancy. These agents include angiotensin II,  $\alpha$ -agonists, and arginine vasopressin [5–7].

The hemodynamic changes described above are mandatory for the continuous growth and development of the uteroplacental and fetoplacental circulations. Interference with the normal growth and development of the uteroplacental and fetoplacental circulations may result in disruption of the oxygen and nutrient supply to the fetus, leading to reprogramming of fetal development. It ultimately may result in intrauterine growth retardation, one of the leading causes of perinatal mortality and morbidity. Thus assessment of uteroplacental and fetal hemodynamics is of primary clinical importance. Until recently, fetal heart rate monitoring and the biophysical profile have been useful routine surveillance techniques for detecting the fetus that is either already asphyxiated or soon likely to become so. Despite three decades of experience in this field, controversies still exist regarding the effectiveness of these tests for reducing perinatal mortality and morbidity.

The use of Doppler ultrasound technology for investigating human fetal and uteroplacental hemody-

namics offers a novel approach to the identification of a wide variety of disorders related to pregnancy. Knowledge of the normal physiology of maternal and fetal hemodynamics is a prerequisite for the development of pathophysiologic hypotheses that can lead to the establishment of clinical principles for investigating the fetomaternal circulatory status. Most of the present knowledge of fetal and maternal cardiovascular physiology is derived from animal experiments, particularly in the pregnant sheep; there is a paucity of comparable information relating to human pregnancy. Although the general course of the fetal and maternal circulations are similar in various mammalian species, it is important to appreciate that significant variations are known to exist among species. This chapter briefly reviews the basic hemodynamic concepts of the fetal and maternal circulations relevant to the potential clinical application of Doppler ultrasound technology for the assessment of fetal well-being.

## Uterine Circulation

### Functional Anatomy of the Uteroplacental Circulation

The main uterine artery branches off the internal iliac artery. At the level of the internal cervical os it bifurcates into the descending (cervical) and ascending (corporal) branches. At the uterine tubal junction the ascending branch turns toward the ovary and anastomoses with the ovarian artery to form an arterial arcade that perfuses the internal genital organs. The tortuous ascending uterine artery gives off approximately eight branches – the arcuate arteries – which extend inward for about one-third the thickness of the myometrium and envelope the anterior and posterior walls of the uterus [8, 9]. The origin of these branches is asymmetric; some are large and thick and supply a large area of the uterus, whereas others are thin and supply smaller areas of the uterine wall. These arteries have a tortuous course and anastomose with the corresponding arteries from the other side closer to the midline [9, 10]. From this net-

work arise the radial arteries, which are directed toward the uterine mucosa. The spiral arteries undergo cyclical changes that are synchronous with the ovarian cycle. During normal pregnancy, trophoblastic cells enter the lumen of the spiral arteries, partially replacing the endothelium and progressing down the inner wall of the arteries up to the level of the endometrium. At the end of the third month of pregnancy the invading trophoblast begins to destroy the elastic lamina, and at 16–22 weeks' gestation it replaces the smooth muscle elements of the intramyometrial portion of the spiral arteries and then degenerates [11, 12]. This transformation eventually leads to formation of a low-resistance vascular system in which relatively large maternal arteries pump blood directly into the intervillous spaces (Fig. 9.1). Failure or impairment of the trophoblastic cells to invade the spiral arteries has been associated with pregnancy-induced hypertension and intrauterine growth restriction [14, 15].

Anatomic and radiographic studies and uterine perfusion have demonstrated the richness of the arterial anastomosis of the human uterine circulation [8–10, 16, 17]. These anastomoses include ipsilateral connections between uterine and ovarian arteries, ipsilateral anastomosis of vessels of differing diameter of the uterine branches (arcuate and radial arteries), contralateral anastomosis between the right and left uterine arteries and their branches, and extrauterine connections between the uterine circulation and the systemic circulation (e.g., inferior mesenteric, middle sacral, and inferior epigastric arteries). This vast ipsilateral and contralateral anastomotic network ensures ample uteroplacental perfusion and may be activated to provide alternative routes of blood supply to the placenta. Data from human pregnancy indicate that anastomotic connections increase in size and are of

functional significance after occlusion of major vessels [16, 17]. In the rhesus monkey the contribution of the ovarian artery to uterine blood flow in the nonpregnant state and during early pregnancy is negligible. During late pregnancy it contributes about half of the flow to the upper third of the uterus [18]. Studies in sheep have shown that the uterine arteries contribute approximately 80% of the total uterine flow [19, 20], and that functional arterial anastomoses are present between the right and left sides of the uterine vasculature. Short-term changes in flow on one side are accompanied by compensatory changes in the flow rate on the contralateral side [21]. The venous drainage of the placenta usually follows its arterial supply, but it has also been demonstrated that in some instances the drainage of placental blood shifts rapidly between the two uteroovarian veins [22]. Thus the uteroplacental circulation is a dynamic system in which the magnitude of blood flow through a single vessel may vary considerably over a short time, making single vessel measurements of blood flow sometimes difficult to interpret.

### Alterations in Uterine Blood Flow

Only limited information is available regarding the changes in uteroplacental blood flow throughout human pregnancy. Total uterine blood flow is estimated to increase from approximately 50 ml/min during early pregnancy to 500 ml/min near term. However, these figures were derived from studies that employed a diffusion-equilibrium technique [23, 24] or radioisotope-dilution methods [25–29], the accuracy of which is questionable [30].

Our most complete knowledge of uterine vascular changes have been obtained in farm animals (sheep, pigs), which have been shown to develop some hemo-

**Fig. 9.1.** Fully developed changes in the uteroplacental arteries of normal pregnancy. The *hatched portions* of the wall of spiral arteries indicate the extent of the physiological changes. *IVS* intervillous space. (Reprinted from [13] with permission)

dynamic alterations during pregnancy similar to those observed in humans. Although these animal experiments allow us to emphasize some common fundamental control mechanisms in both the development and control of the uteroplacental circulation, it should be appreciated that significant variations (e.g., type of placentation) are known to exist among species.

Blood flow to the uterus during early pregnancy has been most comprehensively studied in the pig [31]. In this species, a sharp peak of uterine blood flow to the pregnant horn is observed on days 12 and 13 after mating, before definite attachment of the embryo occurs, suggesting an early, local effect of the blastocyst on uterine blood flow. This phase is followed by a progressive and dynamic increase beginning on day 18 or 19, which corresponds to the day of implantation and the initiation of placentation.

Studies in sheep have correlated the changes in uteroplacental blood flow to the growth and development of the placenta of the fetus and have provided some insight into the long-term regulatory mechanisms controlling the development of the uteroplacental circulation. In the nonpregnant ovariectomized sheep, uterine blood flow is approximately 25 ml/min and increases to 400 ml/min at midpregnancy when definite placentation is complete. Absolute uterine blood flow increases beginning at midpregnancy until term to reach a level of 1,500 ml/min (term is at approximately 146 days), although uterine blood flow per gram of total uterine (and fetal) weight remains constant. These values of uterine blood flows represent approximately 0.5%, 8.0%, and 20.0% of cardiac output, respectively [19, 32].

The distribution of blood flow within the gravid uterus was measured using the radiolabeled microsphere technique [33]. At an early stage of gestation (second month) the myometrium and endometrium receive approximately 70% of total uterine blood flow. During the third month of pregnancy the placenta attains its maximum size and becomes the major component of uterine weight, and placental blood flow represents approximately 60% of the total. During the final 2 months there is no further placental growth, but fetal weight increases exponentially; during this stage of gestation there is a three- to fourfold increase in placental blood flow, and near term it accounts for 80%–90% of total uterine blood flow [19, 33].

These observations suggest that the longitudinal hemodynamic changes in the uteroplacental circulation are directly related to the growth rate of the tissue it supplies. There are two stages in the growth and development of the uteroplacental circulation. The first stage extends from the time of implantation through 80–90 days' gestation and is reflective of the period of placental growth and development of new

blood vessels [34]. The second stage extends over the last 2 months of pregnancy. During this period there is no further growth of the placenta and no formation of new blood vessels, as reflected by the number of maternal and endothelial cells [34]. There is an increase in the cross-sectional area of the uterine vascular bed, however, and placental perfusion continues to increase until term to accommodate fetal growth. The progressive increment in uteroplacental perfusion and the progressive decline in uterine vascular resistance during the second stage of pregnancy are secondary not only to vasodilation of the uteroplacental vascular bed (inasmuch as studies in unanesthetized sheep have shown that the vasculature is nearly maximally dilated [35–38]) but also to the gradual increase in the luminal diameter of the resistance vessels. Indeed, there is rapid, active growth in the uterine arterial wall. The threefold increase in the internal radius of the uterine artery is not merely the result of passive dilatation, as wall thickness is unchanged; there is hypertrophy of its vascular smooth muscle and a decrease in its collagen fraction [39].

## Regulation of Uteroplacental Circulation

The regulatory mechanisms that promote the described sequence of changes in uteroplacental blood flow by influencing the formation and growth of the uteroplacental blood flow are poorly understood. Putative regulatory agents include steroid hormones, angiogenic factors, growth factors, and other unknown substances of fetal or maternal origin.

### *Steroid Hormones and Vasoactive Agents*

The uterine vasculature is sensitive to estrogens [37, 40, 41]. Estradiol is a potent uterine vasodilator in nonpregnant sheep, and the magnitude of increase of uterine blood flow at early gestation can be produced by injecting estradiol into nonpregnant sheep. Exogenously administered estradiol also increased placental blood flow, although the observed percentage increase from baseline is not striking as it is in the nonpregnant state. Furthermore, the response to estradiol appears to be more pronounced during early pregnancy than at later pregnancy [37], suggesting that during later pregnancy the placental vasculature is almost maximally dilated. Uterine blood flow response to estrogen is probably mediated largely by nitric oxide (NO), which can stimulate production of vascular endothelial growth factor (VEGF) and basic fibroblast growth factor (bFGF) [42, 43].

The role of progesterone in regulating the development of uteroplacental circulation and the rate of uterine blood flow is even more complex. In the sheep, progesterone given in pharmacologic doses in-

duces overgrowth of caruncles (highly vascularized areas of the uterine mucosa that become the sites of implantation and the formation of placental cotyledons) [44] and growth of uterine blood vessels [45]. Its role in regulating uterine blood flow is controversial [46].

The uteroplacental vasculature is sensitive to the constrictive effect of catecholamines. Systemic infusion of suppressor doses of norepinephrine has been shown to reduce placental perfusion in the absence of significant changes in arterial pressure [47]. It is also sensitive to other endogenous vasoactive substances (e.g., angiotensin II, prostanoids), which have the potential to either increase or decrease uterine blood flow by acting directly on the blood vessels or indirectly by modifying the intrauterine pressure. Changes in partial pressures of oxygen and carbon dioxide have little direct effect on the uteroplacental circulation. However, severe disruption of oxygenation and acid-base balance (and maternal stress in general) may increase uterine vascular resistance secondary to the constrictive effect of catecholamines released into the circulation and activation of the sympathetic vasomotor nerves [30].

### ***Pressure-Flow Relations***

Data from animal experiments in which the pressure-flow relations in the uterine circulation were examined have demonstrated a negative correlation between amniotic pressure and uterine blood flow [48] and a linear relation between flow and perfusion pressure [20, 35, 49, 50]. In rhesus monkeys confined to restraining chairs, the highest blood flows tended to occur during the period of darkness when arterial and intraamniotic fluid pressures were low [48]. These observations suggest that the uteroplacental circulation is pressure-passive, is fully dilated, and has no tendency toward autoregulation. Meschia [30] compared the placenta and its venous outlets to a collapsible tube (Starling resistor) [51] contained within a cavity in which the pressure can increase above atmospheric pressure in this system, and flow through the placental bed depends on arterial perfusion pressure, the external pressure exerted by the amniotic fluid, and the pressure in the uterine venous outlet. Although these relations have been demonstrated experimentally, disparities were observed in the chronology and amplitude of the 24-h periodic functions for arterial blood pressure, intraamniotic pressure, and uterine blood flow recorded continuously in rhesus monkeys, indicating that uteroplacental perfusion is modulated by factors in addition to those imposed by pressure-flow relations [52].

The high basal rate of uterine perfusion provides a margin of safety for the fetus because the uteroplacental

vasculature does not dilate in response to maternal hypotension or hypoxia but is sensitive to the constrictive effect of catecholamines. In the sheep, oxygen supply to the fetus is approximately twice the level necessary to maintain adequate fetal oxygen uptake and normal oxidative metabolism. Fetal oxidative metabolism can be sustained despite reductions in uterine blood flow of about 50% [53–55]. However, long-term reductions of even small magnitude have cumulative metabolic effects that ultimately affect fetal growth. It has been clearly demonstrated that fetal growth is directly related to the normal incremental increases in uterine blood flow throughout pregnancy [21]. When reduced uterine flow is prolonged, fetal and placental growth are slowed [21, 56]. Under these circumstances uterine blood flow per unit weight of the fetus and placenta may remain constant and does not significantly differ from that of normally growing fetuses [57, 58].

### **Fetal Circulation**

During fetal life oxygenation is carried out in the placenta. A large gradient of oxygen partial pressure ( $PO_2$ ), of about 60 mmHg, has been found between maternal arterial blood and fetal umbilical venous blood. The admixture of the oxygenated umbilical venous blood from the placenta and systemic venous blood from the fetal body further reduces the  $PO_2$  of blood distributed to the fetal body. The  $PO_2$  of arterial blood is 20–30 mmHg (considerably lower than the adult value of close to 100 mmHg); it is somewhat higher in the blood distributed to the brain and the upper body from the ascending aorta than in blood distributed from the descending aorta to the lower body and the placenta. Despite the existence of a low arterial concentration of oxygen, the fetus has adequate oxygen delivery because, similar to the adult, it does not extract more than one third of delivered oxygen [59].

The presence of ductus arteriosus, the large communication between the pulmonary trunk and the aorta (Fig. 9.2), accounts for the almost identical pressures in the aorta and the pulmonary artery in the fetus. Similarly, because of the presence of the foramen ovale, atrial pressures are almost identical, and so the right and left ventricles are subjected to the same filling pressure. Hence, unlike those in the adult, fetal cardiac ventricles work in parallel rather than in series. The output of the left ventricle is directed through the ascending aorta to upper body organs, thus preferentially perfusing the brain, whereas the right ventricle mainly perfuses the lower body and placenta through ductus arteriosus and the descending aorta.

**Fig. 9.2.** Fetal heart showing the percentages of combined ventricular output by each ventricle and traversing the major vascular pathways. Ao aorta; MPT main pulmonary trunk; DA ductus arteriosus; PA pulmonary artery; RV right ventricle; LV left ventricle; RA right atrium; LA left atrium. (Reprinted from [60] with permission)

Before birth both ventricles contribute to fetal systemic flow in parallel, and the term “combined ventricular output” is commonly used to represent fetal cardiac output. After birth the ventricles are arranged in series, and each ventricle ejects a similar volume of blood.

### Fetal Cardiac Output and Distribution

Much of today’s knowledge of fetal cardiac output and distribution is derived from studies of fetal sheep. Fetal cardiac output and its distribution have been measured employing the radionuclide-labeled microsphere method or by electromagnetic flow transducers applied around the ascending aorta and the pulmonary trunk. In the near-term fetus, combined ventricular output is  $450\text{--}500\text{ ml}\cdot\text{min}^{-1}\cdot\text{kg}^{-1}$  of fetal body weight and appears to be consistent throughout the last half of gestation [61–63]. Doppler echocardiographic measurements of the combined cardiac output in the human fetus have yielded similar values [64–67], which far exceed the level of about  $100\text{ ml}\cdot\text{min}^{-1}\cdot\text{kg}^{-1}$  body weight for each of the adult ventricles.

In the fetal lamb, the right ventricle ejects two-thirds and the left ventricle ejects one-third of the

combined ventricular output. The dominance of the right ventricle is also present in the human fetus [64, 68], but in the human the ratio is smaller (1.2–1.5) than in the fetal lamb (1.8). The larger brain mass of humans with respect to sheep may explain the higher left ventricular output and therefore the lower ratio between the right and left ventricular outputs. Reference ranges were established in the human fetus for cardiac output (Fig. 9.3) and ductus arteriosus blood flow (Fig. 9.4) [68]. Central blood flow distribution in the second and third trimesters of pregnancy was measured, confirming the conception of right heart dominance. Estimated pulmonary flow was 11% of biventricular output, higher than in the fetal lamb (6%–8%) [60].

Nearly 90% of the right ventricular output bypasses the pulmonary circulation via the ductus arteriosus to reach the descending aorta, whereas only 30% of the left ventricular output passes the aortic arch (isthmus) to the descending aorta (Fig. 9.2). Thus flow in the thoracic portion of the descending aorta represents about 65% of fetal combined ventricular output. The placenta receives 40% ( $180\text{--}200\text{ ml}\cdot\text{min}^{-1}\cdot\text{kg}^{-1}$  fetal weight) of fetal cardiac output, or about 65% of the flow in the thoracic descending aorta and about 75% of the flow in the abdominal aorta distal to the origin of the renal arteries. In the human fetus, umbilical-placental blood flow measured by the Doppler ultrasound technique is approximately  $120\text{ ml}\cdot\text{min}^{-1}\cdot\text{kg}^{-1}$  fetal weight [69, 70], which represents about 25% of human fetal cardiac output and 50%–60% of the flow in the thoracic descending aorta.

The distribution of cardiac output in the fetal sheep is shown in Table 9.1. Only limited information is available regarding the distribution of fetal cardiac output in human and nonhuman primates. The distribution of blood flow expressed as percent of combined cardiac output in fetal lambs and in human fetuses is demonstrated in Table 9.2 [68]. The distribution of cardiac output was measured in acute studies of monkeys and previsible human fetuses, and in general it is similar to that seen in the fetal lamb. In the human and the monkey, the brain, being proportionately larger than that of the sheep, receives a higher percentage of the cardiac output. In the fetal rhesus monkey, brain flow represents approximately 16% of the cardiac output [71] compared with 3%–4% in the sheep [63].

### Regulation of Cardiac Function

As mentioned above, the right and left ventricles are subjected to the same filling pressures due to the presence of the foramen ovale. The resistances against which the ventricles eject are evidently different [60, 62]. Studies in fetal lambs have suggested that the

**Fig. 9.3.** Individual values and calculated 5th, 10th, 50th, 90th and 95th centiles of biventricular output per minute (upper trace) and stroke volume (lower trace). (Reprinted from [68])

aortic isthmus, the narrowest segment of the aorta between the origin of the brachiocephalic trunk and the ductus arteriosus, represents a site of functional separation between the two ventricles. As a result, the right ventricle is subjected to the afterload of the lower body, including the low resistance of the umbilical-placental circulation through the wide channel of the ductus arteriosus, whereas the left ventricle is presented with the resistance of the upper body and that of the aortic isthmus [60].

The differences in outflow resistance and ejection characteristics to the left and right ventricles are evident in the blood velocity profiles of the ascending

aorta and the pulmonary trunk (Fig. 9.5). There is a much steeper rise in velocity in the pulmonary trunk compared to that of the aorta. After reaching a peak the aortic flow decreases rapidly, and there is a sharp incisura with some backflow at the end of systole. The peak velocity in the pulmonary trunk is greater than that in the ascending aorta. There is a characteristic sharp incisura in the descending limb of the pulmonary trunk velocity curve that may be related to the aortic valve wave reaching the ductus arteriosus and modifying right ventricular ejection [72].

As the ventricular output and velocity profiles are determined primarily by afterload or changes in the

**Fig. 9.4.** Individual values and calculated 5th, 10th, 50th, 90th and 95th centiles of blood flow per cycle (upper trace) and blood flow per minute (lower trace) in ductus arteriosus. (Reprinted from [68])

vascular resistances of the upper and lower circulations, it may be possible to define circulatory changes during fetal distress by examining the relative outputs of the two ventricles by echocardiography or by assessing the velocity profiles in the aorta and the pulmonary trunk by the Doppler technique [73–75]. The acceleration of the aortic flow ( $dV/dt$ ) is one of the most reliable indices of myocardial contractility. Measurement of acceleration time (time to peak velocity) of both the aorta and the pulmonary artery can be used as a good index of ventricular performance [76–78].

During fetal hypoxemia resulting from reduced oxygen delivery across the placenta (uterine blood flow reduction, maternal hypoxemia), blood flow to the fetal body is reduced owing to peripheral vasoconstriction, but umbilical blood flow does not change. Under these circumstances the relative output of the right ventricle, compared to that of the left, may be expected to increase. However, if fetal hypoxemia results from umbilical blood flow reduction (partial cord compression), vascular resistance across the umbilical-placental circulation is increased; and it may be expected to be associated with a reduction of right, relative to left, ventricular output.

**Table 9.1.** Distribution of blood flow expressed as percent of combined (biventricular) cardiac output

**Fig. 9.5.** Velocity tracings in the pulmonary trunk and ascending aorta obtained by electromagnetic flow transducer implantation. Note the rapid rise of velocity in the pulmonary trunk compared with that in the aorta. There is a characteristic notch in the descending limb of the velocity curve. The ascending aortic tracing also shows a sharp incisure at the end of ejection caused by backflow. The area under each curve reflects stroke volume; flow in the pulmonary trunk is about twice that in the aorta. (Reprinted from [72] with permission)

The factors regulating cardiac output in the fetus and the mechanisms responsible for the increase in output after birth have attracted considerable attention. Cardiac function and the volume of blood

ejected by the heart are, in general, determined by cardiac and circulatory factors [79]. Early studies suggested that the normal fetal heart at rest operates close to the top of its ventricular function curve (Frank-Starling curve), with little reserve available to further increase the output [60, 80–82].

In these studies little attention was directed to the changes in arterial pressure that occur with volume loading or withdrawal. It is well known that the fetal heart is sensitive to an increase in afterload, and so the cardiac output falls dramatically as arterial pressure increases. In early studies the arterial pressure (afterload) was not controlled, and therefore left ventricular stroke volume showed little increase above the left atrial mean pressures of about 6 mmHg (slightly higher than normal atrial pressure at rest). However, when the left ventricular stroke volume was related to left atrial pressure at the same levels of mean arterial pressure, the stroke volume continued to increase above the atrial mean pressure of about 10 mmHg [83], suggesting that the fetal heart rate is able to increase its output provided the preload is increased and the afterload is maintained or if the preload is maintained but the afterload is decreased. However, because a large proportion of the fetal blood volume is sequestered in the highly compliant umbilical-placental circulation, the fetus is unable to increase venous return readily and therefore has limited ability to increase its cardiac output acutely [84].

While the plateau observed in the fetal cardiac function curve was related to arterial pressure and increasing afterload, it has been demonstrated that the maximal stroke volume in the fetus is largely determined by the constraining effect that the pericardium and the chest wall-lung combination (i.e., extracardiac constraint) has on ventricular filling [85]. When ventricular transmural pressure, a more appropriate measure of ventricular preload than ventricular filling pressure, is used in ventricular function curve analysis, stroke volume is linearly related to preload and the plateau is absent [85]. The major limitation upon left ventricular function in the near-term fetal lamb results from extracardiac constraint limiting ventricular filling while, at the same time, a much smaller

limitation arises from increasing arterial pressure [86].

### Patterns of Venous Returns

The combined ventricular output represents total venous return to the fetal heart. In the fetal sheep about 70% of the venous return to the heart is derived from the thoracic inferior vena cava (IVC), about 20% from the superior vena cava (SVC), 7% from the lungs, and the remaining 3% from heart muscle [61, 63].

### Umbilical Vein and Ductus Venosus

The umbilical venous return with its well oxygenated blood is either distributed to the hepatic microcirculation or bypasses the liver through the ductus venosus (Fig. 9.6). The ductus venosus is a funnel-like vessel with a narrow lumen at its beginning in the umbilical sinus [87]. This bottleneck at the orifice should contribute most to the flow resistance between the umbilical vein and the caval vein. The resistance is in parallel to the resistance of the hepatic vascular bed. The ratio of conductances between the ductus venosus and the hepatic vascular bed defines the ratio of ductus venosus flow to hepatic flow. In the fetal lamb this ratio approximates 1, with about half the umbilical venous blood passing through the ductus venosus, and the rest of the blood entering the hepatic circulation [88–94]. Doppler measurements in the human fetus have provided similar values [95]. The left lobe of the fetal liver receives only umbilical venous blood, whereas the right lobe receives both umbilical venous blood and portal venous blood. The hepatic arterial blood supply to the liver is small (3%–4%) in the fetus [88]. As a result of these flow patterns, right hepatic venous blood has a lower oxygen saturation than does the left hepatic venous blood [91]. The large blood flow through the ductus venosus and the liver (which together represent about 50% of total venous return to the heart) makes them important organs for regulating venous return to the heart. Streaming patterns in the IVC and right atrium preferentially distribute the highly oxygenated blood that passes through the ductus venosus to the fetal heart and brain [96]. During umbilical cord compression [94], increasing proportions of the blood returning in the umbilical vein from the placenta pass through the ductus venosus. A 50% decrease in umbilical blood flow is associated with a 75% decrease in hepatic blood flow [94]. During acute fetal hypoxemia induced by maternal hypoxia [93] or by uterine blood flow reduction [97], umbilical blood flow is maintained. The proportion of umbilical venous blood that passes through the ductus venosus increases, whereas the percentage to the liver falls. These observations

**Fig. 9.6.** Venous flow patterns in the fetal lamb. Umbilical venous blood is distributed to the left lobe of the liver, through the ductus venosus, and to the right lobe of the liver. Portal venous blood passes almost exclusively to the right lobe, but a small proportion enters the ductus venosus. Ductus venosus and left hepatic venous blood preferentially passes through the foramen ovale, whereas right hepatic venous and distal inferior vena caval blood is preferentially directed through the tricuspid valve. Superior vena caval blood almost all passes through the tricuspid valve. SVC superior vena cava; IVC inferior vena cava; LHV left hepatic vein; RHV right hepatic vein. (Reprinted from [84] with permission)

suggest that the ductus venosus (or actually the blood flow passing through the common orifice of the ductus venosus and left hepatic vein into the IVC [98]) facilitates the preferential distribution of highly oxygenated blood to the fetal brain and heart. The mechanisms responsible for the changes in flow patterns in the liver microcirculation and the ductus venosus have not been clearly delineated. These alterations in distribution can be accounted for by active relaxation of the ductus venosus or by vasoconstriction in the hepatic circulation [60, 99, 100]. The use of Doppler ultrasound techniques to monitor flow patterns and velocity profiles in the intraabdominal portion of the umbilical vein and in the ductus venosus carries the potential of evaluating changes in distribution of umbilical venous return to the liver and to the ductus venosus under conditions associated with fetal stress.

### IVC and SVC

Using the microspheres method it has been demonstrated that almost all SVC blood is directed across the tricuspid valve into the right ventricle and is dis-

tributed to the lower body (Fig. 9.6). Only 2% of SVC blood crosses the foramen ovale to be distributed to the upper body. In contrast, IVC blood is divided between the right and left ventricles, and approximately 40% of IVC blood flow passes through the foramen ovale to the left atrium [61].

Blood entering the thoracic IVC via the distal IVC, the ductus venosus, and the hepatic veins is not adequately mixed (Fig. 9.6) [96, 99]. This phenomenon has been related to the existence of valve-like structures at the orifices of the major veins entering the IVC just below the diaphragm. Thus well-oxygenated blood from the ductus venosus and the hepatic vein passing through a common orifice into the IVC is deflected to the posterior left portion of the thoracic IVC and preferentially streams across the foramen ovale to the upper body, whereas the less-oxygenated blood from the right hepatic vein is directed anteriorly and to the right and, with distal IVC blood, it is preferentially distributed through the tricuspid valve to the lower body and placenta. These flow patterns facilitate the delivery of blood with relatively high oxygen content and glucose concentration from the placenta to upper body organs, including the brain and heart; blood with lower oxygen content goes to the lower body and the placenta for reoxygenation [84].

Changes in the velocity of blood flow in the vessels that join the thoracic IVC may modify the degree of mixing of the various streams and may influence preferential distribution of venous returns. Defining velocity profiles of individual streams in the thoracic IVC of the fetus may help to delineate the factors that influence the various flow patterns in the IVC; it also has the potential to aid in evaluating relative changes in venous in relation to fetal distress. It has been demonstrated that during fetal hypoxemia (induced by maternal hypoxia or uterine blood flow reduction) the distal IVC flow decreases and ductus venosus flow is increased [96, 97, 101]. However, when umbilical blood flow is reduced owing to cord compression, the ductus venosus flow decreases but distal IVC flow is increased [94].

### Phasic Blood Flow Patterns

Phasic flow studies in the fetal lamb show characteristic patterns associated with the cardiac cycle and with fetal respiratory movements in utero. The potential exists for assessing human well-being by examining alterations in these patterns using the Doppler method.

Phasic blood flow in the IVC, SVC, and umbilical vein of fetal sheep was measured with chronically implanted electromagnetic flow transducers [102]. Phasic flow patterns in the IVC and SVC are similar to

those in the adult and are influenced by similar factors: the cardiac cycle and respiratory movements.

Because the fetus is intermittently apneic, the cardiac cycle determines the phasic flow patterns in the absence of fetal breathing movements. Blood flow in the IVC and SVC is pulsatile, and there are two forward surges of flow during each cardiac cycle, one occurring during ventricular systole (systolic surge) and the other during ventricular diastole (diastolic surge) (Fig. 9.7). In the normal fetus, venous flow is always forward in both venae cavae. The peak systolic velocity in the IVC ranged from 9 to 26 cm/s and in the SVC from 12 to 30 cm/s in the absence of fetal breathing movements. The peak diastolic velocity ranged from 6 to 18 cm/s in the IVC and from 8 to 21 cm/s in the SVC [101]. The peak systolic and diastolic velocities are in the same range as has been reported in the IVC of adult men [102].

Changes in fetal heart rate, venous or arterial pressure, and fetal breathing movements are associated with changes in phasic venous flow patterns [101]. Bradycardia increases the negative dip in flow asso-

**Fig. 9.7.** Typical recordings of carotid arterial (CA) and superior vena caval (SVC) pressures, instantaneous blood flow in the superior and inferior vena cava (IVC), and the electrocardiogram (ECG) in a chronically instrumented near-term fetal lamb. Venous blood flow is biphasic. The systolic component begins with the onset of ventricular contraction (1), peaks (PSF), and decreases until the opening of the atrioventricular valves (2, V dip). The diastolic component begins with the opening of the atrioventricular valve, peaks (PDF), then reaches a nadir with atrial contraction (a). Venous flow is inversely related to venous pressure. (Reprinted from [101] with permission)

**Fig. 9.8.** Recordings of aortic pressure, mean and instantaneous inferior vena cava (IVC) flow, and instantaneous heart rate in fetal sheep during a control period and after fetal hypoxemia was produced by administering a low-oxygen gas mixture to the ewe. During hypoxia the amplitude of venous pulsations increased and retrograde flow occurred with atrial contraction. Bar=1 s. (Reprinted from [101], with permission)

ciated with atrial systole and may cause backflow in the IVC; conversely, tachycardia reduces the size of the negative atrial systolic dip and increases the size and duration of the rapid forward flow phase. Increased afterload caused by hypoxia or norepinephrine administration is associated with increased peak systolic flow and even retrograde flow in the IVC (Fig. 9.8). Reduction in afterload caused by acetylcholine injection decreases peak systolic venous flow but augments the peak diastolic venous flow.

The most striking changes in flow patterns occurred with fetal breathing movements. During regular fetal breathing movements the phasic flow pattern is determined largely by the respiratory cycle with the cardiac cycle effect superimposed on it. A decrease in tracheal or intrapleural pressure causes an increase of venous forward flow. When large negative pressures are generated by regular deep breathing movements, marked venous pulsations occur. Blood flow in the intraabdominal portion of the umbilical vein is minimally pulsatile. However, conditions that increase the amplitude of phasic flow patterns (e.g., fetal breathing movements, hypoxia) also increase umbilical venous pulsations. Doppler measurements characterizing the human fetal venous circulation were also performed in normal and distressed fetuses [103].

## Umbilical-Placental Circulation

Total umbilical blood flow increases with gestation in proportion to the increase in fetal weight, although in relation to unit of fetal weight it decreases toward term in humans [69, 104] and sheep [105, 106]. In the near-term lamb, umbilical vessels transport blood at  $180\text{--}200\text{ ml}\cdot\text{min}^{-1}\cdot\text{kg}^{-1}$  at a mean arterial pressure in the descending aorta of  $40\text{--}50\text{ mmHg}$ . Levels of about  $120\text{ ml}\cdot\text{min}^{-1}\cdot\text{kg}^{-1}$  body weight were obtained in the human fetus using the Doppler ultrasound method [69, 70].

## Oxygen Delivery and Oxygen Consumption

Oxygen delivery to the fetal body is determined by umbilical blood flow and the oxygen content of umbilical venous blood. Umbilical venous oxygen content is related to hemoglobin concentration and hemoglobin oxygen saturation. Thus the higher flow rate in the sheep fetus probably compensates for the much lower hemoglobin concentration that normally exists in this species compared with that in the human fetus ( $9\text{ g/dl}$  versus  $15\text{ g/dl}$ ). Although the level of umbilical blood flow is relatively constant, considerable variations do exist. Fetal oxygen consumption (umbilical blood flow  $\times$  umbilical venous-arterial  $\text{O}_2$  difference), however, remains constant [107], which suggests that umbilical blood flow is matched to the oxygen requirement to the fetus. Oxygen consumption in the human fetus is not known. In the fetal sheep it is about  $7\text{--}8\text{ ml O}_2\cdot\text{min}^{-1}\cdot\text{kg}^{-1}$  body weight. Oxygen delivery to the fetus is about  $22\text{ ml}\cdot\text{min}^{-1}\cdot\text{kg}^{-1}$ , and the fetus extracts about 30% of the oxygen delivered [59]. After birth oxygen extraction still represents only 30% of oxygen delivery, but oxygen consumption increases dramatically to levels of  $18\text{--}20\text{ ml}\cdot\text{min}^{-1}\cdot\text{kg}^{-1}$  [108]. These observations indicate that the relatively low oxygen consumption during fetal life is due to the low requirement and not to inadequate oxygen supply. The low energy requirement may be related to the restricted activity in utero and to the fact that fetal body temperature is maintained by the mother [102]  $\rightarrow$  [108].

The rate of umbilical blood flow provides a margin of safety for the fetus against acute reduction in umbilical blood flow. Decreasing the umbilical blood flow and oxygen delivery has little effect on total oxygen consumption until the umbilical blood flow is reduced to 50%–60% of normal flow (Fig. 9.9) [61, 110]. Maintenance of oxygen consumption, and thus aerobic metabolism, during acute reductions in umbilical blood flow is achieved by increasing the amount of oxygen extracted by the fetus (Fig. 9.10) [61]. When umbilical blood flow is reduced to 25% of normal, the fetus extracts up to 75%–80% of the oxygen delivered but cannot maintain normal consumption.

**Fig. 9.9.** Correlation of umbilical blood flow with fetal oxygen consumption. (Reprinted from [59] with permission)

**Fig. 9.10.** Fetal oxygen extraction before (*open circles*) and during (*closed circles*) partial cord occlusion. (Reprinted from [59] with permission)

When reductions in umbilical blood flow of about 35%–40% are maintained for several days or weeks, fetal growth decreases from a normal value of about 4% per day to about 2% per day [110]. These observations indicate that with regard to long-term effects of reduced umbilical blood flow on fetal growth there

is little margin of safety in fetal umbilical blood flow [110, 111].

For technical reasons, chronic studies of fetal circulation have been confined to late pregnancy. Only recently have circulatory and metabolic studies of the fetal lamb at midgestation been reported [106, 112].

**Table 9.3.** Umbilical blood flow and fetal oxygen consumption

Subject	Umbilical blood flow ( $\text{ml} \cdot \text{min}^{-1} \cdot \text{kg}^{-1}$ )	$\text{O}_2$ consumption ( $\text{ml} \cdot \text{min}^{-1} \cdot \text{kg}^{-1}$ )
Human		
Late gestation	120	?
Midgestation	180	?
Sheep		
Late gestation	200	7.5
Midgestation	470	10.9

**Fig. 9.11.** Partition of fetal energy requirement between growth and oxidative metabolism during mid and late gestation. (Reprinted from [106] with permission)

In relation to fetal weight, umbilical blood flow is more than double the normal values for the mature fetus (Table 9.3). Fetal oxygen consumption is greater at midgestation than at late gestation, probably reflecting accelerated rates of protein synthesis. At midgestation the sheep fetus is growing at approximately three times the rate of the mature fetus. The total energy requirement during midgestation is 38% greater than during late gestation, although the partition of the fetal energy requirement between growth (37%) and oxidative metabolism (63%) is similar (Fig. 9.11).

### Regulation of Umbilical-Placental Circulation

The progressive rise in umbilical blood flow during gestation is accomplished by the continuous increase and growth of the number of fetoplacental vessels, as evidenced by the increasing number of endothelial cells in the fetoplacental microcirculation [34]. This statement is consistent with the observations of a progressive decrease in fetoplacental resistance to flow of about 2.8% per day [110].

The umbilical arteries are not innervated beyond the proximal 1–2 cm of the umbilical cord; they consist of several components of circular or longitudinal muscle and contain less collagen and elastin than the systemic arteries [113]. Because of the lack of innervation, the umbilical circulation has been considered to be a passive circulation in which the flow rate is determined by the mean effective perfusion pressure (i.e., the arterial-venous pressure difference) [50].

Acute hypoxemia does not change the magnitude of umbilical-placental blood flow, suggesting that hypoxemia has little or no direct effect on the umbilical-placental circulation [114, 115]. However, umbilical-blood flow may be altered by hypoxemia secondary to changes in arterial blood pressure, fetal heart rate, or the release of vasoactive agents into the systemic circulation. The umbilical-placental vasculature is constricted by certain vasoactive agents, such as prostanoids, norepinephrine, angiotensin II, and bradykinin [116, 117]. Although total umbilical-placental blood flow did not change during hypoxia, the total vascular resistance to flow increased significantly. Paulick et al. [118] measured pressures at various sites of the umbilical-placental circulation and calculated vascular resistances to umbilical-placental blood flow before and during acute hypoxemia. Total resistance to flow was calculated from placental blood flow and the change in pressure between the descending aorta and IVC. As shown in Figure 9.12, this total resistance comprises the individual resistance of: (1) the umbilical arteries and placenta; (2) the umbilical veins; and (3) the ductus venosus and liver. During the control period those individual resistances accounted for 82%, 11%, and 7%, respectively, of the total resistance to umbilical-placental flow. Hypoxemia increased resistance in the umbilical veins 2.3-fold but did not affect resistance in the umbilical arteries or placenta. Hepatic vascular resistance increased and ductus venosus resistance decreased, so the total liver/ductus venosus resistance did not change. The increased placental outflow resistance, which resides in the umbilical vein, may increase the total surface area in the placenta, improving maternal-fetal blood gas exchange.

### Cardiovascular Responses to Stress

Reduced oxygen supply is the usual cause of fetal distress. Although some of the cardiovascular responses to reduced oxygen supply are similar, observations obtained from studies in fetal lambs signify dramatic differences in vascular responses to different types of hypoxic stress.

Oxygen delivery to the uterus is a function of uterine blood flow and oxygen content of uterine blood, whereas oxygen delivery from the placenta to the fe-

**Fig. 9.12.** Sites of pressure measurements (arrows) and calculations of vascular resistance ( $R$ ) to umbilical-placental blood flow. This total resistance comprises the following individual resistances:  $R [Ao - UVp]$  resistance presented by the umbilical arteries plus placenta.  $R [UVp - PS]$  resistance across the umbilical veins.  $R [PS - IVC]$  combined resistance of the ductus venosus and liver. (Reprinted from [118] with permission)

tus is a function of umbilical blood flow and oxygen content of umbilical venous blood. In general, maternal conditions affect uterine blood flow (hypotension, obstruction of the IVC) or uterine arterial blood oxygen content (hypoxia, anemia) without affecting umbilical blood flow significantly. Fetal conditions principally influence umbilical blood flow (umbilical cord compression, hemorrhage) but may also affect umbilical venous oxygen content (anemia, polycythemia) [119]. Oxygen delivery to the fetus can be reduced experimentally by administering a low-oxygen gas mixture to the mother [120] restricting uterine [53, 97] or umbilical [59, 94] blood flows, fetal hemorrhage [92], or altering fetal hemoglobin concentration [120, 121] or its affinity for oxygen [122, 123].

### Acute Hypoxia

Circulatory adaptation to acute hypoxic stress is accomplished by changes in the distribution of cardiac output secondary to the responses of the vasculature in the various organs. In general, blood flow to the priority organs (brain, heart) increase with maintenance of oxygen delivery, whereas blood flow and oxygen delivery to organs that are less essential for immediate survival decreases [115, 116, 124].

Umbilical blood flow reduction is associated with decreased fetal cardiac output, which is closely related to the decrease in umbilical venous return; when flow

is reduced by 50%, fetal cardiac output is reduced by about 20% [94]. With maternal hypoxemia or uterine blood flow reduction, fetal cardiac output may be maintained during mild hypoxemia but decreases by about 20% with more severe hypoxia [97, 114]. The changes in distribution of fetal cardiac output and actual organ blood flows associated with umbilical blood flow reduction show several similarities, as well as a number of significant differences, when compared with the findings during maternal hypoxemia or uterine blood flow reduction. In the latter situation, the proportion of cardiac output and the actual blood flow increase to the brain and myocardium but decrease to the lungs. Whereas the percentage of cardiac output and the actual blood flow to the carcass (skin, muscle, bone) and to the splanchnic organs decrease during maternal hypoxemia or uterine blood flow reduction, they increase during cord compression (Fig. 9.13). Thus although the total umbilical-placental vascular resistance increases during cord compression, total fetal body vascular resistance does not change significantly [94]. Maternal hypoxemia and uterine blood flow reduction are associated with increased fetal body vascular resistance but with only a small change in umbilical-placental vascular resistance [97, 114, 118].

It is possible that the increase in peripheral blood flow during umbilical blood flow reduction may serve as a mechanism for augmenting venous return to the

**Fig. 9.13.** Percent change from control value of fetal combined ventricular output (CVO) and blood flow to fetal organs during hypoxemia or cord occlusion. Fetal hypoxemia was produced by administering a low-oxygen gas mixture (6%) to the ewe. Cord occlusion was produced by inflating a balloon occluder around the umbilical cord to induce a 5% decrease in umbilical flow. (Data are from Cohn et al. [114] and Itskowitz et al. [94])

heart in order to maintain cardiac output and thus systemic oxygen delivery. The patterns of venous returns within the hepatic circulation and through the foramen ovale are also altered differently by the two types of hypoxemia [94, 97]. These observations signify major differences in vascular responses in the fetus to stress, depending on the mechanism by which it is imposed.

### Chronic Stress

Restriction of placental growth results in fetal growth restriction. Owens et al. [57] examined the relation between uterine and umbilical blood flows to fetal growth rate when placental growth is restricted from the beginning of sheep pregnancy by excising uterine implantation sites (carunclectomy). They found that fetal development proceeds at rates that maintain the normal relation between growth, blood flow, and substrate supply. Although significant reductions in total blood flow were observed, umbilical blood flow per kilogram of fetal weight and uterine blood flow per kilogram of total uterine contents were not significantly different than those in control ewes and their fetuses. The response of the fetus and placenta is different when uterine blood flow is restricted at a later stage during pregnancy. This is indicated by the observation that embolization of the uterine circulation after the placenta has attained its maximal weight resulted in fetal growth restriction. However, umbilical blood flow normalized to fetal weight was also reduced [56, 58].

We know a great deal about fetal circulatory responses to acute hypoxemia, but much less is known about the circulatory adaptations to chronic stress. It is unlikely that circulatory responses to acute hypox-

emia are sustained when the oxygen supply to the fetus is reduced over a long term. According to the limited information available, there appears to be some preferential flow to certain vital organs (brain, heart) that helps preserve their weight and cellular composition [56, 125–130]. The decreased perfusion of peripheral tissues and splanchnic organs reportedly associated with acute hypoxemia are not necessarily a feature of prolonged fetal distress. Prolonged hypoxemia is associated with growth retardation and changes in the pattern of tissue growth. The physiologic adjustments performed by the fetus in order to maintain its development are only superficially understood.

# Umbilical Doppler Velocimetry: Normative Data and Diagnostic Efficacy

Dev Maulik

The umbilical artery was the first fetal vessel to be evaluated by Doppler velocimetry and has since become the most widely investigated component of the fetal circulation. The attention paid to this vessel may be explained partly by its ready accessibility to Doppler interrogation, even without guidance by duplex imaging, and because it is a vital component of the fetal circulation, acting as the lifeline between the fetus and the placenta. Numerous studies have reported the methodology of Doppler interrogation of the umbilical artery and have elucidated the factors that modulate the umbilical arterial Doppler indices under normal conditions. This chapter describes the procedure of Doppler sonography of the umbilical circulation and reviews the normative data on the umbilical arterial Doppler indices.

## Doppler Interrogation of the Umbilical Artery

Doppler interrogation of the umbilical arterial circulation is a relatively simple procedure that does not require a large block of time. Consistent with the general approach for conducting fetal surveillance tests, the mother should be counseled regarding the reason for the test, the nature of the information generated by the device, its reliability and safety, and other relevant issues. Similar to the practice for fetal heart rate monitoring, the mother lies in a semirecumbent position with a slight lateral tilt, which minimizes the risk of developing supine hypotension syndrome due to caval compression. The examination should be conducted only during fetal apnea and in the absence of fetal hiccup or excessive movement. Umbilical arterial circulation is amenable to interrogation by either a continuous-wave Doppler device or a pulsed-wave Doppler duplex system. The procedure of Doppler insonation varies with the choice of Doppler mode.

### Continuous-Wave Doppler Interrogation

Continuous-wave Doppler interrogation of the umbilical artery is one of the simplest procedures available for fetal surveillance. However, it is now seldom used

in clinical practice. The procedure is conducted using a freestanding Doppler instrument with an integrated fast Fourier transform-based spectrum analyzer. The transducer is usually a pencil-shaped probe with an operating frequency of 2–4 MHz. The transducer is placed on the mother's abdomen overlying the fetus with an acoustic coupling jelly intervening between the transducer face and the maternal abdominal skin. The method is similar to that used for listening to fetal heart tones with the simpler Doppler devices. The transducer is systematically manipulated to obtain the characteristic Doppler frequency shift waveforms from the umbilical artery, which is seen on the device display. The process of identification is facilitated by listening to the typical audible sound of the Doppler shift. The process of Doppler pattern recognition is relatively simple, can be readily mastered, and is not prone to significant subjective variations. Complete Doppler interrogation of the cord can be ensured by obtaining the umbilical venous Doppler signals simultaneously with the arterial signals (Fig. 10.1).

**Fig. 10.1.** Continuous-wave Doppler interrogation of umbilical vessels. Doppler frequency shift recordings *above* the baseline are derived from the umbilical arteries, and those *below* the baseline are from the umbilical vein

## Pulsed-Wave Doppler Interrogation

Pulsed Doppler sonography has become the most frequently used mode for umbilical arterial interrogation. With a pulsed-wave duplex Doppler system, an obstetric scan is initially performed, and loops of the umbilical cord are identified. Unlike the continuous-wave mode, pulsed-wave Doppler insonation permits selection of the location in the cord for interrogation. As discussed below, the site of interrogation in the cord affects the configuration of the Doppler waveform. Usually a free-floating portion of the cord is insonated. The cursor line representing the beam path is aligned to intersect the selected portion of the cord, and the Doppler sample volume is placed in that location. The Doppler mode is then activated, and the umbilical arterial Doppler waveforms are obtained (Fig. 10.2).

## Doppler Display and Archiving

The Doppler waveforms are exhibited on the video monitor of the continuous-wave or the duplex device. Being generated in real time, the waveforms are scrolled from right to left on the screen. The screen is frozen when appropriate signals are displayed, and the desired measurements are performed on these waveforms. Usually, three to five waveforms are measured, and the individual results are averaged and shown on the screen. The display along with the results can be printed, and the print, can be archived. The display and results may also be saved on a video tape recorder when a duplex system is used and on an audio tape recorder when continuous-wave insonation is used.

## Descriptor Indices of the Umbilical Arterial Doppler Waveform

The Doppler frequency shift information from the umbilical artery is predominantly utilized to assess downstream impedance in the fetoplacental vascular bed. As discussed in Chap. 4, it is accomplished by calculating indices that analyze the pulsatility of the waveform in an angle-independent manner. Of the numerous indices described in the literature, the systolic/diastolic (S/D) ratio, resistance index (RI), and pulsatility index (PI) are most commonly used in clinical practice. The relative merits of the commonly used indices are discussed in Chap. 4.

The comparative diagnostic efficacy of the above Doppler indices and the diastolic/average (D/A) ratio for predicting adverse perinatal outcome was investigated by Maulik and associates [1] in a prospective blinded study in a high-risk pregnancy population. A continuous-wave Doppler device with a 4-MHz transducer was used. The analytic technique consisted of the receiver operating characteristic (ROC) method, which evaluates a test's ability to discriminate the diseased from the nondiseased population. The ROC curves showed that the RI had the best discriminatory ability when compared with other Doppler indices, and the PI fared the worst (Fig. 10.3). The area under the ROC curve of these indices showed that these differences were statistically significant (Table 10.1). Despite its limitations, the S/D ratio remains the most widely used Doppler index for evaluating the fetal circulation, especially for umbilical ar-

**Table 10.1.** Receiver operating characteristic curve areas of Doppler indices (modified from Maulik et al. [1])

Indices	Area $\pm$ SE	Significance ( <i>p</i> ) of the difference in the ROC areas		
		vs S/D	vs D/A	vs PI
RI	0.921 $\pm$ 0.021	<0.05	<0.05	<0.001
S/D	0.905 $\pm$ 0.019	>0.05	>0.05	<0.001
D/A	0.887 $\pm$ 0.029			<0.006
PI	0.803 $\pm$ 0.023			

SE, standard error; ROC, receiver operating characteristic; RI, resistance index; S/D, systolic/diastolic ratio; D/A, diastolic/average ratio; PI, pulsatility index.

terial hemodynamics. Such usage is attributable mostly to widespread knowledge of the S/D ratio within the obstetric community and to the apparent simplicity of the index. In practice, the choice of an index may not significantly affect the clinical efficacy of an umbilical arterial Doppler investigation.

### Reproducibility of Umbilical Arterial Doppler Indices

A critical factor to the utility of a test is its precision, which is defined as the degree to which a measured variable is reproducible. The reproducibility of a Doppler index is determined by all factors that contribute to the variance of that index (see Chap. 4). The variance is affected by hemodynamic and nonhemodynamic factors [2]. The hemodynamic factors may be physiologic, such as gestational age-dependent changes and those associated with fetal breathing, or pathologic, such as maternal preeclampsia or fetal growth restriction. The nonhemodynamic factors constitute the error component, which includes intra- and interobserver variations. Although the latter factors are important when considering the precision of the technique, hemodynamic variations are the principal determinations of the variance of the umbilical Doppler indices [2].

Maulik and colleagues [2] prospectively investigated the reproducibility of the umbilical arterial Doppler indices (S/D ratio, RI, PI, D/A) in terms of the proportion of variance attributable to intra- and interobserver errors. A continuous-wave Doppler instrument with a 4-MHz transducer was used. The analytic method involved determination of the intraclass correlation using analysis of variance. For the various indices, the proportion of total variance attributable to intra- and interobserver errors varied between 4% and 8% and 9.8% and 14.3%, respectively. These results are comparable to those of other investigators [3–7] and are summarized in Table 10.2. As is evident, umbilical

**Table 10.2.** Reproducibility of the umbilical arterial Doppler indices

Study	Doppler index	Interobserver		Intraobserver	
		Reliability	Variation (%)	Reliability	Variation (%)
Schulman et al. [3]	S/D				6

arterial Doppler indices demonstrate satisfactory precision for clinical applications.

### Continuous-Wave Versus Pulsed-Wave Doppler Indices

Although one may not expect any discrepancy between the Doppler indices obtained by continuous-wave or pulsed-wave Doppler interrogation, in practice there are enough differences between these techniques to warrant an objective inquiry into the issue. Brar and associates [8] compared the S/D ratios obtained by continuous-wave and pulsed-wave Doppler ultrasonography from the umbilical artery in high-risk pregnancies during the third trimester and found no significant difference in the mean S/D ratios obtained by either method for the entire population (continuous-wave S/D  $2.81 \pm 1.79$ , pulsed-wave S/D  $2.71 \pm 1.83$ ;  $r=0.98$ ), the normal group (continuous-wave S/D  $1.96 \pm 0.41$ , pulsed-wave S/D  $1.95 \pm 0.40$ ,  $r=0.91$ ), or the abnormal group (continuous-wave S/D  $6.23 \pm 1.58$ , pulsed-wave S/D  $6.35 \pm 1.52$ ,  $r=0.94$ ). Mehalek and coinvestigators [9] also observed no significant differences ( $p > 0.05$ ) between the continuous-wave and pulsed-wave Doppler devices when measuring the peak S/D ratios in the umbilical arteries. The S/D ratios of the umbilical artery measured by each device showed a strong correlation, whether measured by one observer ( $r=0.93$ ) or two observers ( $r=0.89$ ). Most other investigations corroborated this finding [5, 10].

In contrast to the above investigators, van Vugt and coinvestigators [11] found that the AB ratio (same as the S/D ratio), RI and PI were slightly higher for the continuous-wave Doppler system compared to the pulsed-wave Doppler system, but not significantly ( $p=0.18$ ,  $p=0.21$ , and  $p=0.44$ , respectively). The authors speculated that the difference in the signal-to-noise ratio (S/N ratio) between the pulsed-wave and continuous-wave Doppler systems was the reason for the discrepancy. Jorn and associates [12] also observed differences between duplex pulsed Doppler and nonduplex continuous-wave and pulsed-wave Doppler systems in terms of their clinical efficacy. The sensitivity was higher with the simple nonduplex Doppler technique (74.3% versus 52.9%), whereas the specificity was higher with the duplex Doppler technique (77.9% versus 52.6%). The authors thought that this finding was attributable to the inability to localize the vessel precisely using the simpler stand-alone Doppler devices. Gaziano and colleagues [13] reported the use of a threshold value of 4.5 for the umbilical arterial S/D ratio derived with pulsed duplex Doppler ultrasonography. This value is considerably higher than the common S/D ratio cutoff value of 3.0 obtained by continuous-wave Doppler insonation.

Despite these differences, most investigators use the same discriminatory threshold values for the Doppler indices irrespective of the type of Doppler instrumentation. Whether it is justifiable remains an open question.

### Site of Doppler Interrogation

Introduction of duplex pulsed Doppler ultrasound for interrogation of umbilical arteries allowed determination of the sampling site in the umbilical cord. Utilization of this approach led to the realization that the site of Doppler sampling in the umbilical cord may contribute significantly to variations in the Doppler indices. Several studies addressed this issue specifically. Most observed that the location of the Doppler sampling site in the umbilical cord affects the Doppler waveform and is reflected in the Doppler indices, which are higher at the fetal abdominal end of the cord than at this placental end [14, 15]. Abramowicz and coinvestigators [15] studied the effect of the examination site in 30 normal pregnancies and noted statistically significant differences ( $p < 0.01$ – $< 0.0007$ ) in the umbilical arterial S/D ratio between the two measurement sites. The values (mean  $\pm$  standard deviation) at the placental insertion ranged from  $4.2 \pm 0.4$  at 17–20 weeks to  $2.1 \pm 0.5$  at 37–40 weeks. The corresponding values at the fetal abdominal end were  $6.1 \pm 0.8$  and  $3.3 \pm 0.5$ , respectively. In comparison, the continuous-wave Doppler interrogation, which was blind to the site of sampling in the cord, generated values of  $4.8 \pm 1.3$  and  $2.3 \pm 0.3$ , respectively.

Maulik and associates [2] prospectively investigated the components of variance and error contributions of umbilical arterial Doppler indices in a normal pregnant population (308 mothers) with gestational ages ranging from 27 to 40 weeks. In 46 women, duplex pulsed Doppler ultrasound was used to interrogate the placental and fetal ends of the cord. The study demonstrated that the site of measurement was a significant source of variance; the PI was affected the most and the D/A ratio the least (Table 10.3). The effect of the measurement site on the umbilical arterial indices was confirmed by Mehalek and colleagues [15] who performed pulsed umbilical arterial Doppler duplex sonography on 58 patients and noted that the Doppler indices were significantly higher at the fetal end of the cord than at the placental end. Because of the dependence of the indices on the size of interrogation, most investigators emphasize the importance of identifying the sampling location in the cord when duplex pulsed Doppler ultrasound is used. Obviously, this point is not an issue with continuous-wave Doppler insonation without the imaging guidance.

**Table 10.3.** Location of measurement and reliability of Doppler indices (modified from Maulik et al. [1] with permission)

Doppler index	Reliability coefficient (%)	Error variance (%)
D/A	71	29
S/D	62	38
PI	54	46
RI	68	32

D/A, diastolic/average ratio; S/D, systolic/diastolic ratio; PI, pulsatility index; RI, resistance index.

The mechanism of this phenomenon was investigated by Vиейres and coinvestigators [16] in a computer model, which showed that placental resistance is the primary factor for the observed differences between the Doppler waveforms from the placental end and from the fetal end of the cord, whereas viscosity and cord length have secondary influences. The phenomenon may be explained more adequately by the concept of impedance and wave reflection (see Chap. 4). The fetoplacental vascular bed is a low-impedance system associated with minimal wave reflection, which explains the presence of continuing forward flow in the umbilical artery during diastole. The closer the measurement site is to the placenta, the less the wave reflection and the greater the end-diastolic flow. Consequently, the Doppler waveform that represents arterial flow velocity demonstrates progressively declining pulsatility and the indices of pulsatility, such as the RI or the S/D ratio.

Not all studies, however, agree with the above findings. Ruissen and associates [17] observed that although the PI values differed among the various locations in the umbilical artery (within the fetal abdomen, 0–5 cm from the origin of the umbilical cord, in the free-floating part, 0–5 cm from its insertion in the placenta) no unequivocal tendency or statistically significant difference in the PI could be demonstrated. The authors concluded that possible variations in the Doppler waveform along the course of the umbilical artery have no clinical relevance in uncomplicated pregnancies.

### Short-Term Temporal Variations: Diurnal Effect

Short-term temporal variations in the umbilical arterial Doppler indices may affect their reproducibility and efficacy and should be taken into account when interpreting changes in the indices. FitzGerald and associates [18] failed to observe any appreciable diurnal changes in the umbilical arterial Doppler wave-

form. This point was further investigated by Hastie and colleagues [19], who recorded umbilical arterial Doppler indices on 3 days in each of 97 women within a 7-day period. No significant day-to-day variations ( $p > 0.05$ ) were noted in the S/D ratio or the PI over the period of study. The degree of variability was greater before 30 weeks' gestation. It appears that after 30 weeks' gestation diurnal variations in the umbilical arterial Doppler indices have a range of daily variability acceptable for clinical or research applications.

### Long-Term Temporal Variations: Gestational Age Effect

As gestation advances, umbilical arterial Doppler waveforms demonstrate a progressive rise in the end-diastolic velocity (Fig. 10.4). This phenomenon was first described by Stuart and associates [20]. The gestational age at which end-diastolic velocity may be first noticed in the umbilical arterial circulation depends on the examination technique. It is imperative to ensure that the high-pass filter is either turned off or set at the lowest value irrespective of the sonographic approach. In addition, the use of transvaginal Doppler sonography with color flow-assisted pulsed-wave Doppler interrogation significantly improves our ability to identify the end-diastolic velocity during early pregnancy.

Arduini and Rizzo [21] utilized color Doppler-guided transvaginal spectral Doppler sonography and demonstrated that the end-diastolic forward flow may be present in the umbilical artery as early as 10 weeks' gestation. After week 10 the proportion of cases with end-diastolic forward flow progressively increased with the advancing gestation and it was present in almost all cases by about 15 weeks. At this early stage the phenomenon was not noted during every cardiac cycle, although the percentage of cardiac cycles in which end-diastolic velocities were present increased with the progression of pregnancy. In this preliminary experience, the authors found no association between the PI and the later development of pregnancy complications. Other investigators also noted the presence of end-diastolic velocity in the umbilical artery by 15 weeks [22].

Early investigators, utilizing the transabdominal approach, noted the universal presence of the end-diastolic velocity by about 22 weeks' pregnancy [23]. However, the high-pass filter was set at 200 Hz, which is unacceptably high for this application. Our own experience with transabdominal duplex pulsed-wave Doppler insonation indicates that end-diastolic velocity is detectable at the placental end of the cord in most cases by about 18 weeks' gestation. Thereafter

**Fig. 10.4 a–g.** Gestational age effect on the umbilical arterial Doppler frequency shift waveforms. Panels are organized from *top to the bottom* according to the advancing gestation. **a** Waveforms at 16 weeks. **b** At 20 weeks. **c** At 24 weeks. **d** At 28 weeks. **e** At 32 weeks. **f** At 36 weeks. **g** At 40 weeks. Note the progressive increase in end-diastolic velocity and the concomitant fall in pulsatility as the gestation advances

the end-diastolic velocity continues to increase throughout the pregnancy, which is expressed by the umbilical arterial Doppler indices (Fig. 10.5). The indices that reflect the Doppler wave pulsatility, such as the RI, S/D ratio, and PI, continue to decrease, whereas the D/A ratio, which is the normalized end-diastolic frequency shift, continues to increase. In a prospective study involving 308 normal pregnant mothers, Maulik and associates [2] quantified the contribution of the duration of pregnancy to the total variance of the umbilical arterial Doppler indices. It was observed that the gestational age was the single major contributor to the total variance of the indices, ranging from 33% for the PI to 46% for the S/D ratio.

These trends in the Doppler waveform are consistent with the crucial physiological changes that occur in the fetoplacental circulation characterized by the gestational age-dependent decline in the fetoplacental flow impedance [24]. Anderson and Faber [25] estimated that the fetoplacental circulatory resistance in the ovine fetus decreased by 2.8% per day, and during the last third of pregnancy the decrease in resistance was calculated to be tenfold.

The controlling mechanism for this phenomenon remains uncertain. It has been shown in human placental studies that there is continuing expansion of the fetoplacental vascular system throughout the pregnancy [26]. Furthermore, the villous vascular system undergoes a transformation, resulting in the appearance of sinusoidal dilation in the terminal villous capillaries as pregnancy approaches term, and more than 50% of the stromal volume may be vascularized. The progressive decrease in fetoplacental flow impedance is associated with a concomitant decline in the flow wave reflection from the downstream vascular bed, which results in an increase in the end-diastolic velocity. The latter ensures continuing forward flow and perfusion of the fetal placenta during the entire cardiac cycle.

## Fetal Heart Rate

Heart rate influences the configuration of the arterial Doppler waveform (see Chap. 4). Thompson and colleagues [27], did not observe any significant effect of fetal heart rate on the umbilical arterial S/D ratio. The correlation between the fetal cardiac cycle, which is the reciprocal of the heart rate, and the S/D ratio was poor ( $r=0.1$ ). Other Doppler indices (PI and RI) demonstrated a similar relation with the heart rate. This finding was contradicted, however, by Mires and associates [28], who specifically investigated the relation between fetal heart rate and the umbilical arterial Doppler indices in 85 normal pregnancies: 25 of

**Fig. 10.5a-d.** Changes in the Doppler indices with the progression of gestation. Changes in S/D, PI, RI, and D/A

are depicted in **a**, **b**, **c**, and **d**, respectively. See legend to Fig. 10.4 for abbreviations. (From [52] with permission)

the women were antepartum and 60 were in labor. Among the antepartum patients, both the S/D ratio and RI had a significant correlation with heart rate ( $r = -0.49$ ;  $p < 0.02$ ). The intrapartum mothers demonstrated a similar significant negative correlation between the heart rate and the indices ( $r = -0.65$ ;  $p < 0.001$ ). A heart rate variation of 117 and 162 bpm resulted in corresponding S/D ratio values of 2.0 and 2.8, respectively. The effect was more pronounced with a wider range of heart rate. For example, when the latter varied between 90 and 175, the S/D ratio changed from 3.4 to 1.7. Thus significant changes in the indices may occur, not because of any changes in the impedance but due to changes in the fetal heart rate, especially when bradycardia is present. Mires et al. concluded that it is important to correct the indices by changing the fetal heart rate.

To address this contradiction, a prospective study was undertaken by Yarlagadda and colleagues [29]. The population consisted of 194 mothers with uncomplicated pregnancies and gestational ages ranging from 27 to 39 weeks. Linear regression of the data grouped in 2-week intervals demonstrated a moderate but statistically significant ( $p < 0.05$ ) correlation between the fetal heart rate and the umbilical Doppler indices. The influence of the heart rate on the indices

was then further analyzed by a multiple regression technique, which demonstrated that 15%–18% of the total variance of the indices was attributable to fetal heart rate effect. Moreover, when the Doppler indices were standardized for a heart rate of 140 bpm and a gestation of 34 weeks, using a multiple regression-based equation the 95% limits of the umbilical artery Doppler indices were reduced by 32%, 34%, 26%, and 32% for D/A, S/D, PI, and RI, respectively. This study corroborated the findings of Mires and coinvestigators [28], that the fetal heart rate significantly influences umbilical arterial Doppler indices.

The mechanism of the heart rate effect on the Doppler indices is discussed in Chap. 4. To recapitulate briefly, it is well recognized that when the heart rate drops the diastolic phase of the cardiac cycle is prolonged and the end-diastolic frequency shift declines. These changes are reflected in the Doppler indices that depict the pulsatility of the Doppler waveform. It has been reconfirmed [30, 31] that the diastolic time is the main component of the changes in the duration of a cardiac cycle (see Chap. 4) and that the effect of the heart rate changes on the Doppler indices is mediated predominantly through the diastolic phase of the cardiac cycle. There is also evidence that the fetal heart rate may affect the ability of

the Doppler waveform analysis to reflect completely the changes in the downstream impedance [32].

It remains controversial, however, whether correcting the indices for fetal heart rate improves their diagnostic efficacy when the baseline heart rate remains within the normal range. The general consensus is that although the Doppler indices are affected by the fetal heart rate it may not be a significant factor when the rate is within the normal range. For example, Mansouri and colleagues [33] observed in uncomplicated pregnancies that an upper limit of 3.0 for a normal umbilical artery peak S/D ratio was acceptable only if the instantaneous fetal heart rate was 130 bpm or higher. Similarly, Ruhle and coinvestigators [34] found few variations in the umbilical arterial S/D ratio within the normal range of fetal heart rate (120–160 bpm). Most investigators therefore do not recommend correction of the indices for the heart rate.

## Breathing

Substantial changes in the intrathoracic pressure and central hemodynamics occur during fetal breathing, leading to dynamic variations in the umbilical arterial Doppler waveform and Doppler indices (Fig. 10.6). The effect of fetal breathing on umbilical arterial indices has been recognized from the early days of Doppler velocimetry and led to the recommendation that the indices should be measured only during fetal apnea [35]. Fetal breathing movement-induced changes in cardiovascu-

lar function were originally reported in the fetal lamb preparation by Dawes and associates [36]. The initiation of rapid, irregular respiratory movement in the fetal lamb was often associated with tachycardia and hypertension. Vigorous breathing led to increases in the arterial pressure of as much as 20%. However, transient falls in arterial pressure were also seen coinciding with decreases in the intrathoracic pressure. In addition, there were significant variations in the aortic flow, which declined to 400 ml/min and rose to 900 ml/min from a mean of 650 ml/min.

Chiba and coworkers [37] were the first to report changes in the human fetal venous circulation during fetal breathing movements. Using pulsed-wave Doppler ultrasound combined with real-time B-mode imaging, these investigators demonstrated that the umbilical venous blood flow increased with fetal inspiration (during which the fetal abdominal wall moved inward) and decreased with expiration (during which the wall moved outward). Koppelaar and Wladimiroff [38] compared the effect of breathing on the umbilical venous and arterial Doppler waveforms and noted that, in contrast to venous flow velocity, the magnitude of breathing-related modulation of arterial pulsatility was small and independent of breathing amplitude.

In addition to the avoidance of umbilical Doppler interrogation during fetal breathing, there are practical issues to consider. The effect of breathing on the variability of the indices was addressed by Spencer and associates [39], who demonstrated that even dur-

**Fig. 10.6.** Fetal breathing and umbilical arterial Doppler waveforms. Observe the dynamic variations in the arterial and venous Doppler tracings

ing the breathing episodes deriving the indices from a minimum of six waveforms ensured coefficients of variation of 10% or less. The issue of the need to use duplex imaging to ensure fetal apnea was addressed by Hoskins and coinvestigators [40], who showed that when stand-alone continuous-wave Doppler units are used to acquire umbilical artery Doppler waveforms during fetal apnea, the presence of apnea can be ascertained using the variability of the arterial and venous trace without using imaging equipment. Our own experience corroborates this finding.

## Behavioral States

Behavioral states may be defined as the neurobiologic functional conditions, exemplified by sleep or wakefulness. These states are characterized by multiple parameters, including open or closed eyes, eye movement, body movement, breathing, and heart rate activity. Prechtl and Bientema [41] were the first to describe the various behavioral states in neonates. For the human fetus four behavioral states were described by Nijhuis and coworkers [42] based on fetal eye and body movements and the heart rate. Of these states, the quiet sleep state (1F) and the active sleep state (2F) are important considerations for fetal cardiovascular function.

Mulders and associates [35] investigated the effect of fetal behavioral states on 19 normal pregnancies between 37 and 39 weeks' gestation. The fetal heart rate pattern was used to determine states 1F and 2F. The umbilical arterial PI was noted to be higher during the 1F periods than during 2F. This difference disappeared when the effect of the heart rate was taken into account by normalizing all PI values to the standard heart rate value of 140 bpm. This question was further investigated by van Eyck and coinvestigators [43], who utilized simultaneous measurements of fetal heart rate and eye and body movements. The PI values for states 1F and 2F demonstrated no significant differences and considerable overlaps. This insensitivity of the umbilical arterial circulation to behavioral state implies that behavioral states should not be considered when measuring the umbilical arterial Doppler indices.

## Blood Viscosity and Doppler Indices

Viscosity is an attribute of a fluid that reflects its intrinsic resistance to flow. Blood viscosity is a complex phenomenon and is dependent on the plasma and the formed elements. The contribution of viscosity to impedance to flow is defined by Poiseuille's law. With certain pregnancy disorders (e.g., preeclampsia) fetal

blood viscosity has been shown to be increased [44]. The influence of fetal blood viscosity on the umbilical arterial Doppler indices was studied by Giles and Trudinger [45], who observed significantly ( $p < 0.01$ ) higher blood viscosity at high shear in the high-risk group with abnormal Doppler indices. The investigators, regrettably, did not consider the possible effect of gestational age in this analysis. Steel and coinvestigators [46] investigated the contribution of viscosity to the impedance of blood flow in the umbilical artery as determined by the RI for 31 pregnancies complicated by preeclampsia, intrauterine growth restriction, or both and 20 normal pregnancies. The authors found a significant correlation between the RI and both plasma viscosity and gestational age. Furthermore, 55% of the variance seen in the RI could be explained by plasma viscosity. The major determinants of fetoplacental flow impedance, however, were peripheral vascular factors, not whole-blood viscosity. It may be concluded, then, that the viscosity of fetal blood need not be considered when interpreting the umbilical arterial Doppler indices.

## Maternal Posture and Umbilical Arterial Doppler Indices

Most biophysical fetal surveillance tests, including electronic fetal heart rate monitoring, the biophysical profile examination, and Doppler interrogation of the fetal circulation, are performed with the mother in the semirecumbent position with left lateral tilt so the risk of supine hypotension is minimized. For Doppler testing this protocol is implemented on an empiric basis. The effect of maternal posture on the umbilical arterial Doppler indices, however, has been investigated. Kinsella and coinvestigators [47] assessed maternal and fetal cardiovascular effects of position change in 20 women in late pregnancy. On changing from the left lateral to the supine position, there was a 45% reduction in leg blood flow but no changes in femoral, brachial, or uterine arterial resistance as measured with Doppler ultrasonography. The leg blood pressure also did not change, indicating the absence of significant aortic compression. The maternal heart rate increased in the supine position, however, suggesting the presence of inferior vena caval compression. Notably, the fetal heart rate and umbilical Doppler indices did not vary with maternal postural change. The effect of posture was investigated more extensively by Sorensen and associates [48], who studied the effects of orthostatic stress and maternal hemodynamics on the umbilical arterial S/D ratios in normal and hypertensive pregnancies. Although all mothers demonstrated a decline in cardiac output and increased total peripheral resistance

on standing, there was no change in the S/D ratio in normotensive patients when they were moved to the upright position. In contrast, the ratio significantly increased with a postural change in hypertensive patients and was more pronounced with high resistance hypertension.

## Maternal Exercise and Umbilical Arterial Doppler Indices

The fetal circulatory response to maternal hemodynamic stress secondary to maternal exercise may be an important consideration when timing a fetal Doppler investigation. Several investigators have addressed this issue [49–51]. All of these studies, which employed some form of bicycle ergometry, demonstrated an exercise-induced response in the maternal cardiovascular system. The fetal cardiac chronotropic response was variable. Often the response was tachycardia, although a lack of variation was also noted. Most studies failed to show changes in the umbilical arterial Doppler indices. When such changes were noted, they were associated with fetal heart rate alterations. From these investigations it appears that mild to moderate exercise does not affect flow impedance in the umbilical artery independent of changes in the fetal heart rate.

## Summary

The umbilical arterial circulation is readily accessible to continuous-wave and pulsed-wave Doppler interrogation. The procedure is relatively simple. The variance of umbilical arterial Doppler indices is affected by both hemodynamic and nonhemodynamic factors. The latter represent the error component of the measurement and are attributable to observer and probably instrumental factors. The hemodynamic factors include physiologic and pathologic phenomena. Of the former, the gestational age, fetal breathing, fetal heart rate, and site of measurement are the most important contributors.

# Fetal Descending Aorta

Karel Maršál

The first reports on Doppler recordings of blood velocity signals from the umbilical artery [1, 2] stimulated attempts to record blood flow in fetal vessels. In 1979 Gill presented a method combining a quasi-real-time imaging and pulsed-wave Doppler technique for estimating the volume flow in the intraabdominal part of the umbilical vein [3]. The ultrasound system used (Octoson, Ultrasonic Institute, Millers Point, Australia) did not allow the recording of high blood velocities owing to the low repetition frequency of the Doppler ultrasound pulses (2 kHz) necessitated by the long distance between the ultrasound transducers emerged in a water bath and the target vessel. Eik-Nes et al. [4] applied the principle of intermittently using two-dimensional and pulsed-wave Doppler ultrasound by combining a linear array scanner and a 2-MHz Doppler velocimeter [4]. The two transducers were mounted firmly to a unit with an inclination of the Doppler transducer of  $45^\circ$  to the linear array transducer. By placing the linear array transducer on the maternal abdomen so it was parallel with a sufficiently long portion of the vessel of interest, insonation by Doppler ultrasound under a known angle ( $45^\circ$ ) was achieved and thus the possibility of correcting the recorded mean blood velocity for the insonation angle (Fig. 11.1).

With the above arrangement, the Doppler transducer could be located relatively close to the fetal body, and so a high repetition rate (9.75 kHz) of Doppler pulses could be used. This technique allowed velocities up to 1.7 cm/s to be detected down to a depth of 6.5 cm [5], and the first recordings of blood velocity signals from the fetal descending aorta were obtained [4]. Unfortunately, during these first recordings a high-pass filter with a cutoff frequency of 600 Hz was employed, in agreement with the experience from Doppler recordings in the adult aorta, where it is necessary to eliminate disturbing low-frequency Doppler shift signals from the vessel walls. This technique caused an erroneous appearance of the fetal aortic velocity waveforms noted in the two first reports [4, 5] with only systolic velocities present. Today such waveforms would be recognized as highly abnormal [6]. The estimated time-averaged mean velocity was also influenced by erroneous high-pass filtering of

**Fig. 11.1.** Doppler velocimetry of fetal descending aorta: original method combining a linear array real-time scanner and a 2-MHz pulsed Doppler instrument according to Eik-Nes et al. [4]. The Doppler transducer is firmly attached to the linear array transducer at an angle of  $45^\circ$  (*a*)

Doppler signals; consequently, the calculated values of the volume flow cannot be considered reliable.

The Malmö research group, at that time including Sturla Eik-Nes, evaluated and further developed the Doppler method for estimating fetal aortic blood flow. In an experimental study comparing the electromagnetic and Doppler measurements of aortic flow in pigs, the artificial distortion of the aortic signals was recognized [7]. This discovery enabled correction of the original reports on fetal aortic flow and the recommendation of not using a high-pass filter with a cutoff frequency higher than 100 Hz.

For recording Doppler shift signals from the fetal descending aorta, a duplex system combining pulsed Doppler ultrasound and real-time imaging is necessary to localize the vessel and to precisely position the sample volume. Duplex ultrasound systems employing a sector scanner are most often used for Doppler examinations of the fetal circulation. They are less suitable for fetal aorta examination owing to the difficulty of ensuring an acceptable (i.e.,  $<60^\circ$ ) insonation angle. Figures 11.2–11.4 demonstrate the problems of obtaining a good image of a sufficiently long portion of the fetal descending aorta and at the same time an acceptable angle of insonation by Doppler ultrasonography.

**Fig. 11.2.** Recording of fetal aortic velocities with a duplex ultrasound system including a sector scanner and a pulsed and color Doppler mode. A good image of the fetal descending aorta is obtained. The insonation angle for Doppler ultrasound is close to  $90^\circ$ , however, which gives no or low amplitude shift signals in the spectral Doppler mode and no color in the color Doppler mode

**Fig. 11.3.** Fetal descending aorta in an oblique projection illustrates the difficulty of obtaining a suitable angle of insonation for Doppler recording of aortic velocities with a duplex sector scanner

Thus for practical reasons, systems combining a linear array transducer and pulsed Doppler may be advantageous for recording signals from the fetal aorta. As the descending aorta is an easily identified large vessel with flow in the distal direction, color flow imaging does not provide substantial help to the operator.

## Fetal Aortic Doppler Velocimetry

### Aortic Flow Estimation

The combination of the linear array real-time scanner and pulsed Doppler was originally designed to estimate volume flow in the fetal aorta from the values of

**Fig. 11.4.** Examination of the fetal descending aorta with a linear array duplex system. The color Doppler box and the pulsed Doppler beam are inclined; the insonation angle is still high

time-averaged mean velocity and the aortic diameter [4]. For correct estimation of the mean velocity, proper location of a sufficiently large sample volume is necessary; hence the whole lumen of the vessel is insonated during both systole and diastole. Furthermore, the insonation angle must be reliably controlled to enable correction of the recorded mean Doppler shift frequency. The use of a high-pass filter causes overestimation of the mean velocity. Unfortunately, because of the pulsatile character of the aortic flow and the changing velocity profile during the cardiac cycle, it is impossible to use a standard correction factor.

The errors in the velocity measurement can be kept to a minimum by meticulous performance of the examination by experienced operators who are aware of the problems noted above. Much greater risk of error is involved when measuring the aortic diameter because of the relatively low spatial resolution of the ultrasound scanners and dynamic diameter changes during aortic pulsations. Each error is squared in the calculation of the cross-sectional area of the vessel and thus has a significant impact on the resulting value of the calculated volume flow. The smaller the caliber of the vessel, the more significant the impact (Fig. 11.5).

Various methods for measuring the diameter of the fetal aorta have been used: Averaging of measurements using calipers in ten subsequently frozen images of the aorta, M-mode recording, and time-distance recording [8]. The resolution power of the time-distance recording has been improved and a special instrument developed (Diamove, Teltec, Lund, Sweden) that gives reliable measurements of the fetal aortic diameter [9]. It has been shown that recording changes in the fetal aortic diameter can provide an estimate of the changes in intrauterine blood pres-

**Fig. 11.5.** Error in flow measurements due to errors when measuring diameter of four vessels of different caliber. (Reprinted from [5] with permission)

sure. Hence this technique may have potential for research and clinical application [10].

The problems involved when estimating volume blood flow in the fetal descending aorta were elaborated in the paper by Eik-Nes et al. [11]. In a comparative study mentioned above, good agreement was found between simultaneous flow measurements in pig aorta with an electromagnetic and Doppler ultrasound method: correlation coefficient ( $r$ )=0.91 [7]. Similar good correlation was found for the descending aorta of the fetal lamb when comparing the Doppler ultrasonographic estimation of flow with electromagnetic flowmeters ( $r$ =0.93) [12] or radionuclide-labeled microspheres ( $r$ =0.94) [13]. These results were obtained under experimental conditions. Similar accuracy might be achieved in the hands of experienced operators in carefully performed physiologic studies on human fetuses near term. There is little doubt, however, that the method of estimating volume flow in the fetal aorta is open to overwhelming errors when applied in a clinical situation. Therefore the interest of clinicians and researchers has focused on waveform analysis of fetal aortic velocities.

**Fig. 11.6.** Simultaneous recording of blood velocity (upper tracing) and vessel diameter (lower tracing) from descending aorta of a healthy 30-week fetus. (Reprinted from [84] with permission)

Various ultrasound systems that allow estimation of the fetal aortic volume flow have been tested by us in vitro and in vivo – one utilizing the time-domain principle (CVI-Q, Philips Ultrasound, Santa Ana, CA) [14, 15] and the other combining on-line the time-distance recording of aortic diameter using a phase-locked echo-tracking system with the 2-MHz pulsed Doppler estimation of mean blood velocity (Fig. 11.6) [16]. Power Doppler images of the fetal descending aorta were also used for measurement of the vessel diameter to be used together with the mean velocity for calculation of volume flow [17]. All these methods necessitate further evaluation before possible clinical application.

### Aortic Velocity Waveform Analysis

Several of the errors inherent in volume flow estimation are eliminated when waveform analysis of the maximum blood velocity is used: Uniform insonation of the vessel is not as critical as it is when performing the mean velocity estimation, there is no influence of high-pass filters (so long as the diastolic velocities exceed the cutoff frequency of the filter), the waveform indices are independent of the insonation angle, and values for the aorta diameter and fetal weight are not needed. On the other hand, waveform indices do not directly represent the blood flow, and the results should therefore be interpreted with care.

The waveform of the fetal maximum aortic velocity is usually characterized by some of the waveform indices described elsewhere in this book (see Chap. 4). In hypoxic fetuses, similar to the umbilical artery waveform, diastolic velocities in the descending aorta decrease and eventually disappear or even become reversed, a condition called absent or reversed end-diastolic (ARED) flow. In 1984 Jouppila and Kirkinen [6] described the absence of diastolic velocity in the fetal descending aorta and called it a

total end-diastolic block; and in 1986 Lingman et al. [18] reported the first four cases of reversal of diastolic velocities in the fetal aorta. A semiquantitative method of assessing the waveform has been evolved for clinical use, four blood flow classes (BFCs) being defined to describe the waveform with emphasis on its diastolic part (Fig. 11.7) [19]: BFC 0 (normal), positive flow throughout the heart cycle and a normal PI; BFC I, positive flow throughout the cycle and a  $PI \geq \text{mean} + 2 \text{ SD}$  of the normals; BFC II, nondetectable end-diastolic velocity; BFC III, absence of positive flow throughout the major part of the diastole, reverse flow during diastole. More recently, a method has been developed for computerized pattern recognition of ten waveform types [20].

When evaluating the end-diastolic portion of the aortic velocity waveform, it is important for the operator to be aware of the risk of reporting a falsely absent flow. The combination of a high insonation angle and a high cutoff level of the high-pass filter included in the Doppler instrument eliminates Dop-

**Fig. 11.7.** Blood flow classes (BFC) of fetal aortic waveforms. BFC normal positive flow throughout the heart cycle and a normal pulsatility index, BFC I positive flow throughout the cycle and a pulsatility index  $\geq \text{mean} + 2 \text{ SD}$  of the normals, BFC II nondetectable end-diastolic velocity, BFC III absence of positive flow throughout the major part of diastole or reverse flow during diastole

pler shift signals of considerably high amplitude. An example of this effect is presented in Fig. 11.8. Obviously, the recommendation not to use an insonation angle of more than  $55^\circ$  and a high-pass filter higher than 100 Hz [21] is valid not only for estimating mean velocity but also for waveform analysis.

The appearance of the fetal aortic maximum velocity waveform and the values of waveform indices are independent of the direction of insonation (i.e., upstream or downstream). The position of the sample volume is important, as the waveform of aortic blood velocity changes with increasing distance from the heart. Recorded in the fetal thorax, the velocity waveform of the descending aorta shows high pulsatility

**Fig. 11.8.** Effect of insonation angle and high-pass filtering of Doppler shift signals on the aortic velocity waveform of a healthy fetus. Bottom: Combination of a high cutoff level of the high-pass filter (200 Hz) and a high insonation angle ( $60^\circ$ ) erroneously eliminates the diastolic velocities and gives the waveform a false pathologic appearance with a high pulsatility index

**Fig. 11.9.** Doppler shift spectrum recorded from the thoracic descending aorta of a healthy fetus at 28 weeks' gestation

with a low proportion of diastolic flow (Fig. 11.9); recorded in the fetal abdominal aorta, the proportion of diastolic flow increases [22]. It is therefore crucial to standardize the site of recording; typically, in the thoracic aorta the sample volume is located just above the diaphragm.

## Fetal Aortic Flow in Uncomplicated Pregnancies

Blood flow in the fetal descending aorta is characterized by high blood velocity – higher than that found in adult descending aorta [23], and the waveform of the aortic velocity is influenced by the low vascular resistance in the placenta. In the uncompromised fetus during the second half of pregnancy, aortic diastolic velocity is present throughout the cardiac cycle, the proportion of diastolic flow being higher in the abdominal than in the thoracic descending aorta [22]. Consequently, the pulsatility index (PI) [24] and resistance index (RI) [25] are typically lower in the abdominal than in the thoracic fetal aorta. The narrow spectrum of Doppler shift signals recorded from the thoracic aorta during systole indicates a fairly flat flow profile. In the abdominal aorta, lower and more dispersed frequencies can be seen owing to the change of flow profile toward a more parabolic pattern.

The time-averaged mean velocity in the thoracic descending aorta does not change significantly during the third trimester ( $35.0 \pm 5.5$  cm/s, mean  $\pm$  SD) [26], the increase in the volume flow being related to the growing aortic diameter. The volume flow corrected for fetal weight was found to be stable during late pregnancy, the reports in the literature ranging from 206 to 280  $\text{ml} \cdot \text{min}^{-1} \cdot \text{kg}^{-1}$  (Table 11.1). The mean

aortic PI was reported to range from 1.83 to 2.80 and to be rather stable until 36 weeks (Table 11.2). Thereafter a slight increase was observed toward term [22]. Concomitantly, a slight decrease in the volume flow was reported [26].

Estimation of flow at two levels of the fetal descending aorta and in the abdominal part of the umbilical vein enabled calculation of the percentual distribution of the aortic flow (Fig. 11.10). The placental proportion of blood flow in the descending thoracic aorta related to the fetal weight diminished with increasing pregnancy length: At 28 weeks it was 59% and at term 33% [26]. This finding is in good agreement with the reports of other authors, who have described the umbilical venous blood flow to be 64% [44], 55% [31] or 54% [28] of the fetal aortic blood flow from 26 weeks onward. In fetal lambs 65% of the blood flow in the descending aorta was found to be directed to the placenta [45]. The decrease in the placental proportion of the flow with the progression of pregnancy might be due to the changing ratio of fetal to placental weight [46].

The velocity waveform in the fetal aorta is subject to several influences, one of them being fetal heart function. In a study on exteriorized lamb fetuses, a strong correlation was found between the rising slope of the velocity waveform and myocardial contractility (measured as  $dP/dt$ ) in the left heart ventricle [47]. Interestingly, the next best correlation was found for the aortic PI.

Räsänen et al. [32] found in human fetuses a good correlation between the growth of the fetal heart, the lumen of the descending aorta, and aortic volume flow. The aortic velocity indices were independent of cardiac size and fractional shortening. The authors interpreted this finding as myocardial contractility that remained stable despite the changing peripheral vascular resistance so long as the changes of resistance remained within the normal range.

The nonsimultaneous measurements of pulsatile mean flow velocity and vessel diameter in the fetal descending aorta can be synchronized by transabdominal fetal electrocardiography (ECG) [48–50]. A more accurate estimation of the aortic flow is then possible, and the aortic stroke volume can be calculated. In the above studies, the stroke volume has been reported to range from 2.8 to 5.6 ml/min in the thoracic aorta and from 2.4 to 4.3 ml/min in the abdominal aorta of healthy third trimester fetuses. The relative stroke volume was found to be stable during the last trimester of gestation ( $1.7\text{--}2.1 \text{ ml} \cdot \text{min}^{-1} \cdot \text{kg}^{-1}$ ) [48, 50]. The method used for these examinations is laborious, mainly because of the difficulty obtaining transabdominal fetal ECG signals of acceptable quality. To circumvent this problem, Tonge et al. [49] applied their experience from animal experiments and recommended that the

first derivative of the mean velocity and diameter waveforms is used to synchronize heart cycles.

## Intrinsic Influences on Fetal Aortic Flow and Flow Indices

Similar to other fetal vessels (e.g., the carotid artery [51]), a negative correlation has been found between the aortic PI and fetal heart rate, with correlation coefficients between  $-0.43$  and  $-0.73$  [22, 36, 43, 52]. This inverse relation was pronounced mainly during periods of behavioral state 2F in term fetuses [36].

In a series of studies, the Rotterdam research group reported a clear dependence of fetal aortic velocity waveform indices on fetal behavioral states in term pregnancies [36, 43] and on the fetal activity state during the early third trimester [52]. The values for the fetal aortic PI were higher during fetal quiet sleep than during active sleep, with decreased impedance and increased flow in fetal musculature.

All noncompromised fetuses perform periodic breathing movements, with contraction of the diaphragm, expansion of the abdominal wall, and retraction of the thorax during “inspiration” and a return to the rest position during “expiration” [53]. Fetal breathing movements have a pronounced effect on blood circulation in the umbilical cord and the intra-fetal vessels [29]. The aortic blood flow velocity waveforms exhibit modulation of their shape, with rhythmic oscillations in the amplitude of their peak velocities and diastolic velocities. The end-diastolic velocities sometimes eventually disappear during fetal “in-

spiration.” The time-averaged mean velocity usually increases – up to 40% – during periods of fetal breathing movements [29]. Probably, the cardiac output also increases as a consequence of increased venous blood return to the fetal heart [54].

The above observation is important to consider when recording fetal aortic blood velocities: To obtain reproducible results, only Doppler traces recorded during periods without fetal breathing should be accepted for analysis. Fetal breathing movements can usually be recognized in the two-dimensional realtime image of the fetus, the aortic Doppler shift signals, or the Doppler traces of umbilical venous velocities.

## Fetal Aortic Blood Flow During Labor

The fetal aortic volume blood flow has been shown to increase with progression of labor in a study in which the measurements were performed between contractions [55]. The increased fetal flow might be a phenomenon similar to the reactive hyperemia found in the uteroplacental circulation of experimental animals between contractions [56]. In the study by Lindblad et al. [55] there was no change in the aortic PI with advancing labor, and there was no difference between patients with and those without ruptured membranes. Fendel et al. [57] measured the mean fetal aortic velocity during labor and found a decrease in the velocity during contractions. The aortic PI and RI remained unchanged.

## Pathophysiologic Changes of Fetal Aortic Flow During Intrauterine Hypoxia

Blood flow in the fetal descending aorta supplies the placenta and lower body of the fetus, including kidneys, splanchnic and pelvic organs, and lower extremities. The major portion of blood in fetal descending aorta is directed to the placenta. Thus an increase in the resistance to flow in the placental vascular bed can profoundly influence the flow not only in the umbilical artery but also in the descending aorta. It would be reflected by typical changes of the velocity waveform, (i.e., decreased or no diastolic velocity) (Fig. 11.11). Possibly, vasoconstriction in the lower fetal body, which is known to be one of the mechanisms involved in the centralization of flow during hypoxia, potentiates the effect on aortic velocity waveforms.

Doppler indication of increased resistance to flow in the fetoplacental circulation was found to be re-

**Fig. 11.11.** Absence of end-diastolic velocity in the descending aorta of a growth-retarded fetus at 27 weeks' gestation

lated to the increased neonatal nucleated red blood cell counts that are considered a sign of intrauterine hypoxia [58]. Doppler results from the fetal descending aorta, umbilical artery, and maternal uterine arteries were independent determinants of neonatal nucleated red blood cell count.

In an experimental study on the fetal lamb, increasing the placental and hind limb resistance by embolization with microspheres caused a progressive increase in the aortic flow PI [59]. In another study on pigs, the aortic PI, recorded by Doppler ultrasonography, was shown to correlate with the total peripheral resistance calculated from the invasively measured blood flow and pressure ( $r=0.64-0.87$ ) [60]. In the study by Adamson and Langille [59] the aortic PI reflected not only the vascular resistance but also the pulsatile flow and pressure pulsatility (Fig. 11.12). Thus an increasing fetal aortic PI should not be interpreted solely as an expression of increasing placental vascular resistance.

When studying the aortic blood velocity waveforms of lamb fetuses during experimental asphyxia, Malcus et al. [61] found a loss of aortic end-diastolic flow velocities, a significant increase in the PI, and a decrease in mean velocity. Concomitantly, increases in the diameter and mean velocity were recorded in the fetal common carotid artery [62], and there was a slight decrease in the carotid artery PI. These changes indicate a redistribution of flow, although the changes occurred as relatively late phenomena in the development of acute asphyxia.

An interesting observation on fetal aortic isthmus has been reported, based on animal experiments [63] and human studies [64]. With increased resistance to flow in the placenta and fetal lower body, changes in the diastolic flow velocity occurred earlier in the aortic isthmus than in the descending aorta and umbili-

**Fig. 11.12.** Flow pulsatility index (PI), flow pulse amplitude, and mean blood flow measured with an electromagnetic flowmeter in the descending thoracic aorta of sheep fetuses versus the vascular resistance of the lower body circulation during progressive embolization of the hind limbs and placenta. cal artery. In the sheep fetus during an acute increase in placental vascular resistance, delivery of oxygen to the brain was preserved despite a significant decrease in arterial oxygen content as long as net flow through the aortic isthmus was antegrade [65]. These reports offer an interesting possibility of closely following the process of centralization of flow. The suggested concept awaits evaluation in prospective clinical studies.

## Clinical Studies

### Fetal Cardiac Arrhythmias

Doppler recording of fetal aortic velocities provides important information of the hemodynamic consequences of fetal cardiac arrhythmias. Simultaneous detection of Doppler signals from the fetal abdominal aorta, reflecting ventricular contractions, and the inferior vena cava, reflecting atrial contractions, can facilitate the classification of arrhythmias [66–68]. In most cases of fetal arrhythmia, the estimated aortic volume flow remains within normal limits, indicating the ability of the fetal heart to maintain cardiac output [67, 69]. Subnormally low values of aortic flow were found in fetuses with severe arrhythmias that caused heart failure [67]. In cases of bradyarrhythmias and tachyarrhythmias, a decrease in the aortic flow was observed when the fetal heart rate exceeded the limits of 50 or 230 bpm, respectively [69].

In fetuses with premature heartbeats, an increase in peak aortic velocities was observed with the first postextrasystolic beats [70]. Similarly, the peak systolic velocities are higher in fetuses with complete atrioventricular block than in those with regular sinus rhythm [67]. This finding, together with the above-described compensation for negative effects of cardiac arrhythmias on fetal cardiac output, indicates that the Frank-Starling mechanism is valid for fetal myocardium.

Fetuses with congestive heart failure caused by a cardiac arrhythmia sometimes require transplacental treatment with digoxin or antiarrhythmic drugs. In addition to the effect of treatment on heart rhythm, the improved performance of the fetal heart can be followed by serial measurements of fetal aortic volume blood flow [71].

### Fetal Anemia

In isoimmunized pregnancies the degree of fetal anemia can be determined by analyzing fetal blood samples obtained by cordocentesis. It would facilitate their clinical management if these anemic fetuses could be identified with a noninvasive method. One of the early reports suggested that there was an inverse correlation between the cord hemoglobin at birth and the time-averaged mean velocity and volume blood flow recorded antenatally in the intraabdominal portion of the umbilical vein using Doppler ultrasonography [72]. In the descending aorta of previously untransfused isoimmunized fetuses, Rightmire et al. [73] reported an increased mean blood velocity and a negative correlation with the hematocrit of umbilical cord blood obtained by cord puncture under fetoscopic control. Their finding was confirmed by Nicolaides et al. [74], who related the values of mean aortic velocity to the hemoglobin deficit in blood samples obtained by cordocentesis. The findings of increased fetal aortic velocities in anemic fetuses (Fig. 11.13) are in accord with an increase in their cardiac output as a consequence of lowered blood viscosity, increased venous return, and cardiac preload. Doppler cardiac studies of anemic fetuses showed indications of increased cardiac output [76, 77]. After intrauterine transfusion, a decrease or even normalization of the mean velocity in the fetal aorta was observed [78]. In contrast to the changes in aortic time-averaged mean velocity seen with fetal anemia, there were no changes in the waveform indices.

Recently, it has been shown by Mari et al. [79] that Doppler examination of the fetal middle cerebral artery can be used for clinical management of pregnancies with red-cell alloimmunization. The sensitivity of the middle cerebral artery velocimetry for detection of fetal anemia seems to be superior to that of the velocimetry of fetal descending aorta.

**Fig. 11.13.** Three-dimensional presentation of Doppler signals recorded from the descending aorta of a normal fetus (**a**) and an anemic fetus (**b**). Note the increase of velocity amplitudes and the right shift of the velocity power in the anemic fetus. (Reprinted from [75] with permission)

## Diabetes Mellitus

Serial Doppler examinations were performed in a group of 40 pregnant women with diabetes mellitus [80]. A high-volume blood flow in the fetal descending aorta was found during the early third trimester; near term, blood flow approached normal values. The PI in the umbilical artery and fetal aorta was within the normal range, so long as there were no signs of fetal growth retardation or hypoxia. Otherwise no flow variations specific for diabetic pregnancies were seen. Similar findings were also reported for pregnant women with gestational diabetes [81].

## Intrauterine Growth Restriction

Intrauterine growth restriction (IUGR) can have various etiologies, restricted flow through the placental vasculature being the most common cause of this relatively frequent complication of pregnancy. As described above, the increased vascular impedance in the placenta is reflected in a changed blood velocity waveform in the descending fetal aorta, with a reduction of diastolic velocities and a corresponding increase in PI [6, 19, 35]. These findings are similar to those reported for the umbilical artery of growth-retarded fetuses [82].

In a study that evaluated placental morphology in relation to intrauterine flow in IUGR fetuses, only the presence of placental infarction was significantly associated with abnormal flow velocity findings in the fetal descending aorta (high PI, BFC I-III, low mean velocity) [83].

In the descending aorta of growth-retarded fetuses, low values were obtained for the time-averaged mean velocity and volume flow, though they did not differ significantly from those of controls [19]. This similarity was probably due to the already mentioned methodologic difficulty of precisely estimating volume flow. Using an improved technique combining an ultrasonic phase-locked echo-tracking system for diameter measurement synchronized with a pulsed Doppler velocimeter [16], Gardiner et al. [84] found both the relative pulse amplitude, mean blood velocity, and volume flow to be significantly lower in the descending aorta of growth-restricted fetuses than in the controls. Also, the aortic pulse waves of growth-restricted fetuses showed values significantly different from those in controls, reflecting the chronic ventriculovascular responses to increased placental impedance [85].

In severely growth-restricted fetuses developing signs of intrauterine distress, the aortic end-diastolic velocity disappears or even becomes reversed (BFC II and III; Fig. 11.7) [18]. An association has been found to exist between the degree of fetal hypoxia,

hypercapnia, acidosis, and hyperlactemia, as diagnosed in blood samples obtained by cordocentesis from growth-restricted fetuses and changes in the mean fetal aortic velocity [86] and the velocity waveform [87]. The aortic velocity waveform changes have been observed to precede the cardiotocographic changes, the median time lag being 2–3 days [19, 88], though the interval between the first blood velocity changes and the first changes in cardiotocographic tracings may be as much as several weeks [19, 89].

The finding of ARED flow in the fetal aorta is associated with an adverse outcome of the pregnancy [19, 90] and increased neonatal morbidity [91, 92]. Reverse flow during diastole identifies fetuses in danger of intrauterine death. Perinatal mortality in cases with reverse flow is reported to be high – in some series as high as 100% [93]. The combination of ARED flow in the fetal descending aorta and pulsations in the umbilical vein seems to indicate a fetus with severe hypoxia and imminent heart failure [18].

## Aortic Doppler Velocimetry as a Diagnostic Test of IUGR and Fetal Hypoxia

Several prospective studies on IUGR pregnancies have been performed to evaluate the predictive capacity of fetal aortic velocity waveforms with regard to birth weight, occurrence of fetal distress, and perinatal outcome. Tables 11.3 and 11.4 summarize results of some of the studies in terms of sensitivity, specificity, and positive and negative predictive values. For the RI ratios between the common carotid artery and descending thoracic aorta of small-for-gestational-age (SGA) fetuses redistributing their flow, a sensitivity of 94% was reported for prediction of cesarean section for fetal distress [96]. It is obvious that in IUGR fetuses fetal aortic velocimetry is a better predictor of fetal health than fetal size, which is not surprising in view of the multiplicity of determinants of fetal growth.

The accumulated evidence suggests that, as is also the case for umbilical artery velocimetry, Doppler fetal aortic examination is better suited for use as a secondary diagnostic test in preselected high-risk pregnancies than as a primary screening test in a whole pregnant population [97]. In a prospective study of growth-retarded fetuses, Gudmundsson and Maršál [90] compared the predictive value of aortic versus umbilical artery velocity waveforms: The PI in the umbilical artery was found to be a slightly better predictor of fetal outcome than the aortic PI, though the BFC was similarly predictive in the two vessels. Two longitudinal studies confirmed that the changes in the umbilical artery PI preceded changes in the

thoracic aorta of IUGR fetuses [98, 99]. Doppler examination of the umbilical artery is technically easier and can be done with less sophisticated and less expensive instruments. Therefore for simple monitoring of fetal health in suspected cases of IUGR, umbilical artery Doppler velocimetry seems preferable. The investigation of fetal aortic arterial waveforms might provide more detailed information on the circulatory adaptation and pathophysiologic mechanisms in the process of IUGR. It should be validated, however, in randomized clinical trials comprising management protocols based on the results from Doppler examinations of several vessel areas: uteroplacental circulation, umbilical artery, fetal aorta, and fetal cerebral vessels. Possibly such a concept can improve clinical decision making for preterm growth-restricted fetuses, a group usually posing a difficult problem for the clinician.

## Follow-up Studies

It is of interest to follow the postnatal development of infants who suffered growth restriction and hypoxia in utero and to evaluate the possible predictive value

of Doppler fetal velocimetry with regard to long-term prognosis. The Malmö group performed extensive somatic, neurologic, and psychological investigations of 149 children at 7 years of age. All of them had been subjects for Doppler velocimetry of the descending aorta in utero and about half were SGA at birth. A univariate analysis showed that infants with abnormal intrauterine aortic blood flow had an increased frequency of minor neurologic abnormalities [100] and lower mean intelligence quotient [101] than infants with normal intrauterine hemodynamics. Logistic regression analysis revealed a statistically significant association between the aortic BFC and the neurologic [102] and intellectual [101] status at age 7 years (Table 11.5).

The above findings invite speculation as to whether an early intervention in cases of growth-restricted fetuses with an abnormal BFC might prevent not only fetal mortality but also some minor development deficits. Such management policy, however, engenders the danger of iatrogenic prematurity. Therefore a protocol for management of preterm babies, based on the results of fetal velocimetry, should be tested in randomized clinical trials before adopting it in clinical practice.

## Summary

A combination of real-time scanning and pulsed Doppler velocimetry is required for Doppler ultrasound velocimetry of the fetal descending aorta. A combined linear array real-time/pulsed Doppler method makes it possible to estimate fetal aortic volume flow. However, the volume flow method is open to error and is therefore less suitable for application to the clinical situation. The waveform of the maximum velocities recorded from the fetal descending aorta reflects the impedance to flow in the placenta and the lower fetal body. The waveform is also influenced by other factors (e.g., fetal heart function). The aortic waveform can be characterized by various indices (e.g., the PI and the RI). In a situation of increased peripheral vascular resistance, the aortic diastolic velocities decrease and eventually disappear. In extreme cases reversed flow during diastole can be detected. The finding of absent or reversed aortic flow is associated with an adverse outcome of pregnancy. For practical application, a semiquantitative method (blood flow classes) has been designed to evaluate fetal aortic velocity waveforms. The BFC method emphasizes especially the appearance of the diastolic part of the waveform. When recording fetal aortic Doppler signals, caution must be taken to avoid periods of fetal breathing movements, which can profoundly influence the shape of the waveform. The values of waveform indices in the fetal aorta are also dependent on fetal heart rate and activity/behavioral states.

In uncomplicated pregnancies the velocity waveform of the fetal descending aorta shows positive flow throughout the cardiac cycle, the proportion of diastolic flow being higher in the abdominal aorta than in the thoracic aorta. The PI values are stable during the last trimester of gestation, with a slight increase at term. The aortic mean velocity and the relative flow do not change significantly with gestational age

during late pregnancy. About 50%–60% of the flow in the thoracic descending aorta supplies the placenta.

In fetuses with a cardiac arrhythmia, aortic Doppler velocimetry can facilitate diagnosis of the arrhythmia, and the estimation of aortic flow can provide an early indication of imminent heart failure. In anemic isoimmunized fetuses, the mean aortic velocity is increased.

Clinical studies of pregnancies with IUGR showed that examination of fetal aortic velocity waveforms can be used for fetal surveillance. The development of fetal hypoxia is associated with typical changes of the waveform: increased PI and absence or reversal of diastolic flow. These changes usually precede other signals of fetal distress. The predictive capacity of fetal aortic velocimetry is comparable to that of umbilical artery velocimetry with regard to IUGR and the development of fetal distress. As is the case for umbilical artery velocimetry, Doppler examination of the fetal descending aorta is suited for application as a secondary diagnostic test in high-risk pregnancies. Changes in the intrauterine aortic waveforms have been shown to be significantly correlated to the perinatal outcome and to the long-term postnatal neurologic and psychological development. Analysis of the fetal aortic flow velocity pattern can be applied, together with examination of other vessel areas, for a more detailed study of redistribution of flow in the presence of fetal hypoxia. Clinical management protocols based on such a concept should be tested in prospective randomized trials.

# Intrauterine Blood Flow and Postnatal Development

David Ley, Karel Maršál

Fetal experience forms the basis for postnatal life. This relationship may be obvious in the newborn infant, although it is sometimes not apparent until later in development. One fetal condition with known implications for later life is intrauterine growth restriction (IUGR), which ranges from being an important factor in perinatal mortality to affecting morbidity in adulthood.

The process of growth, usually measurable as change in anatomical size, is intimately related to that of development, the latter referring to a gradual acquisition of physiological function. Dobbing defined the *brain growth spurt* as that transient period of growth when the brain is growing most rapidly and the period of time when the brain is most susceptible to adverse influence [1]. Fetal malnutrition during the brain growth spurt may reduce the number of synapses per neuron by 40% [2]. Other authors have demonstrated a lower myelin lipid content in the brain of a small-for-gestational age (SGA) newborn as compared with that of an appropriate-for-gestational age (AGA) newborn [3, 4]. In the human, a large part of the brain growth spurt takes place in the years after birth; therefore, the nutritional as well as the psychosocial environment during the first postnatal years may add to, but equally compensate for, previous adverse influence during fetal development.

## Background

### Neurodevelopmental Outcome in IUGR

In follow-up studies of fetal growth restriction, IUGR has been defined mainly on the basis of gestational age-related birth weight (birth weight SGA). A study group selected on the basis of such a definition will not only include truly growth-restricted infants of various etiologies, but also genetically small but healthy infants. This is probably the main reason why the numerous follow-up studies of SGA infants published in the past did not give a clear answer to the question concerning the effect of IUGR on neurodevelopmental outcome. Another major reason for inconsistent results concerning outcome are the con-

found variables associated with impaired fetal growth, perhaps the two most important variables being prematurity at birth and social class. The lower the socioeconomic status of the parents, the higher the chance of delivering an SGA infant, and, independent of this, the greater the risk of poor cognitive outcome [5].

In prospective studies, SGA infants rarely developed major neurological impairment such as cerebral palsy and seizures, although Fitzhardinge and Stevens [6] reported an incidence of 7% major neurological sequelae at 4–6 years of age in children born SGA. On the other hand, retrospective studies of children with cerebral palsy have shown fetal growth restriction to be an important etiological factor [7].

Several studies have shown an increased frequency of minor neurological dysfunction at early school age [8, 9] and of attention deficit disorder [10] in children born SGA. Ounsted et al. [11] found significantly lower neurobehavioral scores in SGA infants from 2 months up to the age of 1 year. One study, distinguishing SGA infants according to body proportions at birth, found children with symmetrical IUGR to have lower developmental scores at 3 years of age than those with asymmetrical IUGR, both groups having lower scores than AGA infants [12]. Berg [13] found an increased risk of neurological abnormality at 7 years of age in children born SGA only in the presence of hypoxia-related factors, especially in those children with symmetrical body proportions at birth. A part of the cohort previously studied by Fitzhardinge and Stevens [6] has been examined at a later age. Only minor differences were found between those born SGA and those born AGA after the exclusion of subjects with complications related to asphyxia at birth [14].

In a recent review, an intriguing hypothesis was offered, supported by substantial evidence concerning the perinatal anatomical and biochemical correlates of minor neurological dysfunction and behavioral problems observed in numerous follow-up studies of children in perinatal risk groups [15]. Studies using single photon emission computed tomography (SPECT) in children with minor neurological abnormalities have shown evidence of hypoperfusion in the

striatum (globus pallidus and putamen). The striatum samples information from the entire cortex through spiny neurons, enormously rich in glutaminergic synapses. Repeated asphyxia in fetal sheep causing hypotension and acidosis resulted in neuronal loss primarily in the striatum [16]. The reason for preferential neuron loss in the striatum may partly be due to its localization in an arterial border zone making it vulnerable in a state of circulatory compromise. Furthermore, perhaps most importantly, the spiny neurons will be at risk from the high levels of noxious glutamine released during hypoxia/ischemia in this area. IUGR is, as previously mentioned, associated with fetal hypoxia and circulatory changes. One may speculate that the increased frequency of minor neurological dysfunction observed in children with IUGR may be due to damage induced by ischemia in the striatal area.

### **IUGR and Cardiovascular Morbidity**

An increasing body of studies have appeared on the relationship between suboptimal fetal growth and morbidity in adulthood. An early study on Swedish male army conscripts suggested that being born SGA may be a predictor of raised blood pressure in early adult life [17]. Epidemiological surveys of men born in Britain during the first three decades of the 19th century have shown an inverse relationship between weight at birth and blood pressure in adult age [18]. Morbidity in cardiovascular disease and incidence of non-insulin-dependent diabetes have further been demonstrated to relate to low birth weight [19, 20]. Barker and coworkers have speculated that changes in fetal blood flow and in activities of substances engaged in the regulation of fetal growth such as insulin and insulin-like growth factor I (IGF-I) may permanently affect vessel wall structure and have persisting effects on metabolism [21]. An increased vulnerability to maternal glucocorticoid levels in the growth-restricted fetus has also been suggested as a mechanism that may alter vasoregulatory mechanisms during fetal life and lead to subsequent hypertension [22].

Results from prospective postnatal studies have not been as convincing as those derived from large populations studied retrospectively. No inverse correlation was found between size at birth and blood pressure at 8 years of age in a cohort of 616 prematurely delivered children. On the contrary, blood pressure decreased with decreasing birth weight for gestational age [23]. Williams et al. [24] observed a weak inverse association between blood pressure and birth weight for gestational age in children at 7 years of age, but when the same cohort was analyzed at 18 years of age, the relationship had disappeared. In a Dutch study, a U-shaped relationship was shown between

birth weight for gestational age and blood pressure at 4 years of age, implying an increase in blood pressure in children with both low and high birth weight for gestational age [25].

### **Postnatal Implications of Abnormal Fetal Blood Flow**

Abnormal flow velocity waveform in the umbilical artery has been shown in a large number of studies to be associated with adverse outcome of pregnancy and high perinatal mortality rate [26, 27]. A multicenter European study [28] differentiated the outcome according to the presence, absence, or reversal of the end-diastolic flow in the umbilical artery. The odds ratio for perinatal mortality was 4.0 with absent end-diastolic flow and 10.6 with reversed end-diastolic flow when compared with high-risk pregnancies with positive end-diastolic flow in the umbilical artery. The experience from descriptive studies has been used to design randomized controlled trials, which showed that the use of Doppler velocimetry as a method of fetal surveillance in high-risk pregnancies leads to a significant decrease of perinatal mortality [29]. The Doppler method became a method of choice for monitoring fetal health in pregnancies with complications caused by placental dysfunction. The changes of blood velocities recorded from the fetal descending aorta using Doppler ultrasound have been shown to parallel those found in the umbilical artery [30].

### **Neonatal Outcome**

Several studies have been published on the association between abnormal fetal blood flow and short-term perinatal outcome. Absent or reverse end-diastolic flow (AREDF) in the umbilical artery or fetal descending aorta has been associated with an increased neonatal mortality and increased morbidity in terms of cerebral intraventricular hemorrhage and necrotizing enterocolitis (NEC) [31–34]. The relationship between abnormal fetal aortic velocities and necrotizing enterocolitis in the neonate is supported by the study by Kempley et al. [35], who found decreased velocities in the superior mesenteric artery in SGA infants who had absent end-diastolic velocities in the aorta during fetal life.

McDonnell et al. [36] performed a case-control study of AREDF, matching for gestational age and pregnancy complications in 61 pairs of infants. They found that AREDF was associated with a higher degree of growth restriction, thrombocytopenia, and NEC. A more recent case-control study of umbilical AREDF, including 36 pairs of infants, matching for

the same variables as in the study by McDonnell et al. [36] but also for degree of deviation in birth weight, found no differences in outcome except a lower prevalence of ventilator requirement for RDS in infants with AREDF [37]. In a prospective study of mothers with pregnancy-induced hypertension, Eronen et al. [38] found AREDF in the umbilical artery to be associated with a higher incidence of gastro-intestinal complications, bronchopulmonary dysplasia, intraventricular hemorrhage, and vascular hypotension in the newborns. Although the infants with AREDF were delivered at an earlier gestational age, AREDF remained as a predictor of poor perinatal outcome after correction for prematurity. The increased morbidity of infants who showed AREDF in utero was confirmed by other authors with regard to the occurrence of cerebral hemorrhage, anemia, and hypoglycemia [28], as well as chronic lung disease, retinopathy of prematurity, and impaired intestinal motility [39].

Weiss et al. [40] found an increased frequency of abnormal neurological signs in newborn infants with AREDF as compared with a control group, matched for gestational age, with normal umbilical velocity waveforms in the umbilical artery. They found also in fetuses with preceding AREDF a significant increase in the cord blood levels of brain type isoenzyme of creatine kinase (CK-BB) as a possible indication of intrauterine brain cell damage [41]. Rizzo et al. [42] described a decreased fetal cerebrovascular resistance as determined by a decreased pulsatility index (PI) in the internal carotid artery to be associated with post-asphyxial encephalopathy, as determined by neurological signs, in a cohort of high-risk pregnancies. On the other hand, in a study of 117 infants delivered between 25 and 33 gestational weeks in high-risk pregnancies, no relationship was observed between the ratio of PI in the fetal umbilical and cerebral circulation, and neither cerebral hemorrhage nor neurological abnormality in the neonatal period [43]; however, both Ley and Maršál [44], and Scherjon et al. [45] found a sustained abnormal cerebral blood flow in growth-restricted neonates and preterm neonates who showed signs of brain sparing in utero. It was speculated that this might be due to a different setting of cerebral autoregulation as a consequence of intrauterine redistribution of blood flow.

### Long-Term Neurodevelopmental Implications

In comparison with the large body of studies published on short-term perinatal outcome of abnormal fetal blood flow [27], relatively few investigations have attempted to evaluate long-term consequences (Table 12.1).

Weiss et al. [46] found that the combination of AREDF in the umbilical artery, severe RDS, and delivery before 28 gestational weeks was predictive of neurological abnormality at 6 months of age. A similar finding of a greater risk of permanent neurological sequelae at the age of 18 months was reported by Valcamonico et al. [47] for growth-restricted fetuses with AREDF in the umbilical artery. Abnormal fetal heart rate patterns were shown to be more predictive of poor cognitive outcome at 2 years of age than abnormal waveforms in the umbilical artery in fetuses of high-risk pregnancies delivered before 34 gestational weeks [48]. In a descriptive follow-up study, Wilson et al. [49] found no association between abnormal umbilical velocity waveforms and major neurological abnormality at 5 years of age. Similarly, in a group of 193 infants born to women with severe preeclampsia, there were no differences between those with and without AREDF in utero, when their neurodevelopmental outcome was evaluated at the age of 2 and 4 years [50]. The only exception was the lower Performance subscale test at 24 months in the infants with previous AREDF.

The study by Vossbeck et al. [39] demonstrated that infants with AREDF born before 30 gestational weeks and followed up for between 1 and 8 years were more often mentally retarded (44 vs 25%) and had more often severe motor impairment (38 vs 19%) than the matched controls. Another 5-year prospective follow-up of fetuses with AREDF showed 6 of 42 infants to be mentally handicapped [26]. A long-term impairment of intellectual capacity and partial neurodevelopmental delay was also observed at school age in 23 infants who have had severely compromised blood flow in utero [51].

In the previously referred study by Scherjon et al. [43], subsequent assessment of neurological signs at 6 and 12 months of age showed no relationship between the ratio of PI in the fetal umbilical and cerebral circulation and neurological abnormality. A parallel study showed that infants at 6 months of age with a raised umbilical artery/middle cerebral artery PI ratio had shorter visual evoked potential latencies as compared to infants with a normal ratio (Fig. 12.1) [52]. This was interpreted as a sign of accelerated neurophysiological maturation, being of benefit to the fetus. At the age of 3 years, the adverse neurodevelopmental development, as evaluated by Hempel examination [53] in a subgroup of 96 infants from the original cohort, was related to neonatal cranial ultrasound abnormality, rather than to the signs of brain sparing in utero [54]. The authors interpreted this finding as confirmation of their interpretation of the brain sparing as being beneficial. Seventy-three of the children were examined subsequently at the age of 5 years. The mean IQ score was significantly lower for chil-

**Fig. 12.1. a** Recording of visual evoked potentials at corrected age of 6 months (*top*) and 12 months (*bottom*) of infant born very preterm with normal intrauterine blood flow. The  $P_2$  latency has shortened between 6 and 12 months from 150 to 120 ms. (From [52]). **b** Recording of vi-

sual evoked potentials at corrected age of 6 months (*top*) and 12 months (*bottom*) of infant born very preterm, who showed signs of brain sparing in utero. The  $P_2$  latency did not change between 6 and 12 months, being 133 and 129 ms, respectively. (From [52])

dren born with signs of brain sparing, i.e., with a raised umbilical artery/middle cerebral artery PI ratio, than for those with normal intrauterine blood flow [55]. This led the authors to revise their previous interpretation of the fetal brain sparing as being a beneficial adaptive mechanism.

Chan et al. [56] used the ratio of resistance indices in the umbilical and cerebral circulation of high-risk fetuses and did not find any association with major neurological handicap at 2 years of age. Cerebroplacental PI ratio was used by Kutschera et al. [57] to characterize the intrauterine blood flow. At the age of 3–6 years, they did not find any difference in the cognitive, neurological, and somatic development between the group with abnormal cerebroplacental ratio and the group with AREDF in the umbilical artery; however, both groups showed impaired cognitive development as compared with controls [57].

Fouron et al. [58] followed up a group of 44 fetuses with abnormal umbilical artery Doppler velo-

cimetry and related their neurodevelopmental condition at 2 to 4 years of age to the flow patterns in the fetal aortic isthmus. All 5 fetuses with retrograde net isthmic flow had non-optimal neurodevelopment. This finding seems to support the previous conclusion by the authors that the Doppler examination of the aortic isthmus flow pattern in utero might identify fetuses with impending cerebral hypoxia [59].

In a recent paper by Schreuder et al. [60], the neurodevelopmental outcome at 5–12 years of age was related to the presence ( $n=40$ ), absence ( $n=27$ ), or reversal ( $n=9$ ) of the end-diastolic flow velocity in the umbilical artery. The absence of diastolic flow was not associated with adverse outcome; however, the reversal of end-diastolic flow was associated with a wide range of problems at school age, decreased mental ability, and impaired neuromotor function.

## The Malmö–Lund Study

We have performed a longitudinal follow-up study (up to 18 years of age) of subjects previously examined during antenatal life with measurements of intrauterine blood flow and fetal growth. The study has focused on evaluating possible effects of IUGR with abnormal fetal blood flow on subsequent neurological and cardiovascular development including neural and vascular morphology and function.

### Background Material

In two longitudinal prospective studies, serial fetal blood flow velocity examinations and measurements of fetal growth using ultrasound and Doppler velocimetry were performed in 178 pregnancies during a 3-year period, 1982–1985, at the Department of Obstetrics and Gynecology in Malmö [61, 62]. The blood flow velocity waveform in the fetal aorta was transformed into a semi-quantitative variable, blood flow class (BFC), four BFCs being defined to describe the appearance of the waveform, with emphasis on its diastolic part. These classes were as follows: BFC 0 (normal), positive flow throughout the heart cycle and a normal pulsatility index; BFC I, positive flow throughout the cycle and a pulsatility index  $\geq$  mean +2SD of normal; BFC II, non-detectable end-diastolic velocity; and BFC III, absence of positive flow throughout the major part of the diastole and/or reverse flow in diastole. Fetal aortic BFC was defined according to the result of the last measurement performed before delivery. In 74 cases the pregnancy resulted in a birth weight  $\geq$  2SD below the mean of the normal population, i.e., they fulfilled the criterion of being SGA at birth. In 3 cases the fetus died in utero.

### Fetal Aortic Blood Flow and Postnatal Neurodevelopment

#### Neurological and Cognitive Development at 7 Years of Age

At the age of 6.5 years, 148 children (84% of the background population) underwent an intellectual evaluation and at 7 years of age, 149 (85%) children underwent a neurological examination with special emphasis on minor neurological dysfunction (MND) [63, 64]. The neurological assessment consisted of an age-specific and standardized examination which comprised 64 test items grouped into six subsystems or clusters as described by Touwen [65]. The subsystems were: posture; sensorimotor apparatus; coordination and balance; fine manipulative ability; dyskinesia; and miscellaneous dysfunctions. According to the number of deviant subsystems, the result of the

neurological examination was classified as normal, MND-1 (one to two deviant subsystems) or MND-2 (more than two deviant subsystems). The intellectual development was evaluated by a psychologist using a standardized intelligence test (Wechsler Preschool and Primary scale of Intelligence, WPPSI) [66].

The frequency of the more severe form of MND, MND-2, was significantly higher in the BFC III group (8 of 21) than in the group with BFC 0 (normal) (14 of 105; Fig. 12.2) [63]. The frequency of MND-1 was higher in the BFC II group (8 of 21) than in the group with BFC 0 (35 of 91). The group of children with BFC III deviated more frequently in three neurological subsystems as compared with the BFC 0 group; coordination and balance, dyskinesia, and fine motor ability.

The group with abnormal fetal BFC had a lower mean verbal IQ as compared with the group with normal fetal BFC [64]. The groups did not differ significantly in performance IQ, although a tendency towards lower mean performance IQ was observed in the group with abnormal fetal BFC. Global IQ was significantly lower in the group with abnormal fetal BFC. The largest discrepancies between groups were found in the subtests information, comprehension, and arithmetic. These subtests have been shown to be good predictors of reading and school achievement [67, 68]. Furthermore, children with a learning disability have been shown to obtain low scores within these specific subtests [69].

To enable an assessment of the aggregate effect of probable risk variables on neurodevelopmental outcome we performed multivariate analysis [64]. This

**Fig. 12.2.** Neurological score at 6 years of age in relation to fetal aortic blood flow class, gestational age at birth and birth weight for gestational age. Higher score indicates increasing deviation from optimality. AGA appropriate-for-gestational age, SGA small-for-gestational age (From [92])

analysis included independent ante- and postnatal variables and an evaluation of the effect of socio-economic variables and interval complications occurring during postnatal life. In multivariate analysis, MND-1 was best predicted by the combination of increasing birth-weight deviation and male sex, whereas the best combination of variables contributing significantly to MND-2 was abnormal BFC and male sex. Global  $IQ \leq 85$  was best predicted by abnormal BFC, fetal gestational age at measurement, and social group. Fetal gestational age at measurement was present as an additional risk factor, due to interaction with BFC. When the last BFC measurement was normal and performed after 37 gestational weeks of pregnancy, only one child of 40 had a global  $IQ < 85$ . The dichotomous variable SGA/AGA showed no association with any of the intellectual outcome variables. The association of fetal growth restriction to both short-term and long-term outcome will generally be more powerfully expressed when using a continuous variable, such as birth-weight deviation, as compared with birth-weight categories.

A reduction in mean fetal aortic blood flow velocity has been correlated to hypoxia in the IUGR fetus, blood-gas values being obtained by cordocentesis [70]. The association found between an abnormal fetal aortic waveform and unfavorable neurodevelopmental outcome, which remained after adjustment for other confounding variables, may be attributed to fetal hypoxia. The fetal aortic velocity waveform reflects conditions both in the peripheral fetal circulation and in the placental circulation. The hemodynamic mechanism responsible for the abnormal waveform may therefore be both reduced peripheral blood supply due to hypoxia or increased impedance of the placental circulation, or both.

### **Cognitive Outcome at 18 Years of Age**

We continued the prospective follow-up study on a subgroup of the previously described cohort. A total of 51 subjects were examined at a median age of 18.2 years [71]. Twenty-eight of the subjects, 18 women and 10 men, were SGA at birth with a median deviation of weight at birth of  $-31\%$  (range  $-42$  to  $-22\%$ ) from the gestational age-related mean, at a median gestational age of 38.7 completed weeks (35–41 weeks). Nine subjects had BFC III, 10 subjects had BFC II, 2 subjects had BFC I, and 7 subjects had a normal BFC. The remaining 23 subjects, 13 women and 10 men, had a normal estimated fetal weight, normal aortic BFC, and an AGA weight at birth with median weight deviation  $-2\%$  ( $-10$  to  $22\%$ ) at a median gestational age of 39.7 weeks (36–42 weeks).

At 18 years of age, a psychologist evaluated the cognitive capacity using the Wechsler Adult Intelli-

gence Scale (WAIS) that, similarly to the WIPPSI test performed at 6 years of age, consists of several subtests resulting in a performance IQ and a verbal IQ. The SGA subjects had a lower performance IQ as compared with those with birth-weight AGA, but did not differ significantly in verbal IQ. Fetal aortic blood flow class was not related to global IQ; however, the subjects with BFC II and III had a lower processing speed index (PSI) as compared with those with BFC 0 and I. The PSI measures fine motor ability, visual and working memory, and psychomotor speed. We found a high correlation between cognitive test results at 6 years and those at 18 years of age. Interestingly, the correlation between test results at the respective ages was higher for the SGA group. The results suggest that cognitive level at 6 years of age as determined by a standardized IQ test is more predictive of cognitive level at 18 years of age in subjects with IUGR than in those with normal fetal growth and birth weight. A retrospective assessment of attention deficit hyperactivity disorder (ADHD), the Wender Utah Rating scale, showed that the rate of ADHD was increased in the group with birth-weight SGA. These subjects had low IQ scores at both 6 and 18 years of age and also reported more psychiatric symptoms at 18 years. Although the majority of subjects with IUGR had IQ score within the normal range at 18 years of age, we found an increased rate of individuals with multiple impairments, i.e., ADHD, decreased cognitive capacity, and emotional disturbance.

### **Retinal Neural Morphology and Function**

At 18 years of age, all subjects had an eye examination, including fundus photography after cycloplegia. Quantitative analysis of fundus photographs, utilizing a computer-assisted digital mapping system, evaluated two outcome measures: (a) the neuroretinal rim area (obtained by subtraction of the cup area from the optic disc area) as a measure of the optic nerve central nervous tissue; and (b) the number of branching points of retinal arterioles and venules as a measure of vascularization. The mean of the measurements from the two eyes in one subject represented the value of each ocular fundus variable. Visual function was assessed by using Rarebit perimetry which is a recently developed method for measuring central field vision [72].

We found that a more pronounced negative birth-weight deviation was associated with a decrease in neuroretinal rim area ( $p=0.0001$ ) [73]. The subjects with fetal aortic BFC III had a reduced neuroretinal rim area, median  $1.59 \text{ mm}^2$  (range  $1.33$ – $1.86 \text{ mm}^2$ ) as compared with those with fetal aortic BFC II ( $1.85 \text{ mm}^2$ ; range  $1.37$ – $2.13 \text{ mm}^2$ ) and to those with normal fetal aortic BFC ( $2.22 \text{ mm}^2$ ; range  $1.70$ –

2.71 mm<sup>2</sup>;  $p < 0.05$  and  $p < 0.0001$ , respectively; Figs. 12.3, 12.4). These findings indicate that IUGR is associated with a reduced axonal area in the optic nerve at young adult age. Degree of deviation in weight at birth and extent of fetal blood flow velocity abnormality were both associated with an increased reduction of the axonal area of the optic nerve. The observed reduction in axonal area may reflect either reduced axonal growth with a reduction of axonal volume or a decrease in the number of axons, i.e., in the number of neurons.

It can be speculated as to whether the observed reduction in axonal area is restricted to the optic nerve tract or represents a more global affection of neuronal growth within the brain. We found a strong association between MND at 6 years of age and a reduced axonal area suggesting that other regions of the central nervous system might be affected. The subjects with severe MND at 6 years of age had among other deviations consistent abnormalities in test items measuring coordination and balance suggestive of changes in the cerebellum or basal ganglia [63]. Experimental studies on induced fetal growth restriction during late pregnancy in guinea pigs and fetal sheep have shown a reduction in volume of cerebellar layers and in the number of Purkinje neurons in the cerebellum [74, 75]. Neuroradiological studies on humans following IUGR with volumetric quantification of the cerebellar region have, to our knowledge, not yet been performed.

**Fig. 12.3.** Relationship between neuroretinal rim area of the optic nerve examined at 18 years of age and fetal aortic blood flow class (BFC). BFC III corresponds to absent or reverse flow in diastole. (From Ley et al. [72])

**Fig. 12.4.** **a** Ocular fundus photography showing a reduced neuroretinal rim area of the optic nerve in a 18-year-old male subject with an SGA birth weight and reverse diastolic flow in fetal descending aorta (BFC III). **b** Neuroretinal rim area of the optic nerve in an 18-year-old male subject with normal fetal growth and normal fetal aortic blood flow. (From Ley et al. [73])

Fetal hypoxia as well as fetal malnutrition may be considered as plausible causes for the observed reduction in axonal area of the optic nerve. Fetal malnutrition during IUGR may be an important factor in disturbing cellular growth and differentiation in the central nervous system. Trophic factors, such as IGF-I, are essential for cellular growth and differentiation as well as for tissue repair after a damaging insult. Undernutrition in humans and in experimental ani-

mals decreases IGF-I expression in many tissues and in the circulation [76, 77]. Circulatory levels of IGF-I have been shown to be decreased in SGA fetuses and in fetuses with abnormal blood flow velocity [78, 79].

In our study at 18 years of age, the central field vision, as represented by the Rarebit mean hit rate [72], ranged from 93 to 100% in subjects with birth-weight AGA and from 48 to 100% in those with birth-weight SGA with the median hit rate being significantly lower in the SGA group as compared with that in the AGA group ( $p=0.03$ ). Eight of the SGA subjects and none of the controls had a hit rate below the normal range ( $p=0.006$ ). The deviant hit rates detected by the Rarebit microdot perimetry in some SGA subjects may reflect defects in the matrix of detectors, i.e., the neural channels, and may be caused by disturbed axonal growth or development. This finding of abnormal function lends support to the previously mentioned morphological finding of reduced neuroretinal rim area in subjects with IUGR.

## **Fetal Aortic Blood Flow and Postnatal Cardiovascular Function**

### ***Aortic Vessel Wall Characteristics and Blood Pressure at 9 Years of Age***

We used an electronic phase-locked echo-tracking system DIAMOVE (Teltec, Lund, Sweden) for non-invasive monitoring of pulsatile diameter changes in the descending aorta [81, 82] of a subgroup of 68 children from the original Malmö cohort. Neither abnormal fetal aortic blood flow nor birth-weight deviation were reflected in any significant changes in elastic modulus or stiffness of the abdominal aorta at 9 years of age [80]. Within the examined group, the subjects with the highest body weight at the time of examination had the highest levels of systolic blood pressure. These results support the hypothesis that the link between fetal growth failure and high blood pressure in adult life may mainly be expressed among those with obesity.

Children born SGA had significantly lower vessel diameters than those born AGA and these differences remained significant after adjustment for body surface area. These findings resemble in part those of Stale et al. [83] who found lower values of end-diastolic diameters in SGA fetuses than in AGA fetuses of the same gestational age using an identical technique for aortic measurements; however, when the fetal aortic diameters were adjusted for estimated fetal weight, the relationship was reversed. The larger weight-related diastolic diameter taken together with the finding of a lower relative pulse amplitude in the SGA fetuses suggested an increase in diastolic blood pressure, possibly as a response to the increased pe-

ripheral resistance, namely that of the placental circulation, found in pregnancies complicated by IUGR. The present findings obtained at 9 years of age [80] showed no evidence of an increase in diastolic blood pressure related to restricted fetal growth. On the contrary, IUGR was associated with lower diastolic blood pressure. As the influence of the increased resistance to fetal blood flow caused by the abnormal placenta in fetal growth restriction will cease to exist after birth, it would seem plausible that the postulated compensatory increase in blood pressure during the fetal period would no longer be present in childhood.

Pulse pressure was significantly higher within the group of children born SGA than in those born AGA [80]. An increase in pulse pressure has previously been described in SGA infants at 6 weeks of age [84] and has been associated with signs of low arterial compliance and hypertensive disease in adults [85, 86]; however, we were unable to detect any corresponding changes in aortic compliance in association with either abnormal fetal aortic blood flow or SGA birth weight. A previous study of human aortic compliance and its normal variation with age found a profound increase in compliance between 4 and 11 years of age [87]. Aortic compliance thereafter exhibited a gradual decrease with values beyond 16 years being similar to those of healthy adults. This may imply that changes in aortic vessel compliance due to fetal causes may be detectable at a later age when aortic compliance decreases due to the normal ageing process. The increase in pulse pressure observed in the SGA group [80] might suggest, in the absence of changes in elastic modulus and stiffness of the abdominal aorta, the possibility of corresponding changes in more peripheral segments of the arterial tree.

### ***Size and Function of Large Arteries at 18 Years of Age***

At 18 years of age [88], vascular mechanical properties of the common carotid artery (CCA), abdominal aorta (AO), and popliteal artery (PA) were assessed by echo-tracking sonography in 21 adolescents with IUGR and abnormal fetal aortic blood flow, and in 23 adolescents with normal fetal growth and normal fetal aortic blood flow, all belonging to the Malmö-Lund follow-up cohort [71–73, 89]. Endothelium-dependent and endothelium-independent vasodilatation of the brachial artery was measured by high-resolution ultrasound.

The IUGR group had significantly smaller mean vessel diameters compared with controls in the AO and PA in proportion to the body size, with a similar trend in the CCA. Stiffness in all three vascular re-

gions was comparable between the two groups. Men from the IUGR group had a lower compliance coefficient in the AO (corrected for body surface area) than men from the control group. The time course of vasodilatation in the IUGR group appeared to be different from the control group with higher values of flow-mediated vasodilatation at 2 min after cuff deflation in the IUGR group. Smaller aortic dimensions and the lower aortic compliance coefficient seen in male adolescents with previous IUGR may influence the future cardiovascular health of these individuals. Sustained flow-mediated vasodilatation may indicate an increased synthesis of nitric oxide in response to forearm occlusion.

### **Retinal Vascular Morphology at 18 Years of Age [89]**

In the cohort of young adults, followed by us, we found that increasing negative birth-weight deviation was associated with a decrease in the number of retinal vascular branching points ( $p=0.02$ ; Fig. 12.5). Neither age at examination, gender, nor the degree of abnormal fetal blood flow were associated with the number of retinal vessel-branching points. It is unclear whether the finding of reduced vessel-branching points in IUGR subjects is restricted to the retina or whether it reflects a more general affection of vascular growth within the body. A previous study in IUGR rats induced by protein restriction has shown reduced vasculature in the cerebral cortex [90]. Our findings of a reduced size of large arteries in subjects with IUGR detected at 9 and 19 years of age, and that of a reduced number of branches in the retinal vasculature, support a general affection of angiogenesis. Others have shown signs of impaired endothelial function in small and large arteries in school children born SGA [91]. We found that aortic compliance appeared unaffected at 9 years of age [80], whereas men at 19 years of age had signs of decreased compliance [88]. These findings of functional and morphological deficits may contribute to a better understanding of the link between restricted fetal growth and cardiovascular disease.

## **Conclusion**

In conclusion, several studies have shown abnormal fetal hemodynamics in the growth-restricted fetus, especially umbilical AREFD, to be associated with a clear increase in perinatal mortality and neonatal morbidity. The long-term follow-up studies performed until now did not show clear evidence of major neurological handicap being associated with abnormal fetal hemodynamics. This is not surprising as

**Fig. 12.5.** **a** Ocular fundus photography demonstrating a reduced number of retinal vessel-branching points in an 18-year-old female with an SGA birth weight and abnormal fetal aortic blood flow (BFC III). **b** Ocular fundus photography with a normal number of retinal vessel-branching points in an 18-year old female with normal fetal growth and normal fetal aortic blood flow. (From Hellström et al. [89])

the much larger body of prospective follow-up studies on IUGR, in terms of birth-weight SGA, seldom showed an increase in major neurological impairment associated with fetal growth impairment. Minor neurological dysfunction, behavioral abnormality, and learning problems at school age, all frequently reported as overrepresented in perinatal risk groups, would probably be more adequate as outcome vari-

ables when assessing the effects of fetal hemodynamics on postnatal neurodevelopment.

Hemodynamic evaluation of the fetus has increased our understanding of the physiological mechanisms involved in fetal growth restriction and is of proven clinical value in the management of high-risk pregnancies. Knowledge of changes in umbilical and fetal blood flow has also been of great value in the definition of true IUGR in subjects with deviation in weight during fetal life or at birth; thus, follow-up studies in subjects with abnormal fetal blood flow with varying degrees of deviation in weight have supplied valuable information on effects of IUGR on different aspects of postnatal development. Abnormal fetal blood flow reflects changes in the fetoplacental unit associated with a reduced fetal supply of oxygen and nutrients. Other authors, in addition to us, have shown that such fetal deprivation may lead to longstanding disturbances in morphology and subsequent function of the nervous and cardiovascular system. This information, coupled with insights derived from experimental and clinical studies allowing for interaction with genetic differences, will increase understanding of mechanisms leading to postnatal morbidity due to restricted fetal growth. Furthermore, this knowledge will make it possible to design clinical trials evaluating management protocols aiming not only to prevent perinatal mortality, but also to improve the postnatal development and health later in life of individuals with abnormal intrauterine blood flow.

# Cerebral and Umbilical Doppler in the Prediction of Fetal Outcome

Philippe Arbeille, Gabriel Carles, Murielle Chevillot, Alain Locatelli, Philippe Herve, Frank Perrotin, Dev Maulik

## Fetal Cerebral Flow Adaptation to Hypoxia

Hypoxia is present in most of the chronic or acute fetal patency stages. In severely growth-restricted fetuses  $pO_2$  is about 15 mmHg, whereas in normal fetuses it is about 23 mmHg. Fetal adaptation to hypoxia consists mainly of a humoral process and a cardiovascular process. Severe hypoxia is generally associated with a  $pCO_2$  increase and pH decrease. Erythropoiesis is stimulated, leading to polyglobulia, and polycythemia. The fetus protects against hypoxia by using the glucose reserves and the acid–base buffers. The initial cardiovascular response includes a redistribution of the main fetal flows and later blood pressure increase, bradycardia, and modification of the cardiac (left and right) hemodynamics. It is generally accepted that there is a significant vasoconstriction of most of the fetal territories (pulmonary, splanchnic, skeletal, and muscular areas) and an increased perfusion of the brain, the heart, and the adrenal glands [1–4]. This phenomenon, called the “brain-sparing effect”, attempts to compensate for fetal hypoxia by providing more oxygen to the brain via a cerebral vasodilation. Nevertheless, in the case of hypoxia blood oxygen saturation may not be normal [5, 6], and the increased brain perfusion may be responsible for brain edema with tissue deterioration. Finally, although the adapted response to hypoxia (brain vasodilation) is observed, it is difficult to evaluate if the brain tissue is protected against the deleterious effects of hypoxia and to what extent.

It was demonstrated that in cases of transient or chronic placental insufficiency (malaria, hypertension, drug abuse) abnormal fetal heart rate (FHR) occurs after some days and brain damage can develop after some weeks despite flow redistribution [7–10]. These observations suggest that the occurrence of functional (abnormal FHR) or organic fetal damage may depend on the amplitude of the  $pO_2$  decrease as already suggested and on the duration of the exposure to hypoxia [8]. Severe maternal anemia, which induces acute but reversible hypoxia without placental insufficiency, is frequently associated with prematur-

ity, reduced neonatal weight, and infant iron deficiency [11–14]. In this condition, oxygen supply to the fetus might be reduced and result in blood flow redistribution with similar consequences (abnormal FHR) as previously described, despite no evidence of placental insufficiency. On the other hand, several studies have suggested that decelerations in the FHR are a late sign of fetal deterioration before which the fetus might be delivered [15–18]; thus, anticipation of FHR abnormality by Doppler monitoring of the fetal flow redistribution occurring before worsening hypoxia could provide opportunity for early intervention [19–21].

Animal studies have demonstrated that fetal cerebral circulation is also affected by vasoconstrictive drugs administered during pregnancy. For example, nicotine induces in fetal lambs a reduction of the flow toward the brain, and affects the cerebral flow response to the  $CO_2$  test. Even drugs considered necessary to treat a mother’s pathology (hypertension) may have, after long-term treatment, unsuitable effects on the fetus by blocking or reducing the fetal adaptation to hypoxia.

## Examination Technique

### Human Investigations (Duplex B, Pulsed Wave Doppler, and Color Doppler)

The first studies were based on the exploration of the anterior and middle cerebral arteries [22–24] or of the intracranial portion of the internal carotid artery [25]. Due to the generally poor resolution of the ultrasound images, it was necessary to visualize well-known cerebral structures (cerebral peduncles, middle cerebral line) and use them as anatomical references to identify the intracerebral vessels. The significant improvement in ultrasound technology has facilitated this examination. It is now easy to detect the arterial pulsation of the cerebral vessels and to localize correctly the Doppler sample volume (Figs. 13.1, 13.2). On the biparietal image plane the middle cerebral arteries are found on a transverse line passing

**Fig. 13.1.** Investigation of the fetal cerebral arteries (**a, b**). Fetal cranial cross section with the cerebral peduncle and the Doppler sample volume on the anterior cerebral arteries and the corresponding Doppler spectrum. **c, d** Color Doppler of the circle of Willis. **e** Three-dimensional color Doppler

anterior to the cerebral peduncles, and the anterior arteries are found on a line perpendicular to the previous line approximately 2 cm in front of the peduncles' anterior limit.

With color Doppler technology it became possible to visualize and investigate the main cerebral arteries and to evaluate vascular resistance in various vascular areas of the brain supplied by these arteries [26]. In Figure 13.1 the two anterior, middle, and posterior ce-

rebral arteries, and the posterior communicating arteries, can be easily identified. The incidence displaying these vessels is similar to the "biparietal incidence" used for measuring the fetal head diameter. The vessels most easily investigated by this incidence are the middle cerebral arteries, because they are oriented toward the Doppler transducer. In this case the angle between the vessel axis and the Doppler beam is close to zero and the Doppler frequency is maximum.

**Fig. 13.2.** Umbilical and cerebral velocity waveform in normal pregnancies at 22, 30, and 37 weeks of gestation. Note that the cerebral end-diastolic flow velocity is always lower than the umbilical flow velocity; thus, the cerebral to umbilical index is always higher than the umbilical to cerebral index.

### Animal Investigations (Implanted Doppler Sensors)

Although fetal Doppler examinations in the human pregnancy provide useful information to the obstetrician, it is not possible to collect all the biological and hemodynamic data required to understand the physiopathological mechanisms involved in the development of the intrauterine growth restriction (IUGR) and the hypoxia.

With the animal model it is possible to measure blood pressure, blood velocity and blood volume, to collect blood samples, to perform pharmacological tests, and to simulate some human pathologies.

Several studies have been carried out on lamb fetuses using electromagnetic flow meters placed around the umbilical cord and catheters with pressure sensors inserted into the fetal aorta. Mostly, only the umbilical flow was assessed on the fetal side. Flat Doppler probes were developed to be implanted in the fetus and the mother, making it possible to assess atraumatically the fetal (cerebral/umbilical) and maternal flows in real time over a period of approximately 20 days' gestation. The 4-MHz continuous wave (CW) or pulsed wave (PW) Doppler probe consists of two rectangular piezoelectric transducers, pre-oriented at 45° from the surface of the probe, and placed in a plastic case (6 mm high, 2 cm<sup>2</sup> area) with small holes on the edges to sew the probe to the fetal skin. The sensors are affixed to the fetal skin, facing the umbilical cord, the fetal cerebral arteries and in front of the uterine arteries. The output wires and

the fetal catheter connectors are stowed in a pocket affixed to the back of the ewe, and at each measurement session the fetus is simply connected for 1 or 2 h (without any anesthesia) to the Doppler and pressure system (Fig. 13.3).

On the Doppler waveforms the blood flow volume and the vascular resistance changes in the area supplied by the vessel (placenta, brain, uterus) and the fetal heart rate are calculated. This system has been tested on normal gestations, during simulated fetal hypoxia, and during pharmacological treatments (Fig. 13.3) [7, 27, 28].

### Cerebral Hemodynamics and Doppler Indices

#### Cerebral Resistance to Flow

Accessibility to the main fetal cerebral arteries by Doppler has led to the development of various hemodynamic indices. The amplitude of the end-diastolic flow in the fetal vessels is directly related to the vascular resistances in the area supplied by these vessels [29–31]. In order to quantify the vascular resistances, various indices, which measure the proportion of systolic flow within the total forward flow (M) during one cardiac cycle, or the relative amplitude of systolic (S) to diastolic (D) flow, have been proposed:  $PI = (S - D)/M$  [32];  $R = D/S$  [30];  $RI = (S - D)/S$  [33];  $R = S/D$  [34]. Most of these parameters change according to the resistance to flow into the vascular territory un-

**Fig. 13.3.** Instrumentation of the fetus. Flat Doppler sensors are sewn on the fetal skin in front of the artery to be investigated (on the abdomen for the umbilical arteries, on the neck for the internal carotid artery, on the maternal abdomen for the uterine artery). A catheter is inserted into the fetal femoral artery, for blood pressure measurements and blood sampling (blood gases)

der investigation; therefore, any increase of these indices above the upper limit of the normal range corresponds to an increase of the vascular resistances (Fig. 13.4). In contrast, the D/S index decreases as the resistance to flow increases. The vascular resistance increase may be due to vascular disease (placental infarction or fibrosis) or to distal arteriolar vasoconstriction (brain response to increased  $pO_2$  or to vasoactive drugs). Conversely, abnormally decreased resistance to flow values are displayed below the lower limit of the normal range of the index for S-D/M, S-D/S, S/D (Fig. 13.4) and above the upper limit for the D/S index. The decreased resistance to flow may be due to the existence of arterio-venous shunts, or to an arteriolar vasodilation (brain adaptation to hypoxia or to drugs).

### Cerebral–Umbilical Ratio for Evaluating $pO_2$ Changes

The cerebral–umbilical (C/U) ratio (also known as the cerebral/placental ratio (CPR)) changes are indicators of peripheral fetal flow distribution. These parameters, based on the comparison of the brain (cerebral to umbilical index, CRI) and the placental (umbilical to cerebral index, URI) resistances, are expressed as either CRI/URI [22, 23] or URI/CRI [2], the cerebral vascular resistances being measured from one of the intracerebral arteries (anterior or middle) or from the intracranial part of the carotid artery. By measuring the flow redistribution between the placenta and brain, these C/U ratios (in cases of pathologic pregnancies) take into account the placental dis-

turbances due to vascular disease at this level, and the cerebral response (vasodilation) to the hypoxia induced by placental dysfunction.

In normal pregnancies the diastolic component in the cerebral arteries is lower than in the umbilical arteries at any gestational age (Fig. 13.2); therefore, the cerebral vascular resistances remain higher than the placental resistances and the C/U ratio ( $C/U = CRI/URI$ ) is  $>1.1$  (Figs. 13.4, 13.5). The C/U ratio (CRI/URI) becomes  $<1.1$  if any flow redistribution in favor of the brain occurs (Figs. 13.6–13.8). In such case the cerebral diastolic flow amplitude is higher than normal, and the umbilical flow amplitude is lower. Animal and human studies have demonstrated that the C/U changes in proportion to fetal  $pO_2$  [35, 36]. The URI/CRI ratio used by other authors to detect fetal flow redistribution varies in the opposite direction.

### Effect of Fetal Heart Rate on Doppler Vascular Resistance Indices

It is well known that an elevation of the fetal heart rate increases the end-diastolic velocity and therefore decreases the resistance index (Fig. 13.9). On the other hand, diminution of the heart rate increases the index value. This effect of the heart rate is eliminated by the use of the C/U ratios because both indices, CRI and URI, are measured on the same fetus with the same heart rate. The two C/U ratios mentioned above are not heart rate dependent, because the cerebral as well as the umbilical index are equally affected by the heart rate changes. Figure 13.5 shows the fluctuations of both the placental and the umbilical in-

**Fig. 13.4.** Resistance index  $[R=(S-D/S)]$  and cerebral-umbilical ratio  $(C/U=CRI/URI)$  in a population of 90 hypertensive pregnancies, with 17 (19%) having moderate IUGR (S=systolic peak, D=end-diastolic velocity). Normal range delimited from a population of 100 normal pregnancies. **a** Evolution of the umbilical vascular resistance index (URI) in normal (open symbols), and in growth-restricted (closed symbols) fetuses. The URI is abnormal when higher than the upper limit of the normal range. The sensitivity of these indices for the detection of IUGR is about 60%. **b** Evolution of the cerebral (CRI) vascular resistance in normal (open symbols), and in growth-restricted (closed symbols) fetuses. The CRI is abnormal when it is lower than the lower limit of the normal range. **c** Cerebral-umbilical ratio in normal (open symbols) and growth-restricted (closed symbols) fetuses. The sensitivity of this index for the detection of IUGR is about 85%

**a**

**b**

**Fig. 13.5.** **a** Evolution of the cerebral (CRI) and umbilical (URI) vascular resistances in the same fetus during a normal gestation. The fluctuations in parallel on the two indices are related to the variations of the fetal heart rate. Note that the cerebral resistances remain superior to the placental resistances at any gestational age. **b** Evolution of the C/U ratio during the same normal gestation (CRI > URI → normal CRI/URI always > 1.1)

Cerebral A :  $CRI = (S-D)/S = 0.60$

Umbilical A :  $URI = (S-D)/S = 1$

**Fig. 13.6.** Brain-sparing effect. Note the absent diastolic flow on the umbilical velocity waveform and increased diastolic flow on the cerebral velocity waveform in relation to a decrease in the cerebral vascular resistance by vasodilation (growth-retarded and hypoxic fetus delivered at 35 weeks). S systolic peak, D end-diastolic velocity

**Fig. 13.7.** Evolution of URI and CRI in a pregnancy complicated by hypertension. The umbilical resistance increases progressively, whereas the cerebral resistance decreases to adapt to the reduction in fetal  $pO_2$ . When the URI reached 1 (absent end-diastolic flow) the C/U ratio had already entered the pathological area several weeks previously. It is noteworthy that the CRI is not far from its normal zone, but the CRI/URI ratio is very far from the normal limit

**Fig. 13.9.** Effect of the heart rate (beats per minute, bpm) on the end-diastolic flow and on the resistance index (RI). At 110 bpm the diastolic flow decreases during a longer period than at 140 bpm; therefore, the end-diastolic flow amplitude is lower than at 140 bpm and the  $RI = [(S-D)/S]$  at 110 bpm becomes higher (0.91) than at 140 bpm (0.62). A high fetal heart rate (180 bpm) increases the diastolic flow and decreases the RI (at 180 bpm,  $R=0.37$ )

dices (due to the heart rate variations) and the stability of the C/U ratio in a normal fetus. Finally, it was demonstrated that the normal range of the C/U ratio is limited by a single lower cut-off value of 1 to 1.1 at least for the second half of the pregnancy and is unaffected by the FHR value (Fig. 13.5) [22, 23, 37–39].

### Hypoxic Index for Predicting Effect of Hypoxia

In one study, the C/U ratio was used to quantify the flow redistribution (i.e., reduction in  $pO_2$ ) throughout the period of observation until delivery. By adding the successive C/U ratio decreases (in percentage of the cut-off value) measured every 2 days we measured the presumed cumulative relative deficit in  $pO_2$  to which the fetus was submitted during this period. The hypoxic index (HI) is calculated by adding the percentage decrease of C/U ratio (when C/U becomes lower than 1.1) each measurement from admission to delivery. This number corresponds to the area between the percentage C/U curve and the time axis (days) (Fig. 13.10) [8].

**Fig. 13.8.** Different (CRI) and (URI) values associated either with a normal fetus ( $C/U = CRI/URI > 1$ ) or with an IUGR ( $C/U < 1$ ). Normal fetal hemodynamics → normal CRI and URI ( $C/U > 1.1$ ). Abnormal flow distribution: abnormal CRI and URI ( $C/U < 1.1$ ); abnormal CRI, normal URI ( $C/U < 1.1$ ); normal CRI; abnormal URI ( $C/U < 1.1$ ); normal CRI, normal URI ( $C/U < 1.1$ )

**Fig. 13.10. a** Mean variations of the ratio ( $C/U$  = cerebral resistance/umbilical resistance) during the malaria crises in group 1 (1994 short and long crisis) and in group 2 (1996 crisis). The  $C/U$  change is expressed in percentage from cut-off limit 1.1. In group 1  $C/U$  decreased significantly more during long crisis than during short ones ( $p < 0.05$ ). The area between the  $C/U$  ratio curve and the time axis is the hypoxic index ( $HI$ ). As the  $C/U$  ratio changes proportionately to the fetal  $pO_2$ , this area represents the cumulated deficit in  $pO_2$  over the crisis. **b** Correlation between occurrence of abnormal fetal heart rate ( $FHR$ ) vs  $HI$ . The  $HI$  is abnormal when  $>150\%$  →  $PPV = 80\%$ ,  $NPV = 85\%$

In normal pregnancies the  $HI$  remains equal to zero as only  $C/U$  values lower than 1.1 which indicate a flow redistribution are taken into account. A flow redistribution characterized by a  $C/U$  ratio equal to 0.77 ( $-20\%$  below 1.1) means that it could correspond to a  $20\%$   $pO_2$  reduction. If this situation remains stable for 10 days, the  $HI$  will be equal to  $20\% \times 10 = 200\%$ .

### Cerebral Circulation in Normal Pregnancy

#### Cerebral Flow Changes with Gestational Age

The diastolic flow in the cerebral vessels is reduced at the beginning of the second half of pregnancy (20–25 weeks) but continues developing progressively. The increase in the diastolic component with the gestational age is interpreted as a decrease in the cere-

bral resistance due to brain development. The cerebral vascular resistance changes are measured using the same Doppler indices as for the placenta (Figs. 13.2, 13.4, 13.5).

The increase in the diastolic component begins later in the cerebral arteries (at approximately 25 weeks) than in the umbilical arteries (at approximately 15 weeks). The amplitude of the diastolic flow in the cerebral arteries is always lower than in the umbilical arteries, meaning that in normal pregnancy the cerebral vascular resistances are higher than the umbilical resistances. In other words, the umbilical flow volume is higher than the cerebral flow volume. This led to the definition of the  $C/U$  ratio (cerebral resistance/umbilical resistances), which is inversely proportional to cardiac output distribution between brain and placenta, and which is higher than 1.1 in normal pregnancies.

## Variations According to the Site of Examination

In normal fetuses the resistance index is significantly higher in the middle cerebral artery ( $p < 0.01$ ) [26] than in the anterior and posterior cerebral arteries. In pathological pregnancies with cerebral vasodilation (decreased cerebral index) the sensitivity of cerebral Doppler examination is not dependent on the choice of the cerebral artery explored. Since the Doppler indices measured on two different vessels will not differ by more than 5–10%, the conclusions of the Doppler investigation will not be changed. Nevertheless, during assessment of the fetal circulation over several days or weeks, successive examinations must be performed on the same vessel.

## Cerebral Flow Changes with Behavioral States

Fetal behavioral states are defined according to the fetal heart rate pattern and the body and eye movements [40, 41]. In normal pregnancies at 37–38 weeks' gestation, blood flow velocity waveforms in the descending aorta and the internal carotid artery are affected by fetal behavioral states. In both vessels a significant reduction in the pulsatility index was established during behavioral state 2F (active sleep), compared with behavioral state 1F (quiet sleep) [41–43]. The decreased peripheral vascular resistance induces increased perfusion to the musculature and brain required by the increased energy demand during active sleep. In addition, peak flow velocity decrease in the fetal ductus arteriosus during active sleep has been demonstrated [43]. This observation confirms the existence of a redistribution of flow between the two ventricles with increased left cardiac output, which may contribute to the increased brain perfusion.

## Clinical Significance of Cerebral and Cerebral/Umbilical Indices

### Cerebral Flow in Growth-restricted and Hypoxic Human Fetuses

The Doppler indices measured in the main fetal cerebral arteries are sensitive to any vasoconstriction or vasodilatation of the brain vessels. An increase in the diastolic cerebral flow is interpreted as a vasomotor response (vasodilation) to hypoxia [25, 26, 44]. Comparisons between the cerebral Doppler index and the measurement of  $pO_2$ ,  $pCO_2$ ,  $pH$ , and  $O_2$  content by

cordocentesis have demonstrated a good correlation between  $pO_2$  and the cerebral Doppler index in cases of severe hypoxia (the cerebral index decreases with the  $pO_2$ ). Nevertheless, when acidosis appears there is sometimes an increase in the cerebral vascular resistance index due to a decrease in the diastolic flow [36, 45].

At first it appears difficult to quantify hypoxia using the CRI, but if it is measured every day in fetuses with abnormally decreased CRI, the evolution of the hypoxia can be followed through the brain's vascular resistance changes as illustrated in the following scenarios:

- Scenario 1: The cerebral vascular index is abnormal (lower than normal) but decreases progressively, as in normal fetuses. This can be related to high HR values, or to a hypoxic stable stage, but no reliable answer can be provided.
- Scenario 2: The abnormal cerebral index continues to decrease significantly and becomes more and more pathological. Hypoxia develops but the fetus is probably not acidemic.
- Scenario 3: A cerebral RI below the normal range but not changing over 2–3 days means that the small vessels beyond the measuring point can no longer change their diameters. Such a pattern was observed in pre-mortem fetuses in which brain edema and neuronal deterioration were observed at post-mortem anatomical examination [10].
- Scenario 4: Lastly, the cerebral index, already much lower than the normal limit, increases and enters the normal range again. In this case the capability of the brain vessels to vasodilate has been overwhelmed. Hypoxia is decompensated and the fetus becomes acidemic.

In all these circumstances it is hazardous to use only one absolute value of the cerebral Doppler index for the assessment of hypoxia and for making a decision about delivery. Only the evolution of the cerebral index or the C/U ratio over several days may provide information on the development of fetal hypoxia. Nevertheless, a good correlation has been found between the existence of significantly decreased ( $< 2$  SD) cerebral resistance and the development of post-asphyxial encephalopathy in the neonate [46]. In this study, the specificity and the sensitivity of fetal cerebral Doppler as a predictor of neonatal outcome were about 75 and 87%, respectively; however, it is emphasized that the vasodilation compensates only partially for the hypoxia, and its persistence over a long period of time does not guarantee the absence of brain tissue damage.

## Cerebral–Umbilical Ratio Change in Case of Hypoxia and IUGR

The comparison with the cerebral and the placental vascular resistance for the assessment of IUGR was proposed in 1986 [22] and the results were confirmed in 1987 [2, 23]. In pathological pregnancies (hypertensive pregnancies, for example) with IUGR we frequently observe a reduction in placental perfusion, and an increase in flow toward the brain. This phenomenon, called “brain-sparing effect,” is supposed to compensate fetal hypoxia. The main advantage of comparing placental and cerebral vascular resistance is that we take into account, firstly, the existence of placental vascular disease which can be responsible for an alteration of the maternal to fetal exchanges, and secondly, the cerebral hemodynamic consequences of these abnormalities (vasodilation).

Nevertheless, the C/U ratio may become pathological by various situations:

1. There is an increase in the placental resistances but no hypoxia and a normal cerebral perfusion (malaria beginning of crisis).
2. The placental resistances are normal but hypoxia exists and therefore the cerebral resistance is abnormally decreased (moderate anemia).
3. Both placental and cerebral resistances are abnormal (pregnancy-induced hypertension, malaria).
4. Both indices are within their normal range but the cerebral index is lower than the placental one (Fig. 13.8; early stage of pathological process).

All these combinations describe a fetal flow redistribution and are associated in most cases with IUGR and/or hypoxia. Several similar studies using either the ratio between the anterior cerebral artery index and the umbilical index ( $C/U = CRI/URI$ , which is pathologic when  $<1.1$ ; Fig. 13.4) [23, 37, 38, 47], or the ratio between the umbilical index and the internal carotid index ( $I = URI/ICRI$ , which is pathologic when  $>1$ ) [2], demonstrated a sensitivity of approximately 86% and a specificity of about 98%.

The C/U ratio has been tested on hypertensive pregnancies with severe IUGR, moderate IUGR, or twin gestations [23, 48, 49], and showed the same accuracy. This high sensitivity and specificity of the C/U ratio as a predictor of IUGR, including cases of moderate IUGR without fetal distress, confirms that the fetal flow redistribution in favor of the brain always exists, even at the early stage of development of IUGR, and is detectable by Doppler.

Figure 13.7 shows the evolution of both URI and CRI in a pregnancy complicated by hypertension. The umbilical resistance increases progressively whereas the cerebral resistance decreases to adapt to the re-

duction in fetal  $pO_2$ . When the URI reaches 1 (absent end-diastolic flow) the C/U ratio had reached the pathological stage several weeks previously. It may be noted that the CRI is not far from its normal zone, but the CRI/URI ratio is very far from normal.

## Cerebral–Umbilical Ratio and Perinatal Outcome

Kjellmer et al. [6] demonstrated in animals that IUGR is generally associated with cerebral metabolism disturbances and delayed development of the brain. Moreover, Fouron et al. [5] showed that in the case of fetal flow redistribution there is a reverse diastolic flow into the aortic arch, confirming that hypoxic blood coming from the right ventricle flows into the brain. This phenomenon probably limits the beneficial effect of the brain-sparing reflex; therefore, the C/U ratio was tested as an indicator of adverse perinatal outcome. Gramellini et al. [38] studied 45 growth-retarded fetuses and found a 90% sensitivity for the C/U ratio when used as a predictor of poor perinatal outcome, compared with 78% for the middle cerebral artery index and 83% for the umbilical artery index. In their study, the parameters used to evaluate fetal well being were: fetal heart rate; gestational age; birth weight; Cesarean rate; umbilical vein pH; 5-min Apgar score; the incidence of admission to the neonatal intensive care unit; and neonatal complications.

## Hypoxic Index for Predicting Effect of Hypoxia

The hypoxic index (HI) was found to predict abnormal FHR with a sensitivity and specificity close to 80%. The cut-off limit for HI was found retrospectively in a previous study on pregnancies complicated by malaria to be 150% and was 160% in a pregnancy-induced hypertension study [8]. For example, an HI of 150% may correspond either to 3 days under a reduction of 50% in  $pO_2$  ( $3 \times 50\% = 150\%$ ), or 15 days under a reduction of 10% of fetal  $pO_2$  ( $15 \times 10\% = 150\%$ ; Fig. 13.10).

The HI takes into account the amount of reduction in fetal  $pO_2$  as well as the duration of exposure to hypoxia. Moreover the product of the  $pO_2$  value at delivery (umbilical vein  $pO_2$ ) by the number of days with fetal flow redistribution ( $C/U < 1.1$ ) correlated well with the HI value (regression). The HI increases progressively in the case of a non reversible placental insufficiency, whereas it can return to normal (equal zero) in the case of reversible placental insufficiency (malaria) [8] or reversible reduced  $pO_2$  supply (anemia) [50].

### Cerebro-Vascular Reactivity Tests ( $O_2$ , $CO_2$ )

When the cerebral Doppler index is lower than the normal range or when the C/U ratio indicates a fetal flow redistribution, the fetus is considered hypoxic. It is difficult to evaluate the consequences of such hypoxia on the brain structures and on cerebral functions [44, 46].

The oxygen test (maternal oxygenation administration) was used to test fetal brain reactivity [51–54]. During maternal oxygen treatment the cerebral index was measured at the level of the internal carotid artery. In fetuses with brain-sparing effect (cerebral resistance below normal) but who did not develop fetal distress, the oxygen treatment induced an increase in cerebral resistance. In contrast, those fetuses with cerebral vasodilatation who did not respond to the oxygen test (no increase in cerebral resistance) developed fetal distress. The sensitivity of the oxygen test when used as a predictor of imminent fetal distress is about 70% [51]. The positive cerebral response proves that placental transfer is maintained and may justify intrauterine treatment of fetuses with long-term maternal oxygen therapy. Conversely, the absence of vascular response to the oxygen test indicates that either the placental transfer and/or the cerebral reactivity are impaired.

The cerebral vascular resistance of the fetus is also sensitive to the variation of  $CO_2$  content in the air inspired by the mother. It was demonstrated that a mixture with 2%  $CO_2$  induces a decrease in fetal cerebral resistance but does not affect either the fetal heart rate or the umbilical flow [55].

### Cerebral Resistance Index, Flow Redistribution Ratio (C/U), and Hypoxic Index in Specific Human Pathologies

#### Cerebral Resistance Index and C/U Ratio in Acute Reversible Hypoxia: Prediction of Abnormal FHR at Delivery

##### Without Placental Insufficiency: Maternal Anemia

Moderate ( $Hb > 6$  g/100 ml) or severe ( $Hb < 6$  g/100 ml) maternal anemia (Fig. 13.11) may develop during pregnancy and relates mainly to non-adapted food intake (ingestion of iron-chelating agent such as clay in South America or African tropical forest). Severe maternal anemia induces significant cerebral vasodilatation as confirmed by a cerebral resistance lower than normal with an increase in cerebral blood flow which likely increases the fetal oxygen supply and a reduction in amniotic fluid. Umbilical flow is not affected, which is in agreement with the fact that there was no placental alteration. The flow redistribution is probably related to a reduction in maternal blood oxygen carrier induced by the iron-chelating agents and its subsequent reduction in fetal  $pO_2$ . The increase in cerebral resistance and C/U ratio after red cell injection without a significant change in umbilical resistance confirms that maternal anemia does not create placental dysfunction, and that the condition can be relatively quickly corrected by a single red blood cell unit transfusion to the patient [50]. The cerebral adaptation is similar to the one observed in anemic fetuses during pregnancies complicated by red cell alloimmunization [56–58]. These authors showed that the fetal cerebral pulsatility index decreased in anemic fetuses but reached abnormal values only in cases of severe fetal anemia. A he-

**Fig. 13.11.** Changes from admission to 8 days after maternal treatment for the parameters listed below. Group 1: moderate anemia [ $Hb$ ]  $> 6$  g/100 ml; group 2: severe anemia: [ $Hb$ ]  $< 6$  g/100 ml. [ $Hb$ ] maternal hemoglobin content, *Amniot* amniotic index, *URI* umbilical resistance index, *CRI* cerebral resistance index, *C/U* cerebral to umbilical resistance ratio. Note that the parameters change significantly only in the group with severe anemia

moglobin content lower than 5 g/100 ml was closely associated with fetal flow redistribution and abnormal FHR. On the other hand, the occurrence of abnormal FHR was associated with  $C/U < 1.1$ , which indicates that fetal flow redistribution plays a role in the development of cardiac dysfunction. Sixty-seven percent of the fetuses with abnormal FHR had a  $C/U < 1.1$ . Nevertheless, the modest values of the sensitivity (73%), specificity (33%), positive predictive value (PPV; 50%), and negative predictive value (NPV; 57%) confirm that the amplitude of the flow redistribution ( $C/U$  ratio) is not sufficient to predict the effects of this hemodynamic adaptation over time.

Other studies demonstrated that fetal cerebral vasodilation during a period of several weeks does not protect against cerebral organic damages [7, 9, 10]; thus, as the severe maternal anemia triggers a marked fetal cerebral vasodilation, the hemoglobin content has to be recovered as soon as possible in order to suppress the cerebral vasodilation. Moderate maternal anemia ( $Hb > 6$  g/100 ml) did not trigger fetal flow redistribution or abnormal FHR which suggest that fetal oxygenation was still satisfactory.

### ***With Placenta Insufficiency (Malaria)***

During a malaria crisis destruction of red blood cells and inflammatory processes probably affect the placental microcirculation and thus the fetal-maternal exchanges. The fetus triggers a flow redistribution in favor of the brain, most likely in response to hypoxia, but this redistribution disappears at the end of the crisis.

A 1994 study of fetal hemodynamic changes investigated cerebral and umbilical responses to short- and long-term malaria crises [8]. In the short crisis group (<7 days) 61% of the fetuses were premature, 23% had abnormal FHR at delivery (several weeks later),  $C/U$  decreased by  $-8 \pm 6\%$ , and the mean HI was equal to  $-62 \pm 54$ . In the long crisis group (>7 days) 70% of the fetuses were premature, 70% had abnormal FHR at delivery (several weeks later),  $C/U$  decreased by  $-14 \pm 6\%$ , and the mean HI was equal to  $-187 \pm 54$ . (Fig. 13.10).

A second similar study performed in 1996 in the same area and using the same protocol showed only a short crisis (<7 days). In this group, 35% of the fetuses were premature, 17.5% had abnormal FHR at delivery (several weeks later),  $C/U$  decreased by  $-7 \pm 4\%$ , and the mean HI was equal to  $-49 \pm 26$ . In both studies a  $HI > 150\%$  was predictive of abnormal FHR at delivery with a sensitivity of 80% and specificity of 85%.

The HI allowed prediction of abnormal FHR at delivery several weeks in advance. Moreover, the lower amplitude of the hemodynamic response (lower HI

in the second group associated with a lower rate of abnormal FHR was likely related to an improvement in pregnancy recruitment and management or with the acquisition of an adapted immunity by the mother.

### **C/U Ratio in Non-Reversible Hypoxia (Pregnancy-Induced Hypertension) Prediction of Abnormal FHR at Delivery**

In a study of fetal cerebral and umbilical flow adaptation in pregnancies complicated by hypertension, which included 82% with IUGR, the fetal hemodynamics were monitored every 2 days by Doppler over several days from admission until delivery [59]. As flow redistribution was identified at its early stage both the intensity and the duration of the flow redistribution period (hypoxic period) were considered for predicting the occurrence of abnormal FHR. By the end of the study the limit for the HI was 160%. Figure 13.12 shows a graphic representation of HI (area between the  $C/U$  curve and the  $C/U=1.1$  cut-off line). This area represents the total oxygen deficit during the period of observation.

A HI higher than 160% was much more powerful (PPV: 87%; NPV: 88%) than the final URI, CRI, or  $C/U$  value measured for predicting abnormal FHR at delivery [URI (PPV: 63%; NPV: 74%) – CRI (PPV: 59%; NPV: 70%) –  $C/U$  (PPV: 57%; NPV: 92%)]. Moreover, as shown on Fig. 13.12, the  $C/U$  may change from one day to another; thus, a single Doppler measurement is not sufficient to identify the real hemodynamic stage induced by hypoxia. On the other hand, the HI increase is associated with an increase in the degree of fetal growth restriction as expressed in percentile. This suggests that the HI, by measuring the cumulated oxygen deficit during the observation period, also likely expresses the deficit in the nutrition supply responsible for the fetal growth restriction.

Finally, it should be noted that this study addressed high-risk pregnancy but not very poor fetal outcomes: 22% of all fetuses required intensive care assistance (but <2 days and two-thirds of them <33 weeks) and all survived in good health; only one fetus died at delivery. Thus, HI is a very early predictor of poor fetal outcome. In contrast, absent end-diastolic flow in the umbilical arteries was found in 9 cases (13% of the whole population), but all delivered before 33 weeks; all presented abnormal FHR; all were severely growth restricted (centile: 6+2); 8 (88%) delivered by Cesarean section; and 5 (56%) required intensive care assistance. These fetuses presented the lowest  $C/U$  ratio ( $0.7 \pm 0.1$ ) and umbilical cord  $pO_2$  value at delivery ( $16 \pm 6$ ) and the highest HI values ( $387 \pm 173\%$ ) in the population.

**Fig. 13.12.** Evolution of C/U reduction (in percentage from 1.1 cut-off value). The HI is represented as the area between the C/U (%) *bold curve* and the 0% *horizontal dotted line* (corresponding to C/U=1.1). **a** IUGR fetus, delivered at 34 weeks, normal FHR, HI=81% (approx.: mean C/U decrease of  $-5\% \times 17$  days). **b** IUGR fetus, delivered at 34 weeks, abnormal FHR, HI=183% (approx.: mean C/U decrease of  $-18\% \times 10$  days). **c** Correlation between occurrence of abnormal FHR vs C/U ratio (C/U abnormal when  $>1.1 \rightarrow$  PPV=57%, NPV=92%). **d** Correlation between occurrence of abnormal FHR vs hypoxic index. The HI is abnormal when  $>160\% \rightarrow$  PPV=87%, NPV=88%

These results confirm that absent end-diastolic flow close to delivery means that the fetus has already been submitted to severe and long-term hypoxia and has entered the danger zone in which the risk of brain lesion is high [60, 61]. A retrospective study [10] showed that fetuses that developed brain lesions had an HI much higher than those in our study, and frequently showed absent or reverse diastolic flow at admission. In these situations HI is underestimated as we do not know how many days diastolic flow was absent and how long the C/U ratio was below the cut off limit; thus, it is recommended to use other later hemodynamic markers of fetal deterioration, such as the loss of fluctuation of the cerebral RI over 3 days [10], or the presence of abnormal ductus venosus or umbilical vein flow patterns if these signs appear before reaching a HI=160% [19–21, 62, 63].

### Cerebral Flow During Maternal Anesthesia

The fetal cerebral and umbilical flows (Fig. 13.13) were monitored during maternal anesthesia of 7 h duration, the objective being to detect any fetal hemodynamic change (response to hypoxia) in relation to the different drugs used during this period: phenoperidine 7.5 mg, thiopental 500 mg, gamma hydroxybutyrate 6 g, and isoflurane (Forane) 0.3–0.5% at 90 min after the beginning of the anesthesia. The patient was surgically treated at 21 weeks' gestation for angioma of the posterior cranial fossa. Doppler recordings of the umbilical arteries and the fetal anterior cerebral arteries were performed before anesthesia, during the anesthesia (at 10, 45, 60, and 90 min, and 3 and 7 h), and after anesthesia (2 h, 7 days, and 5 months). The fetal heart rate decreased progressively beginning 2 h after the start of anesthesia (from 150/min to 110/min at 3 h), and had recovered partially at 2 h after anesthesia was discontinued. At 7 days and at 5 months, the fetal heart rate was normal for the gestational age (145/min). At the same time, the cerebral (CRI) and the placental (URI) resis-

tance indices decreased moderately, although the C/U ratio stable around its basal value. These three parameters stayed within the normal range for the gestational age throughout the anesthesia. After the anesthesia, the cerebral and placental indices decreased normally from 22 to 40 weeks, and the C/U remained stable. The evolution of the fetal vascular parameters demonstrates the effects of drugs on the fetal heart rate (significant decrease) and the stability of the fetal flow distribution (cerebral and placental) despite the marked hemodynamic changes in the mother.

## Cerebral Flow Response to Induced Hypoxia and Drugs in Animal Models

### Cerebral Flow and Long-Term Nicotine Treatment (Animal Model)

The effect of nicotine on fetal cerebral flow and reactivity has been studied in pregnant ewes ( $n=6$ ) given a daily dose of nicotine equivalent to 20 cigarettes [28]. In the nicotine group there was no decrease in vascular resistance (RI) at the end of gestation, as in the control group (Fig. 13.14). This phenomenon, more evident on the cerebral arteries ( $p<0.01$ ) than in the umbilical arteries ( $p<0.05$ ), could be interpreted as cerebral vasoconstriction, or as a delayed brain development. Moreover, the increased C/U in the nicotine group ( $p<0.01$ ) confirmed reduced brain perfusion. In addition to these hemodynamic findings, there was a higher percentage of stillborns in the nicotine group (63%) than in the control group (13%). The newborns in the nicotine group showed an abnormal cerebro-vascular response when submitted to a CO<sub>2</sub> inhalation test (no cerebral vasodilation). It was concluded that repeated administration of nicotine was responsible for abnormal brain vascular development, with loss of cerebral reactivity and poor fetal outcome. These results led to the hypothe-

**Fig. 13.13.** Evolution of the C/U resistance ratio during maternal anesthesia (3 h). The C/U remains stable even when the FHR changes significantly (no fetal flow redistribution). After the anesthesia, the C/U decreases slightly with the gestational age and stays within the normal range until delivery (normal delivery at 40 weeks, normal fetus)

**Fig. 13.14.** Chronic nicotine administration. Variations of the fetal cerebral resistance index (CRI), on lamb fetuses, during gestation (140 days). On the “control-placebo” group the CRI decreases progressively from gestation day 80 until the end of the gestation, but not on the nicotine group submitted to repeated daily maternal injections of nicotine since gestation day 30. During the same period the C/U ratio remains constant in the control group; however, it increases by 25% in the nicotine group (reduction of cerebral perfusion in the nicotine group)

sis that if fetal hypoxia develops in “nicotine fetuses,” the capability of the brain vessels to adapt by vasodilation is reduced because of the “vasoconstrictive” effect of nicotine and the deleterious effects of the drug on the growth and the maturation of the brain structures.

### Cerebral Flow and Long-Term Cocaine Treatment (Animal Model)

Uteroplacental flow and fetal cerebral flow were assessed by Doppler ultrasonography in pregnant ewes treated daily with cocaine beginning on gestational day 60 (Fig. 13.15). Fetal weight and fetal  $pO_2$  were measured at delivery. The study groups received 70 mg ( $n=7$ ) or 140 mg ( $n=7$ ) of cocaine intramuscularly and the control group ( $n=7$ ) was given an intramuscular placebo. The maternal heart rate and the uterine RI (vascular resistance index) were always significantly higher ( $p<0.01$ ) in the cocaine groups.

The fetal heart rate and the URI were also significantly higher ( $p<0.01$ ) in the two cocaine groups than in the control group.

Prior to delivery, the fetal cerebral RI and the C/U were significantly lower ( $p<0.01$  for CRI;  $p<0.001$  for C/U) in the cocaine groups than in the control group. At delivery the  $pO_2$  was also significantly lower in the cocaine groups ( $p<0.05$  for the 70 mg/kg group;  $p<0.01$  for the 140 mg/kg group) than in the control group (Fig. 13.15). The mean birth weight was significantly lower in the two cocaine groups in comparison with the control group; therefore, repeated injections of cocaine to pregnant ewes induces uteroplacental disorders with fetal growth restriction and a redistribution of the fetal flows in response to moderate hypoxia. This study confirms the value of measuring the C/U ratio for follow-up of the abnormal fetal  $pO_2$  during chronic hypoxia [7].

**Fig. 13.15.** Chronic cocaine administration. Fetal umbilical resistance (*URI*), cerebral resistance (*CRI*), cerebral–umbilical (*C/U*) ratio, fetal weight, and  $pO_2$  (in the “70 mg/kg day<sup>-1</sup>” and “140 mg/kg day<sup>-1</sup>” cocaine groups), expressed in percentage of the control group value. Data collected at the end of the gestation (134 days). The *C/U* and  $pO_2$  are significantly decreased (in parallel) in the cocaine groups (20–25% for *C/U* and 10–15% for  $pO_2$ ). The *C/U* is decreased in response to the development of a chronic fetal hypoxia.

### Cerebral–Umbilical Ratio and Mechanically Induced Hypoxia

Induced hypoxia (Fig. 13.16) in lamb fetuses has demonstrated a sensitive and rapid brain vasodilation. The fetal cerebral and umbilical flows were assessed by Doppler sensors implanted on the fetus during fetal hypoxia induced by umbilical cord compression, aortic compression, and drug injection [27, 35].

Umbilical cord compression ( $n=8$ ) decreases the venous return and the umbilical arterial flow, which induces hypoxia instantaneously and simulates fetal central hypovolemia. During a 10-min compression the cerebral vascular resistance decreased and the cerebral flow was maintained or only slightly decreased. Simultaneous recordings of the cerebral and umbilical Doppler waveforms together with the  $pO_2$  showed that the *C/U* ratio decreased proportionately with the  $pO_2$ . The umbilical flow ( $Q_p$ ) decreased together with the *C/U* (Fig. 13.16a,c). The pH and the heart rate remained normal. In the case of progressive cord compression (progressive changes of the umbilical resistance), the *C/U* closely followed the changes in fetal  $pO_2$ .

Aortic compression ( $n=8$ ) reduced the uterine flow and induced fetal hypoxia after about 30 s. After 1 min of compression, the heart rate dropped and the compression was interrupted. The heart rate recovered 30 s after the end of the compression. The pH did not change during the test and the umbilical flow remained stable; however, the umbilical resistance increased and the cerebral resistance decreased. As with umbilical cord compression, the *C/U* follows the variations of the fetal  $pO_2$  (Fig. 13.16b).

Simultaneous measurements of the fetal  $pO_2$  and the *C/U* during these compression tests showed a good correlation between the two parameters (Fig. 13.16c). Nevertheless, the amplitude of the *C/U* variations were higher during umbilical cord compression than during the aortic compression. In fact,

cord compression induces a central hypovolemia, which does not exist with aortic compression; therefore, one can speculate that during cord compression the *C/U* drop may be related to the hypoxia and the hypovolemia, which may stimulate the baroreflex.

### Cerebral–Umbilical Ratio and Acute Drug Effect

Propranolol (4  $\mu\text{g}/\text{kg}$ ) was injected intravenously into pregnant ewes ( $n=3$ ), which were instrumented 24 h before (Fig. 13.3). The umbilical resistance increased and the cerebral resistance decreased beginning 1 min after injection leading to a significantly decreased *C/U* [27]. In this study,  $pO_2$  was not measured but the fetal flow redistribution detected by *C/U* after each injection leads us to suspect that repeated injections of this drug may induce repeated hypoxic stresses for the fetus; hence, the beneficial effects of any drug (for the mother) and its deleterious effects (i.e., hypoxia) on the fetus must be evaluated before its use.

### Conclusion

The objective of fetal Doppler is to detect at an early stage any hemodynamic changes that allow us to identify and quantify a placental dysfunction (with associated fetal malnutrition and low oxygenation). Fetal Doppler studies also allow us to determine the consequences of this abnormality on fetal growth and well-being.

The *URI* has been used to confirm the existence of placental hemodynamic disorders in the case of IUGR, but the sensitivity of this parameter for the follow-up of fetal growth remains at only 60%. Nevertheless, the absence of end-diastolic flow in the umbilical or aortic Doppler waveform is an indicator of severe fetal distress and neonatal cerebral complications [60, 64–70].

**Fig. 13.16. a** Umbilical cord compression. Variations in percentage from the pre-test value of the: Heart rate (HR), umbilical vascular resistances (URI), umbilical flow (UBF), cerebral-umbilical ratio (C/U), fetal pO<sub>2</sub>, and cerebral flow (CBF) during a period of chord compression. The C/U decreases in proportion with the fetal pO<sub>2</sub> and the UBF, whereas CBF remains unchanged. **b** Aortic compression. Variations in percentage from the pre-test value of the HR, URI, UBF, C/U, fetal pO<sub>2</sub>, and CBF during a period of chord compression. The C/U decreases in proportion with the fetal pO<sub>2</sub>, whereas the UBF and CBF remain unchanged. **c** Relationship between absolute values of the C/U ratio and the pO<sub>2</sub> during induced hypoxia

Cerebral flow changes in relation to hypoxia and fetal distress continues to be one of the most interesting areas of investigation. Even though many studies have already demonstrated positive correlations between cerebral Doppler data and fetal hypoxia or fetal well-being, it is too early to draw a conclusion as to how to use cerebral Doppler studies in routine practice for the management of fetal distress and for making the decision to interrupt a gestation.

The C/U, which measures the proportion of flow supplying the brain and the placenta, is now the most widely used parameter for the assessment of IUGR and hypoxia. Firstly, it takes into account the causes and consequences of the placental insufficiency responsible for IUGR and hypoxia. Secondly, it is not heart-rate dependent. Thirdly, it has a single cut-off value (C/U is normal if >1.1), at least during the second half of the pregnancy. On the other hand, be-

cause IUGR is frequently associated with hypoxia, brain metabolism disturbances, and delayed brain development, the C/U ratio, already an indicator of IUGR, is also an accurate parameter for the prediction of poor perinatal outcome.

It is also clear that because the resistance indices are heart-rate dependent, it is hazardous to draw any conclusion from a single value of any of these parameters. Only several successive daily measures of the Doppler indices can lead to a more realistic evaluation of cerebral hemodynamic changes. Moreover, any significant increase in the umbilical index or decrease in the cerebral or C/U index, even within the normal range, must be considered pathological; however, in such cases the C/U ratio may approach the lowest normal limit (1.1) or pass into the abnormal range (<1.1).

On the other hand, the amplitude of C/U change was in the same range at any of the gestational ages investigated in cases of maternal anemia and hypertension. Such observations suggest that the capacity

of the cerebral vessels to vasodilate does not change during the gestation and thus is not mediated by the nervous system. It may be a biochemical reaction originating from the cerebral vessels. Similar observations were made in animal (fetal lamb: gestation 145 days) studies, the flow redistribution amplitude in response to a calibrated reduction in pO<sub>2</sub> being the same at 80 days or at 134 days (personal data).

In all the acute or chronic fetal hypoxic conditions in relation to placental insufficiency (i.e., anemia, malaria, hypertension) the C/U ratio was the most appropriate parameter to detect and quantify the fetal flow redistribution [3, 8, 70]. The assessment of the flow redistribution amplitude (C/U change) and the duration of the flow redistribution period allowed prediction of the consequences of the exposure to hypoxia (HI).

Finally, even though Doppler measurements increasingly help the obstetrician, the objectives for the near future must be (a) to test the true possibilities of Doppler indices in large randomized clinical stud-

**Fig. 13.17.** a Evolution of the umbilical and the cerebral resistance indices during the early phase of development of moderate IUGR (normal delivery, fetal weight 10 centile). b Evolution of the C/U ratio. Note that the two resistance indices show large fluctuations even within or at the limit of their normal range; however, the C/U decreases regularly toward its cut-off line of normality (1.1)

ies, and (b) to point out the physiopathological phenomena responsible for fetal flow disturbances. For the latter aims, animal experimentation will be of great interest.

Figure 13.17 shows the evolution of URI and CRI in a pregnancy without evident complication but in which the fetal weight at term was at the tenth centile; however, the C/U ratio was at the limit of its normal range, demonstrating that even in the absence of any fetal or maternal clinical signs, the fetal circulation can change with consequent alterations in the oxygen and nutrient supply.

# Cerebral Blood Flow Velocity Waveforms: Clinical Application

Laura Detti, Maria Segata, Giancarlo Mari

This chapter reviews the clinical application of Doppler ultrasound velocimetry of the cerebral blood flow in the fetus. There are two main clinical applications of the fetal Doppler cerebral blood flow velocity waveforms:

1. Intrauterine growth restriction (IUGR) pregnancies
2. Diagnosis of fetal anemia

## Which Is the Cerebral Vessel to Assess in the Fetus?

The circle of Willis is composed anteriorly of the anterior cerebral arteries (branches of the internal

carotid artery that are interconnected by the anterior communicating artery) and posteriorly of the two posterior cerebral arteries (which are branches of the basilar artery and are interconnected on either side with the internal carotid artery by the posterior communicating artery). These two trunks and the middle cerebral artery (MCA), another branch of the internal carotid artery, supply the cerebral hemispheres on each side. These arteries have different flow velocity waveforms (FVWs) [1, 2] and, therefore, it is important to know which artery is being studied (Fig. 14.1). The MCA is the vessel of choice to assess the fetal cerebral circulation because it is easy to identify, has a high reproducibility, and provides in-

**Fig. 14.1 A–H.** Flow velocity waveforms of the arteries of the circle of Willis. The values indicate the pulsatility index. (From [2])

**Fig. 14.2.** Flow velocity waveforms of the middle cerebral artery in appropriate-for-gestational-age (AGA) fetuses at different gestational ages. (From [4])

formation on the brain-sparing effect [3, 4]. Additionally, it can be studied easily with an angle of zero degrees between the ultrasound beam and the direction of blood flow and, therefore, information on the true velocity of the blood flow can be obtained [5]. Flow velocity waveforms of the middle cerebral artery change with advancing gestation (Fig. 14.2). The pulsatility index (PI) of the MCA is lower between 15 and 20 weeks' gestation, whereas it has a higher value at the end of the second trimester and at the beginning of the third trimester (Fig. 14.3) [3]. The lower PI values early and late in gestation may be due to the increased metabolic requirements of the brain in these two periods of gestation [6].

Middle cerebral artery peak systolic velocity (MCA-PSV) increases exponentially with advancing gestation (Fig. 14.4) [5].

### Cerebral Blood Flow Velocity Waveforms in the IUGR Fetus

Animal and human experiments have suggested that in the IUGR fetus there is an increase of blood flow to the brain [3, 4, 7–10]. This increase of blood flow can be evidenced by Doppler ultrasound of the MCA [3]. This effect is called the brain-sparing effect and is demonstrated by a lower value of the PI (Fig. 14.5). The brain-sparing effect appears to be a benign adaptive mechanism preventing severe brain damage [11]. Small-for-gestational-age (SGA) fetuses with brain-sparing effect less frequently developed intraventricular hemorrhage (IVH) than appropriate-for-gestational-age (AGA) premature fetuses with normal pulsatility index value of the MCA [12]. Following

**Fig. 14.3.** Reference range (mean and predicted values) of the fetal middle cerebral artery pulsatility index with advancing gestation. (From [4])

**Fig. 14.4.** Reference range of the fetal middle cerebral artery (MCA) peak systolic velocity during gestation. (From [5])

**Fig. 14.5.** Flow velocity waveform of the MCA obtained in AGA (a) and IUGR fetuses studied at the same gestational age (b)

35 weeks' gestation a low PI is physiologically present in the AGA fetus (unpublished data). In IUGR fetuses with a PI below the normal range there is a greater incidence of adverse perinatal outcome [3]. It has also been reported that in SGA fetuses with normal umbilical artery PI and abnormal MCA there is an increased risk of developing distress and being delivered by emergency cesarean delivery. The risk is increased by the presence of abnormal maternal uterine arteries [13]. The brain-sparing effect may be transient, as reported during prolonged hypoxemia in animal experiments, and the overstressed human fetus can also lose the brain-sparing effect [8]. It has been reported that the MCA PI is below the normal range when the  $pO_2$  is reduced [14]. Maximum reduction in PI is reached when the fetal  $pO_2$  is 2–4 SD below normal for gestation. When the oxygen deficit is greater there is a tendency for the PI to rise, this presumably reflects the development of brain edema.

In IUGR fetuses, the disappearance of the brain-sparing effect is a very critical event for the fetus,

and appears to precede fetal death [15–17]. This has been confirmed in a few fetuses in situations where obstetrical interventions were refused by the parents. Unfortunately, to demonstrate this concept, it is necessary to perform a longitudinal study on severely IUGR fetuses up to the point of fetal demise; therefore, presently we cannot rely on the disappearance of the brain-sparing effect for timing the delivery. It is noted that reversed flow of the MCA velocity waveforms, although it has been reported in pathological situations [16, 18–20], can be observed in the normal fetus and appears to be a consequence of head compression in normal pregnancies (Fig. 14.6) [21]. A number of longitudinal studies have assessed several fetal vessels with Doppler ultrasonography and have reported that the cerebral circulation is one of the first blood flows to become abnormal in IUGR [22–25].

**Fig. 14.6.** Flow velocity waveforms of the MCA in an AGA fetus. The reversed flow is due to head compression

## Cerebral–Placental Ratio

It has been reported that the internal carotid/umbilical artery PI ratio has a sensitivity of 70% in identifying growth-restricted fetuses, as opposed to a 60% sensitivity for the internal carotid artery and 48% for the umbilical artery alone [26]. Others have selected the middle cerebral artery/umbilical artery ratio and have reported that in AGA fetuses this ratio remains constant following 30 weeks' gestation. In AGA fetuses the ratio is equal to 1 [27]. A ratio above 1 is considered pathological. The Cerebral–Placental ratio has also been reported to be a good predictor of neonatal outcome, and could be used to identify fetuses at risk of morbidity and mortality [28, 29]. Another study has reported that in fetuses with suspected IUGR, abnormal Cerebral–Placental ratio is strongly associated with low gestational age at delivery, low birth weight, and low umbilical artery pH. Abnormal Cerebral–Placental ratio is also significantly associated with a shorter interval to delivery and the need for emergent delivery [30]. A question that arises is: Does the Cerebral–Placental ratio make any difference when compared with the umbilical artery? The answer is that the ratio is useful on those conditions characterized by a borderline umbilical artery. If there is absent/reversed flow of the umbilical artery, the ratio is not helpful.

### What to Do in Presence of an Abnormal Cerebral–Placental Ratio?

The management of a pregnancy in the presence of an abnormal cerebral–placental ratio depends on the gestational age. Prior to 34 weeks, steroids and close monitoring with non-stress test (NST) and biophysical profile (BPP) twice a week, and assessment of fetal growth every 2 weeks, is a good management option. Following 34 weeks' gestation the cerebral–placental ratio does not appear very helpful and, therefore, a clinical decision based on the results of the cerebral–placental ratio is not recommended [28]; however, others have reported that cerebral–placental ratio continues to be useful [31, 32]; therefore, this requires further investigations.

Finally, maternal hyperoxygenation could improve fetal hemodynamics in IUGR fetuses [33].

## Prediction of Fetal Hematocrit

Fetal hemoglobin increases with advancing gestation (Table 14.1) [34]. Fetal anemia is categorized as mild, moderate, or severe, based on the degree of deviation from the median for gestational age. Severe anemia may cause hydrops and fetal demise.

There are many causes of fetal anemia (Table 14.2), the most common being red cell alloimmunization in

**Table 14.1.** Increase of fetal hemoglobin with advancing gestation

Weeks	Mean	95	5	0.55 MoM	0.65 MoM

the United States. The primary cause of red cell alloimmunization is maternal sensitization to D antigen of the rhesus blood group system; however, many other antigens, the so-called irregular antigens, may be responsible for maternal sensitization. Prophylaxis with rhesus immunoglobulins has decreased the incidence of Rh-hemolytic disease; however, this phenomenon is still present.

Several other conditions can lead to fetal anemia. Hematological disorders can lead to fetal anemia and they are implicated in approximately 10–27% of cases of nonimmune hydrops [35–37]. Fetal anemia may also result from excessive erythrocyte loss by hemoly-

sis or hemorrhage, or erythrocyte underproduction [36].

In Southeast Asia homozygous alpha-thalassemia-1 (hemoglobin Bart's) is the most common cause of fetal hydrops, accounting for 60–90% of cases [38]. This condition, however, has become more frequent in Canada and in North America due to an increased number of immigrants from Southeast Asia [39, 40].

Massive fetomaternal hemorrhage, defined as loss of more than 150 ml, is a rare condition that may result in severe fetal anemia with or without hydrops, and fetal death [41–43]. Red blood cell enzymopathies, such as autosomal-recessive inherited deficiencies of pyruvate kinase and glucose phosphate isomerase, and G6PD deficiency, are rare conditions that may cause fetal anemia and hydrops [36, 44–46].

Parvovirus infection can lead to severe fetal anemia and consequently hydrops because of virus tropism for immature erythrocytes in the bone marrow or fetal liver [47]. Conditions such as large placental chorioangioma, twin–twin transfusion syndrome, transient myeloproliferative disorder, congenital leukemia, intracranial hemorrhage, and Blackfan-Diamond syndrome, may also cause fetal anemia [48–50].

Noninvasive diagnosis of fetal anemia has been the goal of many investigators for more than 20 years. The pulsatility index of fetal cerebral vessels does not have good parameters to diagnose fetal anemia [51]. The PI of the cerebral arteries can become abnormal when the hematocrit is close to 10%. In such a condition, the pulsatility index of the middle cerebral artery decreases, suggesting hypoxemia in the severely anemic fetus. The MCA PI in 101 cases of fetal anemia was below 2 SD in 7 anemic fetuses (unpublished data). In these fetuses the hematocrit was <15%.

When the anemia is severe, there is an increase of blood flow to the brain, which is reflected by a low MCA PI; however, this phenomenon is not always present and it allows recognition of only a small number of anemic fetuses. The assessment of the MCA plays the most important role in the noninvasive diagnosis of fetal anemia [5, 34].

### Red Cell Alloimmunization and MCA Peak Systolic Velocity

Amniocentesis and cordocentesis are invasive tools for diagnosis and management of fetal anemia due to red cell alloimmunization. They are associated with significant complications. Both invasive procedures could worsen maternal alloimmunization due to secondary fetal hemorrhage. It has been reported that more than 70% of fetuses that underwent invasive procedures, because they were defined as severely anemic based on traditional criteria, were found to be either non-anemic or mildly anemic [34]. The use of MCA-PSV could have detected all the cases of significant fetal anemia requiring transfusion and would have avoided approximately 70% of the unnecessary invasive procedures [34].

In a multicenter study, the sensitivity of MCA-PSV for prediction of moderate and severe anemia prior to the first cordocentesis was 100%, with false-positive rates of 12% at 1.50 multiples of the median (Fig. 14.7) [34].

Other robust data for the use of MCA-PSV have been reported in a multicenter trial with intention to treat. In this study, the authors monitored pregnancies complicated by red cell alloimmunization by studying MCA-PSV longitudinally. The MCA-PSV was used for timing cordocentesis [52]. This prospective

**Fig. 14.7.** Middle cerebral artery peak systolic velocity values used for detection of anemia. Fetuses with a MCA-PSV value above 1.5 multiples of the median are likely to be anemic. (From [34])

study confirmed that MCA-PSV is an accurate method of monitoring pregnancies complicated by red cell antibodies. In this study two anemic fetuses were missed in a group of 125 fetuses at risk of anemia. The interval between the last assessment of MCA-PSV and the delivery in those two fetuses was 3.5 and 2.5 weeks. This suggested that a closer assessment of MCA-PSV is necessary. This study also demonstrated that the number of false positives increased following 35 weeks' gestation. A recent prospective study compared MCA-PSV with Delta OD 450 in the prediction of moderately and severely anemic fetuses [53]. The authors concluded that both procedures are useful in the prediction of fetal anemia, but Doppler ultrasound assessment remains a method that has the advantage of being less expensive and noninvasive than amniocentesis. The MCA-PSV represents a more suitable tool in the diagnosis and management of pregnancy complicated by alloimmunizations than Delta OD 450 [24, 54, 55].

The MCA-PSV performed prior to the first transfusion has been used to estimate the real value of fetal hemoglobin [56]. The difference between the observed and calculated hemoglobin was lower in fetuses that exhibited moderate to severe anemia compared with cases when the fetus was mildly anemic (Fig. 14.8); therefore, MCA-PSV performs better in cases of clinically significant anemia. The explanation is that initial small decreases in fetal hemoglobin only slightly change cardiac output and blood viscosity. When the anemia becomes more severe, these compensatory

**Fig. 14.8.** Quadratic function expressing the correlation of percentage difference between the predicted and the actual hemoglobin value and the hemoglobin multiples of the median. (From [56])  $Y = 0.2876 - 0.922 \times 0.9498 \times X$

mechanisms operate more to maintain the oxygen and metabolic equilibrium in the various organs.

Intrauterine transfusion decreases fetal anemia significantly and normalizes the value of fetal MCA-PSV (Figs. 14.9, 14.10) due to an increased blood viscosity and an increased oxygen concentration in fetal blood [57]. The MCA-PSV may also be used for timing the second fetal transfusion and the cut-off point to detect severe anemia is higher than that used for never-transfused fetuses [58]. This is probably the consequence of the different blood viscosity of the adult blood when compared with the fetal blood.

Several other studies have confirmed the utility of MCA-PSV for diagnosing fetal anemia [59–62]. This parameter may also diagnose fetal anemia in dichorionic twin pregnancies complicated by red blood cell alloimmunization [63].

The above studies have used only one value of MCA-PSV, which indicates whether the fetus is anemic or not at the time of the evaluation; however, it does not predict whether the fetus will become anemic. In a longitudinal study, it has been shown that the MCA slope is an excellent tool for identifying those fetuses that will become severely anemic and, therefore, need to be followed up more closely during the pregnancy (Fig. 14.11) [64]. The same author suggested the following protocol for monitoring pregnancies at risk for fetal anemia due to red cell alloimmunization [65]:

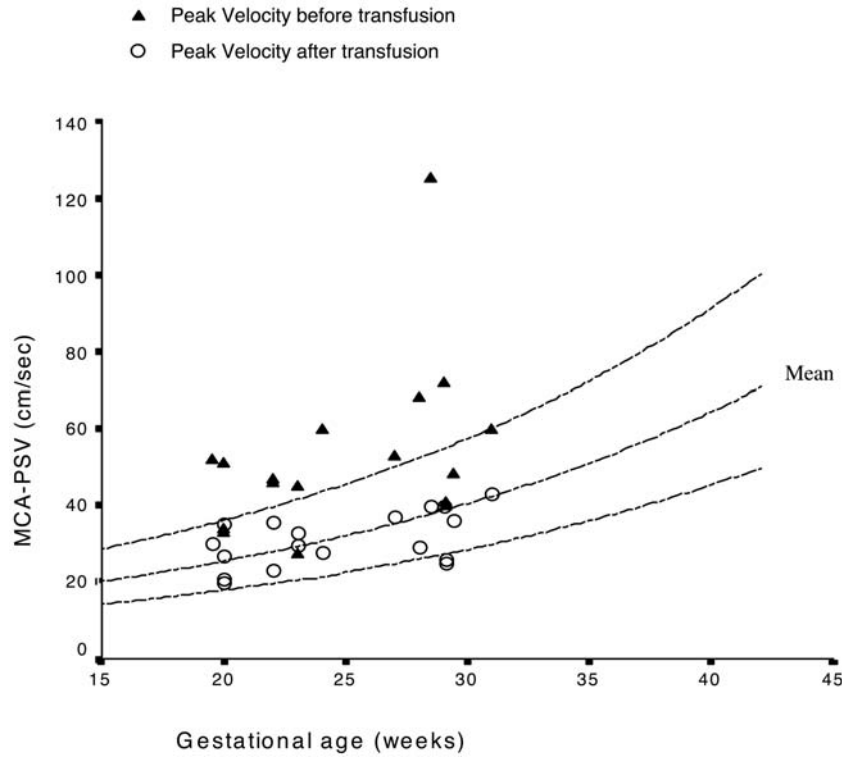

1. MCA-PSV should be performed in fetuses at risk of fetal anemia on a weekly basis for three consecutive weeks.
2. Cordocentesis is indicated when the MCA-PSV value is over 1.5 MoM.
3. If the MCA-PSV remains below 1.5 MoM a regression line has to be obtained from the following three values.

If the plotted regression line is to the right of the dotted line shown in Fig. 14.11, the examination has to be repeated every 2 or 4 weeks based on the initial risk of the patient – with a lower initial risk (e.g., a Coombs titer between 1:16 and 1:32) the examination can be repeated every 4 weeks, but with a higher initial risk it should be repeated every 2 weeks. If the plotted regression line is between the dotted and the thin line (Fig. 14.11), the examination has to be repeated every 1–2 weeks based on the initial risk to the patient. If the plotted regression line is to the left of the thin line and the MCA-PSV value is below 1.50 MoM, the examination has to be repeated in 1 week. Figure 14.12 represents the algorithm we use for the management of pregnancies at risk of fetal anemia because of red cell alloimmunization.

Centers with minimal experience with the assessment of MCA-PSV should initially perform these

measurements in conjunction with serial amniocentesis for Delta OD 450 because of the learning curve associated with performing MCA Doppler [66].

Alloimmunization is also discussed in Chap. 22.

**MCA-PSV in Other Causes of Fetal Anemia**

Delle Chiaie et al. [59] found an inverse correlation between MCA-PSV measurements and hemoglobin values in fetuses at risk for fetal anemia due to red cell alloimmunization and fetal parvovirus infection. In a longitudinal multicenter study on fetuses at risk for anemia resulting from parvovirus infection, the measurement of MCA-PSV predicted fetal anemia with a sensitivity of 94.1%. All cases with moderate and severe anemia were detected either by MCA-PSV alone or in combination with real-time ultrasonography [67].

MCA-PSV may also be a useful test in cases of severely anemic fetuses due to fetomaternal hemorrhages [43]. An increased peak blood flow velocity

has been reported in cases of acute severe fetomaternal hemorrhage [68].

Recently, it has also been reported that MCA-PSV may be helpful for the diagnosis of anemia in twin-twin transfusion syndrome following laser coagulation of the placental vessels [69].

The MCA-PSV appears to be the best test for the noninvasive diagnosis of fetal anemia. It is important to emphasize that training sonographers and sonologists is the “conditio sine qua non” for the correct sampling of MCA-PSV.

The following steps are necessary for the correct assessment of the MCA.

1. The fetus needs to be in a period of rest (no breathing or movements).
2. The circle of Willis is imaged with color Doppler.
3. The sonographer zooms the area of the MCA so that it occupies more than 50% of the screen. The MCA should be visualized for its entire length (Fig. 14.13).
4. The sample volume (1 mm) is placed soon after the origin of the MCA from the internal carotid artery (1–2 mm).
5. The angle between the direction of blood flow and the ultrasound beam is as close as possible to zero degrees. The angle corrector should not be used.
6. The waveforms (between 15 and 30) should be similar to each other. The highest PSV is measured (Fig. 14.14).
7. Repeat the above steps at least three times.

The MCA distal to the transducer can be an alternative to the MCA proximal to the transducer [70]; however, the latter is preferable because it has the lowest intra- and interobserver variability [71].

# Pulsed Doppler Ultrasonography of the Human Fetal Renal Artery

Jean-Claude Veille

The renal arteries arise directly from the aorta just below the projection of the 12th rib and below the superior mesenteric artery. The left renal artery is usually a little higher and longer than that on the right (Fig. 15.1). Close to the renal hilum the renal arteries divide into multiple branches with large anterior and posterior branches. These branches in turn divide into large segment arteries, which eventually terminate in arcuate arteries. The best way to assess the renal arteries is to find the abdominal aorta and the renal hilum using a coronal axis view. The renal arteries are usually seen arising from the lateral aspect of the abdominal aorta. The superior artery is often difficult to visualize in the fetus compared to that in the adult, but the renal artery can be seen using a multipurpose midfrequency scanhead (3–5 MHz). Respiratory or total body movement make it difficult to obtain an adequate duplex signal. With patience, experience, and perseverance, a Doppler examination of the renal artery can be performed successfully in about 90% of patients.

The abdominal aorta and fetal kidney should be localized first using a two-dimensional examination (Fig. 15.2). The Doppler cursor is placed in the area where the ultrasonographer suspects the renal artery to be, with the Doppler sample volume and Doppler

**Fig. 15.1.** Fetal renal arteries. Note that the left renal artery is behind the renal vein and is longer than the right renal artery

**Fig. 15.2.** Two-dimensional examination of a fetus at 30 weeks' gestation. The fetal abdominal aorta is easily seen at the level of the left kidney. On careful inspection, the fetal renal artery is seen at its bifurcation with the aorta

angle adjusted *prior* to turning on the Doppler instrument (Fig. 15.3) so Doppler ultrasound exposure is minimized. The power output should be decreased to about 50%–75% of its spatial peak temporal average (SPTA) specification. Even at this lower power output the Doppler signal is adequate to obtain echoes from the fetal renal artery. Color mapping is used last to confirm the two-dimensional impression that the Doppler signal is indeed coming from the renal artery and not from the fetal aorta (Fig. 15.4). The renal artery Doppler waveform has a characteristically high peak forward velocity and low but continuous forward flow during diastole that is easily differentiated from the adjacent fetal abdominal aorta.

Like any other Doppler examination, the renal velocity waveforms should be obtained during a period of fetal quiescence. The velocity waveforms should be recorded at a fast speed, with the lowest pass filter. Using these guidelines, most ultrasonographers are able to obtain adequate Doppler waveforms from these small renal vessels. It is of the utmost importance to minimize Doppler and color exposure, as the safety of such techniques on human fetuses has not been fully evaluated [1].

**Fig. 15.3.** Doppler sample is placed on the area of the fetal renal artery without turning the Doppler apparatus. It allows adjustment of the Doppler sample volume, the Doppler angle (which should be  $<30^\circ$ ), and the location of the Doppler sample within the lumen of the "presumed" location of the fetal renal artery

**Fig. 15.4.** Color should be the last part of the fetal renal artery localization, not the first. Note the abdominal aorta and its bifurcation as it enters the pelvis. The fetal renal artery is seen bifurcating from the abdominal aorta and entering the renal parenchyma. The Doppler is finally turned on to display the returning signals either on the video monitor or recorded to allow analysis at a later time

## Doppler Principles and Hints

Flow is determined by a pressure difference between two points and by the resistance to flow within that structure. This relation is known as Poiseuille's law and has been mathematically described:

$$Q = \Delta P/R,$$

where  $\Delta P$  is the flow difference, and  $R$  is the flow resistance. The heart (pump) is the driving force behind generating the pressure difference, which in turn is the force behind fluid flow. The flow resistance is mostly determined by the length and radius of the vessel of interest, in this case the renal artery. Increasing the length of the vessel increases the resistance, whereas doubling the radius of the vessel decreases resistance to blood flow by one-sixteenth of the original value [1]. Other than vessel size and pressure differences, the pulsatile nature of blood flow in the fetus results in expansion and contraction of the vessel, which in turn affects the Doppler waveform profile. Thus pulsatile flow in compliant vessels affects forward flow during systole and flow reversal during diastole.

When assessing Doppler flow of the fetal renal artery, attention must be given to whether flow is best described as plug flow or laminar flow [1]. At the immediate bifurcation of the renal artery with the abdominal aorta (i.e., at the entrance of the renal vessel), the flow of the blood is essentially constant across the vessel. Closer to the renal parenchyma, flow becomes more laminar and assumes a parabolic profile (i.e., maximum flow velocity is at the center of the vessel, whereas flow is almost zero at or close to the walls of the vessel). Hence depending on the position of the Doppler sample, the Doppler velocity pattern is affected.

The acute angle between the bifurcation of the abdominal aorta and the renal artery can significantly affect the renal blood flow profile. Theoretically, flow is turbulent at such sites and can result in a random, chaotic flow pattern of red blood cells [1]. Because these aberrant flow patterns can affect the final Doppler waveform profile, the fetal renal artery is sampled close to the renal parenchyma, keeping the Doppler sample within the lumen of the vessel (Fig. 15.3). A Doppler sample size of 1.5 mm is used and is adequate for most studies done on fetuses beyond 20–24 weeks.

Doppler measurement is angle-dependent. Thus it is important to keep the angle at or less  $30^\circ$  when obtaining Doppler signals from the fetal renal artery. Doppler angles of more than  $30^\circ$  could significantly affect the Doppler shift and thus the Doppler wave-

form signals. This point is even more important when using color-flow studies of the fetal renal artery. An angle of 80°–90°, for example, results in no Doppler shift, which in turn results in an inability to visualize color flow of the fetal renal artery. The Doppler angle is not critical, however, when assessing qualitative spectral indices, such as the pulsatility index (PI), resistance index (RI), or systolic/diastolic (S/D) ratio as the angle does not change the relation between the peak systolic and end-diastolic flows. To optimize visualization of the fetal renal artery, Duplex ultrasound is used in order to combine real-time cross-sectional ultrasound images of the fetal renal artery and precisely locate the Doppler sample (Fig. 15.3). These expansive duplex systems are difficult to operate, as data acquisition is machine- and operator-dependent.

Although the diastolic flow of the fetal renal artery is a low-impedance/low-resistance flow, the diastolic flows are not as high as those observed in the umbilical artery. Diastolic flow of this vascular bed has always been present in normal fetuses at gestational ages of less than 16 weeks. Absent or reverse diastolic flows of this vascular bed in the fetus should be considered abnormal. It is imperative to keep the wall filter at a minimum to avoid causing artifacts that may have serious clinical implications. We elect to reduce the wall filter to 50 Hz during the Doppler acquisition in order to avoid this problem.

When this circulation is quantitatively assessed, in addition to the problems associated with signal acquisition it is important to understand the Doppler waveform. The Doppler spectrum is composed of a range of scattered velocities derived electronically using fast Fourier transformation. When tracing the Doppler curve for quantitative flow assessment, it is important to trace the sharpest part of the ascending and the descending part of the curve in order to avoid the inclusion of contaminated signals. This point is particularly important because quantitative determination of blood flow of such a small vessel as the fetal renal artery may easily be over- or underestimated. Consistency when tracing the curve is therefore essential. To make analysis of the Doppler curve consistent, the returning Doppler signals should be as sharp and pure as possible.

## Clinical Application: Fetal Renal Artery Doppler Assessment

The first report on noninvasive measurement of human circulation using ultrasound was published in 1977 by FitzGerald and Drumm [2]. Since then numerous papers have emerged in the literature describing application of the technique to the study of maternal, placen-

tal, and fetal circulations [3–8]. With the introduction of duplex ultrasonography, fetal intracardiac [9] and regional [10–17] circulations have been assessed. Pulsed-wave (PW) Doppler ultrasound is particularly well suited for studying the hemodynamics of the human fetus, as the associated techniques are noninvasive, well accepted by the patients, easily reproducible, and relatively safe for the human fetus.

## Fetal Renal Doppler Imaging

Since the introduction of pulsed Doppler ultrasound to obstetrics, volume flow measurement of the central and the peripheral fetal circulation has been possible (Table 15.1). Previously most of the data on the actual measurement of the fetal circulation were acquired using invasive techniques, which obviously was not possible in human fetuses. Although volume flow measurements are not widely acceptable and are done only in high-risk pregnancies, a few investigators have given some insight on the normal and abnormal human fetal circulation. Pulsed Doppler requires expensive equipment, is usually cumbersome, and has some inherent errors in volume flow [18]. Color flow imaging allows the operator to interrogate most of the fetal vascular beds including the fetal renal artery. This vascular bed is usually easy to identify at its origin, which is at a 90° angle from the abdominal aorta (Fig. 15.3) [11]. The pulsed Doppler range gate is placed in the renal artery with an angle close to zero. This methodology is powerful but needs to be validated. Using such technology, we were able to longitudinally follow normal fetuses in order to determine fetal vascular changes across gestation (Fig. 15.5). Although these values changed with advancing gestation, the changes were not significant.

In one study, using color and pulsed Doppler ultrasonography, interobserver reliability of measurements in the fetal circulation was evaluated in 41 pregnancies of 25–39 weeks' gestation. Two observers recorded flow velocity waveforms from the middle cerebral and renal arteries for measurement of peak systolic, minimum diastolic, and mean velocities, PI, and RI. Intraclass correlation coefficient of reliability was calculated by analysis of variance. Substantial interobserver agreement was found for the pulsatility index and minimum diastolic velocity in both arteries. Therefore, these measurements have the greatest clinical applicability [19].

## Renal Artery Doppler Studies in the Normal Fetus

Vyas et al. established reference ranges for the PI of the fetal renal artery in a cross-sectional study done on 114 human fetuses [11] between weeks 17 and 43

**Fig. 15.5 a–c.** Normal Doppler changes. **a** Longitudinal study of the fetal renal peak flow velocity (PFV) in normally grown fetuses across gestation. There is a slight but nonsignificant increase in PFV with advancing age. **b** Longitudinal study of the systolic-to-diastolic (S/D) ratio in normal fetuses across gestation. There is no significant change in the S/D ratio of the fetal renal artery as gestation advances. **c** Longitudinal study of the time velocity integral (TVI) (area under the curve) in normal fetuses across gestation. TVI progressively increases with advancing gestation

of gestation. In the normal human fetus, impedance to flow in the renal artery decreased with advancing gestational age [11]. In more than 54% of these normal fetuses the renal artery had an absent end-diastolic Doppler velocity. A high-pass filter of 125 Hz was used which may have obstructed low levels of end-diastolic flow. Hecher et al. reported on duplex

Doppler ultrasonography in one normal human fetus studied at week 22 of gestation, seven fetuses studied between weeks 32 and 35, and 12 fetuses studied between weeks 36 and 40 [12]. They noted that end-diastolic flow was absent in four of the seven fetuses studied between weeks 32 and 35 (or 4 of 20 fetuses, >20%) despite normal growth and normal amniotic

fluid [12]. In a longitudinal study of 22 normal human fetuses using color PW Doppler, Veille et al. found that all of the normal fetuses had end-diastolic velocities [20]. Although additional studies may be needed to clarify this issue, absent end-diastolic flow velocities of the fetal renal artery should be considered suspicious for fetal hypoxia especially if oligohydramnios is documented.

With the availability of color Doppler and, more recently, power angiography, the fetal central and peripheral circulation can be assessed. In one study describing the development of uteroplacental and fetal blood flow during the third trimester in 393 uncomplicated pregnancies with uncomplicated term delivery, maximum systolic, mean and maximum end-diastolic velocity after correcting the angle were studied in a cross-sectional study. Quantiles such as quantitative Doppler indices for the maximum systolic, mean time averaged maximum velocity (TAMX), and maximum end-diastolic velocity were calculated and published. Certain conclusions can be drawn as a result of these studies:

1. Resistance to the blood flow in the maternal portion of the placenta does not change during the third trimester.
2. Resistance to the blood flow on the fetal side of the placenta decreases up to week 42 of gestation.
3. Cerebral vascular resistance decreases constantly up to gestational week 42.
4. Vascular resistance to the blood flow of the kidney decreases only slightly during the third trimester [21].

Using the same technology, we evaluated longitudinally the renal circulation from late gestation to the first year of life in order to understand fundamental changes within this vascular bed as the fetus adapts to major circulatory changes occurring during this time period. Sixteen healthy human fetuses were studied during the last trimester of pregnancy, within 2 days of birth, at 6 weeks, at 6 months, and at 1 year. Using noninvasive color pulsed Doppler, blood flow velocities of the renal artery, the tricuspid and mitral valves in the fetus, and in the ascending aorta in the newborn/infants were obtained at each study period. Diameters of these respective areas were also obtained. Total cardiac output and renal blood flow were calculated using the time velocity integral, the area of the structure of interest, and heart rate. We found:

1. Renal artery dimensions, time velocity integral, peak flow velocity, S/D ratio, and absolute volume blood flow (RVBF) were all significantly correlated with advancing gestational age.
2. RVBF relative to body weight and percent RVBF were not.

3. In spite of an overall increase in renal blood flow, flow to the kidney appears to be constant during the time period of this study.
4. Most of the “maturational” changes that occur within this vascular bed appear to be related to changes within the vascular resistance and the renal artery diameter [22].

Konje et al. used color angiography to longitudinally quantify blood flow volume in renal arteries during gestation. They followed 81 appropriately grown fetuses from 24 to 38 weeks of gestation (Table 15.1). When flow was adjusted to the estimated fetal weight, there was an initial and significant fall in the blood flow in all the vessels to a minimal level at 30 weeks of gestation. Blood flow rose thereafter until term. The ratios of flow volume in the ascending aorta to those in the other vessels increased with gestation, with the highest ratio being that between the ascending aorta and the renal arteries [23].

Andriani et al. measured the renal RI, an estimate of renal vascular resistance, from the last trimester of pregnancy to the sixth month of life in a large series of healthy subjects. Ninety-three subjects were studied, 32 were fetuses in the last trimester of pregnancy (group 1) and 61 were children, 30 aged 0–1 month, 20 aged 1–3 months and 11 aged 3–6 months. All subjects underwent color Doppler ultrasonography and the RI of the renal artery was measured for each kidney (Table 15.2). The RI was very high in the “fetal” group but decreased noticeably during the first 6 months of life, reaching values similar to those in adults after the third month. The variability in RI continuously declined with age and there were no statistically significant differences between the left and right kidneys [24].

Maternal meal ingestion has been found to increase fetal renal blood flow. In a cross-over study, fetal Doppler studies of the umbilical, middle cerebral, and renal arteries and the descending aorta were first performed during the fasting state and repeated in the fed state. Maternal meal state did not significantly change the PI of either the umbilical artery ( $n=20$ ), the middle cerebral artery ( $n=19$ ), or the descending aorta ( $n=15$ ). The PI of the fetal renal artery de-

**Table 15.1.** Change in flow volume in middle cerebral artery, ascending aorta, and renal artery of appropriate-for-gestational-age fetuses

Vessel	24 weeks (mm/min)	38 weeks (mm/min)
Middle cerebral artery	39±19	140±64
Ascending aorta	216±77.6	937.4±292.5
Renal artery	27.5±16.8	80.3±57.3

**Table 15.2.** Resistance index (RI) of the renal artery in normal fetuses and children

Age group	Number	RI
Fetuses (3rd trimester)	32	0.67–0.88
0–1 month	30	0.57–0.90
1–3 months	20	0.60–0.84
3–6 months	11	0.65–0.75

creased significantly after maternal meal ingestion in normally grown fetuses during late pregnancy ( $n=14$ ) (fasting= $2.36 \pm 0.16$  versus fed= $2.09 \pm 0.33$ ;  $P=0.021$ ). These authors postulated that the decrease in the resistance may be associated with increased fetal urine production after maternal meals [25].

### Renal Artery Doppler Studies in IUGR Fetuses

Using duplex Doppler ultrasound and a low wall filter (50 Hz), Veille and Kanaan could not demonstrate absent end-diastolic flow of the fetal renal artery in a group of asymmetric fetuses who were suffering in uterine growth restriction (IUGR) [13]. The PI in the IUGR fetuses was significantly higher than in normally grown fetuses. Among the IUGR group, fetuses with signs of hypoxia had an even higher S/D ratio than the fetuses without signs of hypoxia [13]. These investigators suggested that local mechanisms are operational in the fetal kidneys that may in turn influence renal blood flow.

Vyas and Campbell found that 64% of small-for-gestational-age (SGA) human fetuses had a PI higher than the 90th percentile confidence interval of the reference range for gestation (Fig. 15.6) [15]. They found no association between the change in PI and a

**Fig. 15.6.** The 5th, 50th, and 90th percentiles for the fetal renal artery pulsatility index (PI) and gestational age. Sixty-four percent of small-for-gestational age fetuses had a PI above the 90th percentile. (Reprinted from [15] with permission)

change in umbilical cord  $PO_2$  concentration. In this group of SGA fetuses, 20 of 48 (42%) had oligohydramnios. The PI of 16 of 20 fetuses with oligohydramnios (80%) were above the 95th percentile of their normal reference range [15]. The authors concluded that as the impedance to fetal renal blood flow increases, which indicates a higher PI, it is associated with a decrease in fetal urine production.

In a prospective longitudinal study, the changes within the fetal renal circulation were assessed by Doppler sonography in preterm severely growth-restricted fetuses during the period of gradual deterioration prior to delivery; the relationship between Doppler measurements, amniotic fluid index, birth weight, and fetal condition at birth were examined. Sixteen preterm growth-restricted fetuses between 26 and 35 weeks of gestational age were studied. Serial Doppler measurements were made of the renal artery, umbilical artery, middle cerebral artery, and ductus venosus. The PI in the renal artery did not show any correlation with cord blood pH, birth weight, or amniotic fluid index corrected for gestational age (Delta/SDAFI). Peak systolic velocities in the renal artery showed a significant reduction with time ( $n=7$ ,  $P<0.05$ ) and a significant correlation with venous cord pH at delivery ( $n=12$ ,  $r=0.84$ ,  $P<0.001$ ), Delta/SDAFI ( $n=16$ ,  $r=0.67$ ,  $P<0.01$ ), and birth weight ( $n=16$ ,  $r=0.61$ ,  $P<0.02$ ). Birth weight correlated significantly with Delta/SDAFI ( $n=15$ ,  $r=0.57$ ,  $P<0.05$ ), PI values of the middle cerebral artery ( $n=15$ ,  $r=-0.61$ ,  $P<0.02$ ), and PI values of the ductus venosus ( $n=16$ ,  $r=0.55$ ,  $P<0.05$ ). Delta/SDAFI correlated significantly with pulsatility index values of the ductus venosus ( $n=15$ ,  $r=0.51$ ,  $P<0.05$ ) and arterial cord pH values at delivery ( $n=8$ ,  $r=0.78$ ,  $P<0.05$ ). These authors concluded that a progressive redistribution of the circulation occurs with deterioration of the fetal condition in the growth-restricted preterm fetus as reflected by changes in peak systolic velocities, but not by changes in pulsatility values of the fetal renal artery waveforms [26].

Doppler has been used to test the hypothesis that infants exhibiting catch-up growth as an indicator of IUGR have a higher incidence of predelivery abnormal Doppler results. In total, 196 women with singleton pregnancies at high risk of IUGR were followed up for postnatal catch-up growth during the first 7 months. Forty-six of the 196 infants demonstrated catch-up growth and were therefore classified as growth restricted; 85% of this group had had abnormal Doppler results prior to delivery, compared with 14% of the normal growth group. The authors concluded that Doppler appears to distinguish IUGR (as defined by catch-up growth) from normal growth more successfully in infants with an average birth weight ratio than in infants with a low birth weight

ratio and is a better predictor of IUGR than SGA [27].

In another study, the renal volume in fetuses with IUGR fetuses was 31% (95% CI, 20%–40%), which was less than the renal volume obtained in the group of non-IUGR fetuses after adjusting for gestational age. The ratio of renal volume to estimated fetal weight was 15% (95% CI, 1%–26%), which was less than the same ratio in the non-IUGR fetuses. No differences were seen in the renal artery Doppler measurements. These authors concluded that IUGR appears to be associated with a decrease in fetal renal volume. Because renal volume is a likely proxy for nephron number, this study supports the hypothesis that IUGR may be linked to congenital oligonephropathy and potentially to hypertension in later life and other related vascular diseases [28].

Some authors have determined the fetal blood flow redistribution and the amount of amniotic fluid in appropriate-for-gestational-age (AGA) fetuses and growth-restricted fetuses. In one study, Yoshimura determined the blood flow velocity waveforms of the umbilical artery, descending aorta, middle cerebral artery, renal artery, and uterine artery using pulsed Doppler ultrasonography in 100 AGA fetuses and 39 growth-restricted fetuses. The PI values and the amount of amniotic fluid were compared between the two groups. The PI values of the umbilical artery and renal artery were significantly higher in AGA fetuses with oligohydramnios than in fetuses with an adequate amount of amniotic fluid. The PI values of the umbilical artery and renal artery were significantly higher and the PI of the middle cerebral artery was significantly lower in growth-restricted fetuses with oligohydramnios than in fetuses with an adequate amount of amniotic fluid. Furthermore, there was a significant negative correlation between the PI value of the renal artery and the vertical diameter of amniotic fluid, and between the PI value of the renal artery and the amniotic fluid index. The PI value of the renal artery was related to the amount of amniotic fluid in growth-restricted fetuses, and the same relationship was demonstrated in AGA fetuses [29].

Arduini and Rizzo reported on the renal blood flow velocity waveforms of 114 IUGR fetuses and 97 postterm fetuses [16]. They found that the IUGR fetuses had a higher PI than a group of normally grown fetuses especially if there was oligohydramnios. Interestingly, postterm fetuses had PIs similar to those of normal term fetuses. In the postterm fetuses there was no correlation between the amount of amniotic fluid and the fetal renal PI values. To explain these apparent discrepancies, the authors suggested that the etiology of the oligohydramnios could have different mechanisms in these two subsets of fetuses. They speculated that the oligohydramnios in the

IUGR fetuses was related to changes in intrarenal vascular resistance [16], and in postterm fetuses it was related to changes in tubular reabsorption.

Mari et al. [17] found that among four human fetuses affected by asymmetric IUGR who had oligohydramnios and abnormal fetal renal artery velocimetry the perinatal mortality was high (three of four), confirming the findings of Veille and Kanaan [13].

Thus most of the published studies on fetal renal artery waveforms support the concept that IUGR fetuses with oligohydramnios have a PI above the established values for the 95th percentile (Fig. 15.7). The combination of IUGR, oligohydramnios, and elevated PI of the fetal renal artery seems to be associated with an increase in perinatal morbidity and mortality. These Doppler studies support an intrarenal increase in impedance, which in turn affects renal perfusion and urine production.

Akita et al. evaluated renal blood flow in 102 normal human fetuses between weeks 20 and 40 of gestation and compared these normative results to those of 11 IUGR fetuses with normal amniotic fluid, 15 fetuses with oligohydramnios, and 10 IUGR fetuses with oligohydramnios [30]. Color duplex PW Doppler ultrasound was used to evaluate the fetal renal artery. The ascending aorta and pulmonary arteries were evaluated at the same time. Akita et al. concluded that the kidneys of IUGR fetuses with oligohydramnios were poorly perfused because of a decrease in stroke volume, which was found to be associated with these fetuses [30].

Although a prerenal etiology for oligohydramnios is always possible, human and animal data strongly suggest that the human kidney is capable of modifying intrarenal resistances according to alterations in the in utero environment. Evidence obtained from fetal renal arteries of guinea pigs, for example, suggests that the fetal circulation exhibits heterogeneity in

**Fig. 15.7.** Confidence intervals for a group of normal fetuses. This graph and the one in Fig. 15.6 are comparable and point to an elevated pulsatility index (PI) of the fetal renal artery. (Reprinted from [16] with permission)

response to hypoxia [31]. Hypoxia caused the fetal carotids to contract, whereas the same degree of hypoxia caused the fetal renal arteries to relax. In vivo studies suggest that the same vessel responds differently within its length. For example, the proximal carotid of the fetal guinea pig constricts, whereas the distal carotid relaxes under the same hypoxic conditions [31].

Such regional differences are supported by observations in the fetal circulation of normal human fetuses. Normal women during the third trimester of pregnancy were asked to inhale a gas mixture containing 3% CO<sub>2</sub> [32]. The responses of the umbilical, middle cerebral, and renal arteries were analyzed before and during the 15-min CO<sub>2</sub> challenge. A significant decrease in the S/D velocity ratio occurred in the fetal middle cerebral artery but not in the fetal renal artery or the umbilical artery [32]. The authors concluded that human fetal vessels can selectively vary their resistance with the same stimulus, supporting the vascular differences previously reported for guinea pigs.

One study looked at two groups of pregnancies resulting in intrauterine chronic hypoxia in the third trimester. Group 1 comprised 120 pregnant women with pregnancy-associated hypertension and/or proteinuria. Group 2 consisted of 87 pregnancies with IUGR. Both study groups included pregnant women in the third trimester. Hyperechogenic renal medullae were detected in 15 out of 120 cases with pregnancy-associated hypertension and/or proteinuria, and in 22 fetuses of the 87 pregnancies involving IUGR [33]. Fetal renal hyperechogenicity appears to be an indicator of fetal arterial circulatory depression, correlated with pathological changes in the RI for the fetal renal arteries. The fetal renal arterial blood flow RI was significantly lower in hyperechogenic cases. The authors concluded that these findings may represent an indication of subsequent intrauterine and neonatal complications. In such fetuses cesarean section was increased because of intrauterine hypoxia. In those with fetal renal hyperechogenicity there was an increase in fetal distress (43%), admission to a neonatal intensive care unit (51%), and an increase in perinatal mortality (5.4%, as compared with 0.8%–1.0% in the normal population). They concluded that a detailed ultrasound and Doppler examination of renal parenchyma and arteries may be a useful method prenatally to diagnosis fetal reduced renal perfusion [33].

### **Fetal Renal Artery Doppler Studies and Postterm Pregnancy**

Arduini and Rizzo reported on the PI of 97 patients with gestational ages of more than 42 weeks [16].

They found no significant differences in the fetal renal artery PIs for postdate pregnancies when compared to a group of normal fetuses studied between weeks 40 and 42 of gestation, even when these postterm pregnancies had decreased amniotic fluid volume. In a study done on 50 patients with prolonged pregnancies Veille et al. found that the S/D ratio was significantly higher in prolonged pregnancies complicated by oligohydramnios [34]. These authors also found a significant negative correlation between the amniotic fluid index and the fetal renal S/D ratio [34]. Animal and human data indicate and support the notion that moderate to severe hypoxia significantly affects renal blood flow and renal vascular impedance [35, 36]. Since the introduction of the color Doppler technique, small vessels such as the fetal renal arteries can be effectively studied. With technical improvement and standardization of the pulsed Doppler acquisition, studies using such noninvasive methods contribute to our understanding of fetal regional circulation during normal and abnormal development.

The amniotic fluid decreases with advancing gestation in the face of an increase in cardiac output and an increase in renal perfusion. The etiology of oligohydramnios in normally grown fetuses who are born postterm has been studied using Doppler velocimetry. Recently, Oz obtained the RI of the renal and umbilical artery Doppler velocimetry in 147 singleton postterm fetuses (287 days or more of gestation) [37]. The renal artery RI was significantly higher in cases with oligohydramnios [RI: mean ( $\pm$  standard error) = 0.8843  $\pm$  0.11 versus 0.8601  $\pm$  0.05,  $P \leq 0.05$ ]. A renal artery Doppler end-diastolic velocity below the mean for gestation significantly increases the risk of oligohydramnios. These authors concluded that an elevated renal artery Doppler RI was more predictive of oligohydramnios than the umbilical RI. They went on to speculate that a reduced renal artery end-diastolic velocity suggests an increase in arterial impedance and that this may be an important factor in the development of oligohydramnios in prolonged pregnancies [37].

We previously noted that postterm fetuses with oligohydramnios and evidence of fetal acidosis had a significant increase in the RI of the fetal renal artery when compared to a group of fetuses that were also postterm and had oligohydramnios [38]. Scott et al. [39] had similar findings, that the PI of the renal artery was higher in normally grown fetuses with oligohydramnios when compared to those with normal amniotic fluid. These investigators also found that those fetuses who were growth restricted and had oligohydramnios had significant PI values of the fetal renal arteries.

## Fetal Renal Artery Doppler Studies and Intravascular Transfusion

Animal data indicate that renal blood flow is increased during the first hour after volume expansion with maternal whole blood [35]. Mari et al. evaluated the PI of the renal artery waveform from nine anemic fetuses before and after intravascular transfusion [36]. The PI of the fetal renal artery decreased within the first 2 h after intravascular transfusion. The authors speculated that these observed changes represented a fall in renal vascular resistance to accommodate and eliminate the excess infused fluid. Such decreases in the PI have also been reported immediately after intravascular transfusion [37].

## Fetal Renal Artery Doppler Studies and Maternal Drug Intake

### *Indomethacin*

Indomethacin has been found useful for the treatment of preterm labor and in women whose pregnancies are complicated by polyhydramnios [40]. Treatment in utero may cause premature ductal closure, tricuspid insufficiency, and pulmonary hypertension [41]. Such potentially serious complications have significantly reduced its routine use in obstetrics.

Indomethacin has been found to cause a significant increase in fetal renal vascular resistance and a decrease in renal blood flow [42]. Using PW Doppler ultrasound Mari et al. studied the fetal renal blood flow velocity waveforms in 17 fetuses prior to and 24 h after maternal intake of indomethacin [43]. They found no significant differences in the PI values before and during indomethacin therapy [43]. These authors speculated that the decrease in urine production observed in the fetus during maternal intake of indomethacin was vasopressin-mediated and not secondary to increases in renal vascular resistance. This important observation must be confirmed by additional studies.

Van Bel et al. studied the effect of a single dose of intravenous indomethacin on renal blood flow velocity waveforms. Using color PW Doppler imaging on 15 premature infants, they found that a single dose of intravenous indomethacin led to a sharp decrease in peak systolic and temporal mean flow velocities [44]. These effects were maximal 10 min after the indomethacin dosing.

### *Aspirin*

Aspirin, a potent antiinflammatory drug, has been shown to inhibit the biosynthesis and release of prostaglandins, even in low dosage. This observation led many researchers to speculate that the ingestion of

daily low-dose aspirin may result in a decrease in the incidence of preeclampsia and fetal growth restriction, and that it may improve pregnancy outcome in women with positive lupus anticoagulant and anti-cardiolipin antibodies [45, 46].

Veille et al. studied the effect of prolonged maternal ingestion of low-dose aspirin on the fetal renal circulation [47]. They could demonstrate no significant hemodynamic changes in the fetal renal Doppler waveforms in fetuses chronically exposed to low-dose aspirin compared to a group of fetuses not exposed to such medication. Thus the prolonged use of low-dose aspirin in the human fetus does not seem to significantly affect fetal renal circulation.

### *Ritodrine*

The effects of intravenous ritodrine infusion on the fetal renal artery waveforms of eight singletons were assessed by Rasanen [48]. The fetal renal artery waveforms were examined prior to ritodrine and after 2.5 h of infusion. Ritodrine decreased the Doppler waveform indices of the renal arteries, suggesting a decrease in vascular resistance of these vessels [48].

## *Angiotensin-Converting Enzyme Inhibitors*

The angiotensin-converting enzyme (ACE) inhibitors have been used to treat hypertensive disorders during pregnancy. Such treatment can severely and sometimes definitively impair renal function in the fetus, leading to postnatal anuria [49]. Evidence from the published literature suggests that the primary mechanism by which ACE inhibitors affect development of the fetal kidney is through decreasing the renal blood flow [50] and their interference between the renin-angiotensin system and the prostaglandins.

Table 15.3 shows the effects of maternal medication on fetal renal blood flow.

**Table 15.3.** Effects of maternal medication on fetal renal blood flow

Maternal drugs	Effect on fetal renal artery	Reference
ACE inhibitors	Decrease in PI	Martin RA [50]
Aspirin	No change	Veille JC [47]
Betamethasone	No change in PI	Edwards A [51]
Cyclooxygenase-2 inhibitor	No change	Holmes RP [52]
Ibuprofen	No change	Romagnoli C [53]
Indomethacin	PI is increased	Kang NS [54]
Intravaginal Misoprostol	No change	Wang Z [55]
Ritodrine	No change	Rasanen J [48]
Terbutaline	No change	Kramer WB [56]

## Fetal Renal Artery and Fetal Anomalies

### Renal Agenesis

Pregnancies associated with early oligohydramnios have a poor prognosis. The fetal anatomy is particularly difficult to assess because the acoustic window is notoriously poor. In cases of bilateral renal agenesis, the fetal renal arteries are absent.

We identified a case of absent renal arteries using color Doppler transvaginal ultrasonography in a fetus with severe oligohydramnios. This 18-week pregnancy was complicated by severe oligohydramnios. Abdominal ultrasonography was not adequate to evaluate the fetal anatomy, including the presence or absence of kidneys. Using a transvaginal color Doppler ultrasound technique, the abdominal aorta was identified but the renal arteries were not. The fetus subsequently died in utero, and postmortem examination confirmed the ultrasonic finding of bilateral renal agenesis (Fig. 15.8).

Maršál et al. reported similar findings in a group of 14 fetuses during the second trimester in which there was oligohydramnios and a strong suspicion of renal agenesis on ultrasound recordings. Using a color ultrasound technique, the renal arteries were properly identified in six of eight cases, in which normal kidneys were found at postmortem examination. In all six cases of complete renal agenesis proved at autopsy they could not properly identify the renal artery [57].

It is of utmost importance to recognize that the presence or absence of color is angle-dependent. If

**Fig. 15.8.** Transvaginal color ultrasonogram of an 18-week fetus with severe oligohydramnios and for whom the transabdominal scan was not informative. This transvaginal color ultrasound scan showed the abdominal aorta and the absence of fetal renal arteries, strongly suggesting bilateral renal agenesis. The postmortem examination confirmed the ultrasound diagnosis

the Doppler signal is perpendicular to the flow of blood, there is no Doppler shift and therefore no color. Thus an erroneous diagnosis could easily be made if this Doppler principle is violated.

### Pyelectasis

Fetal pyelectasis may affect renal blood flow. In one study, Kara et al. compared the RIs in the fetal interlobar renal arteries (IRAs) of third-trimester fetuses with or without pelvicaliceal dilatation of up to 10 mm with those of full-term healthy infants [58]. They studied three groups according to the antero-posterior diameter of the renal pelvic dilatation: group 1, no dilatation; group 2, 1–5-mm dilatation, and group 3, 6–10-mm dilatation. The IRA of both kidneys were obtained in 139 of the fetuses (Table 15.4). The RI in the fetal IRA did not differ in fetuses with and without renal pelvic dilatation of up to 10 mm. The authors concluded that an increase in the RI of fetuses that have a mild degree of pyelectasis should be investigated further for possible renal pathology.

### Color Doppler Ultrasonography and Fetal Renal Obstruction

Bates and Irving reported on color Doppler imaging of the fetal renal artery in 29 fetuses who had either unilateral or bilateral significant urinary tract dilatation [59]. Although they initially hypothesized that fetal renal obstruction could be detected by analysis of the Doppler waveforms, their study failed to confirm any abnormality of the PI in these fetuses.

Fetuses with hydronephrosis secondary to a ureteropelvic junction (UPJ) obstruction were followed up after birth. Using a urology database (1994 through 1999) Rooks and Lebowitz identified children who had a surgically corrected UPJ obstruction from intrinsic and extrinsic causes. These authors identified 100 who had symptomatic UPJ obstruction and who were treated with surgery. In 11 of these cases (11%), the obstruction was caused by a crossing vessel. Extrinsic UPJ obstruction caused by a vessel is an uncommon cause of obstruction when all patients are considered, but fetal color Doppler should be included in all cases of UPJ obstruction found on prenatal sonography [60].

**Table 15.4.** Resistance index (RI) in fetuses with and without renal pelvic dilatation [58]

	Group 1 No dilatation	Group 2 1–5 mm	Group 3 6–10 mm
Number	172	98	47
RI-X±SD	0.81±0.09	0.80±0.07	0.80±0.06

### Multicystic Fetal Kidneys

The diagnosis of multicystic kidney in utero can be made with reasonable reliability with real-time sonography. However, a cystic hydronephrotic kidney may be difficult to distinguish from a multicystic kidney, necessitating postnatal renography. Gill et al. reported their observations of Doppler waveform variation in cystic fetal kidneys [61]. Five consecutive fetuses with a unilateral cystic kidney and one with a unilateral hydronephrotic duplex kidney and cystic upper moiety were evaluated in utero with color Doppler renal sonography. The Doppler signal on serial ultrasound was consistently absent in the ipsilateral cystic kidney, while normal renal artery Doppler waveforms with a systolic and diastolic component were obtained from the contralateral and unaffected moieties. Postnatal renography confirmed nonfunction in all cystic moieties. The hydronephrotic noncystic moiety of the duplex kidney showed a normal Doppler waveform and good function. Thus absence of renal artery Doppler waveforms in fetal cystic kidneys correlates with renal nonfunction suggesting that fetal Doppler sonography could be an additional tool to diagnose confidently a multicystic kidney in utero [61].

### Fetal Artery Waveforms and Meckel Syndrome

Hata et al. reported on the results of PW Doppler examination of the fetal renal artery of a 21-week-old fetus affected by occipital encephalocele and polycystic dysplastic kidneys [62]. PW Doppler sonography showed an increase in the diastolic component of the velocity

waveform of the renal artery, causing the PI to be significantly lower than in normal fetuses. They speculated that this increase in renal "perfusion" was probably an expression of the enlarged kidney mass [62].

### Quantitation of Fetal Renal Blood Flow

To date, one of the most valuable uses of duplex ultrasound has been for quantitation of stroke volume and cardiac output [63–68]. Doppler ultrasonography estimates the average of all the blood velocities across a vascular structure. If the size of the vascular structure can be measured and assumed to be circular, the area can be calculated. The product of the time velocity integral (TVI), the cross-sectional area of the vascular structure (A), and the heart rate (HR) has been shown to represent the volume of blood flow moving through that structure. The PW Doppler waveform also reflects ventricular contractility.

$$\text{Flow} = \text{TVI} \times A \times \text{HR}$$

Analysis of the upward swing of the initial part of the curve has been correlated with ventricular systolic function. Stated another way, the time from the beginning of the Doppler curve to the peak of the curve can be measured and correlates with systolic ventricular performance [66]. Thus Doppler sonography is able not only to quantify blood flow through individual vascular structures but also to assess ventricular contractility. A typical Doppler waveform is shown in Fig. 15.9.

Volume estimates obtained using Doppler techniques have been shown to correlate well with both the Fick and thermodilution methods for estimating

**Fig. 15.9.** Fetal human renal artery has high peak systolic velocity and low end-diastolic velocity, resulting in a high systolic/diastolic ratio and pulsatility index. The time velocity integral (TVI) is shown in the hatched area. The TVI is multiplied by the area of the renal artery to estimate the renal blood flow

renal artery at the renal hilus and just below the tricuspid and mitral valves. Fetuses with idiopathic polyhydramnios had reduced total cardiac output, decreased right ventricular output, decreased renal blood flow, decreased renal diameter and decreased percent renal perfusion compared to ehydramnic control fetuses [71]. They suggested that in fetuses with polyhydramnios, renal perfusion was not the primary cause for the polyhydramnios.

In summary, with the improvements in ultrasound techniques, color PW Doppler ultrasonography can be applied to qualify and quantify fetal regional blood flow in normal and abnormal human fetuses. These noninvasive methods may reveal how fetal renal blood flow is affected in fetuses with growth abnormalities, certain renal diseases, or oligohydramnios or during maternal intake of certain medications. A complete understanding of the distribution of renal blood flow in fetuses at risk for asymmetric IUGR may lead to an earlier diagnosis of such pathologic conditions, which may permit early intervention. Such intervention may then decrease the morbidity and mortality associated with IUGR fetuses.

# Doppler Velocimetry of the Uteroplacental Circulation

Edwin R. Guzman, Eftichia Kontopoulos, Ivica Zalud

## Introduction

Since the last edition of this volume, interest has continued in uterine artery Doppler velocimetry (UADV) as a screening technique to predict adverse pregnancy outcomes such as preeclampsia, for pregnancy risk scoring, and as an entry criterion for randomized trials on medical therapies for the prevention of preeclampsia and intrauterine growth restriction. These areas have been updated and UADV for predicting pregnancy outcome in medical conditions other than preeclampsia has been added. The areas regarding non-Doppler assessment of uterine artery flow, physiology and development of uterine artery flow, and the development of uterine artery Doppler waveform remain essential and have been retained for historical purposes.

## Non-Doppler Methods to Measure Uterine Artery Blood Flow

Methods developed to measure uteroplacental blood flow in humans, such as the nitrous oxide technique based on the Fick principle [1, 2], clearance of radioactive  $^{24}\text{N}$  [3–6], and the flow probe technique [7], are obviously not suitable for human application. They suffer from various limitations, such as questionable accuracy, invasiveness, requirement for radiation, and being unsuitable for longitudinal observations. Once it was realized that the placenta must utilize maternal dehydroisoandrosterone sulfate, testosterone, and androstenedione in the intervillous space for the synthesis of estradiol, a technique that measured the rate of estradiol synthesis was developed to assess intervillous space perfusion in human pregnancies [8, 9]. This technique was tedious, required sophisticated laboratory equipment (which made it expensive), made use of isotope-labeled prehormone, and proved to be of questionable accuracy. Its clinical applicability is limited. Nonetheless, when all these techniques were applied to human pregnancies they had surprisingly similar results. Normal uterine

blood flow at term was estimated at 500–700 ml/min with a two- to threefold decrease in uteroplacental perfusion noted in the presence of preeclampsia.

Uterine artery Doppler velocimetry was first reported by Campbell and colleagues in 1983 [10]. They showed that, compared to pregnancies with normal uterine artery waveforms, pregnancies with abnormal uterine artery Doppler waveforms were associated with more proteinuric hypertension, required more antihypertensive therapy, and resulted in lower birth weights and younger gestational ages at birth. Thus the capability for this potentially safe, noninvasive, prospective means of analyzing uterine artery blood flow during pregnancy was realized and set off a wave of interest and research that has continued until today.

## Anatomy of Uterine Circulation

The uterine artery originates from the internal iliac artery and meets the uterus just above the cervix. The main uterine artery branches into the arcuate arteries, which arch anteriorly and posteriorly and extend inward for about one-third of the thickness of the myometrium (Fig. 16.1). They are tortuous and vary in thickness and in the area they supply. The arcuate artery network anastomoses near the midline [11]. The radial arteries arise from this network, are directed toward the uterine cavity, and become spiral arteries when they enter the endometrium.

There are a variety of arterial anastomoses of the human uterine circulation that have been demonstrated by anatomic and radiographic studies and uterine perfusion experiments [11–14]. Ipsilateral connections between uterine and ovarian arteries have been demonstrated. Also identified are contralateral anastomoses between the right and left uterine arteries and their branches. The uterine circulation is also connected to the systemic circulation, for example the inferior mesenteric, middle sacral, and inferior epigastric arteries. During pregnancy these anastomotic connections can increase in size and function after occlusion of major vessels.

**Fig. 16.1.** Anatomy of the arcuate, radial, and spiral arteries during pregnancy. (From [112] with permission)

### Normal Growth and Development of Uteroplacental Circulation During Pregnancy

During the first 12 weeks of pregnancy cytotrophoblasts invade the spiral arterial walls in the decidua and replace the endothelium and muscular media with a matrix of cytotrophoblasts and fibrinoid and fibrous tissue [15, 16]. The fibrinoid material is a complex of maternal fibrin and other plasma constituents plus proteinaceous material derived from the trophoblastic cells. Beginning at about 12 weeks' gestation and continuing throughout the remainder of the second trimester, the endovascular trophoblasts move into the myometrial segments of the spiral ar-

teries. Once again the trophoblasts replace the endothelium and establish themselves in the muscular media. The elastic and muscular tissue of the myometrial segments of the spiral arteries is gradually lost and replaced with fibrinoid material (Fig. 16.2). This condition, along with the increase in blood flow and the associated hemodynamic forces, converts the entire length of the spiral arteries from small muscular arteries to dilated, tortuous uteroplacental vessels (Fig. 16.3). At term these changes can be seen at the distal portions of the radial arteries. The mean external diameter of the myometrial segments of the spiral arteries is approximately 500  $\mu\text{m}$ , an increase from 200–300  $\mu\text{m}$  in the nonpregnant state. The small muscular arteries that branch off the radial and spiral arteries, the basal arteries, do not undergo these

**Fig. 16.2.** Normal pregnancy. Spiral artery at the myometrial junction shows extensive structural alterations (physiologic changes). (Reprinted from [15] with permission)

**Fig. 16.3.** Fully developed physiologic changes in the uteroplacental arteries during normal pregnancy. *Hatched portions* of the wall of these vessels indicate the extent of the physiologic changes. *I.V.S.* intravillous space. (From [113] with permission)

changes. In all, approximately 100–150 converted spiral arteries supply the placental bed. It is believed that these uteroplacental vessels have lost their ability to respond to vasoactive substances.

The question arises whether this change from small muscular arteries to dilated tortuous vessels is entirely responsible for the increase in flow from 100 ml/min to 500–800 ml/min. All large vessels of the pregnant uterus, regardless of whether they supply the placental bed, undergo hyperplasia and hypertrophy [17]. Thus the increase in cross-sectional area leads to a reduction in resistance and further development of the uterine circulation. This increase in luminal diameter of the large vessels probably accounts for the increase in uteroplacental flow during the third trimester. In addition, the effects of the hormones estrogen and progesterone, the increased blood volume and cardiac output, the diminished blood viscosity, and the lowered peripheral resistance influence uterine flow.

### Abnormal Development of the Uteroplacental Circulation in the Presence of Essential Hypertension, Preeclampsia, and Intrauterine Growth Restriction

According to Brosens et al. [15], Robertson et al. [16], and Khong et al. [18], a lack of endovascular infiltration by trophoblasts into the myometrial portion of the placental bed spiral arteries is a consistent finding in the presence of preeclampsia. The physiologic changes of the placental bed spiral arteries extend only to the decido-myometrial junction (Fig. 16.4). With preeclampsia the spiral arteries may remain unconverted throughout their decidual and myometrial length (Fig. 16.5). Thus there is both an incompleteness in the degree of endovascular trophoblastic invasion of the spiral arteries, being confined to the decidual portion, and a reduction in the number of uteroplacental arteries formed. The diameter of the spiral arteries remains at 200–300  $\mu\text{m}$ . Sheppard and Bonnar [19] reported the picture not to be so clear-cut, as they observed physiologic changes in the myometrial spiral arteries in preeclamptic pregnan-

**Fig. 16.4.** Difference between normal and preeclamptic pregnancies regarding the extent of physiologic changes in the uteroplacental arteries. With preeclampsia these changes do not extend beyond the decido-myometrial junction. (From [113] with permission)

**Fig. 16.5.** Preeclampsia. Myometrial spiral artery is unaffected by physiologic changes and retains a normal internal elastic lamina. (Reprinted from [15] with permission)

cies. What has not been studied is whether the large vessels in the uterine artery circulation in the presence of preeclampsia undergo the same degree of hyperplasia as is seen in normotensive pregnancies.

Another placental bed lesion seen with preeclampsia is an acute arteriopathy, termed acute atherosclerosis by Zeek and Assali [20]. Here the wall of the spiral artery shows fibrinoid necrosis with lipophages, and there is a mononuclear cellular infiltrate around the artery (Fig. 16.6). This lesion is seen in the decidual and myometrial segments of the placental bed spiral arteries that have not undergone physiologic changes.

In pregnancies complicated by essential hypertension, hyperplastic arteriosclerosis of the myometrial segments of the placental bed spiral arteries can be seen [15, 16]. Here there is proliferation of all coats of the vessel wall, collagenous sclerosis, and stenosis of the lumen. The breadth and severity of the lesions

correlate with the severity and duration of the hypertension. This lesion is not seen with preeclampsia unless there is a history of essential hypertension (Fig. 16.7). When essential hypertension is complicated by superimposed preeclampsia, both acute atherosclerosis and hyperplastic arteriosclerosis are seen [15, 16].

In normotensive pregnancies resulting in intrauterine growth-restricted (IUGR) fetuses, acute arteriosclerosis has been seen in the decidual spiral arteries, with the myometrial spiral arteries retaining their muscular coats [18, 19]. This finding implies that these lesions are not particular to preeclampsia.

## Indices of Uterine Artery Waveform Analysis

Uterine artery Doppler waveforms are most commonly analyzed by simple semiquantitative techniques based on analysis of the maximum Doppler shift frequencies of the time-velocity waveform, which varies during the cardiac cycle. Evaluation of the change in maximal Doppler shifts over time provides information on the impedance of the circulatory bed being fed. Time-velocity waveforms with high diastolic flow are seen when downstream resistance is low, and those with low or reverse diastolic flow are found when downstream resistance is high. The heart rate can significantly modify the waveform: high heart rates shorten the diastolic runoff time, producing high end-diastolic frequency shifts; low heart rates have an opposite effect. The Doppler shift frequencies are proportional to flow velocity. If the angle of insonation is kept constant over the course of the cardiac cycle, comparisons of Doppler frequency shifts from any point of the waveform are angle-independent.

There are three widely used semiquantitative techniques for analysis of uterine artery waveforms. The pulsatility index (PI) is the most complex of the three. The PI is equal to peak systole minus end diastole divided by the mean value of the area under the curve over one cardiac cycle:  $(S-D)/\text{mean velocity}$ . This index has an advantage when analyzing complex waveforms that have absent or reverse flow during parts of the diastole. However, it requires a computer program that can calculate the area under the curve. Whether the computer outlines the maximum frequency envelope or whether it is done manually, some degree of error is involved that is probably

greater than that for other techniques. When uterine circulation resistance is high, the uterine artery waveform has shorter upstroke and downstroke times and an early diastolic notch. Infrequently, there is absent early diastolic flow or reverse flow of the main uterine artery. These characteristics can be incorporated in the waveform analysis if one uses the PI but not when other, simpler methods are utilized.

The other, simpler forms of uterine waveform analysis are the S/D ratio (or A/B ratio) and the resistance index (RI), or Pourcelot ratio  $[(S-D)/S]$ . All that is required here is measurements of peak systole and end diastole. The main problem with the S/D (A/B) ratio is that it becomes infinity when there is no or reversed end-diastolic velocity. The other obstacle is its nonparametric distribution at high values, which could be a problem because there are many occasions in the presence of severe preeclampsia where uterine artery S/D ratios are greater than 5.0. Nonparametric analysis is required when using the S/D (A/B) ratio [21]. To reiterate, these simple techniques would not be affected by the presence of a waveform early diastolic notch. Regardless of any peculiarities inherent in each type of waveform index, none has been proved to offer a clinical advantage over the other.

The general principles of Doppler indices are discussed in depth in Chap. 4.

## Normal and Abnormal Development of Uterine Artery Doppler Waveform

In the nonpregnant state the uterine artery waveform exhibits high pulsatility with a rapid rise and fall in frequency shifts during systole, an early diastolic notch, and low diastolic shifts. Schulman et al. [22],

using transvaginal continuous-wave Doppler revealed high S/D ratios during the proliferative phase of the menstrual cycle ( $12.9 \pm 4.4$ , mean  $\pm$  standard deviation) that dropped significantly during the secretory phase ( $7.2 \pm 3.2$ ;  $p=0.003$ ) (Fig. 16.8). Scholtes et al. [23], using transvaginal pulsed Doppler found no significant difference in the PIs between the two uterine arteries, with mean PI values between 2.9 and 3.2. They found no correlation between the PI and stage of menstrual cycle. Long et al. [24], using transabdominal pulsed Doppler found similar results, with PI values of  $3.25 \pm 0.83$ . They also reported no difference between the uterine arteries and no correlation with the menstrual cycle. Thaler and colleagues [25], using transvaginal pulsed Doppler, obtained S/D ratios of  $5.3 \pm 1.1$  in a group of 27 nonpregnant women (Fig. 16.9). The difference in the data of Schulman et al. and those of subsequent investigators is probably due to the problem of using continuous-wave Doppler sonography when trying to determine if a waveform showing the characteristics of high resistance is from the uterine artery.

Pregnancy results in marked changes in the uterine artery waveform. Schulman et al., using abdominal and vaginal continuous-wave Doppler ultrasonography, showed striking increases in uterine artery compliance between weeks 8 and 16 of gestation (Fig. 16.8) [22]. Increases in compliance continued

until 26 weeks but in a less dramatic fashion. From 26 weeks onward the S/D ratios were similar, whether they were obtained abdominally or vaginally, and did not change in value throughout the remainder of pregnancy. The diastolic notch disappeared by 20–26 weeks' gestation. Thus the full evolution of the uterine artery waveform may not be complete until 26 weeks. These investigators defined abnormal uterine artery waveforms as those with S/D ratios greater than or equal to 2.7 (the average of the right and left uterine arteries) or persistence of the early diastolic notch.

Deutinger et al. [26] repeated Schulman's work using transvaginal pulsed Doppler ultrasonography and reported similar results except for a more gradual, smoother drop in S/D ratios during the first 14–16 weeks of gestation. Their mean averaged S/D values for each trimester were 5.5, 2.9, and 2.1. Deutinger et al. believed the S/D ratios plateaued at 24 weeks.

Thaler et al. [25] followed up using transvaginal pulsed Doppler (Fig. 16.9). Again, during the first 14–16 weeks the drop in S/D ratios was not as rapid as those obtained with continuous-wave Doppler ultrasound. During the first 26 weeks' gestation the S/D ratios were lower and had narrower standard deviations than did the continuous-wave data of Schulman et al. Thaler et al. also showed that the S/D values do

**Fig. 16.8.** Uterine artery compliance during the menstrual cycle and throughout pregnancy (means  $\pm$  SD). S/D systolic/diastolic. (Reprinted from [44] with permission)

**Fig. 16.9.** Systolic/diastolic (*S/D*) flow velocity ratios in the uterine artery in the nonpregnant state and during weeks of gestation. (Reprinted from [28], with permission)

not plateau until 26 weeks. Thus the uterine artery waveform transforms rapidly to one of lower pulsatility during the first 16 weeks and shows continual but less dramatic increases in compliance until 26 weeks' gestation, by which time it should lose its diastolic notch. From 26 weeks onward the waveform has a stable appearance.

Pearce et al. [27], using a pulsed duplex Doppler technique, portrayed similar evolutions in the RI from 16 weeks onward. They noted that there was increased compliance in the placental (versus nonplacental) uterine artery. Trudinger et al. [28] studied the subplacental vascular bed with continuous-wave Doppler ultrasound. They were probably insonating the arcuate and radial arteries, and they reported a progressive drop in *S/D* ratios. Their values were lower than those of other investigators, however, because they were interrogating distal branches of the uterine circulation whereas the configuration of the main uterine artery waveform is affected by the summation of resistances of the entire vascular tree. They did not report a notch in any subplacental waveform.

A lesson learned from these studies is that continuous-wave Doppler ultrasound is probably unreliable for studying the uterine artery in the nonpregnant state and up to 14–16 weeks' pregnancy, as pattern recognition is used to identify the uterine artery. It is not until 14–16 weeks' gestation that there is a generous diastolic component to the waveform, thereby clearly distinguishing it from waveforms of other pelvic vessels.

A number of other investigators have looked at the early development of the uterine artery (during the

first 18 weeks' gestation) using continuous-wave, pulsed-wave, and color Doppler techniques [29–32]. Regardless of the equipment or waveform index used, all showed a significant, smooth, progressive decrease in waveform indices (Fig. 16.10). Using transvaginal color Doppler sonography, Jurkovic et al. [30] and Juaniaux et al. [31] showed uterine artery mean RIs decreasing from 0.80 at 8 weeks to around 0.63 at 17 weeks; and the mean PI of 2.0 at 8 weeks dropped to nearly 1.3 at 18 weeks' gestation. Their variation around the mean was narrower than those of other investigators, probably because they used color Doppler ultrasonography as the method of vessel identification.

## Uterine Artery Diameter and Volume Flow

Estimations of volume flow of the uterine arteries would be an ideal method to determine the state of this circulation. However, to determine volume flow, knowledge of the angle of incidence and vessel diameter is required. Any error when estimating vessel diameter becomes squared, and small errors when determining the angle of incidence result in even larger errors in the velocity calculations. Estimates of volume flow are accurate when the angle of incidence is zero and the vessel of interest is straight. Such conditions are difficult to achieve when studying the main uterine arteries. Volume flow assessments of the uterine artery are confounded further by the abundant collateral circulation.

**Fig. 16.10.** Individual values and reference ranges (mean and 90% confidence interval) of the resistance index (*RI*) and pulsatility index (*PI*) in the uteroplacental circulation with gestational age (*GA*). Both indices decreased significantly with gestation in all three arteries. (Reprinted from [30] with permission)

Three investigative groups have reported their data on uterine volume flow. Thaler et al. [25] used the transvaginal approach to study the left ascending uterine artery. They reported a mean volume flow rate of 94.5 ml/min before pregnancy, which increased to a mean of 342 ml/min during late pregnancy (Fig. 16.11); it represented a 3.5-fold increase. The standard deviation about the mean volume flow during the last trimester was reasonable at  $\pm 50$  ml/min. The mean diameter was 1.6 mm before pregnancy and increased to 3.7 mm at term, which represented more than a twofold increase (Fig. 16.12). Thaler et al. did not see a significant difference in volume flow between the two uterine arteries in a group of 32 women who were studied up to 26 weeks' gestation.

Palmer et al. [33], with transabdominal pulsed Doppler ultrasonography and without the color Doppler technique, reported remarkably similar results for vessel diameter and volume flow measurements. The uterine artery diameter doubled by week 21 (from  $1.4 \pm 0.1$  to  $2.8 \pm 0.2$  mm;  $p < 0.05$ ), did not change between weeks 21 and 30 ( $2.9 \pm 0.1$  mm), and increased between weeks 30 and 36 (to  $3.4 \pm 0.2$  mm). Uterine artery volume flow was approximately 312 ml/min by 36 weeks' gestation. These investigations showed that increases in uterine artery flow during the first 21 weeks of pregnancy were due equally to changes in uterine artery diameter and mean velocity, whereas the rise during late pregnancy (30–36 weeks) was mainly due to increases in mean flow velocity. Their use of two pulsed Doppler devices to separately measure uterine artery diameter and

mean velocity and then combine the measurements to determine volume flow is not technically sound.

Bower and Campbell [34] estimated uterine volume flow using the transabdominal approach. They found marked differences in volume flow between the placental and nonplacental uterine arteries, with values of approximately 400 ml/min and 290 ml/min, respectively, at 42 weeks' gestation. Although their

**Fig. 16.11.** Changes in uterine blood flow during pregnancy. (Reprinted from [28] with permission)

**Fig. 16.12.** Diameter of ascending uterine artery at various gestational ages. (Reprinted from [28] with permission)

mean volume flow values were similar to those of Thaler et al. and Palmer et al., there was great variation around the mean, and their measurements were skewed. Some of their volume recordings of the placental uterine were greater than or equal to 1 l/min – readings that were not seen in the studies of Thaler et al. or Palmer et al.

These data show that changes in the placental spiral arteries do not solely explain the development of the uterine circulation, and that the increase in flow is in part due to hypertrophy of the larger uterine vessels. Moreover, the preliminary data show that volume flow estimates of the uterine artery may be more reproducible with the transvaginal approach. Additional work is requested to assess its association with perinatal outcome and the potential for clinical usefulness.

## Uterine Artery Maximum and Mean Flow Velocity

Maximum and mean velocities of the uterine artery in the nonpregnant and pregnant state have been studied. Jurkovic et al. [30], using transvaginal color Doppler sonography, showed a significant increase in maximum peak systolic velocity, from approximately 53 cm/s at 6 weeks' to 140 cm/s at 18 weeks' gestation. Jauniaux et al. [31], using the same technique, found almost identical changes in peak systolic velocities. At 10 weeks' the peak velocity of  $68.0 \pm 8.5$  cm/s increased to  $74.0 \pm 6.5$  cm/s at 13 weeks' gestation. At 14 weeks gestation there was an abrupt significant increase to  $117 \pm 7$  cm/s ( $p=0.005$ ). A slow increase continued until 17 weeks ( $127.0 \pm 9.3$  cm/s). During these time periods both investigators noted decreasing impedance in the uterine, radial, and spiral ar-

teries (Fig. 16.10). They believed that it supported the hypothesis that endovascular trophoblastic invasion of the spiral arteries reduces resistance. Also, the progressive fall in resistance from the uterine artery to the radial and spiral arteries was due to an increase in branching and cross-sectional area of the circulation.

Palmer et al. [33], using transabdominal pulsed Doppler sonography without color flow mapping, was able to insonate the uterine artery as it branched off the internal iliac artery. They recorded a mean flow velocity of  $8.4 \pm 2.2$  cm/s in the nonpregnant state. At 21 weeks of pregnancy the mean flow velocity rose to  $38.5 \pm 4.9$  cm/s and continued to increase to  $46.6 \pm 3.4$  cm/s at 30 weeks and  $61.4 \pm 3.0$  cm/s at 36 weeks of pregnancy. Bower and Campbell [34], using transabdominal pulsed Doppler sonography with color flow mapping, obtained signals from the uterine artery as it crossed medially to the external iliac artery. Their measurements of mean flow velocity at similar gestational ages were lower, with large variation around the means. Mean velocities in the placental uterine artery were greater than those in the non-placental uterine artery. Their data were also markedly skewed.

These data show that maximal and mean flow velocities of the uterine artery increase throughout gestation. The velocity data during early pregnancy [30, 31] were remarkably similar, showed reasonable variation, and were obtained by the technique that should be best suited for these measurements (transvaginal pulsed Doppler sonography with color flow mapping). However, the data need to be reproduced by others. Mean and maximal velocities from mid-pregnancy onward must be studied with the same technique. The method Palmer et al. used to detect signals from the uterine artery as it branches off the internal iliac artery deep in the pelvis (transabdominal approach with color flow mapping) is difficult, and the transabdominal approach of Bower and Campbell results in considerable variation. The clinical usefulness of such data must also be explored.

## Uterine Artery Waveform Notch

The uterine artery Doppler waveform has an early diastolic notch in the nonpregnant state, and it often persists in the pregnant state until weeks 20–26. What constitutes an early diastolic notch during pregnancy has never been defined. Campbell et al. [35] defined a “true” abnormal notch during pregnancy as a deceleration of at least 50 Hz below the maximum diastolic velocities after 20 weeks. They believed that it is rarely seen on the placental side beyond that point of pregnancy. Fleischer et al. [36] thought that it is a

normal finding until week 26 of gestation. Later, Thaler et al. [37] identified a group of women who had both systolic and diastolic notches in the uterine artery waveform and demonstrated that perinatal outcome was worse than when there was a diastolic notch only (Fig. 16.13). Retention of the early diastolic notch is thought to represent persistence of the inherent total high impedance of the uterine artery circulation. It has been identified in waveforms of the main uterine artery and its most proximal branches.

Fleischer et al. [36] were the first to note the importance of the uterine notch in their study of 71 women with hypertensive disorders of pregnancy. Ninety percent (27 of 30) of women who developed preeclampsia or chronic hypertension with superimposed preeclampsia had a uterine waveform notch. When normal pregnancy outcome was defined as delivery at 37 weeks or later or a birth weight of 2500 g or more, the uterine artery notch had better sensitiv-

ity (93%), specificity (91%), positive predictive value (87%), and negative predictive value (95%) compared to the mean arterial blood pressure, creatine clearance, uric acid level, and uterine S/D ratios.

Thaler et al. [37] evaluated a group of 140 hypertensive pregnant women. Of 39 women with diastolic or systolic notches (or both) in the uterine artery waveform, 82% (32 of 39) had pregnancy-related hypertensive complications. Hypertensive women with uterine systolic and diastolic notches had higher waveform indices of both uterine and umbilical arteries, higher diastolic and systolic blood pressures, and worse perinatal outcomes than those without notches (Tables 16.1 and 16.2). When umbilical artery resistance was normal and both uterine arteries had elevated resistance indices, the group with the uterine waveform notch had worse perinatal outcomes (Table 16.3). When the uterine artery and umbilical artery waveforms were abnormal, the presence of the

**Fig. 16.13.** Subplacental (top), right uterine (bottom left), and left uterine (bottom right) waveforms in a chronically hypertensive pregnant woman at 22 weeks' gestation. Both uterine arteries have systolic and diastolic notches. The pla-

centa was central and posterior. At 26 weeks' gestation she presented with a fetal demise after an arrest of fetal growth at 19 weeks

uterine notch portended a worse perinatal outcome (Table 16.3). When the umbilical RI was normal and there was no notch in the uterine artery waveform, perinatal outcome was similar whether the uterine artery RI was normal or abnormal (Table 16.4). Thaler et al. clearly showed that the uterine artery systolic

and diastolic notches were the better predictor of perinatal outcome than the RI alone. Aristidou et al. [38] undertook uterine artery screening in women with elevated maternal serum  $\alpha$ -fetoprotein levels, and they too noted that the uterine artery notch was a good predictor of poor perinatal outcome.

**Table 16.4.** Pregnancy outcomes in women with normal resistance indexes in umbilical artery flow velocity waveforms and no notch in uterine artery waveforms (from [37], with permission)

Parameter	Normal uterine artery RI (n=30)	Abnormal uterine artery RI (n=11)
Delivery (weeks)	38.5 ± 1.55	38.2 ± 1.4
Birth weight (g)	3,184 ± 738	3,104 ± 544
Perinatal mortality (%)	0	0
Fetal growth retardation (%)	3.3	0
Abnormal FHR during labor (%)	3.3	0
Cesarean for fetal distress (%)	3.3	27.3
Apgar score <7 at 5 min (%)	0	0
NICU >48 h (%)	3.3	0

FHR, fetal heart rate; NICU, neonatal intensive care unit; RI, resistance index.

It is of interest that when Trudinger and Cook [39], using continuous-wave Doppler ultrasonography, studied the subplacental arteries in pregnant women with severe proteinuric hypertension they did not report a diastolic notch. As in the study of Thaler et al. [37], regardless of whether there was normal or increased impedance in the subplacental vessels, there was no correlation with fetal or neonatal outcome.

Rarely, absent early diastolic flow and reverse flow of the uterine artery waveform are seen (Figs. 16.14, 16.15).

**Fig. 16.14.** Absent early-diastolic velocities in the uterine artery velocity wave with pulsed Doppler

**Fig. 16.15.** Reverse flow of the uterine artery of a severely preeclamptic woman

## Influence of Placental Location on Uterine Artery Waveforms

It has been observed that placental location influences the uterine and arcuate artery waveform [22, 40–43]. In the case of a lateral placenta, the placental uterine and arcuate artery waveform frequently shows low resistance (Fig. 16.16). Nomograms for placental and nonplacental uterine and arcuate artery waveforms using transabdominal color and pulsed Doppler techniques have been constructed (Fig. 16.17) [34].

Campbell et al. [40] were the first to report that the RI of the placental uterine artery was significantly lower than that of the nonplacental uterine artery. This difference increased when the waveforms were abnormal.

Schulman et al. [44] developed the concept of divergent uterine arteries. They thought that uterine levorotation or dextrorotation made ultrasonic placental localization difficult. Also, most lateral placentas are not pure lateral placentas. Another confounding variable is the development of a collateral circulation, and that the right and left uterine circulations may or may not have functioning anastomoses. These authors therefore thought it was more important to look at the difference between the right and left S/D ratios. They found that normal pregnancies were associated with more or less equal contributions from each uterine artery, and that the normal S/D ratio difference between the uterine arteries was  $0.3 \pm 0.3$ . Accordingly, divergent uterine arteries were defined as those with S/D ratio differences of greater than or equal to 1.0. They found that 81% of women with abnormal S/D ratios had significant divergence. When there was an abnormal S/D ratio the outcome was worse when there was divergence.

**Fig. 16.16.** Spiral (left), right uterine (top right), and left uterine (bottom right) artery velocity waveforms in a pre-eclamptic woman at 31 weeks' gestation. The right lateral placenta resulted in divergent uterine velocity waveforms, with the right uterine artery circulation much more compliant than that on the left

**Fig. 16.17.** Reference ranges of the uterine and arcuate resistance index, demonstrating the effect of placental site. (Reprinted from [34] with permission)

Kofinas et al. [41] believed that they could define placental location by ultrasonography. They found that in both normal and hypertensive pregnancies with unilateral placentas the S/D ratio of the placental uterine artery was significantly lower than that of the contralateral artery ( $1.73 \pm 0.35$  versus  $2.46 \pm 0.73$ ;  $p < 0.001$ , and  $2.38 \pm 1.01$  versus  $4.04 \pm 1.77$ ,  $p = 0.0012$ ). Ito et al. [42] and Oosterhof and Aar-noudse [43] found the same placental effect on the ipsilateral uterine artery, but in addition Ito et al. [41] observed that the lower the placental site, the lower the uterine waveform index.

Kofinas et al. [45] reexamined the relation between placental location and uterine artery velocimetry and found that perinatal outcome correlated best with the placental uterine artery; the mean index using both uterine arteries had the next best condition, and the nonplacental uterine artery was the poorest predictor. As they pointed out, the placental uterine artery perfuses most of the placental bed and the nonplacental uterine artery primarily perfuses nonplacental myometrial vessels.

It is clear from these studies that the unilateral placenta results in greater erosion and recruitment of the subplacental spiral arteries of the ipsilateral uterine circulation. The question is whether placental location is essential when evaluating uterine artery Doppler waveforms.

## Doppler Waveforms of the Arcuate, Radial, and Spiral Arteries

Color flow mapping has allowed us to interrogate specific sites of the uterine circulation. Several investigators have demonstrated a progressive drop in impedance in all aspects of the uterine circulation, from the main uterine arteries to the spiral arteries, as pregnancy advances (Fig. 16.10) [30–32, 46]. Also, there is a drop in resistance from the proximal to the distal branches of the uterine circulation, the uterine artery having the highest impedance and the spiral arteries the least (Fig. 16.18). These studies are important physiologic observations whose clinical value has yet to be realized.

If one considers the subplacental spiral artery lesions identified in the presence of preeclampsia, essential hypertension, or fetal intrauterine growth restriction (IUGR), the subplacental vessels seem to be the ideal site of Doppler sampling to detect abnormal resistance in the uteroplacental circulation. Trudinger et al. [28], using continuous-wave Doppler sonography, was the first to obtain signals from the arcuate and radial arteries. However, they detected increases in the S/D (A/B) ratios in some but not all high-risk pregnancies. Some subplacental radial and arcuate arteries are normal in the face of significant pathology in others.

**Fig. 16.18.** Flow velocity waveforms (FVW) obtained from both placental circulations at 8 and 16 weeks' gestation, respectively. Note the progressive increase in diastolic flow

of the uteroplacental waveforms from the uterine artery to the spiral artery and as gestational age advances. (From [31] with permission)

Voigt and Becker [47] studied 58 women with pregnancy-induced hypertension ( $n=49$ ) or fetal IUGR using pulsed Doppler sonography of the subplacental arcuate arteries. They correlated the arcuate artery PI with placental bed biopsy findings. There were marked increases in the subplacental arcuate artery PI when the placental bed biopsies were pathologic.

Judging from these studies it appears that using information from sites other than the main uterine artery for clinical purposes requires color and pulsed Doppler sonography. Even with this technology it remains difficult to differentiate the radial, arcuate, and spiral artery waveforms. The difference in the main uterine waveform indices between normal and pathologic pregnancies is probably greater than at other sites. This difference allows clearer distinction between normal and abnormal waveform index values. Measurement of the main uterine artery may be more reproducible and allow standardized longitudinal follow-up. It seems that studying the main uterine artery waveform, a reflector of total subplacental resistance, remains the most clinically important parameter.

### **Effect of Pharmacologic Agents and Epidural Anesthesia on Uterine Artery Waveforms**

Uterine Doppler velocimetry has been used to study the effects of drugs on the uterine circulation. Nifedipine [48], dihydralazine [49], indomethacin [50], oxy-metazoline [51], pseudoephedrine [52], smoking [53], and nicotine gum [53] have not been shown to alter uterine waveform indices during pregnancy. Estrogen and progesterone hormonal replacement therapy after 6–10 weeks or on a chronic basis and magnesium sulfate therapy for tocolysis have been shown to lower uterine artery resistance [54]. Magnesium sulfate was found either to have no effect [55] or to lower [56] resistance. Methyldopa had no effect on the uterine artery PI [57]. The effects of several  $\beta$ -blockers have been looked at with varying results. In one study propranolol had no effect, but pindolol decreased resistance [58]. Atenolol was found to increase the arcuate artery PI [59]. The latter study must be reproduced, as it has important implications for management of the pregnant hypertensive woman.

There is evidence that preeclampsia is associated with a deficiency of prostacyclin, which could lead to generalized vasoconstriction. Therefore prostacyclin infusion seems to be a potential form of treatment

for preeclampsia. Jouppila et al. [60] intravenously infused prostacyclin in 13 preeclamptic women. It resulted in significant decreases in maternal blood pressure and a rise in maternal plasma 6-ketoprostaglandin  $F_{1\alpha}$ . However, there was no effect on uterine artery flow when studied with the intravenous xenon 133 isotope clearance method. This study would be worth repeating using Doppler technology.

Uterine artery waveforms have been studied after infusion of angiotensin II. Erkkola and Pirhonen [61] used color and pulsed Doppler sonography to study the uterine artery between 24 and 26 weeks' gestation and found increases in the S/D ratio after angiotensin II infusion ( $1.6 \pm 0.1$  versus  $2.09 \pm 0.29$ ,  $p < 0.001$ ). This increase was not affected by placental location. Interestingly, the increases in uterine artery resistance followed the increases in blood pressure, providing evidence of a differential response in the uterine circulation versus the systemic vasculature. In a follow-up report they compared the uterine artery response to angiotensin II infusion in normotensive and hypertensive pregnant women [62]. The uterine S/D ratios increased equally in the two groups but the increase was faster and recovery slower in the hypertensive group. Jones and Sanchez-Ramos [63] reported no changes in uterine artery S/D ratios using continuous-wave Doppler ultrasonography in nine normotensive pregnant women.

The effects of epidural anesthesia on uterine artery resistance have been studied using Doppler velocimetry. Four studies using anesthetic agents with and without epinephrine showed no change in uterine artery resistance in normal, term, laboring patients or in those prior to elective cesarean section [64–67].

Ramos-Santos et al. [68] evaluated the effects of epidural anesthesia in normal and hypertensive patients in active term labor. The mean uterine artery S/D ratios did not change in normotensive and chronically hypertensive patients but fell significantly in the term mildly preeclamptic patients – to values similar to those of the normotensive group. Both placental and nonplacental uterine artery S/D ratios fell to values seen in the normotensive group. The uterine S/D ratios in the chronic hypertensive group, which were similar to those of the preeclamptic group, did not change after administration of epidural anesthesia. The authors accepted this finding as evidence of underlying vascular disease. This study demonstrates the benefits of epidural anesthesia in the presence of mild preeclampsia at term. The study must be reproduced and involve women with preeclampsia of varying severity.

## Effects of Exercise on Uterine Velocimetry

Studies that examine the effect of exercise during pregnancy on uterine artery velocimetry are difficult to compare, as they have differences in (1) the degree of exercise employed, (2) the Doppler equipment used, (3) the maternal position during exercise, and (4) the maternal position and time of recording after exercise.

Three studies performed on healthy pregnant women showed no changes in uterine artery waveform indices [69–71]. These findings are not in line with previous studies in animals. The fact that there were no changes in waveform indices despite significant increases in maternal heart rate may be evidence of increased uterine resistance.

Morrow et al. [72] studied healthy, term, pregnant women after 5 min of bicycling at a continuous power of 20 watts. This moderate level of exercise was associated with an increase in uterine artery resistance at 2 min after exercise. There was no evidence of deleterious fetal effects. Erkkola et al. [73] studied the responses of eight healthy women at term to increasing levels of exercise on a stationary bicycle. Maternal heart rate and blood pressure rose during each workload period, as did the uterine S/D ratios. Therefore impedance in the uterine artery rose with increasing degrees of exertion. As in the study of Morrow et al., there were no apparent ill effects on the fetus. One explanation for the lack of adverse fetal effects is that the increases in uterine resistance are counteracted by increases in mean arterial pressure. This situation may not lead to changes in volume flow, as volume flow equals pressure divided by resistance.

Hackett et al. [74] were the first to look at the effects of exercise on uterine Doppler velocimetry in pregnancies complicated by hypertension or small-for-gestational-age (SGA) fetuses. Uncomplicated and complicated pregnancies with and without abnormal uterine artery waveforms comprised the three groups. All three groups showed an increase in uterine artery RI after exercise that rapidly returned to normal within 5 min of rest. The mean change in RI was greater in complicated pregnancies with abnormal waveforms than in complicated pregnancies with normal uterine waveforms. The RI in all complicated pregnancies increased more than those of the normal pregnancies.

The studies of Morrow et al. [72], Erkkola et al. [73], and Hackett et al. [74], which show increased uterine artery resistance during exercise, have important implications for physical activities of pregnant women with uterine or umbilical artery vasculopathy. One must question the validity of uterine velocimetry in the presence of changes of heart rate and blood pressure.

## Effects of Uterine Contractions on Uterine Waveforms

The effects of the contractions of active labor and Braxton-Hicks contractions on uterine artery velocity waveforms has been studied. Fleischer et al. [75] studied 12 pregnant women in labor at term and found that the uterine artery end-diastolic velocity fell progressively during contractions. End-diastolic velocities reached zero when intrauterine pressures exceeded 35 mmHg. An early diastolic notch did not appear. Janbu and Nesheim [76] found that flow velocity begins to drop immediately as the intrauterine pressure rises, and it falls linearly with increasing intrauterine pressures up to 60 mmHg.

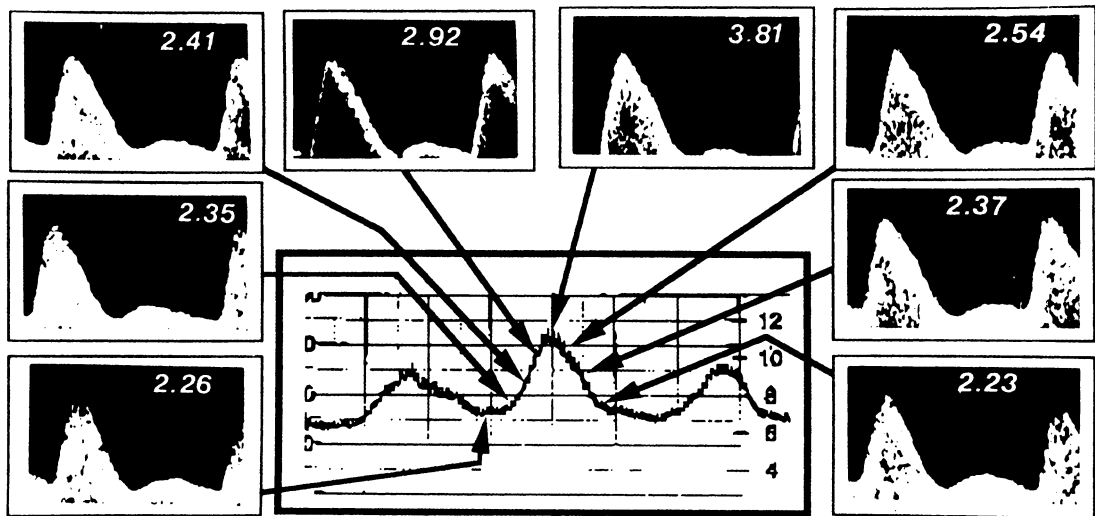

Bower et al. [77] studied the effects of Braxton-Hicks contractions on normal and abnormal uterine artery Doppler waveforms. The PI increased in all cases during spontaneous contractions. In some cases where the uterine waveforms were normal, there was an absence of end-diastolic velocities. However, when the uterine artery waveforms were abnormal and had an early diastolic notch, there was an absence of end-diastolic velocities during contractions in all cases (Fig. 16.19).

Kofinas et al. [78] studied the effects of Braxton-Hicks contractions on the uterine arteries and the arcuate arteries supplying the placental and nonplacental myometrium. When the contractions were localized in the placental myometrium, there was no increase in the subplacental arcuate artery resistance or the main uterine artery resistance. When the contraction involved the nonplacental myometrium, the resistance in the nonplacental arcuate artery and the uterine artery increased. Thus they showed that the human myometrium manifests functional asymmetry, with the subplacental and nonplacental myometrium showing different degrees of contractility.

## Uterine Artery Circulation with Uterine Anomalies

Stege et al. [79] reported a case of severe preeclampsia and fetal growth restriction at 34 weeks' gestation in a woman with a bicornuate uterus. The placenta was in the left uterine horn. There was a marked difference in uterine artery waveforms with the right and left uterine artery PIs being 4.27 and 0.80, respectively. The right uterine waveform had an early diastolic notch, and the authors took it as evidence of a lack of anastomosis between the right and left uterine circulations.

These uterine malformation cases exemplify the complexities of the effects of placentation on the uter-

**Fig. 16.19.** Tocography demonstrating uterine contractions. Alterations of uterine artery flow velocity waveforms in temporal association with a contraction are also shown.

The number in each frame indicates the pulsatility index of individual flow velocity waveforms. (Reprinted from [77] with permission)

ine circulation and the potential of each uterine artery to develop collateral branches. Also, extrauterine collateral circulation may help compensate when the nonplacental uterine circulation is not recruited or available.

### Uterine Velocimetry and Umbilical Vein Gases

Soothill et al. [80] performed funicentesis and uterine velocimetry in 32 pregnancies complicated by IUGR to see if there was a correlation between the uterine circulation and fetal umbilical vein blood gases. A significant negative correlation was found between uteroplacental RI and fetal pH ( $r = -0.37$ ,  $n = 32$ ,  $p < 0.05$ ). Significant positive correlations were found between the uteroplacental RI and fetal hypoxia ( $r = 0.55$ ,  $n = 32$ ,  $p < 0.001$ ) and gestation-adjusted  $PCO_2$  ( $r = 0.36$ ,  $n = 32$ ,  $p < 0.05$ ). In addition, there was a significant positive correlation between gestation-adjusted lactate ( $r = 0.41$ ,  $n = 26$ ,  $p < 0.05$ ) and erythroblast count ( $r = 0.37$ ,  $n = 32$ ,  $p < 0.05$ ). These findings demonstrated that abnormal uterine velocimetry can be associated with inadequate maternal delivery of oxygen and nutrition to the intervillous space. The findings may have been confounded by alterations in umbilical-placental flow and the fetal hemoglobin content, which were not measured.

### Uterine Artery Screening During Pregnancy

There have been several uterine artery screening studies, and the results have varied (Table 16.5) [40, 81–85]. Several factors make comparisons difficult. The timing of the screening affects results. For example, the uterine artery waveform does not complete its evolution until approximately 26 weeks. Also, the uterine notch, which correlates well with adverse pregnancy outcome, can persist until 26 weeks. Thus screening too early leads to false-positive rates and lower positive predictive values because what appear to be abnormal uterine arteries at 18 weeks' gestation may fully develop and normalize by 24–26 weeks. Screening at 24–26 weeks leads to improvement in the false-positive rates and positive predictive values, but it allows pathologic changes to progress and so steps to modify or prevent disease are less effective. Screening pregnancies at risk yields a high sensitivity because of a high incidence of disease, in contrast to screening unselected low-risk pregnancies. Other factors that influence results are the definition of the abnormal uterine artery waveform index used and whether one takes into account the early diastolic notch. The equipment results in variations in sampling sites depending on whether continuous-wave or color with pulsed-wave Doppler sonography is used. These studies have varied in their definition of adverse outcome, including clinical classifications or definitions of hypertensive disorders. Given the same clinical situation, physician management and the decision-making process may vary and so influence the outcome.

**Table 16.5.** Uterine Doppler velocimetry screening studies

Study: first author	Population	Equipment	No.	Time of screening (weeks)	Outcome measure	Sens (%)	Spec (%)	PPV (%)	NPV (%)	Prev (%)

<sup>a</sup> Taken together to define outcome measures.

Abnormal outcomes can occur with normal uterine artery screening, as there could be abnormalities in umbilical flow. In Ducey et al.'s [86] population of hypertensive pregnant women, 44% with preeclampsia, 74% with pregnancy-induced hypertension, and 88% with chronic hypertension had normal uterine artery Doppler studies and would be missed on screening. In their study pregnancy-related hypertension occurred with normal uterine and umbilical velocimetry. This population consisted of many white middle-class women, and so these findings may not pertain to all populations.

The screening studies involved both high- and low-risk patients. The incidence of abnormal uterine artery screening in 11 of the screening programs [40, 82–87] averaged  $15.4\% \pm 14.6\%$  with a range of 2.7%–42.0%. There is a hint that there is more uterine artery disease in the black versus the white population.

The uterine artery screening programs of Harrington [83], Valensise [84], and Bower [85] should serve as the ideal models. Harrington [83] used continuous-wave Doppler sonography for screening at 19–20 weeks; and those women who were abnormal were re-screened at 24 and 26 weeks with color and pulsed Doppler sonography of the main uterine artery. This method standardized the sample site and allowed sampling at the same location during longitudinal studies. Also, they defined abnormal uterine artery waveforms as an averaged RI from both uterine arteries that was above the 95th percentile for gestational age or a diastolic notch (or both). Using proteinuric pregnancy-induced hypertension and IUGR as their endpoints, they achieved good results.

Valensise and colleagues [84] screened 272 low-risk primiparous women at 22 weeks' gestation with color and pulsed Doppler ultrasonography. The average RI of both uterine arteries was considered abnormal when it was more than 0.58. Abnormal testing occurred in 9.5%, but the figure fell to approximately 7.0% at 24 weeks' gestation. These authors reported the best sensitivities for pregnancies with the worse outcomes, such as early onset of hypertension, proteinuric hypertension, and hypertension associated with IUGR.

Bower et al. [85] screened 2,058 unselected women at 18–22 weeks of pregnancy with continuous-wave Doppler sonography. Color and pulsed Doppler sonography was used at 24 weeks to rescreen the 273 women with a high RI or early diastolic notch. On re-screening, 104 remained abnormal (5.1%). The presence of the diastolic notch was a better predictor of preeclampsia than the RI. All cases of delivery before 34 weeks due to preeclampsia were predicted by the early diastolic notch.

## Biochemical Serum Markers and Uterine Artery Doppler Velocimetry

Unexplained elevated maternal serum alpha-feto protein (MSAFP) is associated with an increased risk of perinatal death, preterm delivery, and IUGR. Cuckle et al. [88] demonstrated that inhibin-A levels in the second trimester were significantly elevated in women who developed preeclampsia versus those who did not. Aquilina et al. [89] combined inhibin-A levels with uterine artery Doppler velocimetry at 15 and 19 weeks' gestation to determine their efficacy in predicting preeclampsia and preeclampsia at less than 37 weeks' gestation. They found that combining inhibin-A and uterine artery Doppler velocimetry improved the sensitivity and positive predictive value for predicting preeclampsia above either parameter alone. The sensitivity and positive predictive value of combined inhibin-A and uterine artery Doppler velocimetry for predicting preeclampsia and preterm preeclampsia was 71.4% and 38.5%, and 60% and 32%, respectively. Therefore, this study proves that combining biochemical testing with uterine artery Doppler velocimetry can lead to a better screening test. The biochemical studies reviewed here provide incentive to perform larger studies with the potential to define effective screening tests for randomized controlled trials of therapies to prevent or modify fetal and maternal adverse outcomes.

## Medical Attempts at Modification of Pregnancy Outcome in Women with Abnormal Uterine Artery Doppler Velocimetry

The first study on the prevention of preeclampsia in women with abnormal uterine artery Doppler velocimetry was performed by McParland et al. in 1990 [90]. They identified 100 women at 24 weeks' gestation with abnormal uterine artery Doppler velocimetry and randomly gave them either 75 mg of aspirin ( $n=48$ ) or placebo ( $n=52$ ). There was no significant difference between the aspirin and placebo groups in the frequency of pregnancy-induced hypertension (13% vs 25%), but there were significant differences in the frequencies of proteinuric hypertension (2% vs 19%) and hypertension occurring before 37 weeks' gestation (0% vs 17%) (Table 16.6). Fewer aspirin-treated than placebo-treated women had low-birth-weight babies (15% vs 25%), but this difference was not significant.

The CLASP multicenter randomized clinical trial [91] involving 9,374 women was one of the many studies designed to determine whether aspirin thera-

**Table 16.6.** Pregnancy outcomes in placebo and aspirin groups

<sup>a</sup> Mean ± SD.

py can prevent preeclampsia and/or IUGR. An inclusion criteria for this study was a risk for preeclampsia. This study revealed no overall decrease in proteinuric hypertension, IUGR, stillbirths, or neonatal deaths attributable to aspirin use. However, there was a significant reduction in the incidence of early-onset proteinuric preeclampsia (<37 weeks) in women who were exposed to aspirin therapy. During the performance of the CLASP trial, Bower et al. [92] were performing two-stage Doppler screening studies of the uterine arteries at 18–20 and 24 weeks' gestation. They identified 60 women with persistently abnormal uterine artery Doppler velocimetry at 24 weeks' gestation and entered them into the CLASP study. There

was no significant difference in the incidence of preeclampsia and IUGR between the aspirin and placebo groups. However, there was a significant difference between the two groups (aspirin 13%, placebo 38%,  $p=0.03$ ) regarding the development of severe preeclampsia (defined as diastolic blood pressure  $\geq 110$  mmHg, with proteinuria of  $>300$  mg/24 h or preeclampsia requiring intravenous antihypertensive therapy). These results imply a possible role of aspirin in modifying the severity of preeclampsia (Table 16.7).

In the same year of the Bower et al. [92] study, Morris et al. [93] showed a statistically significant increase in the rates of preeclampsia (4% vs 11%) and

UAV, uterine artery velocimetry; Sig., significance; NS, not significant; RI, resistance index; S/D, systolic/diastolic ratio; IUGR, intrauterine growth restriction.

SGA weight less than 10% (11% vs 28%) for patients with abnormal uterine waveforms; however, there was no benefit from the use of aspirin. One of the concerns of using uterine artery screening at 18 weeks' gestation is the high rate of false-positive testing. In past studies approximately 70% of positive tests at 18 weeks will normalize by 22–24 weeks' gestation. Therefore, using abnormal 18-weeks' test results as entry criteria will require a greater number of participants to produce a study population with a sufficient frequency rate of severe early preeclampsia in order to demonstrate a treatment effect. This is confirmed by the 11% versus 35% incidence of preeclampsia in the Morris et al. and Bower et al. studies, respectively.

A recent randomized prospective study by Harrington et al. [94] also failed to show a reduction in preeclampsia and SGA under the 3rd percentile. However, when these investigators pooled the individual events into the two outcome measures, "severe complications" (preeclampsia <34 weeks, SGA <3rd percentile, placental abruption, Apgar score <7 at 5 min, neonatal intensive care unit admission, stillborn or neonatal death) and "any complications" (severe complications and preeclampsia >34 weeks' gestation and SGA <10th percentile), there was a significant reduction in the treatment versus control group (Table 16.8). There were other interesting findings in this study. The incidence of early-onset preeclampsia was zero and 2.8% in the aspirin and placebo groups, re-

spectively. This represents the lowest incidence of early-onset preeclampsia in women with abnormal screening uterine artery Doppler velocimetry in publication, which may explain the negative results. Another unique finding occurred in the group receiving aspirin therapy. The complication rates in the women who experienced normalization of uterine artery Doppler velocimetry at 24 weeks' gestation was equal to or slightly greater than those who had persistently abnormal velocimetry. This is an observation never published previously and must be taken into account in future studies.

In summary, the studies do not support the use of low-dose aspirin in women with abnormal uterine artery Doppler velocimetry. However, we agree with Harrington et al. [94] that the overall study results are encouraging and our impression is that women with abnormal uterine artery Doppler velocimetry may represent a group of patients uniquely sensitive to the effects of aspirin. The primary endpoint that may be modifiable or reducible appears to be the incidence of severe early-onset preeclampsia, which is the most serious of hypertensive disorders in pregnancy. One of the reasons for the negative results, with the exception of the Bower et al. [92] study, is the lack of sufficient numbers of patients with severe early-onset preeclampsia. Another reason is the varying definitions of abnormal uterine artery Doppler velocimetry. We would recommend that any trials performed today use the entry criteria of bilateral

uterine artery notching which may result in the highest positive predictive value for early-onset preeclampsia. However, as pointed out by Harrington et al., these trials may have to await further refinements in uterine artery Doppler waveform analysis or combining uterine artery Doppler results with biochemical testing to improve screening efficacy. Other variables were differences in patient medical background, parity, socio-economic background, race, prior hypertensive medication use, and timing of screening and initiation of aspirin therapy.

We propose that studies performed in the immediate future should involve multiple centers, to achieve appropriate numbers of outcome events, with screening performed at 18–20 weeks' gestation and bilateral uterine artery notching as the definition of abnormal testing. Doppler reevaluation at 22–24 weeks' gestation should be performed and as in the Harrington et al. trial, aspirin therapy should be terminated if the results are normal. This would leave us with four groups to analyze based on the Doppler results at 22–24 weeks' gestation: aspirin therapy terminated secondary to normal Doppler results, aspirin with abnormal Doppler studies, and placebo with normal and abnormal Doppler studies. Proposed outcomes would be the early onset of preeclampsia (<34 weeks), gestational age at delivery when preeclampsia was the indication for delivery, the degree of severity of preeclampsia, and the incidence and severity (<10th percentile or <3rd percentile) of IUGR. Survival analysis of gestational age at birth would be interesting to determine whether, regardless of indications for delivery, aspirin therapy results in significantly greater pregnancy duration.

Part of the pathophysiology of preeclampsia is endothelial dysfunction, which increases the sensitivity to vasoconstricting agents leading to vasospasm [95]. Free radicals are thought to injure the maternal vascular endothelium and promote endothelial cell dysfunction. Therefore, antioxidant therapy has the potential to prevent and/or modify preeclampsia. Chambers et al. [96] recently showed *in vivo* reversal of endothelial dysfunction in preeclampsia with ascorbic acid. These results require confirmation from larger randomized clinical trials.

Nitric oxide is produced by the endothelium of vessels and is a well-known vasodilator and platelet aggregation inhibitor. In preeclamptic women, inhibition of nitric oxide synthase and cyclooxygenase attenuates endothelial-derived relaxation. It has been suggested by several investigators that since preeclampsia is associated with decreased function of nitric oxide, introducing a nitric oxide agent, such as glyceryl dinitrate, would reduce the severity or prevalence of preeclampsia. Grunewald et al. [97] performed intravenous infusions of nitroglycerin in 12

severe preeclamptics. This resulted in a significant reduction in maternal blood pressure; however, the PI of the uterine arteries did not change significantly [1.23 (95% CI 1.01–1.61) versus 1.30 (95% CI 1.01–1.88)]. Thaler et al. [98] studied 18 women with low-risk pregnancy at 17–24 weeks' gestation, who were given a single 5 mg dose of sublingual isosorbide dinitrate. Blood flow velocity waveforms in the ascending uterine artery were measured by pulsed color Doppler ultrasound before and after the medication was administered. Maternal blood pressure and heart rate were also monitored. The S/D ratio in the uterine artery decreased from 4.83 (95% CI 3.99–5.56) to a nadir of 4.02 at 10 min (95% CI 3.41–4.63,  $p < 0.001$ ). This study suggests a potential benefit of nitric oxide therapy.

Lees et al. [99] identified 40 healthy normotensive women with bilateral uterine artery Doppler waveform notching at 24–26 weeks' gestation and randomized them to transdermal glyceryl trinitrate (GTN) 5 mg/day patch versus placebo patch for 10 weeks or until delivery. There was no statistically significant difference in maternal systolic and diastolic blood pressure, mean uterine artery RI, or the rates of preeclampsia or IUGR. However, there was a significant increase in women who delivered at term an AGA infant without evidence of preeclampsia in the GTN group in comparison to the placebo group [15/21 (71%) vs 5/19 (26%),  $p = 0.004$ , hazard ratio 0.267 (95% CI 0.102, 0.701), 73% reduction in hazard]. Taken collectively these studies suggest that nitric oxide donor therapy needs further investigation.

## Medical Conditions and Uterine Artery Doppler Velocimetry

### Uterine Artery Doppler Velocimetry in IUGR Fetuses and Hypertensive Disorders of Pregnancy

The findings reported in the original article of Campbell et al. [10] in 1983 on uteroplacental Doppler velocimetry – that women with abnormal uterine waveforms had a higher frequency of proteinuric hypertension, poor fetal growth, and fetal hypoxia – inspired a wave of observational studies [28, 35–37, 39, 44, 45, 87, 100–107]. In addition to confirming the work of Campbell et al., these studies found that a significant number of women with hypertension or IUGR fetuses could also have abnormal umbilical artery Doppler waveforms alone or in combination with abnormal uterine artery waveforms. It became clear that a thorough investigation of hypertension during pregnancy and IUGR would require analysis of both uterine and umbilical circulations.

The results of these studies are best summarized by the work of Ducey and colleagues [86], who classified hypertension according to four vascular patterns (Table 16.9). The most common vascular pattern in hypertensive pregnancies is defined by normal uterine and umbilical velocimetry. Although most of these women had chronic hypertension, preeclampsia and pregnancy-induced hypertension also occurred with this pattern. Regardless of the clinical diagnosis, the perinatal outcome was similar to that of a normal obstetric population. These data support optimal medical management of hypertensive women who display this velocimetry pattern rather than aggressive intervention for fear of fetal risk.

The next most common category was abnormal uterine and umbilical artery velocimetry. The authors hypothesized that this group lacks endovascular trophoblastic invasion of the myometrial portion of the subplacental spiral arteries. The women had the worst perinatal outcome and accounted for all the perinatal deaths in the study. They and their fetuses experienced severe early disease. Most of the preeclamptic women and a significant number of the women with pregnancy-induced hypertension had this vasculopathy. For optimal outcome these patients must be identified early, and both mother and fetus require intensive surveillance. The potential for early delivery is great, with many requiring operative delivery. Con-

sideration should be given to using preventive or modifying medication, such as aspirin.

The next two categories consisted of women with isolated deficiencies of either the uterine arteries or umbilical arteries. Surprisingly, the less common of the two was abnormal uterine artery flow only. The Doppler pattern of abnormal umbilical flow belies the popular concept that the placental ischemia seen with pregnancy hypertension is the result of poor maternal perfusion. The perinatal outcome is poorer than when there is abnormal uterine flow only. The fetus is protected by the umbilical artery circulation, and it adapts well to reductions in uterine artery flow. Guzman et al. [108] also described pregnancy-induced hypertension associated with abnormal umbilical flow, only with greater consequences to the fetus than the mother.

When viewing the results of all the observational studies, a pattern emerges wherein abnormalities in uterine artery flow correlate best with maternal complications. Moreover, the state of the umbilical artery circulation is more predictive than that of the uterine artery circulation in terms of fetal-neonatal outcome.

Uterine artery Doppler velocimetry has been shown to correlate very well with pregnancy outcome in women with chronic hypertension. Caruso et al. [109] studied 42 women with chronic hypertension and showed increased incidences of preeclampsia

(60% vs 0%), IUGR (26% vs 0%), and perinatal mortality (46% vs 0%) in women with abnormal uterine RI compared to those with normal RI.

Kofinas et al. [106] studied 65 pregnant diabetics with 34 having pregestational insulin-dependent diabetes and 31 with diet-controlled gestational diabetes. They did not demonstrate a correlation between glycemic control and uterine artery S/D ratios; however, there were S/D ratio elevations when diabetes was complicated by preeclampsia.

Several studies have been performed using both uterine and umbilical artery Doppler studies in women with systemic lupus erythematosus (SLE). Guzman et al. [110] studied 27 pregnancies in 26 women with SLE. The 18 women with normal Doppler studies of both vessels had a normal outcome. Five women had abnormal umbilical artery Doppler studies and the pregnancies were of shorter duration and lower birth weight with two cases of SGA births. Four pregnancies had abnormal Doppler studies for both vessels and they resulted in three perinatal losses and all were SGA births. There was a greater incidence of lupus nephritis, preeclampsia, and chronic hypertension in those with abnormal uterine and/or umbilical studies. Umbilical and uterine artery Doppler studies were better at predicting abnormal antepartum fetal heart rate tracings and SGA fetuses than the presence of lupus nephritis, anticardiolipin antibodies, and lupus anticoagulant. In this study the umbilical-placental circulation was more adversely affected than the uterine circulation.

Uterine artery Doppler velocimetry has been performed in women with antiphospholipid syndrome. Carroll et al. [111] studied 28 women with antiphospholipid syndrome. Of the six cases associated with IUGR, five demonstrated increased impedance to flow in the umbilical artery waveforms, while of those only two had abnormally increased impedance in the uterine arteries. Overall, for patients with autoimmune diseases, more studies need to be completed in order to determine if the development of IUGR and preeclampsia is preceded by abnormal waveforms in the umbilical and the uterine vessels.

Caruso et al. [109] studied 24 women with antiphospholipid syndrome who were treated with prednisone and aspirin during 28 pregnancies. An abnormal RI of the uterine arteries at 18–24 weeks' gestation correlated with reduced gestational age at birth, birth weight, and birth percentile, and predicted four of five cases of preeclampsia.

Thrombophilias can impair the anticoagulation process and lead to an increased tendency toward clot formation in pregnancy. Evidence is building for a strong association between the thrombophilias and adverse pregnancy outcomes, including fetal loss in the late-first, second, and third trimesters, severe

IUGR, placental abruption, and severe and early-onset preeclampsia.

## Conclusions

Uterine artery velocimetry has undergone a remarkable evolution, with present-day color and pulsed Doppler technology allowing the study of each component of the uterine artery circulation. Exceptional observations have been made of its transformation during pregnancy. Reliable reproducible relations between the results of waveform analysis and perinatal outcome have been firmly established by many centers worldwide. The ability to predict early-onset preeclampsia appears to be its strong point, but its exact role in modern obstetrics has yet to be established.

The findings of uterine artery screening studies show that it is an effective means of predicting preeclampsia associated with delivery before 34 weeks' gestation. The ideal time for screening appears to be between 22 and 26 weeks' gestation; the site for screening is the main uterine artery; and the equipment is color with pulsed Doppler technology. Our observations tell us that uterine velocimetry does not predict all forms of hypertensive disorders of pregnancy, as some are associated with normal studies. Those disorders missed do not dramatically affect overall perinatal outcome, as they are associated with near-term deliveries. The screening programs show excellent specificity and negative predictive value and identify a pool of women who require standard care. What needs to be improved is the positive predictive value of the test. The prevalence of the outcome measured will have the biggest impact as will the definition of abnormal uterine Doppler velocimetry. Also important is what percentage of women with abnormal uterine velocimetry will have an abnormal outcome.

We can begin to improve its positive predictive value by concentrating on the definition of an abnormal test. By defining abnormal uterine velocimetry, should we use the abnormal waveform index of one uterine artery or the average of both? Or a unilateral or bilateral early diastolic notch? Or the degree of divergence between the waveform indices of each uterine artery? The data suggest that the presence of the notch is the most important criterion. The early diastolic notch has not been objectively defined, and we could begin by measuring its depth and determining if there is a difference between the persistent notch and the intermittent notch. The volume and velocity of uterine flow should be examined further despite the expected variation in measurements.

Of all the hypertensive disorders associated with pregnancy, early-onset preeclampsia has the most

dramatic impact on perinatal outcome. The low rate of abnormal uterine velocimetry testing (2.6%–12.0%) in unselected populations, the low prevalence and implications of early-onset preeclampsia, and the potential to modify or prevent it favor a screening test with high sensitivity. At worst, the small number of women with false-positive tests would be inappropriately subjected to increased visits to health care providers and to modifying or preventive therapy. This occurrence would be greatly offset by adjustments in the care of women with normal screening. Finally, the impact of uterine artery velocimetry screening depends on the effectiveness of therapeutic regimens designed to alter the course of events of preeclamptic pregnancies.

# Doppler Velocimetry of the Uteroplacental Circulation During Early Pregnancy

Israel Thaler, Amnon Amit

Throughout pregnancy marked changes in uterine blood flow are observed that are related to a decrease in the resistance to flow in uterine vessels and to an increase in their diameter. Fetal growth is directly related to the incremental increase in uterine blood flow, and any long-term alteration in normal flow patterns could disrupt the oxygen and nutrient supply to the growing conceptus and result in an adverse pregnancy outcome.

Early normal pregnancy is characterized by profound morphologic changes in uterine vessels destined to supply the developing placenta. The trophoblast invades the inner third of the myometrium as early as 8 weeks' gestation and migrates through the entire length of the spiral arteries, a process completed by approximately 20 weeks. During these "physiologic changes" the spiral arteries lose their musculoelastic tissue and are transformed into markedly dilated uteroplacental arteries. These changes are probably responsible for the marked reduction in the resistance to flow in the uterine arteries during the first half of gestation and determine the large increase in uterine blood flow that is evident throughout pregnancy. The developing uteroplacental circulation is also regulated by systemic and local vasoactive substances. Of particular interest are the endothelium-derived relaxing and contracting substances.

In the event that the physiologic processes are absent or incomplete, the course of pregnancy may be abnormal, and such complications as pregnancy-induced hypertension and fetal growth restriction could arise. That has become evident is that abnormal conditions during late pregnancy that could adversely affect both the mother and her fetus may reflect abnormal morphologic processes that have occurred at early stages of gestation. Under such circumstances it is theoretically possible to predict such conditions by detecting abnormal blood flow patterns during early pregnancy. Obviously we first have to know the normal characteristics of uteroplacental perfusion.

With the development of sophisticated Doppler ultrasonographic techniques, including color flow imaging, it has become possible to study the uteroplacental vascular bed more accurately and in greater detail

than ever before. In this chapter we focus on the morphologic and physiologic changes of the uteroplacental circulation during the first half of pregnancy and on systemic and local factors that regulate uterine blood flow. Methodologic and anatomic aspects related to Doppler flow measurements of the uteroplacental circulation are highlighted, and patterns of uterine blood flow in normal and abnormal gestations are described. Finally, the use of Doppler sonography to predict pregnancy-induced hypertension, preeclamptic toxemia, and intrauterine growth restriction are discussed.

## Maternal Vascular Response to Placentation

The human placenta is hemochoroidal. Its maternal arterial blood supply is derived from the paired uterine arteries and, to some extent, from the ovarian arteries. The uterine arteries branch in the myometrium, giving rise to the arcuate arteries that encircle the uterus. The arcuate arteries have multiple branches called the radial arteries, which are directed centripetally. As the radial arteries enter the endometrium and approach the uterine cavity, they become the spiral arteries. During early pregnancy, as the maternoplacental circulation is established, profound morphologic and histologic changes take place in the spiral arteries. These morphologic changes are essential during normal pregnancy, as they provide for the ever-increasing demand imposed on the maternoplacental circulation by the advancing gestation. These "physiologic changes" are the result of retrograde intraluminal endovascular trophoblastic growth [1]. The endovascular trophoblasts invade the walls of the spiral arteries, converting them into funnel-shaped, dilated uteroplacental arteries. This transformation occurs in two steps: In the first step, the internal elastic lamina of the spiral arteries disintegrates, so a thin layer of basement membrane is all that remains between the endothelium and the smooth muscle. Next the trophoblast penetrates the arteries, and the media is replaced by a matrix containing cytotrophoblast and fibrin fibers. These morphologic changes

are limited to the decidual portion of the spiral arteries during the first trimester. During the early second trimester a new wave of endovascular trophoblast migration penetrates as far as the myometrial portion of the spiral arteries [2]. The second wave of trophoblastic migration is complete in most women by 20 weeks' gestation [3]. Normal uterine blood supply to the placenta is shown in Fig. 17.1. The physiological changes are functionally complete by 17 weeks as was demonstrated by measuring spiral artery blood flow using color Doppler ultrasound in the second trimester [4].

By 19 weeks' gestation the coiling of the spiral arteries disappears [5]. This event is probably due to stretching of the uterine wall, as the shape of the uterus changes from spheroidal to cylindrical as it grows [6].

The disappearance of musculoelastic tissue from the decidual and myometrial spiral arteries allows them to attain a substantial increase in diameter. A 30-fold increase in diameter, compared to that of the nonpregnant state, has been described [7]. The physiologic correlate of these structural alterations is a reduction in vascular resistance in the spiral arteries and increased uteroplacental flow rates throughout gestation [8]. This change has also been verified by radioisotopic techniques [9–11] and Doppler flow studies [12–14].

In normal pregnancy the trophoblast invades all spiral arteries in both the decidual endometrium and the myometrium. A defective maternal vascular response at the time of placentation is found in pregnancies complicated by preeclampsia and in a proportion of those with small-for-gestational-age (SGA) fetuses [15, 16]. In those pregnancies the vascular changes in the spiral arteries are restricted to the de-

cidal segments or are totally absent. The arterial vascular response may be partial, so only a portion of the spiral arteries undergo normal "physiologic changes", whereas others are not affected by endovascular trophoblast and remain in the same state as in the nonpregnant uterus. It is believed that a defective maternal response to placentation is due to failure of the second wave of intravascular trophoblastic migration [17]. The myometrial segments of the spiral arteries are unaltered in their musculoelastic architecture and so are responsive to vasomotor influences (e.g., vasoactive peptides). Figure 17.2 demonstrates abnormal uterine blood supply to the placenta secondary to abnormal placentation.

Intraluminal trophoblast is a normal finding, then, during the first and second trimesters of normal pregnancy, where it plays a role in establishing placentation [18]. A defective interaction of trophoblast and uterine tissue, well established in preeclampsia and some forms of fetal growth restriction, may be due to immunologic maladaptation [18, 19]. Disturbance of trophoblastic invasion during early pregnancy is frequently associated with renewed trophoblastic migration during the third trimester [16, 20]. The luminal lining in the uteroplacental arteries remains trophoblastic and not endothelial [20]. The disrupted endothelium may be responsible for endothelial cell dysfunction, thought to be of pathogenetic importance in preeclampsia [21]. In addition, many of the affected vessels demonstrate necrotizing vascular lesions – deposition of fibrinoid material and adjacent foam cell invasion – a process also termed atherosclerosis [22].

Hemodynamic studies using radioisotope clearance values [10, 11], dynamic placental scintigraphy [23],

**Fig. 17.1.** Normal blood supply to the placenta. Note the termination of radial arteries each into two spiral arteries that have been physiologically converted to uteroplacental arteries (dotted areas). (Reprinted from [16] with permission)

**Fig. 17.2.** Abnormal blood supply to the placenta. Physiologic changes (*dotted areas*) in some decidual segments of spiral arteries are absent. Myometrial segments are shown without physiologic changes as in preeclampsia or some cases of fetal growth retardation. (Reprinted from [16] with permission)

**Fig. 17.3.** Pulsatility indices (PI) of uteroplacental arteries prior to delivery plotted against the normal reference curve (3rd, 50th, and 90th percentiles). Cases with normal placental bed biopsies are marked by *open* and *closed circles*, and those with pathologic findings are marked by *stars* and *crosses*. The PI values in the group with uteroplacental insufficiency but no hypertension are marked by *encircled stars* and *crosses*. (Reprinted from [28] with permission)

and Doppler flow measurements [12, 24, 25] demonstrated reduced uterine blood flow in cases of preeclampsia and fetal growth restriction. Although these studies were performed during late gestation, it should be recalled that abnormal placentation begins during the early second trimester (with the second wave of trophoblastic invasion) or even during the first trimester. For example, acute atherosclerosis in the decidua, usually found during the third trimester in cases of preeclampsia, has also been observed during the first trimester, from as early as 8 weeks (R. Laurini, personal communication). It is not surprising therefore that abnormal flow patterns (using Doppler flow measurements) can be detected as early as the second trimester [26, 27]. An association between ab-

normal Doppler flow patterns in the uterine artery and histomorphologic changes in the placental bed has been demonstrated [28–30] (Fig. 17.3). However, all studies reported a considerable overlap in the degree of physiologic changes between normal and complicated pregnancies. The association between pregnancy complications and increased uteroplacental resistance as indicated by abnormal Doppler flow cannot then be solely explained by abnormal uteroplacental vessel histopathology [29]. Impaired physiological adaptation of the spiral arteries may not be the single causal factor in preeclampsia and the concept of heterogeneous causes of preeclampsia as was recently suggested [31].

## Regulation of Uteroplacental Blood Flow

During normal pregnancy maternal systemic and uterine vascular functions demonstrate impressive changes. Alterations in the systemic cardiovascular system include a 50% increase in blood volume [32], a similar increase in cardiac output, and a decrease in blood pressure beginning in early pregnancy and reaching a nadir at the midtrimester [33]. The blood pressure is reduced because peripheral vascular resistance during pregnancy is reduced significantly from the normal nonpregnant level [34]. The falls in blood pressure and peripheral resistance occur despite marked activation of the renin-angiotensin-aldosterone system during gestation. Plasma levels of renin, renin activity, angiotensin II, and aldosterone increase early in pregnancy and remain elevated until term [35]. Angiotensin II is thought to have an important role in maintaining blood pressure during normal pregnancy. Thus administration of captopril to normal pregnant women during the first and second trimesters triggers a significant hypotensive response [36].

At the same time, the uterine vasculature undergoes marked alterations, the most prominent being physiologic modification of the spiral arteries, as described before. These changes permit a four- to tenfold increase in uterine blood flow [11, 14], which is necessary to meet the respiratory and nutritional requirements of the growing uterus and gestational products.

Decreased blood pressure in the face of elevated plasma levels of angiotensin II suggests that pregnant women are resistant to its pressor effects [37]. Systemic and uterine vascular beds also exhibit refractoriness to other vasoconstrictors, including vasopressin and norepinephrine [38, 39]. In ovine preg-

nancy the uterine vascular bed is even less reactive than the systemic vasculature to the vasoconstrictive effects of angiotensin II [40] (Fig. 17.4). It has been proposed that the reduced peripheral vascular resistance of pregnancy is due to increased production of vasoactive substances. The substances believed to fill this role are prostacyclin (prostaglandin  $I_2$ , or  $PGI_2$ ) [41] and endothelium-derived relaxing factor (EDRF) [42], considered to be the most important mediators of vasodilation. Both are produced by endothelial cells, lining all vessels in the body. Through these vasodilating substances, the endothelium plays a major role in regulating vascular smooth muscle responses to endogenous vasoconstrictors [43]. An eicosanoid,  $PGI_2$  is a powerful vasodilator and inhibitor of platelet aggregation [41]. After its discovery [42] EDRF was found to be nitric oxide (NO) [44, 45], formed with L-arginine as a precursor. In contrast to the effects of prostaglandin synthesis inhibitors, addition of the false precursor  $N^G$ -monomethyl-L-arginine causes a hypertensive response in both rats and humans [46].

Increased production of these vasoactive substances dilates the maternal vasculature, rendering it less sensitive to the pressor effects of endogenous vasoconstrictive hormones. A compensatory increase in the activity of the renin-angiotensin-aldosterone system along with increasing estrogen production by the fetoplacental unit combine to increase maternal blood volume and cardiac output. The resulting hemodynamic situation is one of high volume, high flow, and low resistance. This point is particularly emphasized in the uteroplacental circulation, where the vessels are maximally dilated [47], volume flow rates are increasing steadily [14], and the resistance to flow rapidly declines during the first half of gestation [13, 14].

Autoregulation is a physiologic mechanism for maintenance of constant organ blood flow with varia-

**Fig. 17.4.** Relative changes in uterine and systemic vascular resistance expressed as the percent of control values at various doses of systemically infused angiotensin II. Uterine vascular resistance was significantly lower ( $p < 0.01$ ) than systemic vascular resistance at angiotensin II doses of  $2.3 \mu\text{g}/\text{min}$ . (Reprinted from [40] with permission)

**Fig. 17.5.** Systolic/diastolic (*S/D*) ratio in the uterine artery in women receiving sublingual nifedipine (*open circles*) or placebo (*closed circles*). The decrease in *S/D* ratio coincided with a decrease in systemic blood pressure. (Reprinted from [51] with permission)

tions in arterial pressure. It may have an important role in the regulation of uterine blood flow during pregnancy. Although not detected in sheep [48], autoregulation has been demonstrated during pregnancy in rabbits [49] and humans [50]. In the latter study, a fall in maternal blood pressure following sublingual nifedipine was not associated with any significant change in uterine blood flow. Lowering of maternal blood pressure by sublingual nifedipine during the midtrimester was associated with a fall in uterine arterial resistance, preventing large changes in flow rates [51] (Fig. 17.5). Autoregulation may operate, with various autacoids probably mediating the action of one another.

Intensive research has been conducted regarding the role of endothelial autacoids in the regulation of uterine blood flow and in the decreased sensitivity of uterine and systemic vasculature to various vasoactive substances. The important autacoids are described in the following sections with particular emphasis on their relation to uteroplacental hemodynamics during pregnancy.

### Prostacyclins

Endothelium-derived prostacyclin ( $\text{PGI}_2$ ) is the primary prostaglandin produced by the uterine and systemic vasculature. Direct infusion of  $\text{PGI}_2$  into the uteroplacental circulation does not change uteroplacental vascular resistance or placental blood flow [52, 53], a finding in agreement with the hypothesis that uterine arteries are maximally dilated during pregnancy [47]. However, a role for prostaglandins in uterine arterial autoregulation, acting directly on the vessel wall, may be obtained from reports where indomethacin, an inhibitor of prostaglandin synthesis, enhances the vasoconstrictor effects of angiotensin II and norepinephrine [54, 55] (Fig. 17.6). Experimental

**Fig. 17.6.** Mean effective pressor dose of angiotensin II before and during indomethacin treatment in 11 normotensive pregnant women. (From [129], with permission)

data support the view that prostaglandins are unlikely to be responsible for normal maintenance of uterine blood flow. However, prostaglandins, possibly  $\text{PGI}_2$ , may be important in controlling vascular reactivity to vasoconstriction. As previously stated, the uterine vasculature is less responsive than the systemic vasculature to infused angiotensin II [40]. Because of this differential sensitivity to the vasoconstrictor effects of angiotensin II, uterine blood flow may increase during systemic infusion of physiologic doses of angiotensin II. This increase in uterine blood flow is reflective of the interaction between the rise in perfusion pressure at a time when the increase in uterine vascular resistance is significantly less than that of the sys-

temic vascular resistance [40]. The difference between the uterine and systemic vascular beds may reflect an adaptive mechanism necessary for the maintenance of uteroplacental perfusion and fetal well-being, as angiotensin II normally increases during pregnancy and likely increases even more, although intermittently, during the course of normal daily activities. The systemic concentrations of the stable metabolite of prostacyclin, 6-ketoprostaglandin  $\text{PGF}_{1\alpha}$ , is increased during pregnancy [56]. Furthermore, the synthesis of prostacyclin by ovine uterine artery is increased during pregnancy [57] (Fig. 17.7). This increased synthesis by the uterine artery cannot by itself explain the blunted response to vasoconstrictors, as indomethacin-treated vessels from pregnant animals are still less sensitive to vasoconstrictors than untreated vessels from nonpregnant animals [55]. Other vascular factors, such as EDRF, may compensate for the loss of endothelial  $\text{PGI}_2$  in the uterine vascular bed.

Prostacyclin has been demonstrated in trophoblastic tissues at 6 weeks' gestation and is known to increase during the first trimester [58]. Both villous core cells and cytotrophoblasts produce thromboxane  $A_2$  and prostacyclin during the first trimester [59]. It has been hypothesized that successful invasion of trophoblast into the spiral arteries may be dependent on a delicate balance between thromboxane  $A_2$  and  $\text{PGI}_2$  [59].

While prostanoids have been proposed to play a major role in the regulation of uteroplacental blood flow, studies on the effect of hypoxia on the produc-

tion of prostaglandin  $E_2$  ( $\text{PGE}_2$ ), thromboxane  $B_2$  ( $\text{TXB}_2$ ), and prostacyclin (measured as 6-keto- $\text{PGF}_{1\alpha}$ ) by human term trophoblast cells and villous placental explants have shown that hypoxia could be responsible for abnormal profiles of prostanoid production commonly observed in women with preeclampsia [60]. The results indicate a putative link between hypoxia and compromised placental perfusion.

## Endothelium-Derived Relaxing Factor

Endothelium-derived relaxing factor, thought to be mainly nitric oxide, originates from endothelial cell metabolism of L-arginine [44]. The vasodilating effects of EDRF and nitric oxide are ultimately mediated by stimulation of soluble guanylate cyclase (cGMP) [44]. Competitive inhibitors of nitric oxide synthetase such as N-monomethyl-L-arginine (L-NMMA) or L-nitroarginine methylester (L-NEMA) reduce the production of nitric oxide (Fig. 17.8). The relation between EDRF and cardiovascular changes during pregnancy is being extensively investigated; in the meantime, experimental data have accumulated demonstrating that EDRF is elevated during normal pregnancy and that the uterine vasculature has a greater ability to release endogenous EDRF. The EDRF-mediated decrease in the uterine artery contractile response to norepinephrine during pregnancy has been described [55, 61] and could result from either increased basal or stimulated release of EDRF.

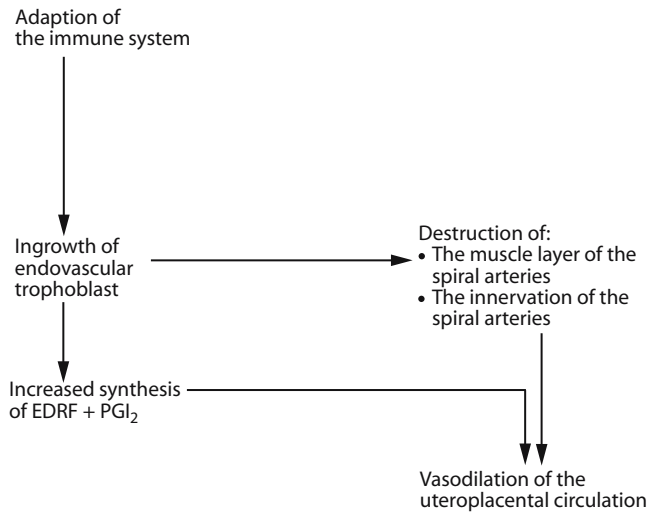

**Fig. 17.7.** In vitro basal production of 6-keto-prostaglandin  $F_{1\alpha}$  ( $\text{PGF}_{1\alpha}$ ) by nonpregnant (NP), pregnant (P), early postpartum (E), and late postpartum (L) uterine and omental (systemic) arteries, \* $p < 0.05$ , values different from NP and L. (Reprinted from [57] with permission)

**Fig. 17.8.** Nitric oxide synthetase pathway in which L-arginine is converted to L-citrulline, giving off nitric oxide in endothelial cells, which leads to stimulation of cyclic guanosine monophosphate (c-GMP) in vascular smooth muscle and vasodilation. L-Nitroarginine methyl ester (L-NAME) competes with L-arginine as substrate for nitric oxide (NO) synthetase and is able to block the synthesis of nitric oxide. VSM, vascular smooth muscle. (Reprinted from [64] with permission)

**Fig. 17.9.** Increases in uterine blood flow as percent of maximum response to estradiol-17 $\beta$  ( $E_2$ ) 1 $\mu$ g/kg plotted against time. Beginning at 120 min after  $E_2$ , L-nitroarginine methylester (*L-NAME*), a nitric oxide synthetase inhibitor, was administered as an intraarterial bolus injection of increasing doses. UBF, uterine blood flow. (Reprinted from [64] with permission)

**Fig. 17.10.** Factors leading to vasodilation of the uteroplacental circulation in normotensive pregnancy. (From [130] with permission)

Indirect evidence supports both mechanisms. Compounds that are known to release EDRF (e.g., acetylcholine, bradykinin, histamine) increase uterine blood flow when infused directly into the uterine vascular bed of chronically instrumented sheep [62, 63]. Acetylcholine increases uterine vascular conductance in nonpregnant and pregnant sheep [63]. Also, local injection of L-arginine analogs causes local decreases in uterine blood flow while avoiding alterations in blood pressure that could directly influence uterine blood flow [69].

An important observation in this regard was the finding that estradiol-17 $\beta$ -induced increases in uterine blood flow are mediated by nitric oxide [64]. Moreover, L-NEMA antagonizes the vasodilating effects of estradiol-17 $\beta$  on the uterine vasculature in a

dose-dependent manner [64] (Fig. 17.9). This antagonism of estrogen-induced vasodilation demonstrates that nitric oxide is important for mediating the vasodilating effect of estradiol-17 $\beta$ , and it could play a role in regulating uterine and possibly uteroplacental blood flow during pregnancy.

When administered systemically, L-arginine analogs increase blood pressure and reverse pregnancy-induced refractoriness to vasopressor agents [65]. These observations support the notion that blunted pressor responsiveness during normal gestation is due largely to increased elaboration of endothelium-derived nitric oxide, which also plays a key role in regulating blood pressure during pregnancy. It has been demonstrated that endothelium-derived relaxing factors (e.g., prostacyclin and EDRF) reduce the con-

tractile response of the uterine artery to thromboxane. Data suggest that the attenuated vascular reactivity of pregnancy is modulated by the interaction of EDRF and PGI<sub>2</sub>, and that one system can adapt when the other is inhibited. Figure 17.10 summarizes the various factors leading to vasodilation of the uteroplacental arteries.

## Endothelin

Control of uterine vascular function by the endothelium is more complex than anticipated because the cells not only release various vasodilator substances but also mediate contractions of the underlying smooth muscle with diffusible endothelium-derived contracting factors [66]. Endothelium-dependent contractions are elicited by thromboxane [56] or by the release of endothelin [67] and superoxide anion [68]. Endothelin-1, a 21-amino-acid peptide, is the most potent natural pressor substance known [67]. It is a vasoconstrictor in the human uterine artery, and the effect is mediated by receptors on smooth muscle cells [69, 70]. This peptide may play an important role in the regulation of vascular resistance on the maternal side of the uteroplacental unit [71].

More studies are needed to evaluate the relation between these (and perhaps other) endothelial mediators of vascular function during pregnancy. Such information can increase our understanding of the physiologic factors that regulate uterine blood flow during normal pregnancy and the pathophysiologic mechanisms involved in disease states where uteroplacental blood flow may be deranged.

## Doppler Velocimetry of the Uteroplacental Circulation

### Methodology

The Doppler devices commonly used for clinical or investigational measurements during early pregnancy are the continuous-wave and pulsed-wave systems. The former consists of a simple transducer that continuously sends ultrasonic sound waves; it is attached to a second transducer, which continuously receives the reflected echoes returning from the sound's beam path. The main advantages of this system are its ease of operation, portability, low output sound intensity (<25 mW/cm<sup>2</sup>), and relatively low price. In addition it permits high-frequency shifts (i.e., high blood flow velocities) to be measured, even in deep vessels. It does not, however, permit visualization of the sound beam as it crosses the tissues or of the blood vessels themselves. Moreover, it is not range-specific, and the rather large volume of overlap between the two

probes' crystals may contribute to the Doppler shift, which is displayed after spectrum analysis. In fact, any vessel that happens to lie across the sound's beam path is sampled and "contaminates" the sonogram obtained. These limitations make the continuous-wave Doppler system unsuitable for sampling small, specific vessels or for obtaining flow measurements from vascular segments at a particular location (e.g., the main branch of the ascending uterine artery or the umbilical artery adjacent to its placental location) [72].

Early Doppler studies of uterine arteries were performed with a continuous-wave Doppler apparatus using either the abdominal [12, 13] or the transvaginal [14] approach. Subplacental vessels [12] and uterine vessels [13] can be studied with this method. Flow velocity waveforms in the uterine vessels were captured by pointing the probe into the paracervical area via the lower abdomen [13]. The vaginal route has the advantage of being close to the main branch of the uterine artery as it enters the lower part of the uterus [13]. Vaginal studies are performed by inserting the transducer (covered by a rubber condom and lubricated with coupling jelly) into the vaginal fornix and directing it along the paracervical area. During the first trimester the failure rate was reported to be 10%. The mean intraobserver and interobserver error between examinations was 4%, with a standard deviation of 2.3% [13].

With pulsed-wave Doppler systems, the transducer sends short pulses of high-frequency sound waves repetitively. The same transducer is used to receive the reflected echoes during the intervals between sending the pulses. With such pulse-echo systems the range (or depth) of the target can be estimated from the corresponding time delay in the reception of echoes following transmission of the ultrasonic pulse, assuming a constant value for the speed of ultrasound (1,540 cm/s). This range-gated detection permits selection of Doppler frequency shift signals from moving targets according to their distance from the ultrasonic probe.

This principle is implemented in duplex scanning, where a pulsed-wave Doppler transducer is integrated into a two-dimensional ultrasound imaging unit to permit accurate identification of the volume in space from which Doppler-shifted frequencies are to be received. This volume is commonly termed the sample volume, and both its width and distance from the transducer can be controlled by the user. This orientation in space and the depth selectivity make the pulsed duplex systems much superior to the continuous-wave Doppler systems [72, 73].

A significant limitation when using pulsed Doppler systems is the maximum range limitation, or the range-velocity limitation [72, 73]. Analog signals

(such as Doppler shift signals) can be unambiguously represented by samples only if they are sampled at a rate that exceeds twice the highest frequency in the signal itself (also known as the Nyquist limit). It means that when high flow velocities are encountered, the pulse repetition frequency must be increased sufficiently to accommodate this limitation. If the vessel is situated far from the transducer (e.g., when performing Doppler studies on deep pelvic vessels using an abdominal probe), the potential increase in pulse repetition frequency is limited by the pulse-echo round-trip delay time. Under such conditions false signals are displayed, a phenomenon termed aliasing [72, 73]. One way to partially overcome this problem is to use a lower-frequency transducer when operating in the Doppler mode on duplex systems. The Doppler shift frequency would then be lower for any given velocity of the target, and the range-velocity ambiguity problem would be less likely to arise [72, 73].

The optimal method for performing pelvic Doppler flow measurements during early pregnancy is the transvaginal image-directed pulsed Doppler system [74]. With such a duplex Doppler system, two-dimensional real-time scanning enables appropriate placement of the ultrasonic Doppler beam. Using real-time imaging, pelvic anatomic structures can be scanned, and particular vessels can be identified (Fig. 17.11). As the female pelvis contains various soft tissue structures that have similar acoustic properties (and are therefore poor reflectors) the transvaginal ultrasonic probe offers the most suitable approach. The close proximity of the transducer probe to the pelvic organs makes it possible to increase its frequency (typically 5–7 MHz). At this range attenuation is still acceptable, and images resolution is greatly improved. As the vagina is a rather elastic organ, the probe can be manipulated so as to bring it as close to a specific structure as possible, thereby placing it within the focal region of the transducer. With the probe situated close to the vessel, the range-velocity ambiguity problem is largely overcome [73, 74]. This technique also makes it possible to use a higher-frequency Doppler transducer and obtain a higher-frequency shift at any angle of insonation, thereby increasing the accuracy of the measurement. Moreover, the examination is performed with an empty bladder, preventing distortion of normal anatomy and vessel displacement. Using this approach, one can study patterns of blood flow in uterine vessels (including spiral arteries and decidual vessels), ovarian vessels, and embryonal and fetal vessels (e.g., umbilical artery, intracranial vessels, aorta) [75].

The introduction of color flow mapping has made vessel localization much simpler. The user can identify the required vessel with certainty, and the duration

**Fig. 17.11.** Transvaginal probe in relation to the female pelvic vessels. (From [131] with permission)

of the examination is considerably shortened [76]. The main application of duplex scanning is the detailed study of well-defined anatomic regions. Such systems do not readily convey information about blood flow throughout the entire scan plane. Doppler color flow mapping is particularly helpful, as it produces real-time two-dimensional images that are color coded according to flow conditions and superimposed on real-time two-dimensional gray-scale pulse-echo images of anatomic structures. It facilitates evaluation of vessels within organs or those that are not readily delineated by conventional scanning. Color Doppler sonography is based on the Doppler autocorrelation flow detector, which rapidly extracts Doppler signals line by line as the ultrasonic beam is scanned through the image plane. The resulting display image is a combination of Doppler and anatomic information. The output from the autocorrelation detector consists of directional real-time velocity (or Doppler frequency) signals. These signals are arranged to color code the real-time gray-scale image. Forward flow is usually presented in red and reverse flow in blue. The degree of turbulence is color coded in green.

Best results are obtained using electronically scanned linear or phased array [72, 73].

During the transvaginal Doppler examination the patient lies in the supine position on a gynecologic examination table or a two-level mattress, with the upper part of the body on the higher level [77]. This positioning enables the examiner to manipulate the probe at various angles, applying the push-pull technique, and locate the vessel of interest [77]. A coupling gel is applied to the vaginal probe, which is subsequently covered with a lubricated rubber glove and is inserted into the vaginal fornix. A real-time image of the uterine artery is obtained employing color flow imaging if practical, and the line of insonation of the Doppler beam is adjusted so it crosses the vessel at the smallest possible angle. Several measurements of vessel diameter are obtained at this stage, and the mean diameter is calculated. The sample volume is then placed to cover the entire cross-sectional area of the vessel (Fig. 17.12). Once achieved, the system is switched to the dual-mode operation, where both the two-dimensional scanning and the range-gated pulsed Doppler operate in a quasimultaneous mode. The flow velocity waveforms are displayed after spectral analysis in real time. Once a good-quality signal is obtained based on audio recognition, visual waveform recognition, and maximum measured velocity, the image is frozen, including good-quality waveform signals. Figure 17.13 demonstrates flow velocity waveforms in the main uterine artery obtained by transvaginal pulsed Doppler ultrasonography before and during pregnancy. Once

the vessel is located and displayed, the angle of insonation is determined by aligning a linear cursor parallel to the long axis of the vessel itself. All the flow parameters are calculated at this stage, and the results are displayed on a separate video display unit. The images and values obtained can be recorded on a video tape for subsequent review. An immediate hard copy can also be obtained using video printer. A high-pass filter of 100 Hz is activated to remove low-frequency/high-intensity echoes originating from vessel wall movements [77].

Some investigators use a combination of continuous-wave Doppler ultrasound and color flow imaging of the uterine artery to calculate the resistance to flow as well as the mean velocity and volume flow [78]. By placing the transducer in the lower lateral quadrant of the uterus and angling it medially, an apparent crossover of the external iliac artery and vein and the main uterine artery can be identified. This "crossover" is used as a reference point to identify the main uterine artery and is easily reproducible. A clear image of a length of the artery can be obtained and the diameter of the artery measured. Direct visualization of the artery and knowledge of the angle of insonation of the vessel enable the calculation of resistance, mean velocity of flow, and total volume of flow to the uterus in both uterine arteries [78].

### Anatomic Considerations

Because investigators use different methodologies it is not surprising that the reported flow impedance values in the uterine arteries for normal pregnancy vary considerably [12, 13, 79–81]. In early studies a large uteroplacental vessel was sampled in the lateral uterine wall by duplex equipment close to the bifurcation of the common iliac artery [24, 80]. The investigators called these vessels the "arcuate arteries". Other groups obtained signals from subplacental vessels using a continuous-wave Doppler apparatus [12, 79]. Another group of investigators used a continuous-wave Doppler system to locate the uterine artery in the lower uterine segment on both sides and averaged the readings [13]. Other groups studied the main branches of the ascending uterine arteries at the level of the internal os [14, 82] using a transvaginal pulsed Doppler system. Figure 17.14 demonstrates the various insonation sites used to study the uteroplacental circulation.

Investigators may then use different Doppler ultrasound equipment and insonate different parts of the uteroplacental circulation. Moreover, different indices of impedance to flow have been used, with each group defining their own normal range, often constructed from measurements obtained in small numbers of retrospectively defined, normal women fol-

**Fig. 17.12.** Transvaginal sonographic scan demonstrating a short segment of the uterine artery, sample volume (situated between the two short parallel lines), uterine wall, and amniotic sac (AF). (Reprinted from [75] with permission)

lowed longitudinally. Some groups also include a description of flow velocity waveforms, particularly the presence of a dirotic or early diastolic notch as an indicator of high resistance to flow [24, 25, 83]. With so many techniques, the results obtained are hardly comparable. For example, the mean resistance index (RI) at 20 weeks' gestation has been reported as ranging between 0.31 [80] and 0.57 [13].

These methodologic problems were highlighted in a large cross-sectional study in which reference ranges for uteroplacental waveforms during the second trimester were established [84]. A 4-MHz continuous-wave Doppler system was used to insonate the

uteroplacental vessels of an unselected group of 977 women. The uterine artery was investigated near its origin ('U'terine site, Fig. 17.14) and in the anterolateral uterine wall halfway between the fundus and the most lateral point, parallel to the abdominal surface insonating only the uterine wall ('Arcuate site, Fig. 17.14). The placental site was also noted. The RI was always higher at the uterine site than at the arcuate site regardless of placental location [84] (Fig. 17.15). At each site the RI was always lower on the placental side (Fig. 17.15). The fall in resistance with placental site and with distance from the origin of the uterine artery can be explained by the increasing

**Fig. 17.14.** Insonation sites used to study the uteroplacental circulation. (Reprinted from [84] with permission)

**Fig. 17.15.** Mean resistance index (*RI*) at four insonation sites: nonplacental uterine (*NPU*), placental uterine (*PU*), nonplacental arcuate (*NPA*), and placental arcuate (*PA*) sites. It shows the difference between uterine and arcuate sites and the effect of placental location. (Reprinted from [84] with permission)

cross-sectional area as the uterine artery branches from its origin, and pressure and impedance fall continuously from the uterine artery to the intervillous space. These facts can be summarized to indicate that it is not possible to study the uteroplacental circulation without having clear definition of the site studied and the position of the placenta. It is likely that Doppler measurements should be obtained from the main uterine vessels. Such measurements should provide more predictive information on impaired uteroplacental perfusion as the major vessels reflect the sum of resistances of the placental bed and therefore are more likely to provide an overall picture of placental perfusion [79, 83]. Moreover, measurements of

the main uterine artery are more reproducible [83], and the likelihood of demonstrating a systolic or diastolic notch in flow velocity waveforms increases [83].

### Changes in Uteroplacental Blood Flow During Early Normal Pregnancy

The development of uterine artery compliance throughout pregnancy was studied by continuous-wave Doppler sonography [13]. Although no significant changes were observed during the first trimester, there was a rapid decline in the systolic/diastolic flow velocity ratio (*S/D* ratio) starting early in the second trimester. These changes plateaued at 22–24 weeks. When a transvaginal image-directed pulsed Doppler system was used, the resistance to flow (expressed by the *S/D* ratio or the pulsatility index, or *PI*) rapidly declined in the ascending branch of the uterine artery from as early as 5 weeks and continued to 22 weeks' gestation [14, 85].

Figure 17.16 demonstrates the decline in *S/D* ratio from 5 to 28 weeks. During this period the vessel diameter increased linearly (Fig. 17.17), and the volume of blood flow to the uterus increased by more than 50% [14] (Fig. 17.18). At 20–22 weeks the second wave of trophoblastic migration is mostly complete [3], and any further increase in volume flow rates may be attributed to an increase in vessel diameter and cross-sectional area of the entire uterine vascular bed [14]. The rate of increase of uterine blood flow was found to be maximal between 20–24 weeks (39 ml/min/week) as was the increase in uterine artery diameter, in a study where uterine blood flow was measured between 20 and 38 weeks' gestation [86]. The rate of increase in mean quantified volume

**Fig. 17.16.** Changes in *S/D* ratio in the uterine arteries (*UA*) during the first and second trimesters of pregnancy

**Fig. 17.17.** Changes in diameter of the main uterine artery at various gestational ages. (Reprinted from [14] with permission)

**Fig. 17.18.** Changes in blood flow in the uterine arteries (UA) during the first and second trimesters of pregnancy

flow per week declined to 14 ml/min/week between 36–38 weeks' gestation [86].

During the first and early second trimesters the decline in resistance to flow occurs not only in the main uterine artery [14, 86] but also in the arcuate [87], radial [88], spiral [88], and trophoblastic [87, 89] vessels. Trophoblastic Doppler signals are obtained by placing the sample volume in the hyperechoic area adjacent to the gestational sac. As could be expected, the resistance to flow was progressively lower as one moved from the main branch of the uterine artery through the arcuate, radial, spiral, and trophoblastic vessels. This phenomenon is demonstrated in Fig. 17.19. When these measurements are performed

in a twin pregnancy, the resistance to flow is consistently lower and volume flow rates are consistently higher than those of singleton pregnancies (Tables 17.1 and 17.2, respectively). Values are presented as the mean  $\pm$  SEM. These changes in the resistance to flow during the early second trimester are consistent with endovascular trophoblastic invasion of the decidual portion of the spiral arteries, as previously described [1–3].

Many investigators described a difference in blood flow velocity between the left and right uterine arteries during the first trimester [85, 90, 91] (Table 17.3). In the latter study [91] there appeared to be no essential difference in frequency or magnitude be-

**Fig. 17.19.** Reference ranges (mean  $\pm$  2 SD) and individual values of systolic/diastolic (S/D) ratio from both main uterine arteries (top), arcuate arteries (middle), trophoblastic vessels (bottom). (Reprinted from [27] with permission)

tween left (L>R) and right (R>L) predominance for both PI and RI values. On average there appeared to be no difference between the left and right uterine arteries. The most likely explanation for the difference in the PI or RI between the left and right uterine arteries is that changes in down-stream impedance in the uterine artery supplying the placenta precede those in the uterine artery on the nonplacental side of the uterus. As clear delineation of the placenta is often impossible during early gestation, one can only assume about the relation between the resistance to flow and placental location at this stage of gestation [91]. Some investigators prefer to calculate the mean RI or PI of both sides of the uterus, which would indicate the total downstream impedance [85, 90, 91].

**Table 17.1.** S/D ratio in uterine arteries during the first and early second trimesters for singleton and twin pregnancies

Gestational age (weeks)	S/D ratio (mean $\pm$ SEM)		
	Singleton	Twins	p
4-7	7.63 $\pm$ 0.45	6.77 $\pm$ 0.34	NS
8-11	5.56 $\pm$ 0.36	4.37 $\pm$ 0.26	<0.01
12-15	4.60 $\pm$ 0.33	2.84 $\pm$ 0.16	<0.0001
16-19	3.23 $\pm$ 0.15	2.38 $\pm$ 0.10	<0.0001

NS, not significant; SEM, standard error of the mean.

**Table 17.2.** Total blood flow to the uterus<sup>a</sup> during the first and early second trimester for singleton and twin pregnancies

Gestational age (weeks)	Total blood flow (ml/min) (mean $\pm$ SEM)		
	Singleton	Twins	p
4-7	237.6 $\pm$ 6.15	242.8 $\pm$ 7.19	NS
8-11	251.2 $\pm$ 7.12	300.0 $\pm$ 8.96	<0.0001
12-15	279.0 $\pm$ 7.19	343.4 $\pm$ 7.73	<0.0009
16-19	323.4 $\pm$ 8.07	391.4 $\pm$ 8.69	<0.0002

NS, not significant; SEM, standard error of the mean.

<sup>a</sup> Sum of flows in both uterine arteries.

**Table 17.3.** Frequency and magnitude of difference of PI between left and right uterine arteries of normal pregnancies at 8-13 weeks' gestation (from [91] with permission)

Gestation (weeks)	Differences in PI				
	No.	L > R	No.	R > L	R = L (No.)
8	7	0.64 $\pm$ 0.37	6	0.86 $\pm$ 0.67	-
9	3	0.27 $\pm$ 0.24	4	0.35 $\pm$ 0.23	2
10	5	0.50 $\pm$ 0.39	4	0.60 $\pm$ 0.32	1
11	5	0.54 $\pm$ 0.31	5	0.53 $\pm$ 0.33	-
12	12	0.48 $\pm$ 0.59	12	0.51 $\pm$ 0.30	2
13	8	0.60 $\pm$ 0.24	9	0.43 $\pm$ 0.40	2

Results are means  $\pm$  SD of the differences between the left uterine artery (L) and right uterine artery (R).

L > R, left predominance; R > L, right predominance; R, L indicates no predominance.

When using the transvaginal pulsed Doppler technique the intraobserver coefficient of variation ranged between 7.6% [84] and 9.0% [14]. The reported range for the continuous-wave Doppler method was between 4.0% [13] and 5.6% [91].

**Fig. 17.20.** Systolic/diastolic (*S/D*) ratios of 19 patients with anembryonic pregnancy (*closed circles*) and missed abortion (*open circles*), plotted on reference ranges for normal gestations. (Reprinted from [27] with permission)

## Doppler Velocimetry During Early Pregnancy and Pregnancy Outcome

### Normal Early Pregnancy and Early Pregnancy Failure

Few investigations have been conducted to study the relation between Doppler velocimetry in the uteroplacental circulation and pregnancy failure; and of those undertaken, most investigators found no association. In one study, no significant modifications were observed in the velocity waveforms obtained from sub-

**Fig. 17.21.** Uterine blood flow in women who aborted (*closed circles*) plotted on normal reference ranges (5th, 59th, and 90th percentiles). Fifty percent were below the 5th percentile, and another 33% were below the 50th percentile

placental vessels of seven pregnancies with early failure [92]. In another study [87] flow velocity waveforms were recorded from different points of the uterine circulation in 19 patients with early pregnancy failure. The *S/D* ratio always fell within the normal range, in both anembryonic pregnancies and in cases of missed abortion (Fig. 17.20). Trophoblastic flow was observed in all cases studied. In another study [93], 77 pregnant women were followed longitudinally by Doppler flow measurements of the ascending uterine arteries, starting from as early as 4–5 weeks' gestation. Twelve patients subsequently aborted. The *S/D* ratio obtained prior to pregnancy loss fell within the normal range. However, when volume flow rates were measured prior to pregnancy loss, the mean flow was significantly lower in women who aborted ( $95.8 \pm 6.9$  ml/min) than in those who did not abort ( $118.8 \pm 3.16$  ml/min,  $p < 0.002$ ) (Fig. 17.21).

One group [94] reported lower RI values in the uterine artery in patients with blighted ovum ( $n=41$ ,  $RI=0.77 \pm 0.11$ ) or missed abortion ( $n=6$ ,  $RI=0.69 \pm 0.13$ ) than in those with normal pregnancies ( $n=6$ ,  $RI=0.81 \pm 0.06$ ). The mean RI in the trophoblastic region was  $0.48 \pm 0.08$  in normal pregnancies compared to  $0.42 \pm 0.15$  in cases of blighted ovum. In several patients with missed abortion and blighted ovum no trophoblastic flow could be detected. Vaginal bleeding with or without subchorionic hematoma was associated with increased radial artery impedance at 7 weeks of pregnancy [95]. Time-average velocity and peak systolic velocity did not change significantly and spiral artery blood flow remained unaffected. In another study, patients with threatened miscarriage also had significantly higher radial artery PI values compared to normal gestations [96]. PI, RI, and peak systolic velocity were measured in patients affected

by uterine bleeding and compared to women with normal intrauterine pregnancy [97]. No significant differences were found in any of the three vascular indices between the normal and the pathologic group of patients.

In another study [98] RI and PI in the uterine and spiral arteries, uterine artery peak systolic velocity, and intervillous blood flow were recorded by transvaginal color Doppler imaging in 30 missed abortions and 30 normal pregnancies matched for menstrual age. The mean uterine PI was significantly higher in missed abortions compared to normal controls, whereas the mean uterine RI and peak systolic velocity and spiral RI and PI did not differ. A continuous intervillous flow was found in 16 out of 23 (69.6%) of the complicated pregnancies before 12 weeks of gestation whereas it was not found in controls. In the missed abortion cases, the trophoblastic shell was fragmented or absent in 53% and trophoblastic infiltration and physiological changes in the spiral arteries were reduced or absent in 43% and 63%, respectively. Extended dislocation of the trophoblastic shell and a massive infiltration of the intervillous space and placental bed by maternal blood was also found in cases presenting with a continuous intervillous blood flow before 12 weeks of gestation. The authors concluded that abnormal flow velocity waveforms in early pregnancies complicated by embryonic death are related to deficient placentation and dislocation of the trophoblastic shell that follows embryonic demise. The premature entry of maternal blood into the intervillous space seems to disrupt the maternoembryonic interface and is probably the final mechanism causing abortion [98].

The absence of detectable intervillous flow during most of the first trimester has lent support to the concept that, during the first 3 months of gestation, blood flow to the intervillous space is largely inhibited. Subsequent studies at that period supported these findings [99, 100].

Subsequently this concept was strongly challenged. Intervillous blood flow was detected from early stages of the first trimester in a monkey model [101, 102] and was also observed in pregnant women [103, 104].

In a prospective study, intervillous and spiral artery flows were evaluated in 49 normal pregnancies (5–10 weeks of amenorrhea) using transvaginal color and pulsed-wave Doppler techniques. In all pregnancies, continuous nonpulsatile intervillous flow and spiral artery flow were detected [105].

Recently, the onset of the maternal-placental circulation was studied by Doppler ultrasonography in 65 pairs of age-matched normal and abnormal pregnancies [106]. In normal pregnancies intervillous blood flow increased with gestational age, being detected in 9 of 25 cases at 8–9 weeks but in 18 of 20 at 12–

13 weeks. By contrast, in abnormal pregnancies flow was detected in nearly all cases (22 of 25) at 8–9 weeks. In addition, regional differences were observed between the groups. Early flow was restricted to the peripheral regions of most normal placentas, whereas in missed miscarriages it was most common in central regions or throughout the placenta. Immunoreactivity for heat shock protein 70 and nitrotyrosine residues was greater in samples from peripheral than from central regions of normal placentas and from missed miscarriages compared to controls. These results indicate, according to the authors, that oxidative damage to the trophoblast, induced by premature and widespread onset of the maternal placental circulation secondary to shallow trophoblast invasion, is a key factor in early pregnancy loss. High oxygen concentrations in the periphery of normal early placentas may similarly induce local regression of the villi, leading to formation of the chorion leave [106].

A clinical descriptive study was conducted using color Doppler ultrasound in 45 women with normal pregnancies (group A) and 44 with nonembryonic sac or missed abortions (group B) [107]. The mean gestational age in these two groups was 9.3 and 7.6 weeks, respectively ( $p < 0.01$ ). The number of myometrial blood vessels (arteries and veins identified by power Doppler mapping), the quantity of intervillous flow, the RI for the arterial system, and the PI of the myometrial arteries were evaluated. The number of myometrial blood vessels in group A was lower than that in group B. The intervillous flow was observed in some cases from early pregnancy and more often after 10 weeks. This characteristic was observed significantly more frequently in group B than in group A. The RI and PI in the uterine arteries were significantly higher in group A than in group B. The RI and the PI of the uterine arteries decreased with the advance of gestational age in both groups.

As it turns out, color Doppler ultrasound provides information about uteroplacental circulation during the first trimester and indicates early development of intervillous circulation. Although a greater uteroplacental blood circulation was observed in failed pregnancies, the overlapping between groups severely limits the application of this characteristic in clinical practice [107].

### **Screening for Preeclampsia and Intrauterine Growth Restriction**

Pregnancy hypertension – including pregnancy-induced hypertension (PIH) and preeclamptic toxemia (PET) – is a disease exclusively associated with pregnancy. It occurs in 6%–8% of all pregnancies beyond 24 weeks [108] and is the most common single cause of maternal mortality [109]. According to the World

Health Organization it is also the most prevalent cause of perinatal mortality and morbidity [110].

Intrauterine growth restriction occurs in 5%–10% of pregnancies and is associated with a four- to ten-fold increase in perinatal mortality and a substantial increase in perinatal morbidity, including neurodevelopmental disorders [111, 112]. Pregnancy hypertension is the most common cause for abnormal fetal growth [113], although the latter condition is also associated with other maternal or fetal disorders.

In many cases no discernible etiologic cause can be elicited. The term fetal growth restriction refers here only to cases where uteroplacental perfusion is decreased; other causes (e.g., fetal infections, fetal malformations) are excluded.

Early detection of pregnant women at risk for subsequent PIH/PET or fetal growth restriction of paramount importance. Close maternal surveillance, early detection on PIH/PET or fetal growth restriction, and above all the ability to provide preventive treatment [114, 115], can greatly improve pregnancy outcome and decrease maternal complications. Ideally, a screening test with a low false-negative rate and a reasonable false-positive rate would fulfill this goal. To implement such a test in large populations, it must be easy, inexpensive, convenient for the mother, quick and simple, easily interpretable, and reproducible. To take maximal advantage of preventive therapy, it should be performed during the late first or early second trimester.

Blood flow studies have demonstrated that PIH/PET [23] and fetal growth restriction [116, 117] are often associated with decreased uteroplacental perfusion. These changes in uteroplacental blood flow reflect abnormal histomorphologic changes in the spiral arteries [15, 16, 32, 118, 119]. Doppler sonography of the uteroplacental circulation could reflect such ab-

normal morphology; and because it fulfills all the described criteria for a screening test, it could theoretically prove to be the optimal method for early prediction of those abnormal conditions.

Most screening studies have been undertaken between 16 and 30 weeks, with most investigators starting between 20 and 24 weeks [26, 27, 81, 120–123]. The sensitivity and predictive values vary considerably in these studies (Fig. 17.22). There are a variety of possible explanations for the discrepancies, some of which have been dealt with before. The most notable ones are different methods of insonation of the uteroplacental circulation, different vessels that were chosen for Doppler measurements, different cutoff levels of resistance indices, noncomparable definitions of pregnancy complications or outcome, and the mode whereby patients were selected. One study [123] gives a detailed description of the differences between the screening studies that could account for the wide variation in the results obtained. In a prospective cross-sectional trial, 175 women at high risk for developing hypertension or FGR were studied and compared with 172 low-risk pregnancies between 21 and 24 weeks' gestation [124]. In the high-risk group, PIH and/or fetal growth restriction were found in 58.3% if the Doppler studies were abnormal (i.e., persistent notching or elevated RIs of more than 0.68 in the main uterine arteries). Only 8.3% of women have such complications when Doppler studies were normal. Doppler was far less predictive in the low-risk group.

It should be emphasized that in none of the reported studies did the investigators include the presence of a dicrotic or early diastolic notch in the flow velocity waveform as an indicator of high resistance to flow. In a recent screening study of 1,300 women [78] a combination of continuous-wave Doppler so-

**Fig. 17.22.** Unselected screening studies demonstrating the relation between normal and abnormal Doppler findings. (Reprinted from [78] with permission)

**Table 17.4.** Resistance index above the 95th percentile or the presence of a diastolic notch for prediction of severe proteinuric pregnancy-induced hypertension (from [79] with permission)

Gestation (weeks)	Sensitivity (%)	Specificity (%)	PPV (%)	HPV (%)
20	79	85	7.6	99.6
24	79	96	25.9	99.7
26	79	98	36.6	99.7

PPV, positive predictive value; NPV, negative predictive value.

Studies of the uterine artery were performed in 1,300 pregnant women using continuous-wave Doppler ultrasonography to screen at 20 weeks and color flow imaging for follow-up at 24 and 26 weeks.

nography and color flow imaging of the uterine artery was used to calculate the resistance to flow as well as the mean velocity and volume flow. The women were recruited from the routine antenatal clinic and had a continuous-wave Doppler ultrasound examination of both uterine arteries at the 20-week admission scan. It the flow velocity waveforms obtained were found to have a high RI ( $>2$  standard deviations from the mean of the normal range), an early diastolic notch, or both, the patient was asked to return for follow-up with color flow imaging initially at 24 weeks and then at 26 weeks if the results were still abnormal. Of the 1,300 women studied, 19 subsequently had severe proteinuric pregnancy-induced hypertension, and 15 of the 19 had abnormal findings on the uterine artery Doppler studies. The results are summarized in Table 17.4. A total of 206 women were identified as having an abnormal waveform at the admission scan; 95% of these women had an early diastolic notch (68% without and 27% with increased RI), and only 5% had an increased RI alone. These findings demonstrate that a notch is a much better predictor that a notch is a much better predictor of poor outcome than the RI alone.

The same investigators [78] also found that the total volume of flow in the uterine arteries in 21 women whose pregnancies were complicated by fetal growth restriction (most of whom were found to be hypoxemic at cordocentesis), was below the 50th percentile; 62% were below the 5th percentile (Fig. 17.23). What needs to be determined is whether patients with low volume of flow at or before 24 weeks have increased risk of having a pregnancy complicated by fetal growth restriction.

More recently a multicenter, cohort study was conducted to determine the utility of transvaginal color Doppler assessment of uterine arteries at 23 weeks' gestation in the prediction of preeclampsia and fetal growth restriction [125]. A mean PI of 1.63 (the 95th

**Fig. 17.23.** Reference ranges of the total volume of flow in the uterine arteries and the total volume of flow in 21 women whose pregnancies were complicated by growth restriction. S.G.A. small for gestational age. (Reprinted from [78] with permission)

percentile) or more or bilateral notching was considered abnormal. In 932 of the 7,851 study patients (i.e., 11.9%) at least one of these abnormalities was present. The sensitivity, specificity, and positive and negative predictive values of an abnormal test were 83.3%, 88.5%, 3.8%, 99.9%, respectively, with a likelihood ratio of 7.3. The sensitivities in predicting either preeclampsia without fetal growth restriction or fetal growth restriction without preeclampsia were much lower, however (40.8% and 24.4%, respectively). The sensitivities in the prediction of either one of the two outcomes further decreased when only one of the uterine artery Doppler patterns was abnormal. The investigators concluded that Doppler screening at 23 weeks is valuable at identifying the more severe cases of preeclampsia and fetal growth restriction (and therefore the most clinically relevant cases).

Recently a metaanalysis was performed to examine how useful uterine artery Doppler flow velocimetry is in the prediction of preeclampsia, fetal growth restriction, and perinatal death [126]. Twenty-seven published and unpublished observational studies involving 12,994 pregnancies were analyzed. These pregnancies were classified into high-risk and low-risk for developing preeclampsia and its associated complications. Based on the results obtained the authors concluded that uterine artery Doppler flow velocimetry has limited diagnostic accuracy in predicting preeclampsia, fetal growth restriction, and perinatal death.

The second wave of trophoblastic migration is completed in most women by 20 weeks' gestation [3].

**Fig. 17.24.** Systolic/diastolic ( $S/D$ ) ratio in the uterine and arcuate arteries of 29 women who developed gestational hypertension (triangles), intrauterine growth restriction (closed circles), or both complications (open circles), plotted on reference ranges. (Reprinted from [27] with permission)

It seems logical that screening studies should be conducted at this period of gestation. By screening too early, the false-positive rate may be too high, leading to lower specificity because the process of physiologic changes is not completed. On the other hand, screening too late during the second trimester may mean that the pathologic process is already well developed and that preventive treatment may be less effective.

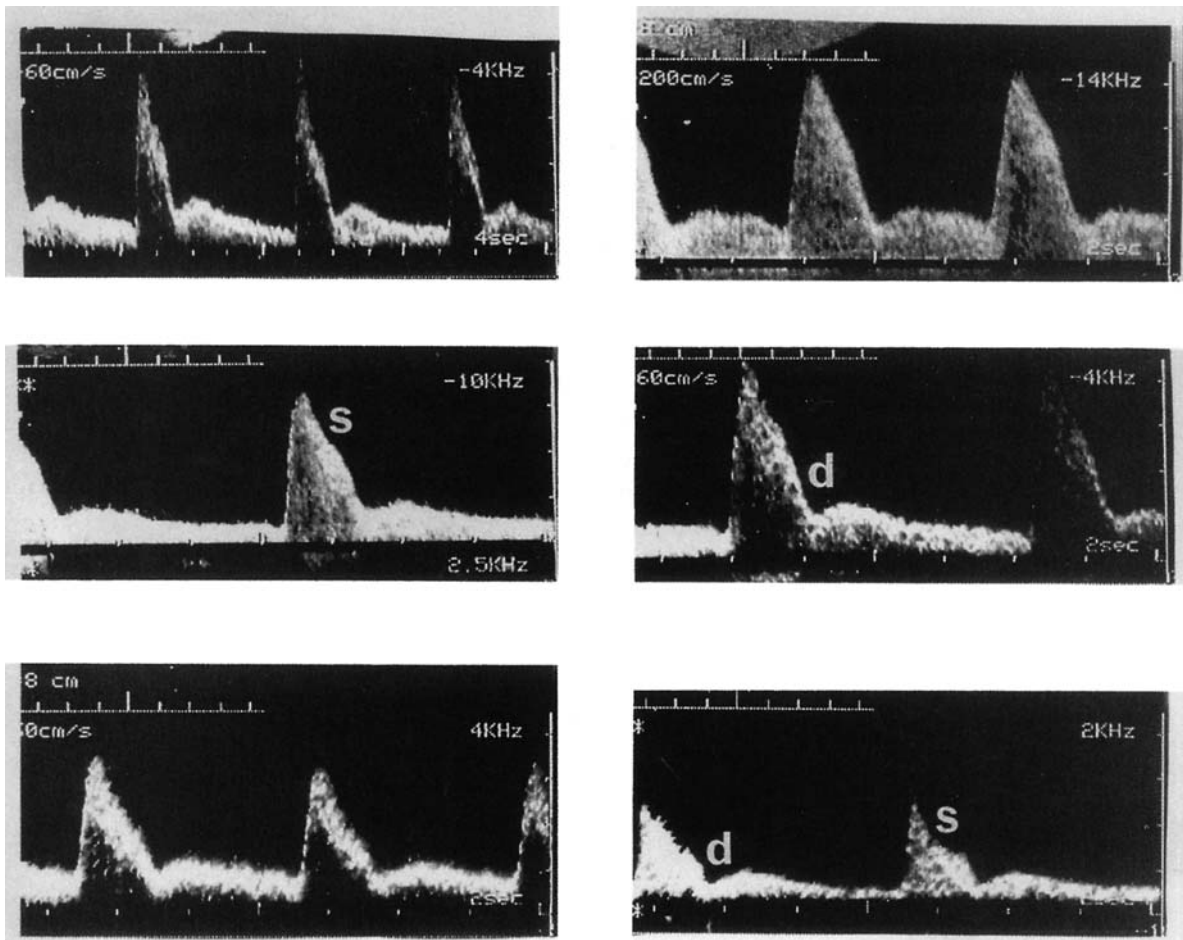

It should be recalled that the first wave of trophoblastic migration may also demonstrate abnormal features (R. Laurini, personal communication), which may be reflected in Doppler measurements of the uteroplacental circulation. One group investigated whether Doppler measurements during early pregnancy can predict adverse pregnancy outcome [27]. Reference ranges of uteroplacental waveform indices

**Fig. 17.25.** Uterine artery systolic/diastolic ( $S/D$ ) ratio during the second and third trimesters in 29 women who developed gestational hypertension (triangles), intrauterine growth restriction (closed circles), or both complications (open circles), plotted on reference ranges. (Reprinted from [28] with permission)

were constructed from a cross-sectional study of 282 women with retrospectively defined normal singleton pregnancies. This group of women was selected from a population with 330 low-risk pregnancies and was followed longitudinally throughout gestation. In the remaining 48 cases, pregnancy complications were evident either at the time of the study or later with advancing gestation. Of the 48 patients, 19 had an abortion and 29 subsequently had intrauterine growth restriction (IUGR), gestational hypertension, or both. The  $S/D$  ratio was measured in the main uterine arteries, the arcuate arteries, and in trophoblastic vessels using an image-directed transvaginal color Doppler system. Measurements were started from as early as 7 weeks' gestation. In the 29 women who subsequently had PIH/PET, IUGR, or both, all  $S/D$  ratio values were within the normal range in all vessels studied (Fig. 17.24). Fourteen patients had an increased  $S/D$  ratio ( $>2$  standard deviations) in the main uterine artery during late second and third trimester of pregnancy (Fig. 17.25). The presence or absence of a notch in the uterine artery flow velocity waveforms was not reported in this study.

Another group [93] investigated the association between abnormal blood flow velocity waveforms and subsequent complications of pregnancy (PIH/PET or IUGR). Serial Doppler examinations of the uterine arteries were performed in 77 pregnant patients. The Doppler studies commenced at 5–6 weeks' gestation and were repeated every 2–3 weeks during the first trimester and every 4–6 weeks thereafter. A transvaginal image-directed pulsed Doppler ultrasound system

**Fig. 17.26.** Blood flow velocity waveforms in the uterine artery demonstrating systolic (s) and diastolic (d) notches. (Reprinted from [83] with permission)

was used for these measurements. A systolic notch was defined as a momentary decrease in the rate of decline of the maximal velocity of flow during the “decelerative” phase of the systolic wave. A diastolic notch was defined as a decrease in the maximal velocity of flow below the maximum diastolic velocities, occurring just after the systolic wave (Fig. 17.26). The presence or absence of a systolic or diastolic notch in each waveform was noted. The presence of a systolic or diastolic notch in uterine artery flow velocity waveforms on both sides of the uterus at 10–12 weeks was considered a positive test. Twelve women aborted during the first or the early second trimester. Of the remaining 65 women, 30 had a positive test during the first trimester. Ten of these women (33%) subsequently had PIH/PET. In the remaining 35 women with a negative test, only 3 (8.6%) had this condition later in pregnancy ( $p < 0.02$ ) (Fig. 17.27). Altogether, 10 of the 13 women (77%) who subsequently had pregnancy hypertension had a posi-

tive test during the first trimester. In comparison, only 38% of women who did not subsequently have PIH/PET had a positive test. Fourteen women had a multiple gestation. When the data were analyzed separately for singleton and multiple gestations, only 29% of women with singleton (who did not subsequently have PIH/PET) had a positive test, compared to 50% with a multiple gestation. Women who aborted had a similar incidence (Table 17.5). The mean S/D ratio in the uterine artery in women with a positive test was  $6.31 \pm 0.26$  compared to  $5.5 \pm 0.17$  in women with a negative test ( $p < 0.02$ ). The performance characteristics of this test are shown in Table 17.6. The positive predictive value is similar to that obtained at 26 weeks [78]. These preliminary data suggest that screening during early gestation is feasible and may reflect abnormal placentation during the first wave of trophoblastic migration. The advantages of early screening were discussed before. The mean birth weight ( $\pm$  standard deviation) in women

**Fig. 17.27.** Proportion of women who subsequently developed pregnancy-induced hypertension (PIH) or preeclampsia (PET) according to the presence or absence of a notch (both systolic and diastolic) in at least one uterine artery) during the late first trimester. The number of women in each group is shown in a box. A total of 65 women were studied

with a positive notch was  $2,647 \pm 612$  g, whereas in those with a negative test it was  $2,999 \pm 629$  g. The presence of a notch, then, signifies impaired growth and is probably related to suboptimal uteroplacental perfusion throughout gestation in women with high resistance (i.e., the presence of notch) during the first trimester.

In a more recent study, uterine artery Doppler was performed at 11–15 weeks in 3,324 singleton pregnancies [127]. Both sides were measured and averaged, and the predictive value of a mean PI over the 95th percentile in the prediction of preeclampsia and/or fetal growth restriction was calculated. The sensitivity of a mean PI over 2.35 (the 95th percentile of the uterine artery mean PI) for preeclampsia (with or without fetal growth restriction) was 27% but for fetal growth restriction alone it was 11.7%. The respective sensitivities for these complications requiring delivery before 32 weeks of gestation were 60% and 27.8%. The sensitivity of the uterine artery mean PI over the 95th percentile in the prediction of preeclampsia and fetal growth restriction is lower when the test is carried out at 11–14 weeks than at 22–24 weeks. However, the potential advantage of earlier screening is that prophylactic intervention may be more effective in the prevention of the subsequent development of PET and fetal growth restriction. A similar study was performed in 380 women at 11–14 weeks [128]. The sensitivity of the uterine artery mean PI over the 90th percentile in the prediction of pregnancy complications (the 90th percentile of the uterine artery mean PI was 2.5) was 25%. However, there were no cases of PET in this series.

**Table 17.5.** Incidence of systolic and diastolic notch in uterine artery flow velocity waveforms in 77 women at late first trimester according to pregnancy outcome

Pregnancy outcome	No.	Incidence of notch (%)
Low risk	38	28.9
Abortions <sup>a</sup>	12	33.3
Twins	14	50.0
PIH-PET	13	77.0

<sup>a</sup> Women who subsequently had a spontaneous abortion. PIH-PET, pregnancy-induced hypertension or preeclampsia toxemia.

**Table 17.6.** Value of systolic and diastolic notch in uterine artery flow velocity waveforms during late first trimester for prediction of pregnancy-induced hypertension or preeclampsia

Parameter	%
Sensitivity	76.9
Specificity	61.5
Positive predictive value	33.3
Negative predictive value	91.4

Although these studies demonstrate that Doppler sonography of the uterine arteries during early pregnancy may predict abnormal pregnancy outcome and can be used for screening purposes, more data are required to reveal the full potential of this test. Studies of the association between abnormal uterine arterial flow patterns and histomorphologic changes in the placental bed during the first trimester are currently under way and should provide us with greater understanding of the mechanisms involved.

# Doppler Ultrasound in the Diagnosis and Management of Intrauterine Growth Restriction

William J. Ott

## Introduction

The antenatal recognition of fetal intrauterine growth restriction (IUGR) is an important goal for every obstetrician, since significant neonatal complications may be associated with altered fetal growth. Numerous studies have reported a 5%–27% incidence of congenital abnormalities associated with IUGR, as compared with a 0.1%–4% anomaly rate in control groups of normally grown neonates [1, 2]. The incidence of chromosomal abnormalities in IUGR infants is four to five times that of average-for-gestational-age (AGA) infants (2% vs 0.4%), and intrauterine infection, especially cytomegalovirus, has been reported in 0.3%–3.5% of IUGR infants [1, 2]. In addition, growth-restricted infants have up to an eight- to ten-fold increase in stillbirth and neonatal mortality [3–8]. Other developmental problems, such as necrotizing enterocolitis or intraventricular hemorrhage, also can be related to IUGR. Those infants that survive the immediate perinatal period are still at risk for neonatal hypothermia, hypoglycemia, polycythemia, or other complications, and have increased risk for long-term neurological or developmental complications [1, 4, 9–11].

Although there is no uniform agreement as to an exact definition of IUGR, it is usually equated with the small-for-gestational-age (SGA) infant, and this is not necessarily the best definition to use. In addition, there is no agreement as to which weight cut-off point (i.e., the 10th, 5th, or 3rd percentile, or two or more standard deviations from the mean) should be used to define it [12–14]. Controversy also exists as to which growth curve should be used. Numerous birth weight curves exist, and there is no universally accepted national standard. It is also controversial as to whether birth-weight-for-gestational-age curves or fetal weight-for-gestational-age curves should be used. Work at our own institution and at other centers has shown that IUGR infants are over-represented in premature deliveries, and therefore the use of birth-weight curves will significantly under-estimate the incidence of IUGR in the premature infant [15–21]. Using fetal weight curves would seem to be more appropriate. Table 18.1 shows the combined fetal weight for gestational age curve that is used in the author's institution [20], whereas Fig. 18.1 shows a comparison of the 10th percentile birth-weight curve of Alexander et al. [22] to the 10th percentile fetal weight curve, illustrating the potential under-estimation of IUGR in premature infants (20–33 weeks' gestation) if the neonatal weight curve is used.

**Fig. 18.1.** Comparison of the 10th percentile curves of the birth weight (*open symbols*) to the fetal weight (*closed symbols*) for gestational age. Between 20 and 33 weeks' gestation the birth weight curve underestimated the incidence of intrauterine growth restriction (IUGR)

**Table 18.1.** Fetal weight for gestational age (weight in grams)

42	3252	3395	4119	4844	4987

Decreased size at birth may be caused by a variety of processes [23–31]. Maternal demographic and anthropometric factors, socioeconomic conditions, and environmental factors all play a role in determining neonatal size at birth [23–29]. Most importantly, the intrinsic growth potential of each fetus may result in an infant that is smaller than standard cut-off value but is otherwise totally normal [30, 31]; therefore, a better definition of IUGR would be: an infant that fails to obtain its inherent growth potential. Although methods to determine what an infant's inherent growth potential may be do exist, they are controversial and frequently inaccurate. Currently (though not the ideal), the definition of IUGR that is most commonly used is to equate it with the SGA infant.

## The Antenatal Diagnosis of IUGR

The diagnosis of IUGR begins with the identification of those patients significantly at risk for delivering a growth-restricted infant. Many socioeconomic and medical complications can lead to IUGR [25, 32–35]. The two most significant historical factors related to IUGR are maternal smoking and a history of a previously growth-restricted infant. The most common

**Table 18.2.** Ultrasound parameters and the diagnosis of intrauterine growth restriction. AC abdominal circumference, HC/AC head circumference/abdominal circumference ratio, AC/FL abdominal circumference/femur length ratio, PPV positive predictive value, NPV negative predictive value

	Fetal weight	AC	HC/AC	AC/FL	Doppler
Sensitivity (%)	65.8	62.2	49.1	28.9	66.7
Specificity (%)	88.9	90.7	83.7	47.8	68.5
PPV (%)	63.6	67.3	47.1	47.8	38.4
NPV (%)	89.8	89.8	84.8	81.3	87.5
False positive (%)	8.6	7.2	12.6	7.2	24.4
False negative (%)	7.8	8.0	11.6	16.2	7.8

maternal medical complication associated with IUGR is hypertensive disease, and a study by Duverot et al. suggests a possible mechanism: early defective volume adaption to pregnancy [36]. Mounting evidence also indicates that both premature labor and IUGR are also related to chronic placental inflammation [37].

One of the most common methods of screening for and identification of the SGA and suspected IUGR infant is the measurement of various fetal parameters by real-time ultrasound [38–45]. A number of ultrasound parameters have been proposed for the antenatal diagnosis of IUGR [46]. In 1986 Benson et al. analyzed a number of these parameters and reported that estimated fetal weight was the most sensitive criterion for the diagnosis of IUGR, while an elevated head circumference/abdominal circumference ratio (HC/AC) was the most specific criterion and had the best positive predictive value [47]. Although other ultrasound parameters or the use of 3D ultrasound have been used to diagnose IUGR, calculation of estimated fetal weight by the standard 2D method is the method most commonly used [48–50].

Ott evaluated a number of ultrasonic parameters for the diagnosis of IUGR in 501 patients at increased risk for IUGR [51]. One hundred fourteen neonates were classified as IUGR (22.8%). Table 18.2 shows the sensitivity, specificity, positive and negative predictive values, and false-positive and false-negative results for the ultrasound parameters used to identify IUGR. Doppler evaluation of the umbilical artery showed the best sensitivity, although this was not a statistically significant improvement. Both abdominal circumference alone and estimated fetal weight showed similar specificity, positive and negative predictive value, and lowest false-positive and false-negative results. Logistic regression analysis confirmed the univariate results. When used in combination, both abdominal circumference and Doppler, or estimated fetal weight

and Doppler, showed almost identical improvements in all of the predictive values. Combining either abdominal circumference (alone) or fetal weight estimation with Doppler studies of the umbilical artery improves the accuracy in diagnosing IUGR. These findings are consistent with previous studies at our own institution and reports from other investigators [52–54].

### Doppler Ultrasound

True intrauterine growth restriction caused by abnormalities in uteroplacental perfusion is characterized by selective changes in peripheral vascular resistance that can be evaluated using any of the angle-independent indices of Doppler velocity flow studies in the fetal peripheral vessels [55–65]. Comparison studies of systolic/diastolic ratios (S/D) between normal controls and IUGR infants by Trudinger et al. [63], and of multiple ratios between normal controls and IUGR infants by Erskine et al. [64] showed significantly increased ratios in IUGR infants, indicating marked increased uteroplacental resistance with IUGR. Giles et al. [65] compared the placentas of patients with normal S/D ratios with a group of patients with elevated S/D ratios and found a significant decrease in modal small arterial vessel count in the placentas of patients with elevated S/D ratios, giving pathological correlation supporting increased uteroplacental resistance in patients with increased S/D ratios. Hitschold et al. studied the placentas of SGA infants with abnormal Doppler blood flow indices and found both a reduction of vascularization within the terminal villi and adverse diffusion conditions, suggesting insufficient functional maturity [66]. The SGA infants with normal Doppler indices or AGA controls did not have these pathological findings in their placentas. Locci et al. did a similar study comparing immunohistochemical evaluation of placentas from SGA infants with normal or abnormal Doppler indices and found histoimmunological abnormalities only in the SGA infants with abnormal Doppler studies [67]. Krebs et al. studied the morphology of the placentas of growth-restricted fetuses with absent end-diastolic flow velocity and found significant maldevelopment of the terminal villous compartment [57]. Giles et al. found significant reduction in nitric oxide synthase activity in the placentas from pregnancies with abnormal umbilical artery flow velocity waveforms, and coupled with their studies in the fetal sheep, suggest that this deficiency in nitric oxide synthase activity reflects inadequate placental function [57, 58]. These placental studies confirm the hypothesis that abnormal umbilical artery flow studies are a reflection of abnormal placental function.

Figure 18.2 shows a normal umbilical artery velocity study, whereas Fig. 18.3 shows absent end-diastol-

**Fig. 18.2.** Normal umbilical artery Doppler wave form at 34 weeks' gestation

**Fig. 18.3.** Abnormal umbilical artery Doppler wave form with absent diastolic flow in a growth-restricted fetus at 34 weeks' gestation

ic flow in the umbilical artery of a significantly growth-restricted fetus. Figure 18.4 presents the fetal umbilical artery S/D ratio norms used at the author's institution.

In a study to evaluate the combined use of fetal weight estimation and Doppler ultrasound to better define true IUGR, Ott studied a series of 578 fetuses at risk for IUGR [68]. Fetuses were divided into four groups based on their weight estimation and umbilical artery Doppler studies:

1. Group 1: AGA with normal umbilical artery S/D ratios (normal Doppler)
2. Group 2: AGA fetuses with umbilical artery S/D ratios above the 90th percentile curve for gestational age (abnormal Doppler)
3. Group 3: SGA with normal Doppler
4. Group 4: SGA fetuses with abnormal Doppler

**Fig. 18.4.** Umbilical artery systolic/diastolic (S/D) ratio curve. Mean (*open symbols*) and 5th and 95th percentile values (*closed symbols*)

**Table 18.3.** Neonatal outcome based on weight and Doppler studies. *GA* gestational age, *NICU* neonatal intensive care, *NS* no significant difference between groups

	Group 1	Group 2	Group 3	Group 4	Significance
Number	231	215	37	95	
GA at delivery	33.9 (3.7)	34.1 (3.6)	33.6 (3.5)	34.0 (3.3)	NS
Birth weight (g)	2779 (757)	2543 (801)	1984 (635)	1916 (623)	1
Cesarean section for distress (%)	4.7	8.9	3.0	10.5	2
Days in the NICU	7.0 (14.8)	11.3 (20.5)	16.0 (25.1)	19.7 (29.7)	3

Group 1: average-for-gestational-age (AGA) fetuses with normal umbilical artery S/D ratios (normal Doppler); group 2: AGA fetuses with umbilical artery S/D ratios above the 90th percentile curve for gestational age (abnormal Doppler); group 3: small-for-gestational-age fetuses (SGA) with normal Doppler; group 4: SGA fetuses with abnormal Doppler. Figures in parentheses are standard deviations.

1 No significant difference between categories 3 and 4; significant differences between categories 1–4 (combined);  $p=0.0241$ .

2 Abnormal Doppler (2 and 4) vs normal Doppler (1 and 3);  $p=0.034$ . No other differences were significant.

3 Significant differences between category 4 vs category 2 or category 1;  $p=0.0001$ . No significant differences between the other categories.

Table 18.3 lists the gestational age at delivery, birth weight, incidence of cesarean section for fetal distress, and length of stay in the NICU for the four study categories. There were no differences in gestational age at delivery between the four groups, and the expected differences in birth weight between the groups was seen. These findings did not change when the patients were analyzed by term or pre-term delivery. There were significant differences between the groups in cesarean section for fetal distress and in the length of stay in the NICU, both for the total patient population and when broken down into term or pre-term delivery. The presence of abnormal umbilical Doppler studies correlated better with cesarean section for fetal distress or length of stay in the NICU than did fetal weight estimation.

There was a significant increase in neonatal morbidity in a combined group of patients with abnormal Doppler studies but not in the combined group of SGA infants. These differences became more apparent when the patients were analyzed by term or preterm delivery, with preterm infants having marked increased morbidity when Doppler studies were abnormal. Logistic regression analysis confirmed these findings. There were no differences in morbidity between AGA fetuses with normal blood flow studies or SGA fetuses with normal blood flow studies.

The results of this study suggest that categorizing fetuses at risk for poor perinatal outcome based on weight estimation and umbilical artery Doppler velocity flow studies has important prognostic significance. Neonatal outcome of SGA fetuses with normal Doppler studies was not significantly different from

their AGA cohorts. Both AGA and SGA infants with abnormal Doppler studies had increased neonatal morbidity, with the SGA infants in this subgroup having the worst prognosis.

Recent studies by Soothill et al. [69], and Holme and Soothill [70], and a study by Craigo et al. [71], using similar ultrasonic techniques, came to the same conclusions: namely, the combined use of fetal weight estimation and Doppler velocity studies better defines true IUGR. The current study seems to indicate that both fetal weight estimation and Doppler evaluation of the umbilical artery are useful in the prediction of neonatal morbidity in high-risk patients. Doppler ultrasound, however, appears to be a more sensitive indicator of potential fetal compromise than does weight estimation. Combining weight estimation (or abdominal circumference) with Doppler ultrasound is currently the best method for diagnosing IUGR.

### Uterine Arteries

Since utero-placental dysfunction is a major cause of IUGR, evaluation of blood flow through the uterine arteries would logically seem to be an excellent method of identifying patients at risk for IUGR; however, controversy does exist as to the value of Doppler velocity studies of the uterine arteries [76]. Steel et al. evaluated 200 primiparous patients at 24 weeks' gestation with Doppler studies of the uterine arteries and found a low sensitivity for the prediction of hypertensive disease of pregnancy, but a very high sensitivity for predicting the development of IUGR associated with hypertension [72]. Vergani et al. found that abnormal uterine artery Doppler wave forms in IUGR fetuses in the third trimester were associated with a fourfold increase in adverse perinatal outcome [75]. Studies by North et al. [73] and Atkinson et al. [74], however, found only slight correlation between abnormal Doppler indices in the uterine arteries at 24 weeks' gestation and the later development of hypertensive disease, with or without IUGR, and both groups felt that uterine artery Doppler velocity studies were not a good method of screening for these complications of pregnancy.

More recent studies by Nicolaidis et al. found that a one-stage color Doppler screening of the uterine arteries at 23–24 weeks of gestation was a highly sensitive method of identifying those patients that subsequently developed serious complications of impaired placentation (pregnancy-induced hypertension and/or IUGR) [76–80]. Calculation of the uterine artery pulsatility indices (which can be done as early as 14 weeks) [81] and evaluation of the presence or absence of uterine artery notches were highly predictive for the development of complications later in gestation. Other investigators have confirmed these findings

**Fig. 18.5.** Normal uterine Doppler wave form at 24 weeks' gestation

**Fig. 18.6.** An abnormal uterine artery Doppler wave form at 24 weeks' gestation in a hypertensive patient who later developed superimposed pregnancy-induced hypertension associated with IUGR. The arrows indicate uterine artery "notching"

**Table 18.4.** Predictive value of uterine artery Doppler studies for IUGR. PPV positive predictive value, NPV negative predictive value, PI pulsatility index

Criterion	Sensitivity (%)	Specificity (%)	PPV (%)	NPV (%)	Reference
Bilateral notching	50	84	40	89	[83]
PI > 1.44 or bilateral notching	13	96	25	93	[77]
PI > 1.6	13	96	23	92	[78]
bilateral notching	20	92	19	92	[78]

[82, 83]. Table 18.4 shows the sensitivity, specificity, and predictive values of uterine artery Doppler studies at 23 weeks in predicting IUGR. Figure 18.5 illustrates normal uterine artery flow at 24 weeks, and Fig. 18.6 shows abnormal uterine artery flow with

diastolic notching in a chronic hypertensive patient at 24 weeks who later developed superimposed pregnancy-induced hypertension associated with IUGR.

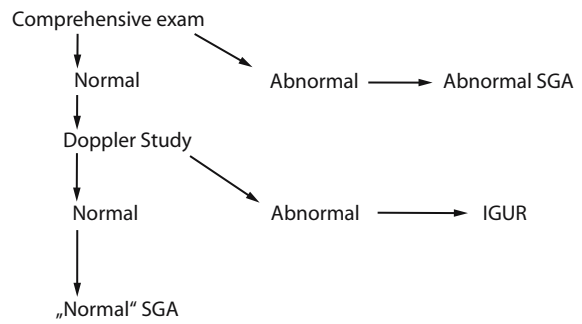

### Other Ultrasonic Methods of Diagnosing IUGR

Other ultrasonic methods of diagnosing IUGR have also been studied. Abramowicz et al. evaluated fetal subcutaneous adipose tissue by measuring cheek-to-cheek diameters from a coronal view of the fetal face at the level of the nostrils and lips [84]. Other measurements of fetal adipose tissues have been studied, such as subcutaneous tissue thickness at the level of the fetal mid-calf, mid-thigh, or abdominal wall; skin fold thickness; liver length; or other methods of fetal body composition [85–91]. Hill et al. [89] recently evaluated these measurements and felt that the degree of overlap in subcutaneous tissue thickness between normal, IUGR, and macrosomic fetuses was too great to be reliable in predicting abnormal growth, whereas Gardeil et al. [90] felt that measurements of subcutaneous fetal fat was as accurate in diagnosing IUGR as any other ultrasonic parameter. Further research in this area is needed to determine the utility of these measurements.

In summary, fetal weight estimation remains an important ultrasound parameter that can be used to diagnose IUGR. Combining fetal weight estimation with Doppler evaluation of the umbilical artery improves the accuracy of the diagnosis of IUGR. The other ultrasound parameters do not appear to add any additional accuracy to the diagnosis. Estimated fetal weight (or abdominal circumference), coupled with Doppler evaluation of the fetus, appears to be the best method of diagnosing and evaluating the fetus suspected of IUGR [52–55].

### Evaluation and Follow-up of Suspected IUGR

Once the diagnosis of IUGR is made, the evaluation of the fetus and decision to effect delivery depends not only on the results of antenatal tests, but also the complete clinical situation. In addition, careful search for the cause of the IUGR should be undertaken. A detailed ultrasonic evaluation of the fetus for the presence of structural abnormalities should always be done. If any abnormalities are seen, the patient should be offered genetic amniocentesis or cordocentesis to rule out fetal chromosomal abnormalities. It is still somewhat controversial as to whether or not fetuses with isolated IUGR (no structural or other abnormalities seen on ultrasound examination) are at increased risk for chromosomal aneuploidy. The pres-

**Fig. 18.7.** Flow chart (after [53]) to differentiate true IUGR from a small but normal fetus. SGA small for gestational age

ence of intracranial or liver calcifications, or evidence of exposure to infectious agents, would indicate an increased risk for intrauterine infection as a cause of IUGR and the need for amniocentesis to rule out this cause. Figure 18.7 shows the flow chart recommended by Soothill et al. for the use of ultrasound and Doppler in the diagnosis of IUGR [53].

In those IUGR fetuses without structural or functional abnormalities, two major causes for the growth restriction should be considered: uteroplacental insufficiency (true IUGR) and a constitutionally small (SGA) but normal fetus. In the differentiation of these two conditions Doppler ultrasound plays an important role.

### Umbilical Artery Doppler

There are a variety of antenatal tests available to evaluate and monitor the growth-restricted fetus. The fetal biophysical profile or modified biophysical profile (NST and fluid volume, only) are currently the gold standard for antenatal fetal evaluation and should be used to evaluate and monitor the IUGR fetus; however, Doppler velocity flow studies of the fetal umbilical artery play a critical role in the management of suspected IUGR.

Doppler ultrasound technology allows assessment of flow patterns and velocities in a number of fetal vessels, and the umbilical artery is the vessel most widely studied. Correlations have been observed between fetal outcome and various abnormal flow patterns, and data are accumulating that support the concept that the use of Doppler velocimetry in combination with other tests reduces the risk of antepartum fetal demise and improves neonatal outcome [92–94]. This is especially true in the IUGR fetus. Alfrevic and Neilson [92] performed a meta analysis of 12 randomized controlled trials of Doppler velocimetry and found:

“There is now compelling evidence that women with high-risk pregnancies, including preeclampsia and suspected intrauterine growth restriction, should have access to Doppler ultrasonographic study of umbilical artery waveforms.”

There is significant agreement that markedly abnormal umbilical artery Doppler velocities (absent or reverse diastolic flow) are strongly correlated with poor perinatal outcome [95]. A high percentage of fetuses with absent or reverse umbilical artery diastolic flow require intervention because of fetal distress or acidemia [96, 97]. Recent prospective studies have confirmed this association [98, 99]. Gaziano et al. evaluated a group of 100 fetuses at risk for IUGR and found that umbilical artery velocity studies could distinguish a subgroup of SGA infants with normal velocity indices that had significantly better neonatal outcomes than SGA infants with abnormal indices [100]. Almstrom et al. published a prospective, randomized, controlled study comparing umbilical artery Doppler studies and non-stress tests for the evaluation of SGA infants and found a greater degree of intervention in the non-stress testing (NST) group without any improvement in perinatal outcome [101]. The authors felt that Doppler was a better modality for the evaluation of suspected IUGR than the NST. DeVore evaluated the clinical implications of umbilical artery Doppler velocity studies in the management of suspected intrauterine growth restriction by surveying maternal-fetal medicine subspecialists [102]. He found that the majority of subspecialists surveyed rely on Doppler studies in the clinical management of IUGR.

Work at the author's institution, and reports of other investigators, suggest that combining biophysical parameters with pulsed Doppler velocity flow wave analysis will provide further information concerning fetal status in IUGR and other high-risk situations [103–105]. Comparison of systolic/diastolic ratios (SD ratio) in the carotid or middle cerebral artery to the SD ratio in the umbilical artery (MC/UA ratio) appears to be an accurate method of prediction fetal outcome, especially in the growth-restricted fetus [106–110]. Arabin et al. proposed and evaluated a new fetal assessment score that included the NST, fetal breathing, fetal tone, response to vibroacoustic stimulation, and the umbilical and carotid artery resistance indices [111]. Baschat et al. [112] and Hecher et al. [113] performed serial evaluation of high-risk growth restricted fetuses using both biophysical parameters and Doppler blood flow studies and found, in general, that the abnormalities in the Doppler studies preceded deterioration in the biophysical parameters by about 1 week.

In a retrospective study combining the NST with Doppler blood flow studies of the middle cerebral

and umbilical arteries, Ott was able to show that the addition of the MC/UA ratio improved the sensitivity for the prediction of poor perinatal outcome in a series of 447 high-risk patients [114]. The combination of the modified biophysical profile and Doppler ratios were then used in a prospective study of patients referred to the author's institution for antenatal surveillance [115]. Although the addition of Doppler studies to the modified biophysical profile did not improve neonatal outcome for the entire patient population studied, in a subgroup of fetuses at risk for IUGR there was a decreased utilization of cesarean section for delivery and an earlier identification of fetal compromise in the group of fetuses who had both modified biophysical profiles and Doppler studies used for antenatal testing (Table 18.5) [116]. A number of other studies have shown the value of Doppler velocity flow studies in the diagnosis and management of IUGR, and have suggested that the MC/UA ratio may be more sensitive in predicting neonatal outcome in IUGR fetuses [116–118]. The combined use of biophysical tests (non-stress test, biophysical profile) and Doppler ultrasound will better enable clinicians to monitor the IUGR infant and determine the optimal time for delivery.

### Central Nervous System Blood Flow

Doppler velocity waveforms have been studied in a variety of other fetal vessels, but the most interest has been directed to the fetal cerebral circulation. The middle cerebral artery has been the most common fetal vessel studied. Middle cerebral artery peak systolic flow velocity has been shown to be of great value for monitoring fetuses with suspected anemia [119].

In other situations of fetal compromise, especially IUGR, there is frequently a redistribution of blood flow in the fetus with increasing flow to the cerebral

**Fig. 18.8.** Normal (high-resistance) Doppler wave form in the middle cerebral artery

**Fig. 18.9.** Increased diastolic flow ("shunting") in the middle cerebral artery in a fetus with IUGR

circulation and a fall in resistance in the middle cerebral artery [120–122]. Figure 18.8 shows the normal, high-resistance flow in the fetal middle cerebral artery, whereas Fig. 18.9 shows increased diastolic flow ("shunting" or "brain sparing") in the middle cerebral artery of a fetus with significant IUGR. Serial Doppler flow studies of previable fetuses prior to fetal demise have shown progressive increased resistance in the umbilical artery with decreasing resistance in the middle cerebral artery until just prior to fetal demise, when resistance in the middle cerebral artery increases and signs of fetal heart failure (such as tricuspid regurgitation) develop [123, 124]. Of particular interest is the ratio of resistance indices of the middle cerebral artery and the umbilical artery. This ratio remains relatively constant throughout pregnancy but is significantly altered in fetuses with IUGR [125]. A number of studies involving fetal cerebral circulation suggest that there is an increase in cerebral flow in infants affected by uteroplacental insufficiency [126–129]. Studies at the author's institu-

tion of the ratio between carotid or middle cerebral and umbilical artery S/D ratio velocity waveforms (MC/UA) showed significant differences in neonatal outcome when these ratios were abnormal [130, 131]. A number of studies have shown the value of Doppler velocity flow studies in the diagnosis and management of IUGR, and have suggested that the MC/UA ratio may be more sensitive than other antenatal tests for the prediction of neonatal outcome in IUGR fetuses [130–134].

Growth-restricted fetuses, especially those that are delivered prematurely, are also at increased risk of intracranial hemorrhage or other CNS complications. The use of Doppler blood flow studies of the CNS in the fetus and neonate to identify those infants at increased risk for CNS complications may be an important tool; however, conflicting results have been obtained. Some investigators have shown a correlation between CNS complications and increased blood flow to the brain, whereas other investigators have shown a correlation between CNS complications and decreasing blood flow to the brain (increased resistance), or no correlation at all [135–140]. A recent study at the author's institution attempted to evaluate the ability of Doppler flow studies of the fetal CNS to predict CNS complications in the neonate.

Neonatal outcome of singleton pregnancies who delivered within 1 week of their final antenatal testing and had NST and fetal Doppler ultrasound (including measurements of blood flow in the fetal umbilical artery and middle cerebral artery [systolic/diastolic ratios (S/D)]) done at that time were studied. Since S/D ratios in both the umbilical and middle cerebral arteries decrease with advancing gestational age, these values were converted to multiples of the mean (MOM) derived from previously published norms [141, 142]. Both univariate and multivariate analyses were used to correlate the Doppler blood flow studies with the development of CNS complications. Correlations were also made for other tests of fetal well-being (NST and amniotic fluid volume), birth weight, and gestational age at delivery with the development of CNS complications.

Three hundred eighty-five patients were evaluated. The CNS complications occurred only in infants that were delivered at less than 37 weeks of gestation; therefore, the analysis was limited to the 131 patients that delivered at less than 37 weeks. Fourteen of the 131 patients (10.7%) developed CNS complications (IVH(1) 8; IVH(4) 1; encephalopathy 2; neonatal seizures 3), and Table 18.6 compares neonatal outcome parameters and results of antenatal testing between neonates with and without CNS complications. Univariate analysis showed that only birth weight, decreased amniotic fluid volume, and a non-reactive NST were statistically correlated with CNS complica-

tions. Neither abnormal blood flow in the fetal umbilical artery or in the middle cerebral artery, nor evidence of “brain-sparing” (elevated umbilical artery/middle cerebral artery ratios), were found to be associated with CNS complications. Multivariate logistic regression analysis showed that a non-reactive NST had the strongest correlation with CNS complications, whereas there was a trend towards decreased CNS complications with increasing middle cerebral flow.

A number of investigators have evaluated the relationship between middle cerebral artery Doppler blood flow and the development of CNS complications in the neonate with conflicting results. Mullaart et al. [143], studying flow in the internal carotid artery, found a correlation between increased diastolic flow and CNS complications, but determined that fluctuations in flow, rather than the flow itself, was the significant correlate. VanBel et al. [144] evaluated the flow in the anterior cerebral artery and found similar results. Bada et al. [135] and Mires et al. [136] performed similar studies but came to the opposite conclusion: a correlation between CNS complications and increased resistance to flow in the CNS (decreased diastolic flow). Other investigators, however [138–140], could find no association between alterations in middle cerebral artery flow and CNS complications, whereas Mari et al. [145] found a lower risk of CNS complications in fetuses with increased middle cerebral artery blood flow.

These conflicting findings might be partially explained by the complex mechanisms that regulate fe-

tal blood flow during developing uteroplacental insufficiency [144]. Akalin-Sel et al. studied Doppler flow in multiple fetal vessels and obtained umbilical venous blood gases in 32 severely growth-restricted fetuses [146]. They found that there are multiple mechanisms that regulate redistribution of blood flow in the fetus so that different clinical circumstances may result in difference changes in CNS blood flow. Investigators have also shown that just before fetal death, increased diastolic flow in the middle cerebral artery is lost, with a return to high resistance to flow, so that both the clinical cause of altered flow and the timing of the study may affect results [147].

In the author's study of CNS blood flow, neither abnormal umbilical artery nor middle cerebral artery blood flow were correlated with the development of CNS complications; but a non-reactive NST did show a strong correlation. Serial studies of high-risk patients with biophysical and Doppler tests have shown that the biophysical parameters (which include the NST) become abnormal only very late in the course of fetal deterioration, and this is consistent with the author's findings [148, 149]. This suggests that serial biophysical and Doppler studies could determine the time course of developing fetal anoxia and lead to a timely intervention.

## Venous Doppler

Evaluation of the venous side of the circulation in fetuses suspected of IUGR also provides important in-

**Fig. 18.10.** Normal inferior vena cava flow at 30 weeks' gestation. Note the tri-phasic pattern with a small reverse A wave during atrial contraction

**Fig. 18.11.** Normal ductus venosus flow at 24 weeks. Note that there is always forward flow during the entire cardiac cycle

formation concerning fetal status [150–156]. Rizzo et al. evaluated numerous Doppler indices from the inferior vena cava and ductus venosus in a series of normal and growth-restricted fetuses prior to cordocentesis [157]. They found the inferior vena cava preload index (the peak velocity during atrial contraction divided by the peak velocity during systole) was the best index for predicting acidemia. Figures 18.10 and 18.11 show normal venous flow in the inferior vena cava and ductus venosus, respectively.

During pathological situations, transmission of increased reverse flow in the inferior vena cava and ductus venosus may result in venous pulsations in the umbilical vein. Indik et al. have postulated that it may be possible to distinguish subgroups of fetuses with abnormal umbilical artery S/D ratios by evaluating fetal vena cava flow [156]. Nakai et al. evaluated 209 patients and found 9 (4%) fetuses with umbilical venous pulsations, 7 of which (78%) had significant growth restriction [158]. Mitra followed seven single-

**Fig. 18.12.** Abnormal inferior vena cava waveform with a large A wave in a fetus at 22 weeks' gestation who died from placental abruption

**Fig. 18.13.** Markedly abnormal ductus venosus flow with reverse flow during atrial contractions and transmitted venous pulsation in the umbilical vein in a severely growth-restricted fetus at 32 weeks' gestation

ton fetuses and two sets of twins with umbilical venous pulsations [159]. All fetuses showed tricuspid regurgitation and abnormal right-to-left ventricular diameter ratios – suggesting fetal heart failure. All seven of the singleton fetuses were significantly growth restricted, while the two twin pregnancies had twin–twin transfusion syndrome with the donor twin being growth restricted and the recipient twin being macrosomic. Studies in the fetal lamb have supported these clinical findings, suggesting that umbilical venous pulsations develop as a result of significant fetal venous pressure elevations [160]. In many clinical situations umbilical venous pulsations are a significant pathological event that require careful fetal evaluation, especially evaluation of the fetal cardiovascular

system; and fetal umbilical venous pulsations are related to very poor perinatal outcome. Figure 18.12 shows abnormal inferior vena cava blood flow; and Fig. 18.13 shows markedly abnormal ductus venosus flow with reverse flow during atrial contractions and transmitted venous pulsation in the umbilical vein in a severely growth-restricted fetus.

Ott evaluated 70 patients, over half of which were being followed for IUGR, to determine the value of the inferior vena cava flow as a tool to identify the very high risk fetus [161]. In addition to standard tests of fetal well-being the fetal inferior vena cava pre-load index (IVCPI) was also obtained. This value was calculated by placing the Doppler gate within the fetal inferior vena cava just proximal to its insertion into the right atria. The inferior vena cava pre-load index was calculated from the average of three consecutive cycles during a period of no fetal movement or respiration using the following formula:  $IVCPI = |A|/|S|$ , where A represents the peak velocity of reverse flow during atrial contraction and S represents the peak velocity of IVC flow during systole. The ability of the IVCPI to predict poor perinatal outcome was compared with three methods utilized in our laboratory to monitor fetal well-being: the NST; fetal umbilical artery S/D ratio (UAS/D); and the ratio of the fetal middle cerebral artery S/D ratio to the fetal umbilical artery S/D ratio (MCUA).

As shown in Table 18.7, the IVCPI had the highest odds ratios for predicting morbidity or prolonged stay in the NICU. Logistic regression analysis indicated that the combination of MCUA and IVCPI was the best predictor of neonatal outcome. When both tests were normal only 16% of these very high-risk fetuses had significant neonatal morbidity, whereas when both tests were abnormal 80% of the fetuses developed significant neonatal morbidity. Fetal IVC flow, therefore, gives additional important information concerning fetal status in suspected IUGR [162].

The fetal ductus venosus transmits well-oxygenated blood from the placenta to the right atria, and, via the anatomical and physiological mechanisms of the fetal heart, the majority of the ductus venosus blood is directed across the foramen ovale to the left heart [163, 164]. In normal pregnancies ductus venosus-pulsed Doppler waveforms show forward flow throughout the fetal cardiac cycle, and, unlike flow in the inferior vena cava, there is continued forward flow during atrial systole in the ductus venosus [165, 166].

Both DeVore and Horenstein [165] and Kiserud et al. [166] found that in seriously compromised fetuses, most of whom were also growth restricted, the lack of forward ductus venosus flow during atrial contractions was significantly associated with perinatal mortality or serious morbidity. Experience at the author's

**Table 18.7.** Neonatal outcome: univariate analysis. NST non-stress test, UAS/D umbilical artery systolic/diastolic ratio, MCUA middle cerebral artery/umbilical artery systolic/diastolic ratio, IVCPI inferior vena cava pre-load index

Significant morbidity when:	Test normal (%)	Test abnormal (%)	Odds ratio
NST	28 (17 of 60)	50 (5 of 10)	2.6 (0.4–14.6)
UAS/D	18 (8 of 45)	44 (11 of 25)	5.7 (1.7–18.8)
MCUA	19 (10 of 54)	56 (9 of 16)	3.6 (1.2–10.9)
IVCPI	16 (8 of 50)	55 (11 of 20)	6.4 (2.0–20.5)

own institution and animal experimentation has also confirmed these findings [167]. Detailed reviews of the clinical value of blood flow studies of the ductus venosus by Sherer et al. [168] and Kiserud et al. [169] suggest that evaluation of this vessel provides important clinical information regarding both fetal welfare and the timing of pathological events related to fetal hypoxia. Lack of forward flow during diastole or, more significantly, reverse flow during diastole, is a sign of very significant fetal compromise.

## Conclusion

The combined use of Doppler velocity wave form analysis of fetal vessels and the ultrasonic estimation of fetal weight (or abdominal circumference) appears to be the best method for both the identification and evaluation of IUGR (see Table 18.8). Once identified, the IUGR fetus should undergo serial evaluation on a weekly (or more frequent interval if the clinical situation warrants) basis with both Doppler velocity wave form studies and biophysical testing (the full or modified biophysical profile). Determination of the optimal time of delivery depends not only on the results of the antenatal testing, but also on the individual

**Table 18.8.** Role of Doppler studies in the diagnosis and management of IUGR

<i>Diagnosis</i>
Estimated fetal weight (or abdominal circumference) < 10th percentile = SGA fetus
Plus increased resistance in the fetal umbilical artery = IUGR fetus
<i>Management</i>
Serial biophysical testing and Doppler ultrasound
Absent or reversed diastolic flow in the umbilical artery or evidence of "brain sparing" (better diastolic flow in the middle cerebral artery than in the umbilical artery) = consider hospital admission for daily monitoring
Plus abnormal inferior vena cava or ductus venosus flow, and/or non-reactive NST = strongly consider delivery

**Fig. 18.14.** Non-reactive non-stress testing with no acceleration and absent variability at 32 weeks' gestation

clinical situation [170]. In situations where the data is unclear, especially in the preterm fetus, the use of amniocentesis to determine lung maturity may be helpful. Growth-restricted fetuses will frequently have lungs that are more mature than would be expected for their gestational age. Fetal venous Doppler studies give additional information about the time frame and significance of the IUGR [134].

An aggressive approach to the management of IUGR would, hopefully, lead to a reduction in perinatal mortality and morbidity in these high-risk fetuses. A study from the UK showed that IUGR infants identified in the antenatal period (and managed aggressively) had a lower perinatal mortality and less severe 2-year neurodevelopmental, clinical, or growth morbidity than similar IUGR infants that were not identified antenatally [171].

Since approximately half of IUGR fetuses are found in otherwise low-risk pregnancies, a strong point could be made for routine screening for IUGR. At the author's institution it is recommended that an ultrasound examination to evaluate fetal growth in all patients be done at 32–34 weeks' gestation. If fetal weight estimation is below the 10th percentile of the fetal weight curve, additional evaluation is undertaken, which would include a detailed ultrasound examination to look for structural abnormalities and Doppler velocity flow studies of the fetal umbilical artery. If any abnormalities are found, then additional testing is done; if not, then the fetus is considered to be constitutionally SGA and not IUGR. A repeat scan

may be done in 2–3 weeks if the clinical condition warrants and IUGR is still suspected. In those patients with the diagnosis of IUGR weekly (or more frequent) evaluation of the fetus should include both biophysical testing and Doppler studies of the umbilical artery and middle cerebral artery, and in many clinical situations venous Doppler studies are extremely helpful [172–174].

Once the fetus reaches 34 completed weeks of gestation, little is to be gained by prolonging the pregnancy, although in situations where the biophysical testing is normal and the Doppler studies are only minimally abnormal, waiting until 36 weeks may be permissible. In premature fetuses (<32–34 weeks) with immature fetal lung studies, it may be difficult to determine the best time for delivery. Factors that might suggest the need for immediate delivery despite an early gestational age include:

1. Persistent non-reactive non-stress test; the presence of spontaneous late decelerations on the non-stress test; severe oligohydramnios
2. Evidence of "brain sparing" on Doppler ultrasound (lower resistance in the middle cerebral artery than in the umbilical artery)
3. Ominous Doppler studies: reverse diastolic flow in the umbilical artery; umbilical vein pulsatile flow
4. Maternal compromise.

Figures 18.14–18.16 illustrate the combined use of weight estimation, Doppler studies, and biophysical testing in a 32-week singleton gestation being evalu-

**Fig. 18.15.** Fetus from Fig. 18.14. High-resistance flow in the middle cerebral artery (loss of “shunting?”)

**Fig. 18.16.** Markedly increased A wave and tricuspid regurgitation in the fetus from Figs. 18.14 and 18.15

ated for IUGR. The estimated fetal weight was 1420 g (less than the 5th percentile) and there were no obvious anomalies seen on the ultrasound examination. The fetus had a non-reactive NST and received a score of 2 on the biophysical profile (only normal fluid). Doppler blood flow studies showed increased resistance in the umbilical artery but no CNS shunting, abnormal inferior vena cava flow, and tricuspid regurgitation. A viable male infant was delivered by cesarean section with Apgar scores of 2 and 6, an arterial pH of 7.15, and a pCO<sub>2</sub> of 61. Placental pathology showed hypoplasia with chronic infarction and decidual necrosis. No organisms were isolated. In this case significant uteroplacental dysfunction leading to IUGR and a compromised fetus was reflected in abnormal weight estimation, biophysical studies, and Doppler ultrasound. The combined use of these modalities enabled the clinicians to better evaluate the seriousness of the fetus' condition.

# Doppler Velocimetry and Hypertension

Hein Odendaal

## Introduction

Pre-eclampsia and to a lesser extent hypertension in pregnancy is a vascular disease affecting both maternal and fetal circulations. On the maternal side, one of the very early characteristics of the disease is the deficient infiltration of the spiral arteries by the trophoblast, failing to convert it to uteroplacental arteries [12]. Subsequently, the 10- to 12-fold increase in uterine perfusion, as is seen in normal pregnancy, does not occur. This affects blood flow in the uterine artery [16]. On the fetal side there is poor vascularization of the terminal villi, villous stromal hemorrhage and hemorrhagic endovasculitis [50, 51] or even obliteration of stem villi [26, 27]. As Doppler techniques enable one to study flow velocity waveforms in a non-invasive way, it became one of the most ideal methods to analyze the maternal and fetal circulations and in particular that of the uterine and umbilical arteries. Although Satomura [86] described the feasibility of Doppler ultrasound to determine flow velocity in a peripheral artery, it took almost 20 years until the next important development in this field, when Fitzgerald and Drumm [34] used Doppler ultrasonography to investigate the human fetal circulation. Six years later Campbell et al. [16] reported, for the first time, the importance of uterine artery Doppler in obstetrics. Subsequently, developments have been summarized in very good recent reviews to which the interested reader is referred [13, 24, 26, 27, 36, 50, 51, 64, 65]. Although the research on the umbilical artery preceded that on the uterine artery and the use of its flow velocity waveforms is more established in clinical medicine, the uterine artery is discussed first to follow chronological events in pregnancy.

## Uterine Artery

As a result of the trophoblast invasion of the spiral arteries, and increase in uterine perfusion, end-diastolic flow in the uterine artery increases as the pregnancy advances. This gives the flow velocity waveform of the uterine artery a unique shape, character-

ized by high end-diastolic velocities with continuous forward blood flow throughout diastole [27]; however, in abnormal pregnancy there is poor trophoblast invasion of the spiral arteries. Subsequently, the end-diastolic flow does not increase or the diastolic notch does not disappear (Fig. 19.1).

To be able to apply the use of uterine artery flow velocity in clinical practice the following questions need to be answered:

1. How accurate is the screening?
2. When should the screening start?
3. What is the best method of screening?
4. Should any high-risk women be screened?
5. Which risks should be identified?
6. Can intervention in the identified women improve the outcome of pregnancy?

## Screening in the First Trimester

Schuchter et al. [87] examined both uterine arteries in 380 singleton pregnancies during the 11–14 weeks of screening for nuchal translucency. They used a pulsatility index at and above the 90th percentile to identify fetal growth restriction, pregnancy-induced hypertension, pre-eclampsia and placental abruption. Their screening was positive in 10% of women. The sensitivity was 25%, and 8.4% of tests were false positive. They also assessed the placental volume at the same examination and found that a combination of the two examinations reduced the sensitivity but increased the number of false-positive tests.

## Screening in the Second Trimester

Coleman et al. [21] studied 116 pregnancies in 114 women at high risk of pre-eclampsia. They screened the women between 22 and 24 weeks' gestation using a resistance index (RI)  $>0.58$  as abnormal. Outcome measures were pre-eclampsia, small for gestational age (SGA), placental abruption, intrauterine death and "all" and "severe" outcomes. The sensitivity of any RI  $>0.58$  for pre-eclampsia, SGA, "all" outcomes and "severe" outcomes was 91, 84, 83 and 90%, respectively. Specificity for these outcomes was 42, 39, 47 and 38%, respectively. The positive predictive val-

**Fig. 19.1.** Different flow velocity waveforms of the uterine artery. **a** Good velocity, no notch. **b** Slightly reduced velocity with visible notch. **c** Reduced diastolic velocity with visible notch. **d** Poor diastolic velocity with visible notch

ue for these outcomes was 37, 33, 58 and 24%, respectively. Using both values and a RI of  $\geq 0.7$  the positive predictive value improved to 58, 67, 85 and 58%. In the cases of bilateral notches the positive predictive value was 47, 53, 76 and 65%, respectively. They concluded that uterine artery Doppler waveform analysis was better than the clinical risk assessment in the prediction of pre-eclampsia and SGA babies.

Ohkuchi et al. [77] examined 288 normal women attending the antenatal clinic between 16 and 23.9 weeks of gestation, using the notch depth index (NDI) to identify the patient at risk. End points were pre-eclampsia, which developed in 3.1% of women and SGA which occurred in 6.3% of newborns. The sensitivity, specificity and positive predictive values were 67, 92 and 22%, respectively. Using receiver-operating characteristics curves, they found that the NDI was better than the RI or peak systolic to early diastolic velocity ratio in predicting pre-eclampsia or the SGA infant.

Recently, a one-stage screening for pregnancy complications by color Doppler assessment at 23 weeks' gestation was introduced [4]. A mean PI of more than 1.45 was considered increased. Bilateral uterine artery notches were also noted. Increased PI was noted in 5.1% of the 1757 pregnancies. Bilateral notches were noted in 4.4%. Examining how bilateral notches or the mean pulsatility index above 1.45 could predict pre-eclampsia, they found that the sensitivity, specificity and positive predictive value was 45, 94 and 23%, respectively. For pre-eclampsia delivered before 34 weeks these values were 90, 93 and

7%, respectively. They then looked at the PI and bilateral notches individually and in combination and concluded that the screening results were similar for increased PI or bilateral notches. Women with bilateral notches and a high mean PI had a 40% chance of developing pre-eclampsia.

McCowan et al. [66] concentrated on high-risk pregnancies. First of all they selected 224 women with suspected SGA babies ( $< 10$ th percentile by abdominal circumference on ultrasound) and who were normotensive when the uterine artery Doppler studies were performed. Of the 50 women who developed subsequent hypertension, 42 had gestational hypertension and 8 had eclampsia. When the first uterine artery Doppler examinations were done, both RIs were  $> 0.58$  in 7% of pregnancies which remained normotensive, in 17% of pregnancies where gestational hypertension developed and in 50% of pregnancies where pre-eclampsia developed. For bilateral abnormal uterine artery Doppler, in the prediction of gestational hypertension or pre-eclampsia, the sensitivity, specificity and positive predictive value were 22, 93 and 45%, respectively. They also found that more severe uterine artery Doppler abnormalities were associated with more severe fetal disease.

In a different approach, Valensise et al. [100] studied 36 normotensive women with a uterine artery RI  $> 0.58$  and bilateral notching at 24 weeks' gestation. Twelve of them developed gestational hypertension and 3 had SGA newborns. When compared with the pregnancies with a normal outcome, these 15 patients (at 24 weeks) had smaller left ventricular outflow

tract and left ventricular diastolic diameter. Atrial and ventricular functions were significantly lower in the pathological outcome group. The authors concluded that abnormal placentation has a wide effect on the whole cardiovascular system.

### Screening in the Third Trimester

Few studies addressed the significance of abnormal waveforms in the uterine artery in the third trimester. One of these, by Park et al. [81], followed the outcome in 198 pregnant women with an early diastolic notch after 28 weeks' gestation, 9.1% of the pregnant women who were initially screened. Outcome according to the notch index (NI; early diastolic flow/peak diastolic flow) was compared in different categories viz.  $<0.7$ ,  $0.7$  to  $<0.8$ ,  $0.8$  to  $<0.9$  and  $\geq 0.9$ . Perinatal outcome improved as the NI increased. For example, there were 9.5% perinatal deaths when the index was  $<0.7$  but no perinatal deaths when the notch index was  $\geq 0.9$ . Unfortunately, they did not look at the development of hypertension.

### Method of Screening (Quantifying Poor Diastolic Flow Velocity)

Aardema et al. [1] compared the PI with NI (peak of notch – nadir of notch/mean flow) at 21–22 weeks' gestation in 531 nulliparous women and 94 multiparous women at risk. Both values were poor predictors for mild gestational hypertension and pre-eclampsia; however, for severe disease the prediction was much better. Logistic regression analysis showed that the NI had no additional value compared with the PI in the prediction of either mild or severe disease.

Using color flow/pulse Doppler, Aquilina et al. [7] examined both uterine arteries at 20 weeks in 614 primiparous women. They then created receiver-operator characteristics curves for systolic/end-diastolic ratio, resistance index and systolic/early diastolic ratio, individually or in the presence or absence of unilateral or bilateral notching. The highest sensitivity (88%) in predicting pre-eclampsia and specificity (83%) was obtained when bilateral notching and mean  $RI \geq 0.55$  (50th percentile) were used. They concluded that at 20 weeks' gestation, bilateral notches with mean RI cut-offs is the best method if further screening later in pregnancy is proposed.

### The Effect of Gestational Age

In studying 88 patients with abnormal uterine Doppler velocimetry at 24 weeks' gestation, it was found that 49% of patients had normalization of uterine artery velocimetry after 28 weeks' gestation, some of which normalized after only 32–34 weeks [91]. No

patient developed pre-eclampsia or other severe complications when the uterine artery velocimetry returned to normal. The gestational age when the velocimetry was done therefore has an effect on the predictive value. To study these findings further, Antsaklis et al. [6] examined both uterine arteries in 654 healthy nulliparous women with color Doppler ultrasound at 4-week intervals between 20 and 32 weeks' gestation. Fifteen percent of women had abnormal flow velocity waveforms at their first visit. Pre-eclampsia developed in 3.2% of women. The sensitivity of the best way declined from 81% at 20 weeks to 71.4% at 32 weeks; however, the specificity and positive value increased significantly. At 24 weeks the sensitivity, specificity and positive predictive power was 76, 95 and 34%, respectively.

### Position of the Placenta

Uterine artery impedance is elevated in the contralateral side of the placenta [56]. This finding was also confirmed by Antsaklis et al. [6], who found that the predictive value of the test was lower when the placenta was in a full lateral position on the contralateral side.

### Overview

To assess the usefulness of uterine artery Doppler flow velocimetry in the prediction of pre-eclampsia, intrauterine growth restriction and perinatal death, Chien et al. [19] did a semiquantitative review of 27 observational diagnostic studies involving 12,994 women. The measurements studied were the flow velocity waveform ratio  $\pm$  diastolic notch derived by transabdominal Doppler ultrasound. Likelihood ratios were used to measure diagnostic accuracy. A likelihood ratio of 1 indicated no predictive value for outcome. Likelihood ratios  $>10$  or  $<0.1$  were regarded as conclusive for a positive or negative test result, respectively. Moderate prediction was indicated by likelihood ratios of 5 to 10 or 0.1–0.2. The test was regarded as abnormal when the diastolic notch was present in the velocity waveform of one or both uterine arteries.

In a low-risk population, a positive test result predicted pre-eclampsia with a pooled likelihood ratio of 6.4 (95% CI 5.7–7.1). In a high-risk population a positive test result predicted pre-eclampsia with a pooled likelihood ratio of 2.8 (95% CI 2.3–3.4). A negative test had a likelihood ratio of 0.8 (95% CI 0.7–0.9). They came to the conclusion that uterine artery Doppler flow velocity had limited diagnostic accuracy in predicting pre-eclampsia.

## Time to Establish the Ground Values

In an excellent opinion article, Lees [58] expressed his disappointment about the systemic review by Chien et al. [19] and referred to recent findings that would help one to interpret results more uniformly. He stressed the optimal screening time of 20–24 weeks and the acceptance of bilateral notching above unilateral notching. A high mean uterine artery pulsatility index was more reproducible and objective basis for screening than bilateral notches alone. He expressed the hope that these recommendations will be accepted for standardized large multicentre studies to elucidate some of the existing uncertainties.

## Other Predictions

Although this article concentrates on the prediction of hypertension and pre-eclampsia, other clinically important outcomes were also determined; however, the overview by Chien et al. [19] demonstrated that the prediction of intrauterine growth restriction and intrauterine death was poor. Uterine artery Doppler velocimetry has also been studied in women with antiphospholipid syndrome [32, 102]. They found it to be useful in predicting pre-eclampsia and SGA infants. Outcome of pregnancy in women with normal uterine artery Doppler flow velocity waveforms was good.

## Aspirin

The well-known CLASP study showed a disappointing effect of aspirin on the prevention of pre-eclampsia, demonstrating only a 12% reduction in its incidence, which was not significant. No significant effect on the incidence of IUGR or perinatal deaths was detected; however, a 22% reduction (9.9% CI, 40% reduction to 3% increase;  $p=0.02$ ) was found in women where the prophylaxis started at 20 weeks or earlier [20]. A later meta-analysis for the Cochrane library [55] addressed 42 trials in more than 32,000 women. A 15% reduction in the risk of pre-eclampsia was associated with the use of antiplatelet agents (RR 0.85, 95% CI 0.78–0.92). The number needed to treat was 89. The reduction in the risks of pre-eclampsia was statistically significant for women randomized before 20 weeks' gestation (RR 0.86, 95% CI 0.77–0.97) but borderline for those entered after 20 weeks. Not all studies found aspirin to be protective. For example, a large study, in 2539 women at high risk, enrolled between 13 and 26 weeks, failed to demonstrate any beneficial effect of low-dose aspirin on the incidence of pre-eclampsia [17, 18]. Predictors of pre-eclampsia in women at high risk were nulliparity and a mean arterial pressure  $>85$  mmHg at enrolment [17, 18].

Following the success of aspirin prophylaxis in early pregnancy in the CLASP and other small stud-

ies, several randomized controlled trials were done in women with abnormal uterine artery Doppler flow velocity waveforms.

Vainio et al. [99] randomized 90 women with bilateral notches to receive either a placebo or 0.5 mg/kg per day acetylsalicylic acid; the latter was associated with significant reduction in the incidence of pregnancy-induced hypertension (11.6% vs 37.2%; RR 0.31; 95% CI 0.13–0.78). The incidence of pre-eclampsia was also reduced (4.7% vs 23.3%; RR 0.2; 95% CI 0.05–0.86).

Harrington et al. [45] randomized 2116 women for abnormal uterine artery Doppler flow velocity waveforms (bilateral notches with a mean RI  $>0.55$ , unilateral notch with a mean RI  $>0.65$  or with a mean RI  $>0.70$  in the absence of notches) to receive a placebo or 100 mg slow-release aspirin daily from 17–23 weeks' gestation. Although the incidence of pre-eclampsia was not reduced, there was an improvement in outcome by reducing complications associated with uteroplacental insufficiency. Goffinet et al. [37] randomized 3317 low-risk women from 18 centers into a Doppler group or a control group. An abnormal Doppler result was defined as diastole:systole  $>35\%$  or a notch on at least one of the uterine arteries. These patients received 100 mg aspirin daily until they reached a gestational age of 35 weeks. There was no effect on the incidence of pre-eclampsia (RR 1.99; 95% CI 0.97–4.09). Bar et al. [9] found no effect of 60 mg aspirin on fetal circulation parameters in their 87 women who were recruited for the CLASP study. In a similar study, Grab et al. [39] found no effect of 100 mg aspirin per day on the uteroplacental or fetoplacental hemodynamics. It also did not cause moderate or severe constriction of the ductus arteriosus.

As the mentioned results were conflicting, Coomarasamy et al. [22] did a meta-analysis of five trials which assessed the effect of low-dose aspirin on the incidence of pre-eclampsia in women with abnormal uterine Doppler. Five relevant trials were found. Pooling their results demonstrated a significant reduction in pre-eclampsia (OR 0.55; 95% CI 0.32–0.95). The baseline risk of pre-eclampsia in these women with abnormal uterine artery Doppler flow velocity waveforms was 16%. The number of women to be treated to prevent one case of pre-eclampsia was 16. Babies of mothers who received aspirin were on average 82 g heavier.

## Summary

When one tries to answer the initial questions, there are still many uncertainties; these relate more to the method and timing of the screening (Table 19.1) than to the prevention of complications with early administration of low dose aspirin:

**Table 19.1.** Screening in the second trimester: umbilical artery. *SGA* small for gestational age, *PIH* pregnancy-induced hypertension, *IUGR* intrauterine growth restriction

Method	End points	Gestational age (weeks)	Reference
Pulsatility index	Abruptio placentae IUGR Pre-eclampsia Pregnancy-induced hypertension	11–14	[87]
Resistance index >0.58 Bilateral notches	SGA Abruptio placentae Pre-eclampsia PIH	22–24	[21]
Notch depth index	Pre-eclampsia SGA	16–23.9	[77]
Pulsatility index > 1.45	Pre-eclampsia	23 24–36	[4] [66]
Bilateral notches Both RI > 0.58	Pre-eclampsia SGA Gestational hypertension		

- How accurate is the screening?  
Not accurate as reflected by the poor sensitivity, specificity and positive predictive value
- When should the screening start?  
As the prediction is poor, one does not really know when to screen. From a practical point of view, the best times to screen are obviously when pregnancies are routinely screened at 11–14 weeks or at 20 weeks
- What is the best method of screening?  
The best method is still uncertain, but it seems that a combination of abnormalities, such as bilateral notches with a high RI or PI, is preferable.
- Should any high-risk women be screened?  
High-risk women would in any case be put on low-dose aspirin from early pregnancy. A patient at high risk according to the obstetrical or medical history, but at low risk according to uterine artery Doppler examination, would probably be put on aspirin; however, the primigravida may benefit from screening as the outcome of pregnancy would be more uncertain.
- Which risks should be identified?  
Risks associated with poor placentation should be determined. They are “abruptio placentae”, gestational hypertension, pre-eclampsia and IUGR. Small for gestational age should not be regarded as abnormal because many babies with low birth weight are constitutionally small.
- Can intervention in the identified women improve the outcome of pregnancy?

Early administration of aspirin will improve the outcome in the majority of high-risk patients.

## Umbilical Artery Doppler

Nicolaides et al. [69] examined the oxygen tension and pH of umbilical cord blood, obtained by cordocentesis, in 59 fetuses with an abdominal circumference below the 5th percentile and absent end-diastolic velocity. Only 7 fetuses had normal oxygen tensions and pH. This important finding stimulated further research on the clinical use of umbilical artery Doppler.

The poor oxygenation of the fetus is most likely to be caused by deficient development of the villous structure of the placenta. Volumes and surface areas of intermediate and terminal villi are reduced [46], terminal villi are smaller [61] and more stem villi have medial hyperplasia and laminal obliteration. In addition, terminal villi are poorly vascularized [85] and gas-exchanging villi are poorly developed [96]. For the interested reader, there are several very good review articles which give more detail [3, 8, 40, 49, 51, 78, 84].

Higher endothelin-1 levels are reported in mother and the fetus complicated by IUGR, but the values are surprisingly not related to umbilical artery blood gases. Elevated endothelin-1 levels were significantly associated with pregnancy-induced hypertension [30]. Abnormal umbilical artery Doppler findings are also associated with greater nucleated red blood cell counts, signifying an association with fetal hypoxia [10].

## Clinical Findings

Several studies associated abnormal umbilical artery Doppler flow velocity waveforms with poor perinatal outcome [48, 71, 96]. Hypertension and pre-eclampsia

were most frequently the primary cause for the abnormal flow velocity [48]. It is important to note that third-trimester fetal growth rate correlated better with intrapartum fetal distress than fetal size alone [79]. The same principle could be applied to Doppler flow velocity waveforms, where abnormal flow velocity is of greater significance than calculated fetal weight.

### **Umbilical Artery Flow Velocity Waveforms in Low-Risk Populations**

Routine use of umbilical Doppler in low-risk pregnancy is not recommended [28, 37]. These findings are also supported by a Cochrane Library review of the findings in 14,338 women in 5 studies [14].

### **Umbilical Artery Flow Velocity Waveforms in High-Risk Pregnancy**

In 1995 Alfirevic and Neilson [5] published their first systematic review with meta-analysis and concluded that women with high-risk pregnancies, including pre-eclampsia and suspected IUGR, should have access to Doppler flow velocity waveform examinations. In a more recent study [70], they examined eleven good quality trials in nearly 7,000 women. Most of the causes for the high-risk pregnancy were hypertension and presumed poor fetal growth. There was a trend towards a reduction in perinatal deaths (odds ratio 0.71, 95% CI 0.50–1.01). Use of Doppler ultrasound was also associated with fewer inductions of labor (odds ratio 0.83, 95% CI 0.70–0.93) and fewer admissions to hospital (odds ratio 0.56, 95% CI 0.43–0.72).

More recently, Westergaard et al. [104] only considered well-defined studies; 1,307 patients had suspected IUGR and 852 had IUGR and/or hypertension. There were 13 RCTs in 8,633 mothers. These well-defined studies showed significant reductions in antenatal admissions, inductions of labor, elective deliveries, and caesarean sections with the use of umbilical Doppler velocimetry. More perinatal deaths were potentially avoidable by Doppler velocimetry ( $p < 0.0005$ ).

### **Doppler Ultrasound and HELLP Syndrome**

Joern et al. [47] investigated the umbilical artery, both uterine arteries and the middle cerebral artery in patients with different grades of hypertension. The worst perinatal outcome was found when all four vessels were abnormal. The largest proportion of abnormalities was in the women with HELLP syndrome. Bush et al. [15] studied 50 women with HELLP syndrome. Although abnormal umbilical artery velocimetry was associated with a high likelihood of delivery

by cesarean section, the Doppler findings did not correlate with the severity of maternal disease.

### **Effect of Antenatal Steroids**

As many patients with severe pre-eclampsia need delivery before fetal pulmonary maturity has been reached, administration of steroids is strongly indicated before delivery is considered. It has been established that the administration of steroids is indeed safe in patients with severe pre-eclampsia [89]. It should be kept in mind that betamethasone treatment has been associated with a temporary (2–7 days) decrease in placental vascular resistance [103]. Other ways of fetal assessment, such as fetal heart rate monitoring, should therefore be relied upon during this period.

### **Fetal Assessment Before Admission to Hospital**

There are many forms of fetal assessment in mothers with hypertension in pregnancy such as the biophysical profile [62], amniotic fluid volume assessment and Doppler flow velocity studies in other fetal and maternal vessels [24, 57, 80, 93]. Many of these are time-consuming, need sophisticated instrumentation and are difficult to interpret. It is also necessary, especially from the point of view of a developing country, to limit unnecessary expenditure. For this reason we prefer Doppler flow velocity of the umbilical artery as the screening test in high-risk pregnancies as identified by hypertension or poor symphysis pubis growth [95].

Based on the nomogram of Tygerberg Hospital [82, 83], the 50th percentile was initially regarded as the cut-off line for normality. As few fetal complications were observed when the RI fell between the 50th and 75th percentile lines, the 75th and 95th percentiles are now accepted as the dividing lines. The green area below the 75th line is regarded as normal (Fig. 19.3). No further tests for placental function are indicated unless there is a change in the clinical condition of the mother. The orange area between the 75th and 95th percentiles indicates uncertainty. The test should be repeated after 2 weeks and the fetal heart rate pattern recorded immediately and at all subsequent visits. The red area above the 95th percentile indicates that the Doppler should be repeated weekly and that a non-stress test should be done twice a week. Absent end-diastolic flow velocity in the umbilical artery is an indication for admission to hospital for intensive fetal monitoring or delivery, depending on the gestational age.

**Fig. 19.2.** Different flow velocity waveforms of the umbilical artery. **a** Normal end-diastolic flow. **b** Reduced end-diastolic flow. **c** Absent end-diastolic flow. **d** Reversed flow

### Fetal Assessment in Hospital

As abruptio placentae caused 36% of intrauterine deaths in patients with early onset severe pre-eclampsia [72] frequent fetal heart rate monitoring has been introduced [73]. Many intrauterine deaths from “abruptio placentae” are now being prevented as it has been shown that abnormal fetal heart rate patterns preceded the clinical diagnosis in the majority of cases. For these reasons there is a limited place for the use of umbilical artery flow velocity waveforms in the daily assessment of patients hospitalized for severe pre-eclampsia.

### When Should the Patient Be Delivered for Severe Pre-eclampsia?

Although there is some controversy about the timing of delivery in patients with severe pre-eclampsia, researchers at Tygerberg Hospital believe fetal outcome could be improved in many cases by expectant management. Rather than delivering for pre-eclampsia as such, patients are only delivered for specific maternal or fetal indications [41, 42, 74]. It has also been demonstrated that delivery can be postponed in patients with early onset severe pre-eclampsia. This enables one to achieve a relatively low perinatal mortality rate in patients with early onset severe pre-eclampsia [41, 42].

Severe pre-eclampsia necessitating admission to hospital between 24 and 27 weeks’ gestation was studied in 39 women. By expectant management, gestation was prolonged with a median of 12 days (range 3–47 days). Overall perinatal loss was 26% and neonatal loss only 17%. Unless for a specific maternal or fetal reason, termination of pregnancy or very early delivery is not always indicated in these patients. They should therefore, after informed consent has been obtained, be given the opportunity to have expectant management, provided that there is not reversed or absent flow (Fig. 19.2) [43, 44].

### Abruptio Placentae

The frequency of abruptio placentae in mothers admitted for severe pre-eclampsia is 18%–20% [41, 42, 92]. It is therefore essential to assess whether the patient with severe pre-eclampsia, at risk for this complication, can be identified. In a case-controlled study [75], 69 patients with severe pre-eclampsia who had developed abruptio placentae were compared with the same number of patients, matched for gestational age, who did not develop abruptio placentae. Absent end-diastolic flow velocity and a resistance entry above the 95th percentile were seen in 7 and 31%, respectively, of patients who did not develop abruptio placentae, and in 1 and 23% of patients who developed abruptio placentae. Abnormal umbilical artery Dop-

**Fig. 19.3.** Nomogram for the management of pregnant patients with suspected placental insufficiency according to Doppler flow velocity waveforms of the umbilical artery. The *green area* indicates that the pregnancy could be allowed to continue. No further tests for foetal well-being are indicated unless there is a change in the condition of the mother. The *yellow area* means caution. The test should be repeated and a non-stress test should be done. The *red area* indicates that the patient should be watched very carefully. A resistance index above the 95th percentile mandates an immediate non-stress test and thereafter twice weekly. Patients with absent end-diastolic flow should be admitted for intensive fetal monitoring or immediate delivery

pler flow velocity waveforms were therefore of no value in identifying the risk patient for abruption. On the other hand, abnormal fetal heart rate patterns were found in the majority of patients who developed abruptio placentae. The fact that there were only two intra-uterine deaths due to abruptio placentae demonstrates the value of monitoring the fetal heart rate every 6 h in these patients.

### Congenital Abnormalities

The risk of euploidy should always be remembered especially in the case of absent end-diastolic velocity without any apparent reason such as hypertension or poor fetal growth [50, 51, 98].

### Severe Asphyxia

Several authors [50, 51, 98] also warn against severe IUGR with severe asphyxia; however, this is unlikely when the fetal heart rate is monitored every 6 h [76].

### In Utero Treatment in Cases of Poor Umbilical Artery Doppler Velocimetry

It is still uncertain whether treatment of the fetus is possible. In a study of 12 pre-eclamptic women with oligohydramnios and elevated PI in the uterine arteries, Nakatsuka et al. [68] used long-term transdermal nitric oxide donors to reduce the blood pressure.

In addition to lowering the blood pressure, the PI of the umbilical artery was also reduced. It is still uncertain whether this improvement was just symptomatic or whether a real improvement in uteroplacental function was achieved. Further studies are therefore needed to demonstrate the real benefit to the fetus.

### When to Deliver for Reverse End-Diastolic Velocity

Several findings have an effect on the maternal and perinatal outcome in patients with severe pre-eclampsia. Unless there is a very clear abnormal finding such as an alarming fetal heart rate pattern or uncontrollable blood pressure, a single abnormality should usually not be an indication for delivery in these patients. One should therefore always take the complete clinical picture into consideration, balancing maternal against perinatal risks but also the risks of further intra-uterine life against that of severe prematurity. Depending on the gestational age and estimated fetal size, reversed end-diastolic flow velocity is usually an indication for delivery; however, if the fetal heart rate pattern is still reassuring, the maternal condition stable and corticosteroids have not yet been administered, one may administer steroids to improve lung maturity and deliver 24–48 h later [29].

### When to Deliver for Absent End-Diastolic Velocity

It is still uncertain when to deliver the patient with absent end-diastolic velocity as such. Usually these patients do not reach a gestational age of 34 weeks, when the neonatal outcome is very good. Either fetal or maternal condition often demands earlier delivery.

The GRIT study [94] was done at 67 hospitals in 13 European countries, using Bayesian data monitoring and analysis, to assess the correct timing of delivery between 24 and 36 weeks. In all the cases the umbilical artery Doppler was recorded and there was uncertainty as to when to deliver. The median time-to-delivery intervals were 0.9 days in the immediate group and 4.9 days in the delay group. There was a lack in the overall difference in mortality but the total caesarean sections were 91% in the immediate group and 79% in the delay group (OR 2.7; 95% CI 1.6–4.5). The authors concluded that the timing of delivery was correct as there were not a major delay in delivery (4.9 days) and the morbidity was similar in the two groups; however, in developing countries, later delivery which will enable the baby to start sooner with kangaroo care [52] and the lower caesarean section rate are major advantages. This approach of expectant management of mothers with severe pre-eclampsia helped the group at Tygerberg Hospital to

achieve perinatal morbidity rates comparable to those of developed countries [41, 42].

The ACOG [2] recommends that the growth-restricted fetus should be delivered when the risk of fetal death exceeds that of neonatal death; however, if one looks at the reported perinatal morbidity rates in patients with severe pre-eclampsia, even when an expectant regime is followed, there are more neonatal than intrauterine deaths. Concern about the maternal condition could be partly responsible for the early delivery as the safety of the mother should also be considered. On the other hand, a neonatal death may be better explained to the mother than an intrauterine death, and this may sometimes influence the obstetrician towards earlier delivery; however, with intensive fetal monitoring, especially the heart rate, the chances of intrauterine death are very small, even when abruption of the placenta occurs [75]. The timing of delivery should therefore be individualized carefully, balancing the maternal, fetal and neonatal risks.

### Method of Delivery

Intrapartum umbilical artery Doppler velocimetry is a poor predictor of adverse perinatal outcome, according to a meta-analysis of 2,700 women in eight studies [32]. There is also no change in the pulsatility index during labor [31]. Patients with an increase in resistance index can be allowed a trial of labor [90]; however, elective delivery is recommended when there is reversed end-diastolic flow or non-reassuring fetal heart rate patterns. Hall et al. [43, 44] examined the route of delivery in 335 women with early onset severe pre-eclampsia. Labor was induced in 103 (31%) of patients of whom 46 (45%) delivered normally. Although non-reassuring fetal heart rate patterns, necessitating delivery for fetal distress, occurred in 38 (37%) of these patients, when compared with elective caesarean section, these babies had lower rates of severe hyaline membrane disease and needed intensive care less often. Fewer developed sepsis; however, they were 1.6 weeks older at birth.

### Other Effects on Umbilical Artery Doppler Flow Velocity Waveforms

There is no correlation between the umbilical artery Doppler flow velocity waveforms and coiling index of the umbilical cord [23], and there is a negative correlation between heart rate and the A/B ratio or RI [63, 67, 101, 105]; however, the influence is small when the heart rate varies between 120 and 160 beats per minute. A decrease in the S/D ratio was also found during ritodrine infusion to suppress preterm labor [11]. It is likely that this effect is due to the increase

in fetal heart rate caused by ritodrine. Moderately high altitude has no effect on fetal vascular Doppler indices [35].

### Neonatal Outcome

As brain sparing in cases of severe IUGR reduces blood supply to the bowel, this ischaemia could facilitate the development of neonatal necrotizing enterocolitis. Kirsten et al. [52] compared the proportion of necrotizing enterocolitis in babies who had absent end-diastolic flow velocity ( $n=68$ ) with those who had a resistance index between the 95th and 99th percentile ( $n=43$ ) or those with normal flow velocity ( $n=31$ ). All these babies were born to mothers with severe pre-eclampsia. No baby who had absent end-diastolic flow velocity developed necrotizing enterocolitis.

Kirsten et al. [52] also followed up these babies for 4 years. There were no differences between the developmental quotients of the infants with normal and absent end-diastolic velocities, either at 24 or 48 months of age; however, looking at fetal aortic blood flow velocity, Ley et al. [59, 60] found an association between abnormal waveforms and intellectual function and minor neurological dysfunction at the age of 7 years.

### Conclusion

It has been demonstrated, without doubt, that the clinical use of umbilical artery flow velocity waveforms reduces perinatal deaths and unnecessary admission to hospital or induction of labor for suspected placental insufficiency. It can also be used in primary health care settings to differentiate between a normal fetus with poor growth and placental insufficiency.

**Acknowledgements.** The author thanks E. Foot for typing the manuscript and L. Geerts for the Doppler flow velocity waveform images.

# Doppler Velocimetry and Multiple Gestation

Emanuel P. Gaziano, Ursula F. Harkness

The role for fetal Doppler sonography includes detecting fetal growth restriction (FGR), serving as a modality for fetal surveillance, predicting adverse neonatal events, and determining the optimal time for delivery. Multiple-gestation pregnancies afford a unique opportunity for fetal Doppler application, as abnormalities in growth and potential disturbances of the fetal circulation are relatively common. Doppler data add a physiologic parameter not previously available to the clinician. By reflecting downstream resistance to flow in the umbilical artery, it serves as an accurate proxy for placental insufficiency [1]. By including the cerebral circulation, inferences may be made as to the redistribution of fetal blood flow under conditions of chronic asphyxial stress, while multiple vessel interrogation is useful in studying the extremes of circulatory changes seen in some monochorionic twins with twin transfusion syndrome (TTS). In multiples as in singleton pregnancies, application of fetal Doppler velocimetry permits the assessment of the sequence of fetal cardiovascular adjustment to asphyxial stress in the arterial and venous circulations yielding useful insights into the timing of delivery.

Among the risks for multiple gestations listed in Table 20.1, Doppler velocimetry helps define the status of the fetus with restricted growth, TTS, and congenital anomalies. In these instances Doppler information facilitates the appropriate and selective application of perinatal resources. For decisions regarding patient management, Doppler data become a part of

the clinical mosaic to be used in tandem with other historical, examination, sonographic, laboratory, and biophysical data.

## Twin Prevalence

The prevalence of twin gestation varies from 1 to 5% depending on the gestational age at assessment, as a significant number of twins suffer intrauterine fetal demise of one of the pair [2]. The overall incidence of spontaneous twin gestations has declined, but reproductive technologies, including ovulation induction and surgical transfer of gametes or ova, have resulted in an increasing number of high-order multiple gestations [2].

## Twin Placentation

Twins are derived from either a single ovum (monozygotic) or two ova (dizygotic). Dizygotic twinning is influenced by maternal central gonadotropin levels [3, 4] and varies among ethnic groups. For example, Nigerian women have a high level and frequency of twinning and Japanese women have a low level and frequency. Occurring at a fixed rate of 1 per 250 births, proportionately more complications occur in twin monozygotic pregnancies probably owing to both placental vascular anastomosis and placental asymmetry [5, 6].

Because dizygotic twin pregnancies arise from two entirely separate placental disks, each gestational sac has one amnion, one chorion, and rare vascular anastomosis [5]. Diamniotic dichorionic gestations account for about 80% of all twin pregnancies, and their placentas may be fused or separate [7]. This type of placentation also may include monozygotic twins if the zygote divides early after fertilization. The type of placentation seen in a given monozygotic twin pregnancy depends on when in development splitting occurs [8]. If division of the ovum occurs before the chorion develops in the first 2 or 3 days, a diamniotic dichorionic gestation will result [8]. If the split occurs between 3 and 8 days post-fertilization, a

**Fig. 20.2.** Dividing membrane in dichorionic diamniotic twin pregnancy. Note the anterior and posterior placentas and relative thickness of the dividing membrane

diamniotic monochorionic gestation will result [8]. Monoamniotic monochorionic pregnancies occur when the division occurs between days 8 and 13 after fertilization [8]. Any pregnancy that splits later than this develops into conjoined twins [8]. The type of

placentation is important since this factor defines the relative risks for vascular anastomosis and the complications that result in the greatest fetal morbidity. Growth restriction may have a different mechanism in fetuses from dizygotic pregnancies than in those from a monozygotic pregnancy [9].

Figure 20.1 shows the relation of amnion to chorion and the dividing membrane in diamniotic dichorionic (DADC), diamniotic monochorionic (DAMC), and monoamniotic monochorionic (MAMC) placentation; the latter is rare, accounting for 1% of all twin pregnancies [7]. The number of amnion/chorion layers present in the dividing membrane is also shown in Fig. 20.1. The ultrasonographic appearance of the thicker diamniotic dichorionic dividing membrane is apparent in Fig. 20.2. Monochorionic placentation (20% of all twins) is associated with artery-to-artery (AA), artery-to-vein (AV), and vein-to-vein (VV) superficial anastomosis, although deep capillary villous anastomoses are also possible (Fig. 20.3) [5, 7, 10]. All gradations of anastomoses are possible; hence, the variable clinical presentations and variable Doppler velocimetry findings observed. Most cases of twin transfusion occur with diamniotic monochorio-

**Fig. 20.3.** Deep arteriovenous anastomosis in monochorionic diamniotic twin placentation. Twin-to-twin transfer. *IUGR* intrauterine growth restriction, *AGA* appropriate-for-gestational age

nic placentation, and perinatal mortality (25%–50%) occurs principally with this type of placentation compared with the 10% mortality in the diamniotic dichorionic group [2, 11].

Figure 20.4 demonstrates a monoamniotic monochorionic twin gestation and no dividing membrane. These fetuses are at risk for cord entanglement and death. Recently, 50% mortality was reported for pregnancies with monoamniotic monochorionic placentation [12].

## Fetal Doppler and Complications of Multiple Gestation

In the United States, the infant mortality rate among multiple births was more than five times higher than among singleton births in both 1989 and 1999 [13] and the perinatal mortality was similarly increased [14]. Two-thirds of the perinatal losses before 30

weeks occur at gestational ages of 26 weeks or less [15]. Whereas multiple gestations resulted in 3% of live births in 2000, 14% of infant deaths in the same year were multiples [16].

Studies on multiple gestations have focused on using fetal Doppler data in three clinical areas: (a) identification or prediction of growth restriction; (b) the TTS; and (c) prediction of perinatal morbidity and mortality. We address the use of Doppler velocimetry for each of these separately.

### Growth Restriction and Discordance

Prior to 30 weeks' gestation, the major causes of neonatal death relate to immaturity while stillbirths due to growth restriction contribute a significant number of perinatal losses after 32 weeks' gestation [15]. Growth restriction occurs in one-fourth of multiple gestations [17]. Representing 1% of pregnancies, twins account for 12% of early neonatal deaths and 17% of all growth-restricted infants [17]. Triplets and other higher-order multiple gestations also lend a disproportionate contribution to the number of growth-restricted fetuses.

### Evaluation of Fetal Growth

Two methods are used to evaluate fetal growth in multiple pregnancies: (a) growth discordance (differences in fetal weight frequently expressed as a percent); and (b) longitudinal assessment of the weight or growth for the individual fetus.

Since the introduction of Babson et al.'s correlation between severe growth discordance and neonatal developmental delay [18], the concept of differences in weight (discordance) has gained popularity. No uniform cutoff value is reported for growth discordance, although 15% or more birth-weight difference between twins is considered mild discordance, and more than 25% birth-weight difference is classified as

severe discordance [19–22]. When the weight difference between twins is >25%, perinatal death rate is increased by a factor of 2.5 and risk of fetal death is increased by a factor of 6.5 [23].

Differences in ultrasound measurement parameters or Doppler indices in twins are commonly reported as the percent difference and are expressed as delta change or intrapair difference. A number of studies [24–35] rely upon the discordance concept and have reported Doppler results accordingly.

The advent of high-resolution real-time ultrasonography and duplex Doppler systems diminishes the need to view multiple gestations only in terms of discordance because the individual fetus in multiple gestations can be independently and accurately assessed. Expressing either Doppler or estimated fetal weight (EFW) differences between twins is less useful, as neonatal morbidity appears to be best predicted by individual fetal assessment. Using 30% disparity in birth weight, O'Brien et al. [36] were able to determine only one in five growth-restricted twins. Bronsteen and colleagues [37] evaluated 131 consecutive sets of surviving infants and showed that individual evaluation for intrauterine growth was more effective than discordance or other classifications for predicting adverse neonatal outcomes. Regarding neonatal morbidity among twins, neither birth-weight discordance of >20% or >25% was a factor for predicting adverse events compared with individual birth-weight percentiles of <15th and <10th, respectively. The most clinically relevant outcomes, such as neonatal death, congenital anomalies, small for gestational age (SGA) and periventricular leukomalacia, are defined by a birth-weight difference of 30% [38]. In a study of 192 twin pairs who had ultrasound within 16 days of delivery, intertwin estimated fetal weight discordance of 25% or more had a sensitivity of 55%, specificity of 97%, positive predictive value of 82%, and negative predictive value of 91% for predicting actual birth-weight discordance [39]. The antepartum diagnosis of discordance was correct in 4 of 5 cases; however, discordance may be overdiagnosed in almost 20% of cases and almost half of the significantly discordant twin pairs were missed.

Gaziano et al. [33] focus on the individual fetus and classify the Doppler value, EFW, abdominal circumference, or other measurement parameter for each fetus as a percentile for the gestational age at which it is obtained. Deter et al. [40, 41] recommended multiple individual parameter assessment (individualized growth assessment) for the twin fetus suspected of growth restriction. This approach simplifies interpretation of clinical data, allowing the fetus to be followed over time and permitting focused surveillance.

### ***Doppler Sonographic Prediction of Fetal Growth Restriction***

A number of difficulties are inherent in assessing the fetal Doppler results and their relationship to growth restriction. Firstly, the heterogeneous cause of FGR in singletons also apply to multiple gestations and can be broadly categorized as follows: (a) malformations, intrauterine infections, or chromosomal abnormalities; (b) maternal vascular and nutritional deficits; and (c) constitutionally small fetuses. In addition, causes specifically related to twins must be considered, such as twin transfusion, primary uterine or placental pathology, and anomalies due to the twinning process. Secondly, although the umbilical arteries are relatively accessible compared with the internal fetal vessels, careful establishment of individual fetal circulations by real-time ultrasonography is necessary to prevent sampling the same umbilical circulation twice. This point is particularly important for suspected TTS, as the smaller “stuck” twin with oligohydramnios may be relatively difficult to image. Thirdly, studies differ in instrumentation, pulsed-wave vs continuous-wave (CW) technology, and the resistance index selected: systolic/diastolic ratio (S/D); pulsatility index (PI); or resistance index (RI). A variety of end points for Doppler-diagnosed abnormalities are reported. Outcomes may be reported as birth-weight differences of >20% or >25% and the cut-off for defining growth restriction is reported at various percentile ranges (<10th, <5th, or <2.5th). Finally, the latter definitions for FGR, as for singletons, are not always satisfactory, as some constitutionally small twins are normal in all other respects, while some “normal”-weight fetuses may be growth restricted.

Pathologic studies suggest an anatomic lesion in some cases of FGR. For example, histologic examination of placentas shows fewer placental tertiary stem villi in twin pregnancies complicated by “placental insufficiency” and abnormal S/D ratios than in fetuses with normal S/D ratios [42]. These findings are similar to those observed in some singleton pregnancies with FGR and suggest a placental vascular pathology rather than a uteroplacental one [1, 42]. Furthermore, in twin pregnancies the PO<sub>2</sub> levels in the individual fetus appear unaffected among a wide range of umbilical RI values [43]. Differences in the RIs for twin fetuses were of little value for detecting PO<sub>2</sub> differences until the differences in the RI between the fetuses was 76% [43].

Doppler prediction for fetal growth restriction has been evaluated by a number of investigators [24–35]. Table 20.2 summarizes the experience of these investigators, indicating the method of assessment, outcome variable measured, and the sensitivity for SGA prediction.

**Table 20.2.** Fetal growth restriction prediction using umbilical artery in twin-gestation pregnancies. *CW* continuous-wave Doppler, *S/D* systolic/diastolic ratio, *SGA* small-for-gestational age, *GA* gestational age, *PI* pulsatility index, *EFW* estimated fetal weight, *RI* resistance index, *US* ultrasonography

Reference	No. of twin pregnancies	Method of assessment	Outcome variable	Sensitivity (%)
[24]	76	CW; S/D ratio differences of 1.57 or >75th percentile difference	Birth of SGA infant	70
[25]	43	CW; S/D ratio differences between twins of >0.4	Birth of SGA infant	73
[26]	56	Duplex pulsed Doppler; abnormal Doppler value for GA	Weight discordance >25%	82
[27]	30	Duplex pulsed Doppler; percent difference PI umbilical artery	Unfavorable outcome (9 of 11 were SGA)	50
[28]	69	CW after real-time US; S/D difference >0.4	Birth of SGA infant	42 <sup>a</sup>
[29]	58	Real-time US followed by CW; delta S/D or EFW >15%	Birth-weight discordance >15%	78
[30]	89	CW after real-time US	Birth of SGA infant (25th percentile)	29
[31]	31	Duplex pulsed Doppler PI difference >0.5	Birth-weight difference >20%	75
[32]	37	Duplex pulsed Doppler; abnormal Doppler value for GA	Birth of SGA infant (<10th percentile)	58
[33]	94	Duplex pulsed Doppler; abnormal S/D >95th percentile for GA	Birth of SGA infant (<10th percentile)	44
[34]	32	Delta RI	Birth-weight discordance	78
[35]	40	Pulsed Doppler/mechanical sector scanner; PI difference >0.2	Birth of SGA infant	42

<sup>a</sup> Reported as positive predictive value.

Pioneering studies reported by Giles et al. [24] and Farmakides et al. [25] were conducted with CW Doppler, and the S/D ratio (A/B ratio) differences between twins were correlated with the birth of an SGA infant. Index ratio differences of >0.40 or 1.57 demonstrated sensitivities of 73% and 70%, respectively.

In a study of 56 twin pregnancies using real-time and pulsed-wave Doppler ultrasonography, an abnormal Doppler result predicted a weight discordance of >25% with a sensitivity of 82% [26]. Adequate fetal growth was accurately predicted in 44 of 45 normal sets of fetuses and discordant growth in 9 of 11 twin sets. A 50% sensitivity has been demonstrated for unsatisfactory outcomes using abnormal umbilical artery Doppler sonography as an end point. One such adverse outcome was SGA which was found in 9 of 11 fetuses [27]. A 42% positive predictive value for the birth of an SGA infant has been reported when the intrapair difference for the S/D ratio was >0.4 [28]. Some investigators report no difference between ultrasound-derived EFW and the S/D ratio (intrapair differences of >15%) for predicting the birth of discordant-weight twins (>15% birth weight) [29]. Both

methods showed a sensitivity of 78% for these parameters [29]. Yamada et al. [31] demonstrated a sensitivity of 75% for a birth-weight difference of >20% when the umbilical artery PI difference between twins was >0.5, similar to the 78% sensitivity reported by Kurmanvicius et al. for birth weight discordance [34].

In summary, of the studies reviewed, a disparity was observed for FGR prediction among the investigators, and one-third noted sensitivities of <50%.

### Ultrasonographic Biometry and Fetal Doppler Studies

Ultrasonographically detected differences in discordant growth pairs can be seen as early as 23–24 weeks, with the smaller twin exhibiting a slow rate of growth between 33 and 37 weeks (Fig. 20.5) [44]. In pathologic twins, differences can be suggested as early as the beginning of the second trimester.

Ultrasound measurements, such as the biparietal diameter (BPD), are insensitive predictors of neonatal growth discordance [23]. In twin gestations the BPD is determined in only 79% of all fetuses, whereas

**Fig. 20.5.** Discordant head size in a monozygotic twin gestation

femur length and abdominal circumference are obtained for 96% and 99% of fetuses, respectively [45]; thus, the ultrasonographically determined EFW is superior to the BPD or femur length for predicting discordance [46]. No apparent advantage is anticipated using abdominal circumference alone for predicting growth discordance or restriction, as it is part of most formulas for estimating fetal weight. In addition, multiple measurements allow potential classification into symmetric and asymmetric patterns of restricted growth.

Sensitivity for SGA prediction is reported as high as 58% in the presence of an abnormal pulsed-wave Doppler result from the umbilical artery, while Doppler abnormality precedes ultrasonographic diagnosis of FGR by an average of 3.7 weeks [32]. Combining sonographic measurements with an abnormal Doppler result may improve the sensitivity to 84% [32]. Both Hastie et al. [30] and Gaziano et al. [33] found relatively low sensitivities (29% and 44%, respectively) for SGA prediction in multiple gestations using abnormal Doppler results in the umbilical artery. Gaziano et al. [33] compared ultrasonographically determined EFW (expressed as a percentile for the gestational age at which it was obtained) with abnormal umbilical artery velocimetry and found biometry to be superior to abnormal Doppler results for SGA prediction. The overall sensitivity for SGA prediction with an ultrasonographic EFW of <10th percentile was 50%, and the best positive predictive value (PPV) was 87.5%, achieved with an ultrasonographic EFW of 35th percentile. Other authors have demonstrated no difference in diagnostic accuracy for twin discordance between Doppler velocimetry and ultrasonography [29].

When Doppler waveform indices and serial measurements of EFW and abdominal circumference were compared in singletons, serial biometric measure-

ments were superior to a number of Doppler indices for FGR prediction [47]. Similar findings are suggested from the limited data on twin pregnancies.

Deter et al. [40, 41] developed a detailed ultrasound biometric assessment technique applicable to the twin fetus. It included measurement of head circumference (HC), abdominal circumference (AC), thigh circumference (ThC), femur diaphysis length (FDL), and EFW. The authors recommended using a multiple-parameter technique rather than standard growth population curves for the detection of FGR in twins. According to their data, single anatomic parameters are inadequate for distinguishing the normal twin from the growth-restricted twin. By assessing the number and magnitude of deviations of the parameter changes, all growth-restricted infants in 34 twin pregnancies were identified; none in the sample were misclassified [41].

### Cerebral Vessels

In one study of 17 consecutive twin pregnancies, the sensitivity for FGR prediction was 83% for PI of internal carotid artery (ICA) compared with 33% for the PI of the umbilical artery [48]. Multiple vessel interrogation may increase diagnostic accuracy, and in singletons the ratio between the PI of the umbilical artery and the PI of the internal carotid artery show sensitivities of 84.2% for FGR prediction at a PPV of 97% [49]. The cerebral/umbilical artery ratios may have a greater sensitivity for FGR prediction than does a single-vessel evaluation [50].

### Summary

Correlations between ultrasound biometry, Doppler, and FGR identification in multiple gestations are summarized as follows:

1. An abnormal umbilical artery Doppler result is significantly associated with the birth of a growth-restricted infant.
2. A wide range of accuracy for FGR detection is reported, varying according to the population characteristics and the technique employed.
3. Ultrasound biometry is superior to fetal Doppler examination for purposes of diagnosis.
4. Multiple parameter measurements and serial measurements are superior to final individual values for either Doppler studies or biometry.
5. Combinations of biometric with Doppler measurements and cerebral/umbilical artery ratios probably increase the likelihood of FGR detection.

Other than methodologic or technical parameters, a number of factors account for the differences among the studies regarding FGR prediction. Not all

FGR fetuses exhibit abnormal Doppler velocimetry. In singleton fetuses, for example, the birth of an SGA infant was associated with a normal umbilical artery Doppler waveform in 44%–51% of such births [51, 52]. It is unknown what proportion of these infants were constitutionally small instead of growth restricted.

### Twin Transfusion Syndrome

Twin transfusion syndrome (TTS) and its manifestations result in a high frequency of fetal loss and significant neonatal morbidity. Becoming clinically evident at the lower limits of fetal viability, intensive maternal and fetal therapy may result in the birth of viable but profoundly ill neonates. The complex vascular arrangements possible within the placental circulations of these monochorionic pregnancies suggest an area of promise for fetal Doppler investigation.

The TTS is characterized by clinical findings which include a recipient fetus who is usually appropriate for gestational age (AGA) or large for gestational age (LGA), and a donor fetus who is small or growth restricted. The recipient's sac demonstrates hydramnios that is sometimes massive. Oligohydramnios is often present in the donor's sac. The marked oligohydramnios results in the "stuck" twin due to compression from the recipient sac [53]. Ultrasonographically, the separating membrane may be difficult to visualize because of its close adherence to the donor and its thin monochorial origin. Signs of fetal hydrops or cardiac failure may develop in either twin, usually the larger.

A scoring system has been proposed for TTS based on sonography, Doppler findings, and cordocentesis [54]. Sonographic and Doppler findings (minor) include an abdominal circumference difference  $>18$  mm, poly- or oligohydramnios, signs of monozygosity, and an intrapair S/D ratio of  $>0.4$ . Major criteria include evidence of transplacental shunt, a birth-weight difference of  $>15\%$ , and a hemoglobin difference of  $>5$  g/dl. Antenatally or postnatally two criteria are needed (two major or one major and one minor). Other authors have suggested variations on these criteria for defining TTS [55, 56].

Although discordant fetal size, amniotic fluid differences, concordant gender, and evidence of monochorial placentation suggest TTS, neonatal criteria for TTS, which include a hemoglobin differential of  $>5$  g/dl, is not uniformly found. In four cases of TTS, cordocentesis was performed and no intrapair hemoglobin differences of  $>2.7$  g/dl were observed [57]. In another study using cordocentesis, others have noted significant hemoglobin differences in only one of nine fetuses with TTS [58]. Ultrasonographic findings in TTS do not always correlate with the classic neonatal

criterion of a hemoglobin difference of  $>5$  g/dl. [59]. Classic TTS was confirmed in only 44% of fetuses by direct injection of transfused blood to the donor while simultaneously assessing evidence for transfused cells in the recipient fetus by direct fetal blood sampling [59].

Ultrasound evaluation of TTS includes a general fetal anatomic survey to rule out gross anomalies and an assessment of the fetuses for signs of fetal hydrops, including scalp edema, ascites, hydrothorax, and pericardial effusion. The sex of the fetuses should be determined and membrane thickness assessed for evidence of zygoty. To infer zygoty, placental localization in multiple pregnancies is best assessed during the early part of the second trimester (12–14 weeks) when fused or separate placentas can be distinguished.

The amniotic fluid volume in each sac should be assessed, and detection of hydramnios or oligohydramnios by a modified four-quadrant technique may be helpful. A cutoff of 8 cm vertical depth for amniotic volume is suggested [60]. In addition, the degree of hydramnios is correlated with the probability of fetal abnormality [60]. For twin pregnancies, abnormal monochorionic placentation (TTS) is the most frequently cited association with hydramnios [60].

The fetal weight should be estimated ultrasonographically for each fetus using the formulas of Hadlock et al. [61], Shepard et al. [62], or others and then the EFW classified into a percentile ranking for the gestational age at which it was determined. The individual fetal growth can then be classified as appropriate for gestational age (AGA), SGA, or LGA. On the basis of Rossavik growth models and using detailed measurements in normal twins, individual assessment for the growth of the twins can be performed with the same methods used for singletons and the results are similar [63]. A multiple parameter individualized growth assessment technique as described by Deter et al. [40, 41] may be the most precise biometric method, but its clinical application remains to be evaluated.

Standards of birth weight in twin gestation stratified by placental chorionicity are a recent contribution. Singleton charts tend to underestimate twin growth at earlier gestational ages and overestimate twin growth at later gestational ages [64].

Irrespective of the neonatal findings regarding hemoglobin differences, the ultrasonographic findings described previously portend a poor prognosis. Based on ultrasound findings, Pretorius et al. [12] noted possible TTS in nine twin pairs. Patients in their series with TTS had a relatively high death rate. The overall mortality rate for TTS depends on birth weight and gestational age at delivery and is reported to be as high as 70% [6]. Among pregnancies deliver-

ing at <28 weeks, a survival rate of only 21% was reported for TTS and neither decompression amniocentesis nor tocolysis altered this outcome [65].

### **Pathology of Monochorionic Placentation**

When placentas from monochorionic twins are compared with the presence or absence of TTS, placentas from pregnancies with TTS had fewer anastomoses overall, and fewer anastomoses for each specific type, such as arterioarterial (AA), venovenous (VV) and arteriovenous (AV) [66, 67]. In addition, anastomoses in the TTS group tended to be indirect or AV, rather than direct AA or VV when compared to monochorionic twins without TTS. Hemodynamic models of TTS in monochorionic twins support the pathologic findings that fewer anastomoses effect greater discordance between monochorionic twins and that the discordance increases beyond fetal compensatory capacity [68]. Color Doppler insonation of placental vasculature in monochorionic twins also demonstrates an absence of functional AA anastomoses in monochorionic twins with TTS [69]. In assessment of clinical outcomes, AV anastomoses in the absence of AA and VV, especially if present with placental asymmetry, carry the worse prognosis [67]. Unidirectional AV flow in the absence of compensatory bidirectional anastomoses results in adverse fetal effects and poor outcomes for some monochorionic gestations.

The placenta of the donor twin may have a small, inconspicuous vascular supply and may demonstrate a large number of villi per unit volume of placenta, whereas the recipient twin demonstrates an increase in the volume of fetal capillaries [70]. Donor twins may have a deficiency of maternally transferred immunoglobulin G (IgG), indicating impaired intervillous maternal-fetal transfer [71].

### **Placental Symmetry and TTS**

Abnormalities of monochorionic placental symmetry have received less attention than the anastomoses but are of importance. Monochorionic twin placental asymmetry has been variously described as unequal sharing of venous return zones, unequal allocation of parenchyma, and discordant vascular perfusion zones, but a precise quantitative definition is lacking [6].

The morphogenesis of MC placental asymmetry is also unknown, but the monochorionic monozygotic (monochorionic MZ) twin blastocyst has an intrinsic polarity defect at implantation [6]. The portions of the monochorionic twin placenta in TTS are often asymmetrical with the donor twin's placenta typically the smaller [5, 67, 72]. The threshold for significant asymmetry (e.g., 60:40, 70:30, 80:20, 90:10, etc.) and clinical placental insufficiency in one twin may vary in each case and depend on gestational age and

type and number of anastomotic vessels. In the absence of anastomoses, unequal sharing is an important cause of growth discordance in monochorionic twins [73]. The vascular anastomoses place an monochorionic twin with an adequate placental share at risk for pathophysiologic processes of the twin with placental insufficiency. Conversely, the anastomoses may sustain a twin with a small share by supplementing nutrients, which would otherwise be deficient. In addition to quantitative differences, the asymmetric monochorionic portions may differ qualitatively in placental circulation relative to umbilical cord insertions, chorion surface vessel pattern, and villous capillaries. In monochorionic twin gestations, the relative roles of reduced placental mass, abnormal cord insertions, and intertwin vascular anastomoses are difficult to ascertain and often occur together.

### **Umbilical Artery Doppler Velocimetry – TTS**

A summary of fetal Doppler evaluation of TTS is presented in Table 20.3, including the method of assessment, principal findings, and conclusions.

Umbilical artery velocimetry was first reported in 5 of 76 twin pregnancies with TTS [24]. Using CW Doppler technology and a cutoff for A/B (S/D) ratio difference of 1.57 (greater than the 75th percentile), TTS pregnancies showed normal A/B ratios that were concordant. Growth restriction was present in 12 of 18 monochorionic pairs, but an elevated A/B ratio was present only in 7 pairs. The authors concluded that the A/B ratios in TTS are normal and concordant, and that differences in size on ultrasonography in the presence of no S/D difference suggest TTS.

Another report described TTS in two twin pregnancies – one at 20 weeks and one during labor [25]. The amniotic fluid volume assay indicated hydramnios/oligohydramnios in the first case and a normal state in the second case. Using CW Doppler technology, the S/D ratio of the umbilical artery was abnormal in the SGA donor twin and normal in the recipient, and the S/D ratio difference was 1.9 (an S/D ratio of >0.4 was the cutoff for twin abnormality).

Serial Doppler and ultrasound examinations were reported in a twin pregnancy with TTS [74]. The donor twin showed abnormal velocimetry with cyclic variations thought to be due to an arterial anastomosis. This donor fetus demonstrated abnormal flow (zero and reversal) and died in utero. The recipient survived, demonstrating normal velocimetry.

Pretorius et al. [75] reported fetal Doppler ultrasound findings in eight cases of TTS. Pulsed-wave duplex Doppler sonography was employed with high-resolution ultrasound, and A/B ratios were determined for the umbilical artery. Significant A/B ratio differences were noted in seven of the eight cases,

**Table 20.3.** Fetal Doppler evaluation of the umbilical artery in TTS. *CW* continuous-wave Doppler, *S/D* systolic/diastolic ratio, *US* ultrasonography, *PI* pulsatility index, *IUGR* intrauterine growth retardation, *UA* umbilical artery, *MCA* middle cerebral artery

Reference	Technique	No. of pregnancies	Method of assessment	Doppler findings	Conclusions
[24]	CW	5	CW; S/D ratio differences	No S/D ratio differences; 2 of 10 perinatal deaths	No S/D ratio difference in presence of size (US) difference suggests TTS
[25]	CW	2	CW; S/D ratio differences >0.4 abnormal	S/D ratio difference  Case 1: 1.9, SGA twin: abnormal value Case 2: one twin with abnormal value	TTS: high/low resistance values
[74]	Pulsed Doppler	1	CW/real-time US; serial PI values in donor and recipient	PI in small donor cyclical but showed 0 to reversal during diastole; PI recipient normal	Artery-to-artery anastomosis suspected; morbidity not confined to volume exchange alone in TTS
[75]	Pulsed Doppler duplex	8	Pulsed Doppler; individual S/D ratios	All S/D differences between twins >0.4  Five fetuses had absent/reversal of diastolic flow One recipient and 6 donors with abnormal Doppler	Variable findings unable to differentiate donor and recipient; poor outcome with abnormal Doppler
[31]	Pulsed Doppler	6	Pulsed Doppler; PI differences	Of 31 sets of twins, PI difference >0.5 in 7 cases; 6 of the 7 were associated with TTS	Of 12 infants with abnormal ratios, 5 suffered perinatal death
[76]	Pulsed Doppler; individual Doppler values	11	Pulsed Doppler; high-resolution US	Of 11 donor twins, 7 showed severe IUGR and elevated S/D ratios; 2 of recipient fetuses also showed abnormal values  Oligohydramnios in donor sac; hydramnios in recipient sac	Variable Doppler findings, but donor SGA fetuses more commonly had high S/D ratios than did recipient fetuses
[78]	Pulsed Doppler	4	Pulsed Doppler; PI in MCA, UA	UA increased resistance in 3, absent end-diastolic flow in 1 (recipient) MCA decreased resistance in 3 that could be measured (recipient) UA and MCA PI in donors were normal	Doppler velocimetry helps explain changes in fetal hemodynamics in TTS

and in all cases the A/B ratio differences were >0.4. Pretorius et al. [75] concluded that Doppler findings are commonly abnormal in the presence of TTS, differing with Giles et al. [24], and that the Doppler findings were variable, suggesting “an extremely complex dynamic physiologic state.”

Later, in 31 twin pregnancies, Doppler ultrasound findings were described for six pregnancies with TTS [31]. The PI was determined using pulsed-wave Doppler interrogation of the umbilical artery. Of the 31 twin pregnancies, 7 had intrapair differences for PI of >0.5; 6 of the 7 were associated with TTS.

Gaziano et al. [76] described 11 pregnancies with TTS from 101 multiple-gestation pregnancies using high-resolution real-time ultrasonography and a comprehensive assessment of the fetus that included detailed biometry and a fetal anatomic survey with amniotic fluid and placental assessment. Donor twins tended to be severely growth restricted, with 7 of the 11 showing elevated S/D ratios. Amniotic fluid tended to be decreased in the donor's sac and normal or increased in the recipient's sac. Normal S/D ratios were seen most frequently in the recipient fetus, although abnormal velocimetry was seen in two fetuses.

Other authors studying suspected TTS patients noted normal blood flow measurements in the umbilical artery of some fetuses [77]. They confirmed the observations that pathologic velocimetry patterns usually affect the smaller (donor) fetus.

In another study, four pairs of twins with TTS were described [78]. The three recipients for whom blood flow in the middle cerebral artery (MCA) could be measured had a decreased PI and each of the four recipients had abnormal umbilical artery waveforms (increased PI or absent end-diastolic flow). The middle cerebral and umbilical artery PIs were normal in the donors.

The heterogeneity of placental and clinical findings for, and the lack of strict criteria for, the diagnosis of TTS may explain some of the variability of findings reported for Doppler in TTS.

### Venous Waveforms

Umbilical venous blood flow sampling in twin pregnancies using fetal Doppler ultrasonography was described by Gerson et al. [26]. The sampling was normal in cases of discordant growth due to abnormal placentation but was abnormal in one fetus with TTS. Pretorius et al. [75] described a biphasic venous waveform in the umbilical vein at 29 weeks' gestation in a fetus with TTS who also had Doppler echocardiographic findings suggestive of tricuspid insufficiency. Abnormal umbilical venous flow has been seen in other cases of fetal hydrops and most likely reflects right-sided cardiac failure. Figures 20.6 and 20.7 illustrate a case of fetal hydrops in TTS with an abnormal venous waveform pattern and fetal abdominal ascites.

Findings of reversed flow in the inferior vena cava and reversed flow in the ductus venosus is suggestive of right heart failure in a larger recipient twin [78]. In addition, echocardiography may demonstrate mitral and tricuspid regurgitation in twins with ultrasound evidence of hydrops [78].

Doppler velocimetry may differentiate between twin pregnancies complicated by FGR and TTS. This distinction is important since the death of one fetus

Fig. 20.6. Zero diastolic flow and abnormal venous waveform in the recipient fetus with TTS

Fig. 20.7. Ascites in recipient twin from TTS

in TTS can be deleterious to the other, whereas death of an FGR fetus in a diamniotic dichorionic twin gestation poses less risk to the co-twin. Abnormal uterine artery Doppler values and brain sparing can be seen with both FGR and TTS [79]. Venous flow of the larger twin in TTS can be abnormal [79]. If FGR is due to poor placental function or chromosomal abnormality, venous flow in the larger twin is expected to be normal [79].

### Outcome in TTS Pregnancies

Absent or reversed flow in five of the eight fetuses with TTS was associated with perinatal death in each instance [75]. Doppler abnormality in the setting of TTS portends a poor outcome [75]. Gaziano et al. [76] also noted increased morbidity and mortality in TTS fetuses with abnormal velocimetry. The PI difference in twins was greater in those destined to develop fetal hydrops [31]. In another study of 23 sets of twins with TTS, the following factors independently predicted poor survival: absent or reversed end-dia-

stolic flow in the donor umbilical artery; abnormal pulsatility in the venous system of the recipient; and absence of an arterioarterial anastomosis [80].

Unbalanced arteriovenous shunting is probably the major pathophysiologic event in TTS, while the variety of potential vascular arrangements does not allow for uniformity of the fetal Doppler findings. In most cases the donor twin becomes progressively hypovolemic and sometimes, but not always, relatively anemic [57, 58]. The donor twin is not infrequently oliguric following delivery [76]. In the donor these events most likely result in increased umbilical vascular resistance, as reflected in an abnormal umbilical artery waveform. Because of the hypovolemia, urine output diminishes in the donor fetus, resulting in significant oligohydramnios. Mari et al. [81] found that the PI of the renal artery in the twin with oligohydramnios was higher than that in the renal artery of the twin with hydramnios. The hypervolemia in the larger twin results in right-sided cardiac failure, abnormal venous waveforms, and fetal hydrops. With increased urine output and possibly decreased fetal swallowing, hydramnios usually occurs in the recipient's sac [82]. Occasionally, the shunt reverses with high resistance, which is then reflected in the umbilical circulation of the larger (recipient) twin, with the smaller (donor) twin consequently developing hydrops. We have observed spontaneous reversal of these events, indicating the likely development of a compensatory anastomosis. Other authors have reported resolution of hydrops following the death of one of the twins [83].

The rigid neonatal standards (e.g., hemoglobin and birth-weight differences) for the diagnosis of TTS seem no longer tenable. Any number of weight and hemoglobin differences are possible (reflecting varied hemodynamic arrangements) in monochorionic twin pregnancies [84, 85].

Quintero et al. [86] proposed a staging system for TTS which considers a sequence of events in progressive TTS. A negative correlation was noted between survival of at least one fetus and stage and TTS was defined as polyhydramnios (maximum vertical pocket >8 cm) in the recipient and oligohydramnios (maximum vertical pocket of <2 cm) in the donor. All cases also had a single placenta, absent twin-peaks sign, and same-sex fetuses. The individual stages are as follows:

1. Stage I: polyhydramnios in the recipient, severe oligohydramnios in donor but visible bladder in the donor (BDT)
2. Stage II: polyhydramnios in the recipient, a stuck donor, BDT not visible, diastolic flow present in the umbilical artery and forward flow in the ductus venosus
3. Stage III: polyhydramnios and oligohydramnios, BDT not visible, critically abnormal Doppler (at

least one of absent or reverse end-diastolic flow in the umbilical artery, reverse flow in the ductus venosus, or pulsatile umbilical venous flow)

4. Stage IV: presence of ascites or frank hydrops (fluid collection in two or more cavities) in either donor or recipient
5. Stage V: demise of either fetus

In Quintero et al.'s report [86] on staging, a number of patients were treated with laser or umbilical cord ligation. Taylor et al. [87] applied this staging methodology on a population treated with serial amnioreduction, septostomy, and selective reduction alone or in combination. They found no significant influence of staging at presentation with survival in their conservatively treated group. Survival was significantly poorer where stage increased rather than decreased. These authors concluded that the Quintero et al. [86] staging system should be used with caution for determining prognosis at the time of diagnosis, but may be better suited for monitoring disease progression.

### Treatment

Options to improve prognosis in TTS include serial amnioreduction for hydramnios (Fig. 20.8), laser ablation of anastomoses between twins, septostomy, and selective feticide.

In a study of eight pregnancies with severe polyhydramnios secondary to TTS, uterine artery mean blood velocity, and volume of flow was significantly increased after amnioreduction [88]. The RI and PI in the same vessel were decreased after amnioreduction compared with Doppler values prior to the procedure, although the difference was not significant. Four of the eight RI measurements were >97.5th percentile of published reference for twins before the

**Fig. 20.8.** Massive hydramnios in recipient sac of a fetus with TTS

procedure compared with only one such measurement after amnioreduction.

Improvement in TTS has been reported after therapeutic amniocentesis [89]. At 22 weeks after several amniocenteses, the smaller twin developed signs of congestive heart failure and absent diastolic flow. Another amniocentesis was performed after which the hydrops resolved and the diastolic flow in the umbilical artery improved.

Doppler values in the MCA have been monitored in women undergoing therapeutic amnioreduction [90]. Pulsatility index of the MCA fell after amniocentesis in all fetuses, although there was no consistent trend in response of the umbilical artery PI. Fetal stress is expected to cause a reduction in PI of the MCA as a brain-sparing response. An acute fall in amniotic fluid pressure likely creates an effective hypovolemia to which the fetus responds with dilation of resistance vessels in the brain reflected as a decrease in cerebral artery PI. Close fetal monitoring is recommended to avoid acute changes in pressure during amnioreduction [90].

Long-term outcomes were reported in 33 women with TTS who underwent amnioreduction [91]. None of the infants (16 sets of twins) developed major neurological handicap if both twins met the following conditions: were delivered after 27 weeks; were without congenital malformations; and both twins survived the neonatal period. Eight sets of twins had at least one twin with absent end-diastolic flow in the umbilical artery before the first amnioreduction; all except one of these twins either died in utero or after birth.

Survival was reported [92] for 13 of 14 co-twins (93%) after selective reduction using bipolar diathermy of either the donor or recipient twin in pregnancies complicated by stage III/VI TTS as defined by the staging system of Quintero et al. [86]. Three donors and four recipients had absent or reversed end-diastolic flow in the umbilical artery prior to the procedure. In all those with absent end-diastolic flow before the procedure, positive end-diastolic flow was restored, in the majority of cases, within 24 h following selective reduction. None of the co-twins later developed absent end-diastolic flow.

Laser ablation of the connecting vessels in TTS is an appealing option in the management of the worse forms of TTS since it is the sole treatment modality which corrects one of the underlying pathophysiologic defects and has been demonstrated to be effective [6]. Randomized clinical trials are now underway to assess laser ablation. All treatment options are subject to failure since many cases of TTS are in pregnancies in which there is significant asymmetrical distribution of the placental mass (see placental symmetry) as well as the presence of abnormal cord insertions in the affected twins.

## Summary

Given the limited data from multiple relatively small studies and the causes of the fetal Doppler findings in TTS, the following list attempts to summarize current observations:

1. Twin transfusion syndrome is a complex pathophysiologic event for which there is no predictable pattern of vascular anastomosis and no uniform pattern of Doppler abnormality.
2. Differences in umbilical artery Doppler parameters are relatively common in twin pairs with TTS.
3. Abnormal umbilical artery velocimetry may be seen in either the donor or the recipient fetus, but it is more common in the growth-restricted donor fetus with oligohydramnios.
4. Abnormal umbilical venous flow may be seen in the circulation of the hydropic recipient fetus.
5. Abnormal velocimetry in TTS, particularly low diastolic velocities in the umbilical artery, is associated with a poor outcome and justifies the use of intensive surveillance.
6. Clinical criteria for TTS are difficult to define because of the individual and varying complexity of the vascular arrangements.
7. There may be a role for Doppler velocimetry in TTS staging, to determine the most appropriate treatment options, and to monitor disease progression.

## Doppler Velocimetry and Outcome in Twin Pregnancies

### *Third-Trimester Doppler Studies*

Velocimetry of the umbilical artery appears superior to that in the fetal ascending aorta, pulmonary artery, or internal carotid artery [93]. Singleton SGA infants with abnormal umbilical artery velocimetry have increased admission rates and prolonged courses in the neonatal intensive care unit (NICU) [51]. Fetuses with growth restriction and normal Doppler values have less morbidity than growth-restricted fetuses with abnormal values [94]. A variety of adverse events, including fetal distress, premature delivery, the presence of SGA, and low birth weight, are more common in Doppler-abnormal than in Doppler-normal fetuses [95].

The outcome of fetal growth restriction can be classified according to umbilical artery Doppler values [96], and the increased neonatal morbidity in SGA infants with abnormal antenatal umbilical artery Doppler findings has been repeatedly supported [97]. Abnormal resistance in the descending fetal aorta is associated with increased perinatal risk for death, necrotizing enterocolitis, and hemorrhage, whereas 75% of SGA infants with normal values had uncom-

plicated courses [52]. Gaziano et al. [98] demonstrated that preterm growth-restricted infants with abnormal umbilical artery Doppler studies were admitted to the NICU more frequently and remained twice as long as preterm growth-restricted infants with normal values. Finally, studies suggest that the perinatal mortality rate in pregnancies complicated by growth restriction and/or hypertension is higher in fetuses with reversed end-diastolic flow (33%–73%) or absent end-diastolic flow in the umbilical artery (9%–41%) [99–101]. These data in singletons support a role for fetal Doppler velocimetry as a predictor for adverse neonatal events. Although present outcome data are modest for multiple gestations and abnormal velocimetry, the initial information parallels that reported for singleton pregnancies.

Table 20.4 shows studies in twins that correlate abnormal Doppler studies with adverse outcome. In four fetuses from twin pregnancies with persistently absent end-diastolic velocities, three were born SGA, and one died in utero [30]. In seven fetuses the RI was normal early but later showed absent end-diastolic velocities; six of seven of these infants were subsequently born SGA.

Abnormal Doppler velocimetry in the fetal descending aorta and the umbilical artery are correlated with unsatisfactory outcomes including preterm delivery before 32 weeks, >500 g birth weight discrepancy, <10th percentile birth weight, and admission to an NICU [27]. Measures of the PI of the umbilical artery had a 50% sensitivity for adverse outcome prediction, while PI abnormality in the descending aorta showed a 44% sensitivity for unsatisfactory outcome.

Gaziano et al. [76] described outcomes relative to umbilical artery velocimetry in 207 fetuses from multiple-gestation pregnancies and noted 17 with an abnormal Doppler result; 15 of the 17 had adverse perinatal outcomes. Infants with abnormal waveforms delivered 3–4 weeks earlier and were more likely to have structural malformations (12% vs 1%), to be <1500 g at birth, to suffer intrauterine death, and to have lower 5-min Apgar scores than twins with normal antenatal waveforms. Most of the morbidity and mortality occurred in the Doppler-abnormal group, which accounted for 8% of this twin population.

Joern et al. [102] studied 130 women with multiple gestations and compared cardiotocography, sonography, and Doppler for prediction of intrauterine growth restriction and “pathological fetal outcome”; included in the latter were umbilical artery pH <7.20, 5-min Apgar <8, or NICU admission for primarily asphyxia and only secondarily prematurity. These authors correctly identified 63 of 81 neonates with birth weights below the 10th percentile (sensitivity 76%) and 47 of 76 children who would have a “pathological fetal outcome” using Doppler data (sensitivity

**Table 20.4** Fetal Doppler and adverse outcome among twin studies. *PI* pulsatility index

Reference	Vessel interrogated	Comment
[30]	Umbilical artery	Persistently absent end-diastolic velocities associated with poor outcome
[27]	Umbilical artery; descending fetal aorta	For unsatisfactory outcomes: PI of umbilical artery=50% sensitivity; abnormal PI of descending aorta=44% sensitivity
[76]	Umbilical artery	Abnormal waveforms in 8% of fetuses; 15 of 17 infants with abnormal waveforms showed significant morbidity; abnormal waveforms associated with earlier delivery (by 3 weeks), <1500 g birth weight, increased structural malformations and stillbirths
[102]	Umbilical artery, middle cerebral artery, descending aorta	Doppler better than biometry or cardiotocography at predicting growth restriction (76%) and “pathologic fetal outcome” (sensitivity 60%)
[103]	Umbilical artery	Increased risk of adverse outcome if abnormal PI

60%). Fetuses were said to have a pathological “total Doppler result” if any of the following were abnormal: fetal descending aorta; umbilical artery; or middle cerebral artery. Doppler sonography appeared superior to cardiotocography and ultrasound biometry in detection of acute and chronic placental insufficiency, although better for prediction of chronic placental insufficiency as manifested by growth restriction.

In another study of outcomes in 206 twin pregnancies [103], 32 of which had at least one twin with an abnormal umbilical artery PI, the group with abnormal Doppler values had an increased risk of FGR or preeclampsia, cesarean section for fetal distress, premature birth, small-for-gestational-age infant, umbilical artery pH  $\leq$ 7.15, neonatal intensive care unit admission and birth weight <500, 1000, and 1500 g.

Giles et al. [104] studied fetal Doppler velocimetry and twin pregnancy outcomes in 272 pregnancies. They reported a decrease in uncorrected perinatal mortality from 42.1/1000 to 8.9/1000, after the Dop-

pler result was made available to the referring obstetrician. The Doppler data was made available to the clinician at 28 weeks' gestation, allowing focused, and intensive surveillance for the pregnancies at risk.

Abnormal velocimetry in the umbilical artery reflects increased resistance to flow in the uteroplacental circulation. These changes most likely reflect longstanding compromise of the maternal-fetal gaseous and nutrient exchange, which corresponds to an alteration in fetal growth and a marked reduction in fetal reserves.

Questions remain relative to the morbidity issue. What is the frequency of normal velocimetry in the FGR fetus from a twin pregnancy, and is this finding prognostic? Are all growth-restricted neonates with normal umbilical artery Doppler findings constitutionally small, or are they growth-restricted but at low risk for adverse events? Can fetal vascular inter-rotation change the need for, or the frequency of, fetal surveillance?

### **Brain-Sparing Effect**

There is a relative increase in blood flow to the brain in the growth-restricted fetus which has been called the "brain-sparing effect." This event is more likely to be seen in the fetus with placental insufficiency and chronic asphyxial stress, manifested by increased resistance in the umbilical artery. Blood flow redistribution occurs when resistance in the cerebral circulation is less than the resistance in umbilical circulation. The cerebroplacental ratio (CPR) was first defined by Arbeille et al. in 1997 [105]. The CPR is equal to the cerebral resistance index (CRI) divided by the umbilical resistance index (URI). The CPR has been shown to be a more sensitive predictor for poor perinatal outcome in growth-restricted fetuses than either cerebral RI or placental RI alone [105].

The work of Gaziano et al. [106] suggests that CPR is also superior to the umbilical artery RI and middle cerebral RI in predicting adverse neonatal events in twins. Birth weight, total length of stay, and total length of stay in special care nursery correlated more closely with CPR than with umbilical artery resistance index or MCA resistance index. The CPR was also significantly lower in diamniotic monochorionic vs diamniotic dichorionic twins. Finally, among the Doppler variables, CPR showed the highest sensitivity for growth restriction (67%).

The predictive benefits of comparing velocity recordings in the cerebral and umbilical arterial systems has been substantiated in studies showing improved risk prediction using ratios of cerebral to umbilical PI. These studies were done on singletons at risk for intrauterine growth restriction or growth-restricted fetuses [107–109]. Akiyama et al. [110] evaluated altera-

tions in various fetal regional arterial PIs with increasing gestational age in appropriate for gestational-age singletons, twins, and triplets, and found no significant differences based on number of fetuses.

Gaziano et al. [111] used the ratio of the MCA and umbilical artery RIs to measure blood flow redistribution in 83 twin pairs. Brain sparing was seen significantly more frequently in growth-restricted ( $\leq 10$ th percentile) babies. Brain sparing was seen in 67% of growth-restricted babies and only 7% of non-growth-restricted babies. Diamniotic monochorionic twins from the lower birth weight group more often demonstrated blood flow redistribution compared with dizygotic twins of similar low birth weights. Placental vascular connections in diamniotic monochorionic pregnancies and the associated hemodynamic changes are likely responsible for the difference.

### **Second-Trimester Doppler Studies**

Can fetal Doppler measurements taken in the second trimester predict uteroplacental complications which might occur later in pregnancy? For multiples, many complications, such as growth restriction, are likely to occur at higher rates than in singletons.

Transvaginal uterine artery Doppler measurements were taken at 22–24 weeks' gestation in 351 twin pregnancies [112]. Using mean PI above the 95th percentile and bilateral notches, screening with Doppler data identified women destined to develop complications related to uteroplacental insufficiency. Pregnancies with a high mean PI and bilateral notches were particularly worrisome. Women with a high mean PI had a 10-fold increased risk of becoming preeclamptic, a 14-fold increased risk of having an abruptio placenta, and a 7-fold increased risk of having an intrauterine fetal demise.

The frequency of complications in women with normal uterine artery RIs is higher in twin compared with singleton pregnancies [113]. Twin compared with singleton nomograms yield a higher sensitivity for the occurrence of complications such as preeclampsia, growth restriction, and growth discordance of  $\geq 20\%$ . Still, the sensitivities for developing preeclampsia, fetal growth restriction, birth-weight discordance, and any adverse outcome using the twin nomograms were relatively low at 36%, 27%, 29%, and 27%, respectively.

Uterine artery Doppler nomograms are different in dichorionic twins compared with singletons [114]. Twins showed lower RIs at all gestational ages (18–40 weeks). For both twins and singletons, uterine artery RI decreased linearly with increasing gestational age. Abnormal Doppler values at 20–24 weeks demonstrated low predictive value for gestational hypertension and/or preeclampsia.

## Future Research

The value of Doppler velocimetry in twin and other pregnancy applications is questioned since this modality has yet to demonstrate an improvement in pregnancy outcome by prospective studies [115]. While this remains a challenge, those who apply Doppler studies to their at-risk patients appreciate its utility in improving diagnostic precision by allowing a greater understanding of pathophysiology, and permitting an insight into therapeutic interventions. As evidence supports the association of abnormal Doppler values with poor perinatal outcome, studies will focus on using Doppler velocimetry to alter treatment patterns in an effort to decrease perinatal morbidity and mortality.

Reverse end-diastolic umbilical artery flow can be seen as early as 11 weeks [116], while differences in fetal size and amniotic fluid volume may be appreciated at as early as 9 weeks of gestation [117]; thus, early ultrasound and continued improvements in amniotic fluid estimation in twin pregnancies will facilitate early diagnosis of twin disorders [118, 119].

Continued advances are expected detailing the pathophysiology of twin pregnancies. Doppler observations in the fetal circulation of discordant twins allow differentiation between growth discordance due to placental insufficiency and twin-to-twin transfusion [120]; for the latter, continued Doppler investigations into the venous side of the fetal circulation will clarify right-sided failure and cardiac function in affected fetuses [121, 122]. In addition, cordocentesis studies in monochorionic twins can assess the diagnostic value of serum erythropoietin, pancuronium bromide, and hematological and other biochemical studies in TTS [123–125].

Finally, Doppler sonography may play a role in the early identification of pregnancies at risk for TTS by color Doppler identification of communicating vessels. Less clear is color Doppler's role in supporting surgical approaches to this disorder by defining the location of these vessels. Furthermore, the inclusion of Doppler parameters into the evaluation of patients with TTS will prove useful in counseling patients, monitoring disease progression, and determining appropriate interventions. There is a need for randomized trials to determine the most effective treatments for TTS.

## Conclusion

Doppler velocimetry supplements ultrasound biometry in multiple pregnancies for detection of the growth-restricted fetus. Fetal Doppler abnormality may precede alterations in growth and allow early identification of the at-risk fetus [32]. Similarly, abnormal velocimetry

may precede other adverse events, such as the development of fetal hydrops [31] or the development of hypertensive disorders of pregnancy. Initial reports also suggest a role in predicting neonatal outcome. This technology adds to our understanding and knowledge of the complex hemodynamic changes in the TTS. Finally, Doppler velocimetry in multiple gestations serves as an important and accurate indicator of fetal vulnerability, allowing for appropriate surveillance and intervention for these at-risk pregnancies.

# Doppler Sonography in Pregnancies Complicated with Pregestational Diabetes Mellitus

Dev Maulik, Genevieve Sicuranza, Andrzej Lysikiewicz, Reinaldo Figueroa

## Introduction

During the past few decades, tremendous advances have been made in the medical and obstetrical management of pregnancies complicated with pregestational diabetes resulting in considerable improvements in maternal and perinatal outcomes [1]. Stringent periconceptional glycemic control and advances in fetal surveillance have significantly contributed to this improvement. The successful management of a pregestational diabetic mother requires timely and appropriate antepartum fetal surveillance which permits the pregnancy to progress while identifying the fetus who may be compromised and may benefit from delivery. Doppler velocimetry enables the investigation of fetal circulatory decompensation, and thus provides a noninvasive monitoring tool for assessing fetal well-being. There is considerable evidence affirming the efficacy of umbilical arterial Doppler sonography in predicting and improving adverse perinatal outcome in pregnancies with fetal growth restriction (FGR) and preeclampsia; however, the utility of Doppler fetal surveillance in managing uncomplicated pregnancies with pregestational diabetes remains controversial.

This chapter presents a review of the role of Doppler sonography in assessing the fetus of a pregestational diabetic mother and recommends a management plan based on the current evidence.

## Maternal Glycemic State and Fetal Hemodynamics

Fetal circulatory response to altered maternal glycemic state appears to be complex. This section briefly addresses this issue pertaining to both hyper- and hypoglycemia.

In an experimental model involving late gestation ewes, induction of acute maternal hyperglycemia produced a 27%–29% reduction in the placental share of the cardiac output which was redistributed to fetal carcass, heart, renal, adrenal, and splanchnic circulations [2]. Concordant with the changes in perfusion,

the fetuses also developed systemic hypoxemia and mixed acidemia during induced maternal hyperglycemia without any alterations in fetal cardiac, brain, and renal oxygenation. The response to hyperglycemic challenge, however, was different in the fetuses of ewes rendered diabetic by streptozocin administration [3]. The umbilical–placental blood flow did not change significantly in these fetuses but significantly declined in the controls, whereas fetal brain and renal perfusion was significantly higher in the former at all times than in the controls. The fetuses of the diabetic mothers were also more hypoxemic than the controls. Fetal hypoxemia induced by maternal hyperglycemia could be explained by the earlier observation that chronic fetal hyperglycemia is associated with accelerated fetal oxidative metabolism. In the latter study, chronic fetal hyperglycemia produced by fetal glucose infusion via chronic in utero catheterization led to an increase in calculated fetal  $O_2$  consumption by approximately 30% ( $p < 0.01$ ) [4]. The intensity of fetal hyperglycemia, and not the degree of fetal hyperinsulinemia, was the prime determinant of the magnitude of fetal  $O_2$  consumption which was associated with a significant increase in fetal  $O_2$  extraction with no alterations in either fetal  $O_2$  delivery or fetal blood  $O_2$  affinity.

The relationship between fetal hypoxemia and acidemia, and fetal and uterine hemodynamics, was investigated in a cross-sectional study involving women with well-controlled diabetes mellitus [5]. Of the 65 patients who had Doppler investigations performed, 41 had cordocentesis performed. The changes in the umbilical arterial Doppler indices correlated well with the changes in fetal pH (correlation coefficient  $-0.402$ ;  $p < 0.01$ ) and in  $pO_2$  (correlation coefficient  $-0.544$ ;  $p < 0.001$ ); however, this correlation was limited to the cases with FGR or preeclampsia as the Doppler findings were abnormal only in the presence of these complications. This finding is consistent with the known association between umbilical arterial abnormality and fetal growth restriction and preeclampsia. As the mothers' glycemic state was well controlled, this study did not address the issue of human fetal hemodynamic response to in utero hyperglycemia.

The effect of maternal hypoglycemia on fetal cardiovascular system has been investigated in an animal model and also in humans. Maternal hypoglycemia induced by infusion of insulin in a ewe model led to increased fetal plasma catecholamine and free fatty acid levels ( $p < 0.01$ ) [6]; however, no significant effects were noted on the fetal heart rate, blood pressure, or arterial blood gases. Moreover, fetal insulin and glucagon levels were also unaffected. The studies in pregnant diabetic mothers were experimental in design and involved the use of the insulin clamp method for inducing hypoglycemia. Moderate maternal hypoglycemia induced by the insulin clamp technique in ten insulin-dependent diabetic women in the third trimester was associated with no consistent changes in the umbilical arterial Doppler waveform. No significant alterations were observed in fetal breathing movements or the heart rate, although maternal epinephrine and growth hormone levels were significantly ( $p < 0.001$ ) increased [7]. In a similar study, the effect of hypoglycemia induced by hyperinsulinemic hypoglycemic clamp on the fetal heart rate and the umbilical artery flow velocity waveforms was investigated in a prospective experimental study in ten women with insulin-dependent diabetes mellitus in the third trimester of pregnancy. Maternal hypoglycemia led to increases in the frequency and amplitude of fetal heart rate accelerations and maternal catecholamine levels but only a slight decline in the pulsatility index of the umbilical artery [8].

In summary, the above experimental and clinical studies enhance our understanding of maternal diabetes-induced modifications in fetal circulatory homeostasis. Fetal response to hyperglycemic challenge is modulated by the chronic glycemic state and the intensity of the glycemic challenge. In the presence of maternal diabetes, the fetus increases its oxidative metabolism becoming more hypoxemic. Perfusion of the brain and kidneys increases without any significant changes in the fetoplacental perfusion and the Doppler velocimetry of the umbilical arteries remains unchanged unless FGR is also present. Cordocentesis data confirm that significant hypoxemia and acidemia in maternal diabetes mellitus may not be associated with Doppler-recognizable changes in fetal flow impedance unless the pregnancy is complicated with FGR or preeclampsia. Human and animal studies indicate that the fetal response to moderate maternal hypoglycemia is unremarkable and inconsistent.

## **Umbilical Artery Doppler Sonography in Diabetic Pregnancies**

This section reviews the role of Doppler ultrasound investigation of the umbilical artery in relation to ad-

verse perinatal outcome and also in relation to maternal glycemic state.

### **Umbilical Artery Doppler and Perinatal Outcome**

The efficacy of umbilical arterial Doppler indices for predicting adverse perinatal outcomes in high-risk pregnancies has been affirmed by numerous studies. Abnormally elevated umbilical arterial Doppler indices have been associated with low Apgar score, fetal distress (late and severe variable decelerations), absent variability, low fetal scalp and umbilical cord arterial pH, presence of thick meconium, and admission to the neonatal intensive care unit [9]. As presented in Chap. 25, an absent or reversed end-diastolic velocity in the umbilical arterial Doppler waveform is particularly ominous and is associated with markedly adverse perinatal outcome including a high perinatal mortality rate.

It remains somewhat controversial whether such diagnostic efficacy of Doppler sonography also encompasses pregnancies with diabetes. The studies in this area differ in several respects including the sample size, the Doppler parameter used and its threshold value, the measures of perinatal outcome, and prevalence of complications such as vasculopathy. Although there is no complete unanimity in the conclusions regarding efficacy, critical appraisal of these studies reveal that the controversy is mostly apparent. The relevant studies regarding adverse perinatal outcome are summarized in Table 21.1 and are selectively discussed below.

Bracero and associates [10] observed a significant correlation between elevated umbilical arterial S/D and adverse perinatal outcome including increased stillbirths and neonatal morbidity such as hypoglycemia and hyperbilirubinemia in a mixed population of class A and insulin-dependent diabetic mothers. In a more recent report, the same investigator noted that umbilical arterial SD ratio was superior to biophysical profile or nonstress test in predicting preterm labor (<37 weeks), FGR, hypoglycemia, hyperbilirubinemia, respiratory distress and cesarean for fetal distress (relative risk 2.6, 1.7, and 1.7, respectively;  $p < 0.001$ ).

Landon and colleagues [11] performed multiple umbilical arterial S/D measurements in 35 insulin-dependent diabetic women and observed significantly elevated mean second- and third-trimester S/D values in women with vasculopathy compared with women without the complication ( $4.34 \pm 0.7$  and  $3.2 \pm 0.65$  vs  $3.72 \pm 0.42$  and  $2.55 \pm 0.32$ , respectively;  $p < 0.03$ ). The elevated ratio preceded development of preeclampsia and fetal growth restriction.

Johnstone and associates [12] prospectively investigated the efficacy of the umbilical arterial resistance

**Table 21.1.** Diagnostic efficacy of umbilical arterial Doppler in diabetic pregnancy. *PPV* positive predictive value, *NPV* negative predictive value, *LR+* positive likelihood ratio, *LR-* negative likelihood ratio, *FGR* fetal growth restriction, *FD* fetal distress, *C/S* cesarean section. [5]	$\Delta$ PI		0.011, NS	

index in 128 pregnancies with uncomplicated diabetes mellitus. Abnormally elevated umbilical arterial RI significantly predicted nonassuring antepartum fetal heart rate tracing and/or a low biophysical profile score requiring immediate caesarean delivery; however, the RI was not predictive in four of seven pregnancies with fetal compromise which led the authors to caution against undue dependence on umbilical arterial RI in uncomplicated diabetic pregnancies.

In a patient population of 56 diabetic mothers including 14 with vasculopathy, Reece and associates [13] observed higher mean umbilical arterial indices in those with vasculopathy than those without vasculopathy or diabetes. Elevated Doppler indices were significantly associated with FGR and neonatal metabolic complications. This relationship between abnormal umbilical arterial Doppler indices, and the presence of maternal vasculopathic complication and various adverse perinatal outcomes has been corroborated by other investigators [14–17].

### Umbilical Arterial Doppler Sonography and Maternal Glycemic Control

In contrast to adverse outcome, the relationship between abnormal umbilical arterial Doppler indices

and the quality of glycemic control remains highly controversial. Bracero and associates [10] first noted a significant positive correlation between umbilical arterial S/D and mean serum glucose values ( $r=0.52$ ,  $p<0.001$ ). This finding however was refuted by Landon and associates [11] who found no significant correlation between mean third-trimester umbilical arterial S/D, and glycosylated hemoglobin ( $r=0.25$ ) or mean blood glucose levels ( $r=0.15$ ). This lack of correlation was corroborated by other investigators. These studies are summarized in Table 21.2.

In summary, most studies suggest significant diagnostic efficacy in diabetic pregnancies complicated by the presence of FGR or hypertension. It is noteworthy that these studies were heterogeneous regarding the outcome measures and the population size, and that the Doppler method demonstrated varying degrees of diagnostic efficacy. Moreover, the presence of normal Doppler may not always rule out fetal compromise. The ability of the umbilical artery Doppler indices to reflect maternal glycemic control remains controversial.

## Doppler Sonography of Other Fetal and the Uterine Circulations in Pregestational Diabetic Pregnancies

### Fetal Middle Cerebral Artery Doppler

There is insufficient information regarding the clinical value of Doppler investigation of the fetal cerebral circulation. In the neonate, Van Bel and associates found unaffected cerebral hemodynamics in the macrosomic infants of insulin-dependent diabetic mothers during the first 4 days of life even in the presence of ventricular septal hypertrophy with reduced cardiac output and stroke volume [18]. Salvesen and co-workers found no significant changes in the fetal circulation in a longitudinal Doppler study of 48 relatively well-controlled diabetic pregnancies except when complicated by preeclampsia or FGR [5]. The study included Doppler velocimetry of the middle cerebral artery. In a separate report, the authors

found normal Doppler results in the uterine and fetal circulations including the middle cerebral artery of most patients (five of six) with diabetic nephropathy despite the cordocentesis evidence of fetal acidemia within 24 h before delivery [19]. Ishimatsu and colleagues observed that the Doppler waveforms of the middle cerebral artery in 43 pregnant women with diabetes mellitus between 24 and 38 weeks of gestation were unaffected by maternal glycemic control [20].

### Fetal Cardiac Doppler

Rizzo and colleagues studied fetal cardiac function in 37 mothers with type-I diabetes [21, 22]. The ratio between the peak velocities during early passive ventricular filling and active atrial filling (E/A ratio) were measured at the level of mitral and tricuspid valves. The investigators demonstrated that the E/A ratios were significantly lower in fetuses of diabetic mothers than in control fetuses, and were significantly and independently affected by the interventricular wall thickness, heart rate, and hematocrit values. No significant alterations were observed in aortic and pulmonary peak velocities or in time-to-peak velocity values. The investigators also noted interventricular septal hypertrophy despite adequate glycemic control. This was corroborated by Miyake who observed significantly smaller E/A ratios of the left and right ventricles in later gestation in the fetuses of diabetic mothers than those in the controls [23].

Rizzo and associates also investigated the venous blood flow patterns in insulin-dependent diabetic mothers in early gestation, and observed higher values of percent reverse flow in inferior vena cava and a significantly higher frequency of umbilical venous pulsations at 12 weeks which lasted until 16 weeks [24]. These abnormalities were more pronounced in pregnancies with poorer glycemic control. In fetuses of well-controlled insulin-dependent diabetic mothers, Gandhi and co-workers demonstrated that the ratio of the right ventricular shortening fraction/left ventricular shortening fraction was significantly higher from that in the control group indicating increased right ventricular hypercontractility in late diabetic pregnancy [25].

The cardiac dysfunction apparently continues in the neonatal period as shown by Kozak-Barany and colleagues who investigated the left ventricular systolic and diastolic functions in term neonates of mothers with well-controlled pregestational and gestational diabetes between 2 and 5 days after birth [26]. Prolonged deceleration time of early left ventricular diastolic filling was observed. The authors speculated that this probably reflected an impaired left ventricular relaxation related to maternal hyperglycemia

leading to subsequent fetal hyperinsulinemia and cardiac hypertrophy.

### Uterine Artery Doppler

The efficacy of uterine artery Doppler for managing pregnancies with pregestational diabetes remains unproven despite initial enthusiasm.

Bracero and associates noted abnormal uterine artery velocity waveforms in 15.4% of 52 diabetic pregnancies compared with 2% in a nondiabetic population ( $p < 0.001$ ) [27]. Those with abnormal uterine Doppler had a higher occurrence of suboptimal glycemic control, chronic hypertension, polyhydramnios, vasculopathy, preeclampsia, cesarean delivery for fetal distress, and neonates with respiratory distress syndrome. In 37 pregnant patients with pregestational and gestational diabetes, uterine Doppler demonstrated a sensitivity of 44.5%, specificity of 100%, positive predictive value of 100%, and negative predictive value of 84.3% in predicting the later development of vascular complications [28].

Bracero and associates studied the association between uterine artery Doppler velocimetry discordance and perinatal outcome in 265 women with singleton pregnancies complicated by diabetes who underwent Doppler examinations within 1 week before delivery [29]. Adverse outcome was defined as stillbirth, intra-uterine growth restriction, delivery before 37 weeks' gestation, or cesarean delivery for fetal risk. Considerable overlap in discordance was present between the good and adverse outcome groups. The discordance between right and left uterine artery systolic-diastolic ratios was significantly higher in pregnancies with adverse outcome ( $p = 0.018$ ). The uterine artery S/D ratio differences of 0.60 or greater was predictive of cesarean delivery for fetal risk. In diabetic women with chronic hypertension the discordance was not predictive of adverse outcome.

Grunewald and associates noted the absence of the normal third trimester decline in uteroplacental pulsatility indices in 24 well-controlled insulin-dependent pregestational diabetics [30]. The pulsatility index was not influenced by glycemic control. Barth and co-workers investigated the uterine arcuate artery Doppler and decidual microvascular pathology in 47 gravidas with type-I diabetes mellitus [31]. Significant correlation was noted between the abnormal Doppler indices from the uterine arcuate arteries and decidual microvascular pathology including fibrinoid necrosis, atherosclerosis, and thrombosis ( $p < 0.05$ ).

In contrast to the above findings, other studies failed to confirm any predictive utility of the uterine Doppler velocimetry in pregnancies complicated with diabetes. Kofinas and associates observed that in gravidas with gestational ( $n = 31$ ) and insulin-depen-

dent ( $n=34$ ) diabetes mellitus, the umbilical and uterine artery flow velocity waveforms could not differentiate between good and poor glycemic control, although it discriminated the patients with preeclampsia from those without preeclampsia [32]. The investigators concluded that the clinical utility of Doppler waveform analysis in diabetic pregnancies might be limited to only those with preeclampsia.

In a cross-sectional study of 65 well-controlled diabetic pregnancies, Salvesen and co-investigators found that the Doppler indices of the placental and fetal circulations were essentially normal, except when complicated by preeclampsia or FGR [5]. In a study involving 43 pregnancies with insulin-dependent diabetes mellitus, Zimmermann and colleagues reported that long- and short-term glycemic control were unrelated to vascular resistance in the uterine artery, although the latter was higher in the presence of vasculopathy; however, more than half of the diabetics without vasculopathic complications showed a persistent notch in the uterine artery Doppler waveforms. Furthermore, uterine artery Doppler velocimetry did not demonstrate efficacy in predicting diabetes-related adverse fetal outcome [33].

In summary, the Doppler sonographic investigations of fetal central and cerebral circulations, and the maternal uterine circulation have yielded information of varying degrees of importance on maternal and fetal hemodynamic changes in pregnancies complicated with pregestational diabetes; however, there is no evidence that they are clinically useful in managing these pregnancies.

## Clinical Effectiveness and Guidelines

As discussed in Chap. 30, the clinical effectiveness of umbilical Doppler velocimetry has been demonstrated in high-risk pregnancies by randomized clinical trials. But no such level of evidence exists for other biophysical tests of fetal well-being, which still constitute a critical component of the antepartum management of these pregnancies, and most often include the nonstress test (NST) and the biophysical profile (BPP). These tests are usually initiated at 32 weeks and performed twice a week. Daily fetal movement count is also used as an adjunct screening test. There are no randomized trials dealing exclusively with the clinical effectiveness of Doppler fetal surveillance in pregnancies complicated with pregestational diabetes mellitus; however, in a randomized trial recently reported by Williams and colleagues, umbilical artery Doppler was compared with NST as a test for fetal well-being in a population of 1,360 high-risk gravidas 11% of whom had diabetes mellitus [34]. The Doppler group had a significantly lower

cesarean delivery rate for fetal distress than the NST group (4.6% vs 8.7%, respectively;  $p<0.006$ ). The greatest effect was observed in pregnancies with hypertension and suspected FGR suggesting diabetic pregnancies with these complications may benefit from the use of Doppler velocimetry of the umbilical artery.

In utilizing the Doppler results, the clinical practice guidelines derived from the available evidence are also applicable to managing selected pregnant patients with pregestational diabetes. These guidelines are summarized here. It is emphasized that the overall obstetrical management in pregestational diabetes in pregnancy depends on multiple factors which include the severity of diabetes, adequacy of glycemic control, presence of vasculopathic complications, gestational age, assurance of fetal well-being, and past obstetrical history.

In diabetic pregnancies with FGR or preeclampsia, umbilical artery Doppler sonography should be added to the current standards of practice for fetal surveillance involving the NST and the BPP. If the Doppler index remains within the normal limits or is not progressively rising, weekly Doppler tests should continue. A high or increasing S/D ratio warrants more intense fetal surveillance consisting of umbilical Doppler ultrasound twice a week or more along with NST and BPP. If absent end-diastolic flow velocity (AEDV) develops, the likelihood of poor perinatal outcome is high and urgent clinical response is indicated. At or near term, the development of AEDV should prompt immediate consideration for delivery. Cesarean delivery may be preferable in the presence of reversed end-diastolic velocity or other ominous fetal monitoring findings (nonreactive NST, poor FHR baseline variability, persistent late decelerations, oligohydramnios, and BPP score  $<4$ ). In preterm pregnancies, further assurance of fetal well-being is sought by daily surveillance with umbilical Doppler, NST, and BPP. Determination of fetal lung maturity may also assist in timing the delivery in this circumstance. In preterm pregnancies, considerations should also be given to steroid administration along with the modification of glycemic management as needed. Delivery is indicated when a single or a combination of the fetal tests indicate imminent fetal danger irrespective of lung maturity or when fetal risk from a hostile intrauterine environment is judged to be greater than that from pulmonary immaturity in a given neonatal service.

Current concepts and controversies on the general management of diabetic pregnancies and also on fetal surveillance may also be found elsewhere [35–37].

## Conclusion

Antepartum fetal surveillance constitutes an essential component of the standards of care in managing pregnancies complicated with pregestational diabetes mellitus. Fetal hyperglycemia is associated with increased oxidative metabolism, hypoxemia, and increased brain and renal perfusion without any significant changes in fetoplacental perfusion. Moreover, the relationship between abnormal umbilical arterial Doppler indices and the quality of glycemic control remains unproven; however, observational studies suggest significant diagnostic efficacy of the umbilical arterial Doppler method in diabetic pregnancies complicated with FGR or hypertension. Although there are no randomized trials specifically addressing this issue, existing evidence suggests that Doppler velocimetry of the umbilical artery may be beneficial for antepartum fetal surveillance in diabetic pregnancies in the presence of these complications. Such utilization should be integrated with the existing standards of practice.

# Doppler Velocimetry in Maternal Alloimmunization

Andrzej Lysikiewicz

Obstetrical management of isoimmunized pregnancy is determined by the severity of fetal anemia. Early and accurate diagnosis of anemia makes safe and effective clinical management. In fetal Rh disease, fetal anemia leads to cardiovascular changes in blood flow through the major fetal vessels, detectable by Doppler velocimetry. Diagnosis by Doppler velocimetry is particularly attractive since examination can be quick, safe, and cost-effective.

## Doppler Velocimetry as the Preferred Diagnostic Tool

The most accurate assessment of fetal anemia is by direct fetal blood examination obtained by cordocentesis; however, it is also the most invasive diagnostic method with substantial maternal morbidity and fetal mortality reported at 1%–2.7% [1, 2]. Even when no immediate fetal mortality results, lesser complications of the procedure have the potential for delayed fetal adverse effect; therefore, this diagnostic method is used if no safer alternative exists and only when fetal health and survival are in question. Those limitations, however, make clinical diagnosis of fetal anemia less available to the clinician.

Another common diagnostic procedure, amniocentesis, which has become the standard for diagnosis [3] is also not without risks and is less accurate than cordocentesis [4]. These risks have long been recognized and various management schemes have been suggested [5] to minimize maternal/fetal exposure in diagnosis. No management proposals, however, eliminate procedure-related risks completely unless invasive procedures can be avoided. Doppler velocimetry measurements are noninvasive and could be superior in terms of safety, patient comfort, and cost.

The natural disease process in alloimmunization leads to increased dynamics of fetal circulation, well suited for Doppler studies. The need for cordocentesis for presumed fetal anemia initially provided an opportunity to compare fetal Doppler velocimetry before and after the procedure with actual fetal blood hemoglobin values. Such studies have, however, the

disadvantage of cross-sectional data that may not be representative to the extent of prospective longitudinal observations [6]. Prospective longitudinal studies avoid this limitation [7, 8].

## Maternal Alloimmunization and Fetal Disease

Most maternal alloimmunizations occur due to the presence of D antigen Rh blood group system incompatibility, but other fetal antigens will also result in alloimmunization if they are absent in the mother [9]. The clinical picture varies in those cases when fetal anemia is inconsistent with the antibody concentrations as correlated in Rh disease. There is no evidence, however, that fetal blood velocities are related to any other factors than fetal anemia, and no specific findings of Doppler velocimetry have been reported in alloimmunizations of different antigens.

## Fetal Pathophysiology in Alloimmunization

### Fetal Anemia

Destruction of fetal red cells by maternal antibodies in the reticulo-endothelial system is the mechanism of fetal Rh disease [9]. Erythrocyte destruction is initially well compensated by fetal intramedullary hematopoiesis. This process increases with increased maternal antibody production leading to increased fetal red cell turnover. As more immature cells are released into the fetal circulation, their maturation decreases. Eventually, medullary fetal red cell production is complemented by erythropoiesis in the liver and the spleen [10]. Initially this process compensates for red cell destruction with little or no fetal anemia; however, in time, this fetal reserve becomes exhausted and fetal anemia results.

Increased red cell production in the fetal liver is associated with increased hematopoietic cellular mass that affects liver portal circulation, producing portal hypertension, and compromising fetal liver function

[11]. Hypoproteinemia that develops from impaired protein synthesis in the liver contributes to development of fetal hypervolemia and hydrops. Fetal hydrops can present as a spectrum of ultrasonographic findings, from a mild form with little fetal circulatory overload to an end-stage disease, involving all major systems that, with no intervention, will progress to fetal death. Development of fetal hydrops is associated with significantly increased fetal loss even if intervention with fetal intravascular transfusion is attempted [12].

The fetus appears to be resistant to decreased oxygen-carrying capacity in fetal anemia as there is little of fetal hypoxemia in anemic fetuses [13]. Increased dynamic of fetal circulation compensates well initially for the decreased fetal erythrocyte mass, maintaining adequate oxygenation. Fetal hypoxia develops relatively late in the process as fetal hemoglobin oxygen-carrying capacity is efficient even at low concentrations.

### **Fetal Cardiovascular Changes in Alloimmunization**

A substantial amount of information has been collected about fetal circulation during the course of alloimmunization. Fetal anemia consists of reduced red cell mass/cc and "thinning" of the fetal blood. Significant fetal anemia has been reported as 5 g/dl below the mean hemoglobin concentration for gestational age, since at this level risk for development of fetal hydrops increases [14]. Lower fetal hemoglobin levels reduce oxygen-carrying capacity that could eventually lead to fetal hypoxia. Hypoxia is, however, not observed until late in the process, presumably due to increased 2,3-diphosphoglycerate concentration and increased cardiac output that maintain adequate tissue oxygen delivery [15]. At this level, anemia leads to reduction of fetal blood viscosity that is further multiplied by decreased fetal plasma protein production in the fetal liver. The compensatory increase of cardiac output and faster blood circulation, a combination described as the fetal hyperdynamic state [16], prevents development of hypoxia and acidosis early in the process.

Increase of the fetal blood flow velocities is not equally consistent in all vessels. Selective redistribution of the blood flow, similar to those of chronic hypoxic growth restriction, has not been confirmed [16]. With terminal hydrops, however, hypoxia is likely and some redistribution of the fetal blood flow may be expected. In early fetal anemia, however, the selection of the most representative vessels reflecting the fetal condition is important to obtain pertinent measurements [17].

### **Cardiac Blood Flow**

In early fetal Rh disease, in the absence of fetal hydrops, there are no indications that fetal anemia of less than 5 g/dl of hemoglobin deficit from the mean hemoglobin concentration expected for gestational age value affects fetal cardiac functions.

At the end stage of alloimmunization generalized fetal hydrops develops. Decreased serum oncotic pressure owing to reduced liver albumin production, umbilical venous and portal hypertension, hypoxic endothelial damage, and congestive heart failure are postulated as mechanisms of hydrops, with congestive heart failure being infrequent. Hecher et al. [15] examined fetal flow-velocity waveforms from the atrioventricular valves, ductus venosus, right hepatic vein, inferior vena cava, middle cerebral artery (MCA), and descending thoracic aorta with concurrent cordocentesis in 38 fetuses with red blood cell isoimmunized pregnancies. Increased blood flow velocities in the thoracic aorta, MCA, and the ductus venosus were consistent with hyperdynamic state. In this study, increased velocity in the thoracic aorta was associated with fetal anemia as in other previous reports [18, 19]. The authors did not notice major changes in the venous blood flow. They concluded that congestive heart failure is not a major factor in development of fetal hydrops and that it happens late in the process, if at all.

### **Fetal Heart Rate**

Fetal hypoxia is often a concern in anemic fetuses in alloimmunization because of presumed reduced oxygen-carrying capacity. Hypoxic fetal response can be expected to involve compensatory tachycardia and redistribution of the fetal blood flow similar to chronic hypoxia in intrauterine growth restriction; however, several studies have shown that the correlation between fetal anemia and fetal acid base is inconsistent [13, 20]. Fetal hypoxia does not appear until late in the process and fetal hemoglobin, even if diluted, can carry a sufficient amount of oxygen. Fetal tachycardia that may be observed is more likely to result from the fetal hyperdynamic state [16]; therefore, only in the very late stage of fetal disease in alloimmunization, reduced oxygen-carrying capacity will lead to hypoxia and fetal tachycardia. With fetal tachycardia a higher end-diastolic flow can be recorded with shortened diastole period. This represents a nonspecific finding related to tachycardia itself.

### **Sinusoidal Fetal Heart Rate**

Abnormal cardiac rhythm characteristic for fetal anemia is a sinusoidal rhythm (Fig. 22.1). It has been observed in severely anemic fetuses, regardless of the

**Fig. 22.1.** Sinusoidal fetal heart rate pattern

cause of fetal anemia. Intermittent, low-frequency 3- to 5-Hz sinusoidal variations of the fetal heart rate are more likely a result of stressed cardiac neuroregulation than actual changes in fetal blood flow [21, 22].

The inability of the medullary centers to control the fetal heart rate results in a sinusoidal heart rate pattern. Observations of fetal heart rate in severe anemia, fetal brain maldevelopment, cytomegalovirus infection and during alfaprodine or pancuronium bromide administration as reported by various authors appear to confirm this mechanism [23, 24].

In the absence of significant hypoxia a mechanism of sinusoidal heart rate pattern is not well understood. It is likely that more than one compensatory mechanism is involved in such a severely affected fetus. Decreased fetal blood viscosity, increased blood volume, increased preload, baroreceptor, and volume receptor stimulation all affect fetal heart rate. Hecher et al. [15] reported increased fetal blood viscosity after fetal intravascular transfusion that occurred only in whole blood but not in serum, suggesting that it is increased erythrocyte mass that leads to increased blood viscosity. In anemic fetuses the cumulative effects of increased blood volume and decreased blood viscosity may lead to increased venous blood return and increased preload as reflected by the preload index in inferior vena cava velocimetry.

No systematic studies of Doppler velocimetry during sinusoidal rhythm have been reported. In our one case fetal Doppler velocimetry in umbilical artery, descending aorta, MCA, and inferior vena cava were recorded. The elevation of “a” wave in the inferior vena cava was noted, and fetal anemia was confirmed by cordocentesis. Subsequently, sinusoidal rhythm was relieved by fetal intravascular transfusion with the return of the inferior vena cava Doppler waveform to normal values shortly after transfusion. Association of abnormal Doppler velocimetry with a sinu-

soidal heart rate pattern has not been definite and needs more observations; however, the presence of fetal sinusoidal rhythm has been reported consistently as an ominous sign and an emergency requiring prompt diagnosis and treatment [21].

## Changes in Fetal Systemic Arterial Blood Flow

### Doppler Flow Velocity Measurements

Fetal blood flow velocity is the parameter that can be adequately measured, provided that the angle of insonation is known and laminar blood flow is taken into consideration [25]. Accuracy of these measurements depends on the angle of insonation,  $<60^\circ$  being acceptable [26]. Volumetric flow measurements are also possible but require accurate data on the size of the vessel that are not easy to obtain. With current technology, they are not of practical use in fetal Rh disease.

According to the law of physics, low viscosity “thinned” fetal blood in anemia flows faster in fetal blood vessels [16]. With unchanged peripheral resistance that translates into increased systolic and diastolic velocities. A similar increase in both systolic and diastolic blood flow velocities may be an explanation for generally unchanged S/D ratios and other indices in fetal arterial circulation. An increase in blood flow velocity does occur and to measure this change in flow the maximum velocity (or “peak velocity”) may be a more appropriate measurement [17]. This single measurement of absolute velocity at its maximum peak is angle dependent and as such requires consistency in the technique of measurements. In extreme conditions, in a terminally ill fetus, additional factors (hypoxia, neural regulation) may be affecting blood flow distribution and blood flow velocity in specific vessels, but it is not observed in mild to moderate anemia.

### Fetal Aortic Arch

Increased fetal blood flow velocity in the aortic arch can be expected in anemic fetuses consistent with increased blood flow velocity in the fetal descending aorta but specific studies are lacking. The standard measurements have not been established for this complex blood flow velocity pattern that varies according to changing physiologic conditions [26].

### Fetal Descending Aorta

An example of blood flow velocity measured in the fetal aorta in an anemic fetus is presented in Fig. 22.2.

**Fig. 22.2.** Fetal descending aorta Doppler velocity in the anemic fetus

Blood flow mean velocity measured in the fetal descending aorta was inversely correlated with fetal hematocrit [27, 28]. Rightmire et al. [27] compared the fetal umbilical artery Pourcelot index with fetal hematocrit and a numerical correlation allowed for retrospective development of a formula predicting fetal hematocrit. Prospective clinical confirmation of the accuracy of this method has not been published. A similar study by Copel et al. [29] led to development of formulas that had limited accuracy for predicting fetal hematocrit when based on fetal descending aorta Doppler velocities alone.

Descending aorta Doppler velocities were again studied by Nicolaidis et al. [17] and the conclusion of this group did not support use of fetal descending aorta Doppler velocities for prediction of fetal hematocrit. A correlation with fetal hematocrit was shown only when descending aorta velocimetry data was analyzed in relation to gestational age [30]. The authors concluded that the correlation, although statistically significant, has no sufficient predictive value for clinical application.

### Splenic Artery

The splenic artery, a branch of the celiac axis, can be identified with color Doppler and, within its straight segment, a Doppler velocity measurement can be carried out. If done at an insonation angle of close to  $0^\circ$ , a high accuracy of such a measurement can be expected [30, 31].

According to this study, the deceleration angle of Doppler waveform correlates well ( $r=0.68$ ) with fetal hemoglobin deficit (mean expected for gestational age minus actual hemoglobin). Also splenic artery mean velocity is a good predictor of fetal anemia, with sensitivity approaching 100%. Although the authors re-

ported success in obtaining satisfactory blood flow waveforms in 95% of patients, the procedure is highly specialized, which limits its application.

### Renal Arteries

Limited information exists on blood flow in renal arteries in Rh disease. Mari et al. [32] indicates improvement in the pulsatility index before fetal intravascular blood transfusion in anemic fetuses and return of absent end-diastolic flow after transfusion. The authors attribute these findings to fetal increase in renal flow to eliminate excess fluid after transfusion. Diagnostic applications of renal artery velocity measurements in fetal anemia have not been established.

### Umbilical Arteries

No significant correlation has been found between umbilical artery S/D ratio, pulsatility index, or resistance index and fetal anemia [33, 34]. Perhaps steady placental resistance and consistent umbilical vessel diameter does not alter systolic/diastolic flow ratio even with increased flow of both.

Doppler velocimetry of the fetal umbilical artery reflects fetal placental resistance. There is no evidence that placental vascular resistance is affected by maternal alloimmunization; hence, no changes in umbilical artery indices should be expected.

### Internal Carotid Artery

A significant association between the degree of fetal anemia and the increase in mean velocity in the fetal common carotid artery has been reported by Bilardo et al. [34]. In their series of 12 fetuses with primary anemia (previously untransfused) measurements were made immediately before cordocentesis. They suggested that increased fetal cardiac output associated with fetal anemia is an underlying mechanism and not the redistribution in blood flow that occurs in chronic hypoxia in growth-restricted fetuses.

### Middle Cerebral Artery

Middle cerebral artery peak blood flow velocity can be visualized on an axial view of the cranium (Fig. 22.3).

Significant and consistent increase of peak flow velocity in the MCA was seen in anemic fetuses when measured at the bifurcation from the circle of Willis and at an angle of insonation of  $<30^\circ$  [35]. This finding was reported in several other studies [16, 36, 37], including a multicenter clinical trial [7], and was linearly correlated with the degree of fetal anemia (Fig. 22.4) [16].

Fig. 22.3. Middle cerebral artery peak velocity

Fig. 22.4. Fetal middle cerebral artery peak velocity in anemic and nonanemic fetuses. *Open circles* indicate fetuses with either no anemia or mild anemia [0.65 multiples of the median (MoM) hemoglobin concentration]. *Triangles* indicate fetuses with moderate or severe anemia (<0.65 MoM hemoglobin concentration). The *solid circles* indicate the fetuses with hydrops. The *solid curve* indicates the median peak systolic velocity in the middle cerebral artery and the *dotted curve* indicates 1.5 MoM. (From [16])

The accuracy of Doppler diagnosis of fetal anemia varies depending on previous history of fetal blood transfusions. In anemic, previously untransfused, nonhydropic fetuses, MCA peak velocity correlates well with fetal hemoglobin level obtained at cordocentesis [36]. When there is a history of a previous transfusion given to the fetus, the correlation is not as strong [37]. These cross-sectional studies have also been confirmed recently by observational data of fetal MCA peak velocity in a longitudinal study of fetal blood flow in alloimmunization reported by Zimmerman [7].

In this multicenter study, 125 fetuses at risk of anemia were longitudinally monitored in 7- to 14-day intervals for abnormal velocimetry or signs of hy-

drops. Cordocentesis or delivery was performed if signs of fetal anemia were detected. Sensitivity of 88%, specificity of 87%, positive predictive value of 53%, and negative predictive value of 98% was achieved. The method was not effective after 35 weeks. The authors' recommendation of this method as primary fetal surveillance in alloimmunization appears well founded and may reduce the need for invasive diagnosis.

Middle cerebral artery peak velocity was compared with other sonographic methods for diagnosis of fetal anemia. In 16 fetuses with isoimmunization, Doppler evaluation of MCA peak systolic velocity was a better predictor than intrahepatic umbilical maximum velocity, liver length, or spleen perimeter [39].

**Fig. 22.5.** Fetal preload index and fetal hematocrit at cordocentesis

### Changes in Fetal Venous Blood Flow

High arterial fetal blood flow velocity and increased tissue perfusion in the fetal hyperdynamic cardiovascular state is followed by a blood volume shift from arterial to venous circulation resulting from decreased blood viscosity [40]. The resulting high venous return may lead to right heart overload and right heart failure that can be detectable by Doppler velocimetry [41]; therefore, fetal venous flow has been extensively studied as an indicator of fetal condition in alloimmunization.

#### Umbilical Vein

An early study by Jouppila reported an inverse correlation between umbilical venous flow and fetal hemoglobin at birth within 4 days from delivery [42]. It was later confirmed by Warren et al. [40] and Iskaros et al. [6] who noted increased venous blood flow in the umbilical vein associated with development of fetal hydrops. Dukkler et al. [39] attempted to correlate intrahepatic umbilical venous maximum velocity and MCA peak velocity with fetal anemia in six fetuses with alloimmunization. They found that in prediction of fetal anemia, the MCA was 100% specific, while intrahepatic umbilical venous blood flow had specificity of 83%.

#### Inferior Vena Cava Blood Flow

Inferior vena cava blood flow has been described as the A/S index or the atrial flow velocity to atrial regurgitation velocity ratio (Fig. 22.5) [41]. This index

**Fig. 22.6.** Inferior vena cava A/S ratio

is a sensitive indicator of the right cardiac function, especially fetal right heart failure.

In fetal hyperdynamic circulation in anemic fetuses with isoimmunization, an increased venous return could lead to right heart failure. Studies of inferior vena cava blood flow do not, however, support this assumption. In an early study by Rightmire et al. [27] inferior vena cava average velocity was elevated prior to the first blood transfusion in anemic fetuses, but the correlation with fetal hematocrit was not significant. In our own series, 20 fetal preload index measurements were followed by fetal hematocrit evaluations by immediate cordocentesis in 13 fetuses in alloimmunized pregnancies (Fig. 22.6) [43]. An asso-

ciation with low fetal hematocrit was weak with 66% sensitivity, 75% specificity, 50% positive predictive value, and 86% negative predictive value.

Diagnostic use of the preload index is further limited by the difficulty in obtaining consistent measurements from a specific site [44].

### Ductus Venosus

The ductus venosus in anemic fetuses demonstrates higher flow, reflecting increased venous return, and cardiac preload. Oepkes found the ductus venosus elevated in anemic fetuses with marked improvement following fetal transfusion [37]. A study by Hecher did not, however, show any significant association with fetal anemia sufficient for use as a diagnostic tool [15].

### Maternal Uterine Artery

The pulsatility index of the uterine arteries and thoracic aorta peak velocity were used in a multiple regression model to predict fetal hematocrit following fetal transfusion on the assumption that resolving placental edema after transfusion improves uteroplacental circulation. The uterine artery pulsatility index alone has not been found to change in fetal anemia.

### Fetal Morphologic Changes and Doppler Velocimetry in Alloimmunization

Fetal cardiovascular changes reflected in Doppler velocimetry precede development of fetal hydrops. During development of anemia in alloimmunization fetal hydrops develops gradually and relatively late in the process. Fetal signs of hydrops appear infrequently if the fetal hemoglobin level is within 5 g of the median value for gestational age. With more severe anemia fetal hydrops appears, often gradually, over a period of days. The following conditions are observed:

1. Increased amniotic fluid volume
2. Increase in placental thickness
3. Fetal liver enlargement
4. Fetal pericardial effusions
5. Ascites
6. Free loops of bowel in ascites
7. Double-walled bladder
8. Scalp edema ("halo")
9. Facial swellings
10. Pleural effusions
11. Extremities edema
12. Umbilical cord pulsation

Moderate increase in amniotic fluid volume enhances the resolution of ultrasound imaging and often facilitates detection of even small amounts of fluid in fetal body cavities. Findings of fluid in any fetal compartment in isoimmunized pregnancy should prompt a complete fetal morphology review for signs of fetal hydrops. Polyhydramnios in alloimmunization may reach a significant degree that is detrimental to the clarity of the imaging. Preterm labor, that often follows, can make fetal examination even more difficult. Polyhydramnios will frequently regress with correction of fetal anemia.

Placental thickness also increases as part of the process of isoimmunization; however, it is not a reliable indicator of fetal anemia [45].

Liver enlargement is often seen during fetal anemia in alloimmunization as a result of increased fetal extramedullary erythropoiesis [46]. This increased liver size is associated with increased venous Doppler blood flow velocity in fetal intrahepatic venous flow as reported by Oepkes et al. [37]. Although it was postulated by Vintzileos to be a good indicator of fetal compromise [47], it was not as accurate as evaluation with MCA peak velocity measurements [39].

A certain amount of fluid is not unusual in the pericardium. When measured at the valvular level, 2 mm of fluid is often found and is not abnormal. This small fluid collection is not associated with abnormal Doppler velocimetry; however, large pericardial effusions are one of the signs of fetal hydrops and indicates fetal anemia.

Ascites are defined as sonolucent areas in the fetal abdomen with loops of bowel visible, floating in the ascites and the fetal bladder visible with fluid inside and outside the bladder wall (Fig. 22.7). The presence of ascites is commonly associated with fetal anemia and abnormal Doppler velocimetry of the MCA and other vessels. Pleural effusions when present in hydrops fetalis suggest advanced disease.

Fig. 22.7. Fetal ascites

Scalp edema and generalized edema are nonspecific changes that may not be related to fetal anemia and changes of Doppler velocimetry.

In summary, it appears that fetal hydropic changes occur as a result of severe fetal anemia. They should not be used as predictors of fetal disease because of their poor predictive value [11, 45]. Abnormal Doppler velocimetry detects changes in fetal circulation that precede fetal hydrops and therefore can detect fetal anemia early. According to data by Mari et al. [35] early detection of fetal anemia is feasible using fetal cardiovascular monitoring with Doppler velocimetry.

A finding of severe fetal hydrops in isoimmunization should be considered as evidence of advanced fetal disease but may be avoidable with intensive fetal diagnosis and active clinical management.

## Fetal Blood Redistribution and Fetal Hypoxia in Alloimmunization

Fetal blood redistribution in chronic fetal hypoxia has been reported in growth-restricted fetuses. With decreased oxygen-carrying capacity in fetal anemia, similar findings could be expected due to presumed fetal hypoxia. Initial response to fetal hypoxia is an increase in fetal heart rate [21]. In alloimmunization, however, this heart rate increase may more likely be related to the blood volume increase and blood viscosity decrease resulting in increased fetal circulation [16]. Contrary to expectations, fetal hypoxia is not common in isoimmunized fetuses. Fetal hemoglobin, even if diluted, is able to transport oxygen without developing significant fetal hypoxia [48]. There is no evidence that fetal blood redistribution plays a significant role in fetal cardiovascular changes in isoimmunization [16].

## Doppler Velocimetry in Clinical Management of Alloimmunization

Fetal anemia determines the management of alloimmunization.

Use of specific Doppler velocimetry measurements requires a selective, evidence-based approach in choice of measurements. Multiple Doppler-detectable changes of the fetal circulation do not have equal diagnostic value. Methods not adequately studied should only be used with caution, if at all, for diagnostic purposes as those findings often prompt major therapeutic interventions.

The standard of care in alloimmunization has been changing rapidly. The traditional biochemical monitoring is being supplemented by fetal Doppler velocimetry supported by clinical studies.

## History of Previous Pregnancy

A history positive for a previous pregnancy with complications should increase the index of suspicion as it is predictive of the general severity of fetal involvement. Maternal history of alloimmunization, previous affected pregnancy or previous neonatal disease are risk factors for development of fetal anemia. Although the correlation is strong, history alone is not sufficient to guide obstetrical management.

## Maternal Antibody Titer

Maternal antibody titer has been a landmark in management of alloimmunization for several decades. Maternal antibody, if present, should prompt paternal blood type zygosity evaluation to determine the likelihood of the presence of an antigen in the fetal blood. If such a risk is not 100%, as in paternal homozygosity, then fetal blood typing should be carried out. Absence of an antigen in the fetal blood rules out fetal involvement and makes further testing unnecessary (Fig. 22.8).

Maternal antibody concentration has been correlated with the presence and severity of fetal disease but is not accurate in prediction of specific cases. High initial titer or rising titer indicates the possibility of fetal anemia, but specific critical titers requiring intervention are difficult to define. Depending on laboratory methods, commonly, values 1:16 or higher are being investigated because of the probability of fetal hemolytic anemia. In this range fetal anemia and hemodynamic changes may be better detected by Doppler velocimetry than by antibody titer alone [7].

## Amniotic Fluid Densitometry

A change in optical density at 450 nm wavelength detects the presence of bilirubin, an end product of fetal hemolysis. It has been used for four decades in combination with standards developed by Liley [3] to predict severely anemic fetuses that could benefit from intervention. A recent review of values by Queenan et al. improved accuracy of the curve, especially for early pregnancy [5]. According to their report, specificity of detecting severe anemia was 79%. In 21% of fetuses, however, severe anemia would not be detected by this method. This low accuracy of the Liley curves has been a concern in management of fetal anemia [5]. Doppler velocimetry is expected to improve accuracy of this diagnosis.

## Detecting Fetal Anemia

For management of alloimmunization an accurate diagnosis of fetal anemia is essential. High specificity is mandatory for this testing to avoid development of

Fig. 22.8. Management of alloimmunization – maternal antibodies

Fig. 22.9. Management of alloimmunization – detection of fetal anemia

severe fetal disease and fetal losses. Figure 22.9 presents diagnostic options for detecting fetal anemia in alloimmunization.

Physical signs, such as fetal tachycardia, polyhydramnios, fetal movements, and fetal heart changes have historically guided physicians; those, however, were not accurate enough to assure fetal survival.

Detecting fetal anemia by sonography is not accurate. Morphologic markers do not predict the severity of fetal anemia [11] sufficiently enough to guide clinical management. Detection of fetal anemia using umbilical vein diameter (intrahepatic portion) [49], liver size [46], spleen size [30, 31], placental thickness, abdominal circumference, abdominal diameter, and other parameters have been developed. Although some were reported as accurate predictors, those methods did not gain widespread use. Methodology,

experience and reproducibility were likely limiting factors as much as the fact that fetal hemodynamic changes are first to occur in fetal anemia, preceding other changes. Abnormal fetal morphology occurs as a result of this process and absence of those signs does not prove fetal normality. Monitoring fetal morphology should not be used alone in management of alloimmunization.

Detection of fetal hyperdynamic state indicates fetal anemia. According to a longitudinal study of 125 pregnancies monitored by MCA peak velocity in pregnancies with red cell isoimmunization, 88% sensitivity can be achieved [7].

Methodologic considerations are important. Appropriate training and experience is required to correctly measure the peak velocity in the fetal MCA. Insonation angle is a potential source of error, as is

selection of the level of measurement outside the bifurcation of the MCA from the circle of Willis. An insonation angle of  $<30^\circ$  allows for minimal error.

Other blood flow measurements await clinical validation before they can be adopted as clinical tools; some already have been shown to be ineffective. For example, the umbilical artery blood flow indices are not informative in alloimmunization and normal values do not represent useful clinical information. A study reported by Bilardo et al. [34] found no correlation between umbilical artery pulsatility index and fetal anemia. A highly specialized measurement of flow velocities within the splenic artery requires specific techniques and experience that may not be universally available. This method of interrogation has not been widely used in clinical management. A study by Dukkler et al. [39] did not show intrahepatic vein velocity to be more predictive than the MCA peak velocity.

Without reliable estimation of fetal blood vessel size, attempts to quantitatively measure fetal blood flow do not yield any new information. In addition, with no changes in vessel size in the process of fetal anemia, blood flow measurements will provide no more information than peak velocities.

Middle cerebral artery peak velocity appears to contain the most accurate information on fetal circulation to allow for noninvasive diagnosis of fetal hyperdynamic circulation in fetal anemia and to select patients for invasive procedures.

A review by Divakaran included eight primary studies with 362 pregnancies affected by red cell alloimmunization evaluated by noninvasive methods. The cumulative metaanalysis of studies with the highest methodologic quality reported a positive likelihood ratio of 8.45 (95% CI 4.69–15.56) and negative likelihood ratio of 0.02 (95% CI 0.001–0.025) [8]. Although those results are encouraging, more clinical data may be needed before Doppler velocimetry will be recommended as a primary standard evaluation of fetal anemia.

### **Diagnostic Invasive Procedures to Detect Fetal Anemia and Doppler Velocimetry**

Diagnostic procedures have to be weighted between risk of procedure and quality of information obtained for fetal anemia in alloimmunization.

Amniocentesis is considered a safe procedure with a complication rate of less than 1%. A major risk in using this method lies in the low accuracy of predictions. According to Queenan et al. [5], if used for detection of fetal anemia in combination with the OD curve, it is only 89% specific, whereas 21% of anemic fetuses remain undetected. Frigoletto et al. [50] conservatively managed 11 zone-III fetuses with no ad-

verse fetal outcomes. Fetal Doppler velocimetry of the MCA has the potential to replace amniocentesis in diagnosis of fetal anemia (Fig. 22.8).

Cordocentesis is the most accurate procedure for detection of fetal anemia. It is also the most risky of all procedures with associated fetal loss of 1% [1] and as high as 4%. If cordocentesis is used as a primary diagnosis, a large number of fetuses will be exposed to this risk unnecessarily since only 25% of all fetuses develop severe anemia requiring fetal blood transfusion, but all will have multiple cordocenteses to confirm normal hemoglobin concentration.

With five diagnostic cordocenteses during pregnancy the cumulative fetal mortality risk may reach 10%–20%, too high for a diagnostic procedure. Clearly, fetal Doppler velocimetry may not be as accurate but is safer and should be considered as an alternative to cordocentesis.

## **Doppler Monitoring During Cordocentesis**

### **Fetal Intravascular Transfusions**

Accurate estimation of fetal anemia by cordocentesis, before and after intravascular blood transfusion, can be compared with Doppler velocimetry and numerous cross-sectional data sets were obtained in this fashion.

Fetal MCA Doppler velocimetry can detect fetal anemia and provide timing for initiation of intravascular transfusion prior to the development of fetal hydrops. The role of Doppler velocimetry is to guide timing of transfusions frequently enough to maintain sufficient fetal hemoglobin levels, but not too often, in order to avoid unnecessary risks from the procedure.

Clinical guidance for fetal intravascular transfusions currently rely on clinical findings and the observation that fetal hematocrit decreases at the rate of 0.3%–1.0% per day. Using mathematical formulas and known hematocrit at the time of cordocentesis, an estimate can be made regarding appropriate amount of time for repeated intrauterine intravascular fetal transfusion. Longitudinal Doppler velocimetry assessment of fetal anemia is the other alternative in guiding frequency and timing of fetal intravascular transfusions.

Several management schemes have been developed to guide frequency of transfusions. Less frequent, larger volume transfusions can be safer by reducing the total number of fetal intravascular blood transfusions [51], thereby reducing the risk of fetal blood volume overload [52]. Use of Doppler velocimetry during transfusion to assess fetal condition has not

been widely used except for detecting acute fetal bradycardia.

Posttransfusion hemodynamic changes can be detected by Doppler velocimetry. Rizzo et al. reported changes consistent with transient right and left heart overload following transfusion that lasted up to 2 h after transfusion [53] and overall reduction of the hyperdynamic state.

In our own series [43], in 18 cases that required blood transfusion due to hematocrit level, a less significant decrease in the fetal preload index was noted following fetal intravascular transfusion  $p < 0.05$ . There is a fall in the fetal preload index following fetal intravascular transfusion. The fetal preload index predicts fetal anemia with a sensitivity of 66% and a negative predictive value of 86% (Fig. 22.5).

Increased blood viscosity, congestive heart failure, and cardiac humoral regulation are likely all involved in the posttransfusion changes. It is still unclear if such changes can be used to guide the physician regarding the amount of blood necessary to be transfused and the timing for consecutive transfusion.

Posttransfusion changes occurred immediately but delayed effects are also observed:

- Immediate posttransfusion changes:
  - Increase of fetal red cell mass
  - Increase of blood viscosity and peripheral resistance
  - Vascular overload
  - Decreased cardiac output
  - Fetal humoral response
- Delayed changes:
  - Fetal fluid resorption and loss within hours after transfusion
  - Decrease of fetal venous return
  - Relief of the acute fluid overload and hyperdynamic state.

Rizzo et al. [53] found a temporary decrease in cardiac output after intravascular transfusions due to an increase in fetal vascular resistance that returned to normal 2 h later. Similarly, Mari et al. [54] found decreased middle cerebral peak velocity following fetal intravascular transfusion. Copel et al. [29] studied blood flow velocities in the descending aorta and found no significant changes following the transfusion. In a series by Weiner et al., a decrease in resistance after blood transfusion was attributed to vasodilatory humoral fetal response [52].

Clearly more than one fetal physiologic response is observed after blood transfusion. Severity of fetal anemia, amount of blood transfused, dynamic of transfusion, and fetal humoral response all have an effect on fetal Doppler velocimetry and represent limitations in fetal evaluation.

## Early Delivery

Historically early delivery has been advised for severe alloimmunization; however, prematurity, fetal anemia, and hydrops are associated with high mortality and morbidity. Early delivery is therefore advised after fetal lung maturity can be confirmed or if additional fetal indices are non-reassuring and fetal conditions worsen despite adequate intrauterine treatment. Fetal biophysical profile is often used for fetal surveillance. Decreased fetal activity unresponsive to fetal transfusions may result from additional pathology other than alloimmunization, requiring delivery. Biophysical fetal assessment has been used in those circumstances as a primary method of fetal surveillance. Fetal umbilical artery blood flow can occasionally reveal absent end-diastolic flow that is more likely to be a reflection of placental vascular pathology. Abnormal umbilical Doppler indices are often difficult to interpret in severe fetal anemia. If fetal lung maturity can be confirmed, an early delivery is preferable.

## Noninvasive Therapies, Gamma Globulin, Plasmapheresis, Nonintervention

None of these treatments have gained wide use, and since advances in fetal diagnosis and intravascular transfusion therapy have been developed, these methods have been largely abandoned.

## Conclusion

Fetal anemia with low fetal blood viscosity and hyperdynamic fetal circulation is a mechanism of fetal disease in isoimmunization. Doppler-detectable changes occur in arterial and venous circulation. Doppler velocimetry in specific vessels and specific measurements can be used in clinical management.

Fetal MCA peak velocity is the best studied, specific Doppler marker for fetal anemia, and is preferable to other Doppler-based diagnostic methods.

Intravascular fetal blood transfusions are associated with temporary cardiovascular overload that can be detected by Doppler velocimetry.

The role of Doppler velocimetry in technical aspects of fetal intravascular transfusions remains to be determined.

# Doppler Velocimetry in Prolonged Pregnancy

Ray O. Bahado-Singh, Maria Segata, Chin-Chien Cheng, Giancarlo Mari

## Introduction

Registry data [1] indicate that the increased risk of stillbirth in post-term pregnancies is partly due to an increased risk of small-for-gestational-age (SGA) fetuses; the latter is in turn partly due to an increased risk of congenital anomalies. When malformations were excluded, the post-term SGA had a higher stillbirth rate than term SGA and post-term appropriate-for-gestational-age fetuses. Similarly, the risk of 5-min Apgar score  $<5$  was higher among the post-term SGA than the other two groups. Naeye [2] estimated that 50% of the excess perinatal mortality in post-term pregnancy was due to problems related to uteroplacental perfusion inadequacy (25%) or congenital malformations (25%).

As a result of data indicating an elevated risk of adverse perinatal outcomes, antenatal testing is now a standard feature of the clinical management of prolonged gestations [3]. There is convincing scientific evidence that Doppler velocimetry of the umbilical vessels identifies uteroplacental insufficiency in high-risk pregnancies. Furthermore, it has been shown that when umbilical Doppler information is made available to clinicians it improves decision making and ultimately the outcomes in such pregnancies [4]. Not surprisingly, therefore, there was initial interest and optimism in deploying Doppler for the management of prolonged gestation.

Whether or not umbilical Doppler velocimetry proves to be beneficial depends on a single overriding consideration, namely, the pathological basis of poor perinatal outcome in prolonged gestations. The answer to this question remains unresolved. If uteroplacental vascular insufficiency is the principal cause of poor outcome, then it is reasonable to expect that umbilical artery Doppler will identify the prolonged pregnancies destined for poor outcome; if not, then Doppler is likely to be of little value in clinical management.

## Umbilical Artery Doppler

In one of the earliest studies, Rightmire and Campbell [5] prospectively evaluated the umbilical artery Pourcelot index (PI) in 35 singleton pregnancies between 42 and 44 2/7 weeks' gestation. A "labor-compromised" fetus was defined as one with either Apgar score  $<7$ , asphyxia or meconium aspiration requiring neonatal intensive care unit (NICU) admission, or operative delivery for fetal distress. The eight pregnancies with adverse outcome had a mean  $\pm$  standard deviation (SD) PI of  $0.56 \pm 0.027$  compared with cases with acceptable outcome ( $0.49 \pm 0.017$ ). The difference was statistically significant. This study suggested that compromise in postdates pregnancy is due to fetoplacental rather than uteroplacental insufficiency.

Guidetti et al. [6] evaluated the umbilical artery S/D ratio in 46 pregnancies at  $\geq 41$  weeks' gestation using continuous-wave Doppler. An abnormal outcome included an abnormal non-stress test (NST), oligohydramnios in which the largest fluid pocket was  $<2$  cm, moderate or thick meconium, intrapartum distress, or low 5-min Apgar. Postmaturity syndrome was diagnosed based on neonatal physical exam. The mean gestational age of the study population was  $42.4 \pm 0.4$  weeks at delivery. There was no statistically significant difference in the umbilical S/D ratios of the 21 infants with normal intrapartum and postnatal outcome compared with the 25 cases experiencing complications. The authors reported that the study was sufficiently powered to detect a statistically significant difference. They concluded that postmaturity may be due to placental changes that compromise nutrient transfer to the fetus rather than clinical uteroplacental vascular insufficiency.

In a larger study of 82 patients at  $\geq 41$  weeks' gestation at the time of Doppler, Battaglia et al. [7] did not find a significant difference in the umbilical artery Doppler resistance index (RI) between 58 cases with normal-descending thoracic aorta mean Doppler velocity compared with the 24 cases with decreased mean aortic velocity (umbilical artery RI  $0.52 \pm 0.06$  vs  $0.53 \pm 0.07$ ,  $p = \text{NS}$ ). The authors did demonstrate a statistically significantly higher frequency of oligohy-

dramnios and meconium staining of the amniotic fluid and abnormal non-stress test in the group with decreased time-averaged mean velocities in the thoracic aorta. There was no direct comparison of umbilical Doppler values in the adverse outcome compared to normal groups; however, this study as designed did not appear to find umbilical artery velocimetry to be a useful tool for the prediction of intrapartum compromise in prolonged gestation.

Fischer et al. [8] did a detailed analysis of 75 postdates pregnancies,  $\geq 41$  weeks at the time of evaluation. Cases suspected of having intrauterine growth restriction (IUGR) based on prenatal ultrasound or those having chronic vascular disorders, such as hypertension, diabetes, and renal disease, and other conditions predisposing to IUGR, were excluded. Abnormal perinatal outcome was defined as non-reassuring fetal heart rate patterns, low cord arterial and venous pH, and meconium below the vocal cords, NICU admission, and birth weight below the 10th percentile. Continuous-wave Doppler ultrasound was used to measure the umbilical artery S/D ratio. Fairly detailed statistical analyses were performed. The mean (SD) umbilical S/D ratio was significantly higher in the 21 cases with abnormal outcome compared with the normal group ( $2.43 \pm 0.43$  vs  $2.19 \pm 0.25$ ;  $p=0.03$ ). When a threshold S/D ratio value of  $\geq 2.40$  was used to define abnormal umbilical Doppler, a sensitivity of 57.1%, specificity of 77.8%, positive predictive value of 50.0%, and negative predictive value of 82.4% was obtained for the prediction of complications. Multiple logistic regression confirmed that S/D  $\geq 2.40$  was a statistically significant predictor of abnormal perinatal outcome with adjusted odds ratio 2.40 (1.50–13.56). This was a fairly well-designed study and had stringent criteria for adverse outcome. Their adverse outcome groups are therefore more likely to be truly clinically compromised and therefore likely to manifest Doppler abnormalities. Consistent with this view is the finding that 16.7% of the newborns in the abnormal Doppler group, i.e., S/D  $\geq 2.40$ , had birth weights less than the 10th percentile vs 0% in the others ( $p=0.009$ ).

Malcus et al. [9] found no difference in umbilical artery PI when 102 pregnancies  $\geq 42$  completed weeks were compared with previously derived normative data. Subgroup analysis of postdates pregnancies with normal testing and spontaneous labor, a subgroup with induced labor, a group with abnormal NST, and finally a subgroup with asphyxia, defined as umbilical artery pH  $\leq 7.10$ , low Apgar score, or operative delivery for fetal distress, did not yield umbilical Doppler values outside of the normative range. Overall, the prolonged-pregnancy group did not have a significantly different rate of acute fetal asphyxia during labor compared with the contemporaneous group of 2,630 cases  $< 294$  days

delivered at the same institution. Along with the small number of study and subgroup patients and the low rate of compromise it is possible that this study was not sufficiently powered to detect Doppler differences in the prolonged-pregnancy group.

Pearce and McParland [10] studied 534 pregnancies exceeding 42 weeks with twice weekly umbilical Doppler velocimetry using a continuous-wave Doppler machine. Abnormal umbilical waveforms were defined as those with S/D ratio greater than the 95% confidence limits or absent end-diastolic velocity. Absent umbilical artery end-diastolic velocity, which occurred in 11 fetuses (2.1%), was highly sensitive (91%) and specific (100%) for detecting fetal distress in the first stage of labor. Fetal distress was defined as operative delivery for fetal distress, confirmed by scalp pH  $< 7.25$ , low Apgar scores, or low umbilical venous pH at birth. Doppler was not, however, effective in predicting fetal distress in the second stage of labor. The latter finding may reflect the fact that distress in the second stage is largely the result of acute factors, e.g., cord compression due to the descent of the fetal presenting part or nuchal cord. Such problems have no relationship to chronic placental insufficiency and are unable to be detected by antepartum testing. A reasonable overall conclusion from this study is that milder impairment of placental function in prolonged pregnancies does not have an identifiable effect on umbilical Doppler measurements. Severe grades of dysfunction can, however, result in umbilical artery Doppler abnormalities that strongly correlate with perinatal outcome.

Stokes and coworkers [11] could find no difference in the umbilical S/D ratios in a study of 70 singleton pregnancies at  $\geq 41$  weeks. Abnormal outcome categories included abnormal fetal heart tracing, reduced amniotic fluid volume, intrapartum fetal distress, or moderate to thick meconium. There was no significant difference in the mean S/D ratio between paired subgroups with and without particular categories of abnormal outcomes. There were 48 neonates with no abnormal tests or outcomes and 22 with one or more abnormal outcomes. No significant differences in umbilical S/D ratios were noted between these two groups. The authors posited that failing placental transport of nutrients and byproducts likely occur in the ageing placenta without affecting vascular resistance. This then would explain the lack of sensitivity of umbilical Doppler velocimetry.

In a prospectively designed study of 142 sonographically dated pregnancies  $> 41$  weeks, Weiner et al. [12] evaluated umbilical Doppler RI greater than the 95th percentile as a predictor of adverse outcome; the latter was defined as either 5-min Apgar  $< 7$ , NICU admission, cesarean for fetal distress, and birth weight less than the 5th percentile. There were 12

cases with one or more abnormal outcome of which 6 had IUGR. A total of 5 (3.8%) compared with 2 (16.7%) of abnormal vs normal groups had abnormal umbilical artery Doppler measurements. This difference was not statistically significant. The mean umbilical artery RI was not significantly different between the two groups. Doppler had a low sensitivity for predicting an adverse outcome, as did other antepartum tests such as NST and amniotic fluid volume.

Anteby et al. [13] studied 79 well-dated pregnancies  $\geq 41$  weeks. Patients at known risk for adverse outcome based on medical conditions or with abnormal antepartum testing based on NST or fluid volume were excluded. In addition, patients scheduled for cesarean section or planned induction were also excluded. The authors therefore considered only low-risk patients with prolonged pregnancy. The outcome measures used were moderate to thick meconium and moderate to severe persistent intrapartum heart rate abnormality and finally heart rate abnormalities requiring operative delivery. The umbilical artery S/D ratio was statistically elevated in cases with FHR abnormalities requiring operative delivery. No such difference was observed when the PIs of the two groups were compared. An umbilical S/D  $> 2.5$  had 60% sensitivity and 71% specificity for fetal distress requiring intervention. The authors suggested that a normal umbilical Doppler identifies post-term pregnancies at low risk for intrapartum fetal distress.

Zimmerman et al. [14] studied umbilical artery Doppler RI in 153 well-dated pregnancies  $\geq 41$  weeks. Cases with maternal diseases, prolonged rupture of membranes, malpresentation, and growth-restricted fetuses were excluded. Outcomes included asphyxia defined by Apgar scores, low arterial pH or encephalopathy, thick meconium, neonatal signs of post-maturity, abnormal FHR patterns in labor, and non-asphyxial causes of operative delivery such as arrest of labor. Pregnancies with normal and abnormal outcomes had umbilical RI values within the 95% confidence interval used to define normal. Thirty-eight pregnancies had asphyxial-related complications, whereas 30 had non-asphyxial complications. The umbilical RI for the prediction of asphyxia had a sensitivity of 37% with a specificity of 75%. For non-asphyxial complications these values are 7% and 75%, respectively. Overall, the umbilical Doppler was not a significant predictor of asphyxial or non-asphyxial outcome based on inspection of the respective receiver-operating characteristics curves.

Olofsson et al. [15] performed longitudinal comparison of umbilical Doppler in 34 women who delivered after 43 weeks. Doppler values were also compared with those of 32 controls delivered at  $< 41$  weeks. All pregnancies were well dated with the assistance of mid-trimester ultrasound. The mean Doppler

velocity and estimated blood volume flow in the umbilical vein was noted to increase significantly on longitudinal evaluation of the 34 study cases from 42 weeks to delivery. There was no significant change in the umbilical artery RI over time. Compared with the control group, the umbilical artery RI was significantly reduced, consistent with reduced vascular resistance and increased blood flow in prolonged gestation. Of the entire study group, 41.2% experienced one or more complications, namely oligohydramnios, meconium staining, fetal distress in labor, or birth asphyxia. The study findings were novel in that the authors demonstrated reduced placental resistance and enhanced blood flow in post-term pregnancies. Presumably enhanced flow would facilitate further fetal growth in such patients. These findings are at odds with the generally accepted view of compromised placental function with aging. An explanation might be that in the "normal" prolonged gestations, even though placental senescence limits nutrient transfer, this bottleneck is overridden by enhanced placental flow. Indeed, it would explain the observation that macrosomia is a common feature of prolonged pregnancies. The study by Olofsson et al. [15] had findings that deviated significantly from the published literature cited above. Forty-four study cases were booked from the first trimester and had dating confirmed based on 16–19 weeks ultrasound. There were no cases of perinatal death, thick meconium of the amniotic fluid, meconium aspiration, or low 5-min Apgar. There were 16 cases with light meconium, fetal distress requiring operative delivery or birth asphyxia based on cord pH values. The umbilical artery pH was significantly less in this compromised group than in the 28 patients without complications ( $0.73 \pm 0.14$  vs  $0.82 \pm 0.14$ ;  $p = 0.03$ ). Dichotomized analysis of cases with and without fetal distress showed significantly lower umbilical artery RI in the group with distress. The same was found when comparing groups with and without light meconium staining. The authors explained these unlikely results by hypothesizing that vasodilatation developed in response to mild hypoxia possibly through the release of vasoactive agents. Contradistinction was drawn to the situation where severe or prolonged hypoxia results in increased vascular resistance. A transient increase in placental perfusion reflecting reduced vascular resistance reportedly has been demonstrated with acute hypoxia in healthy lambs [16].

Every effective screening test has varying sensitivity values depending on the false-positive (1-specificity) threshold that is chosen. As the false-positive threshold increases, e.g., 10% compared with 5%, the sensitivity value will generally also increase. It is therefore misleading and erroneous to compare the sensitivities of two screening tests without regard to

**Table 23.1.** Umbilical artery Doppler: diagnostic performance for adverse outcome in prolonged pregnancies. *AEDF* absent end-diastolic flow, *PPV* positive predictive value, *NPV* negative predictive value, *LR* likelihood ratio (sensitivity/false-positive rate)

Reference	Test	Sensitivity (%)	Specificity (%)	PPV	NPV	LR <sup>a</sup>
[8]	S/D $\geq$ 2.4	57.1	77.8	50.0	82.4	2.6
[10]	AEDF	91	100	91	180	– <sup>a</sup>
[12]	RI	16.7	96.2	28.6	92.6	4.4

[4]	RI > 0.62	37	75	40	73	1.5

<sup>a</sup> LR=infinity.

their respective false-positive rates (or their specificities). The various Doppler studies quoted different specificity values for their reported sensitivities. This makes it very difficult to compare the diagnostic accuracy of umbilical Doppler between different studies. One way of surmounting this limitation is to calculate the so-called likelihood ratio (LR). The likelihood ratio is calculated by dividing the sensitivity value by the false-positive rate. The false-positive rate in turn is equal to 1–specificity expressed as a decimal or alternatively 100%–specificity expressed as a percentage. The higher the LR of a test, the stronger is the correlation between the test measurement and outcome; thus, a test with a higher LR is generally a better test than one with a lower value. Table 23.1 lists the diagnostic indices of umbilical artery Doppler velocimetry in prolonged pregnancies from studies reporting more complete data.

The issue of whether umbilical artery Doppler consistently predicts adverse outcome in prolonged pregnancy remains unresolved. Of the 10 studies reviewed, only three reported increased vascular resistance identifiable on Doppler in prolonged pregnancy with adverse outcome. Indeed, one study paradoxically found a reduction in placental resistance in prolonged pregnancies as determined by umbilical Doppler. There is currently insufficient evidence to propose that Doppler velocimetry of the umbilical artery should be used in routine management of prolonged gestation. The significant variability in the design of these various studies quite predictably makes it impossible to draw any strong conclusions regarding the value of umbilical Doppler in prolonged gestations. The many areas of differences in study designs included differences in defining prolonged pregnancies, varying umbilical Doppler thresholds used to define abnormal variation in ultrasound equipment, and Doppler modality used, i.e., continuous- vs pulsed-wave Doppler and, most importantly, significant variation in outcome end points used to define perinatal complications. Very few of the studies with negative association performed power analysis. There is a significant possibility that many of the negative trials were underpowered.

## Umbilical Artery Doppler Versus Other Antepartum Tests

Currently, the most commonly employed protocols for the antepartum monitoring of prolonged pregnancies incorporate the NST and amniotic fluid volume assessment. A few studies compared umbilical Doppler velocimetry to these more commonly used tests. In a study that found a correlation between Doppler and perinatal complications, Fischer et al. [8] compared umbilical Doppler S/D to NST and amniotic fluid measurements (Table 23.2). The umbilical artery Doppler was a better test than NST and amniotic fluid volume assessment combined.

In another study that found the umbilical artery to be a useful predictor of outcome in prolonged pregnancy Pearce and McParland [10] compared absent end-diastolic flow velocity (AEDF) umbilical Doppler to NST and largest fluid pocket <3 cm for prediction of fetal distress. The Cohen kappa statistic was used. Kappa values vary from 0 to 1.0. Values of 0–0.2 denote test results that may be chance findings, 0.2–0.8 indicates increasing agreement, and values > 0.8 show strong correlation between the test results and the outcome of interest. Based on the kappa statistic, umbilical Doppler AEDF appeared to be a superior predictor of fetal distress in the first stage of labor compared with either the NST or amniotic fluid pocket. Kappa statistic for AEDF, NST, and fluid pocket fetal distress in the first stage of labor was 0.91, 0.41, and 0.68, respectively. Fluid pocket and Doppler AEDF were modest predictors of second-stage distress with NST showing no meaningful correlation with this particular outcome (kappa values 0.39, 0.29, and 0.05). All except fluid volume had poor correlation with 5-min Apgar <5 (kappa statistic 0.03, 0.07, and 0.37 for NST, AEDF, and fluid pocket, respectively).

Weiner et al. [12] compared NST, oligohydramnios (<5 cm), and umbilical RI >0.68 for the detection of perinatal compromise; the latter consisted of 5-min Apgar <7, NICU admission, cesarean for fetal distress, and birth weight less than the 5th percentile. The umbilical artery Doppler performance based on

**Table 23.2.** Comparison of umbilical artery Doppler velocimetry to other biophysical tests in prolonged pregnancies. *NST* non-stress test, *AF* amniotic fluid, *CST* contraction stress test, *Doppler* umbilical artery Doppler, *MCA/UA* ratio of the Doppler S/D ratio of the middle cerebral artery to the umbilical artery, *LR* likelihood ratio (sensitivity/false-positive rate)

Reference	Test	Sensitivity	Specificity	PPV	NPV	LR
[8]	NST+AF	19.1	84.9	33.3	72.6	1.3
	Doppler	57.1	77.8	50.0	82.4	2.6
	NST	8.3	95.4	14.3	91.6	1.8
[12]	AF	25.0	93.8	27.3	93.1	4.0
	Doppler	16.7	96.2	28.6	92.6	4.4
	NST/CST	8	96	63	71	2.0

	Doppler	37	75	40	73	1.5
	NST	40	89.7	50.0	85.4	3.9
[17]	AF	20	97.4	66.7	82.6	7.7
	BPP	30	92.3	50	83.7	3.9
	MCA/UA	80	94.9	80.0	94.9	15.7

All values except LR are expressed as percentages.

LR values appear superior to NST, with slightly higher diagnostic accuracy compared with the amniotic fluid volume measurement (Table 23.2). When an abnormal test was defined as either NST, Doppler, or fluid-volume abnormal, the test performance appeared to be substantially improved.

In the study by Zimmerman et al. [14], abnormal umbilical Doppler velocimetry, defined as RI  $\geq 0.62$ , was a poor predictor of perinatal asphyxia. Doppler appeared to be inferior to fluid volume assessment, while fetal heart rate monitoring using the NST or CST appeared slightly better than Doppler.

Finally, Devine et al. [17] compared middle cerebral artery to umbilical artery S/D ratio to a biophysical profile ( $\leq 6$ ), amniotic fluid index  $\leq 5$  cm, and NST for the prediction of adverse outcome. This was defined as meconium aspiration syndrome, cesarean delivery for fetal distress, or fetal acidosis in a total group of 49 pregnant women  $\geq 41$  weeks' gestation. Of this group, 10 (20.4%) experienced adverse outcome. Middle cerebral to umbilical artery ratio ( $< 1.05$ ) was the only significant predictor of adverse perinatal outcome.

Three of the four studies reviewed in Table 23.2 suggested that the Doppler involving umbilical artery by itself or as a component of a Doppler index was superior to NST and amniotic fluid assessment in prolonged gestations. Only one study, that by Devine et al. [17], confirmed statistical significance of this apparent superiority of Doppler. In the other two studies, those by Fischer et al. [8] and Weiner et al. [12], tests of significance were not performed to evaluate apparent differences in diagnostic accuracy between Doppler and other biophysical markers. The study by Pearce and McParland [10] also indicated the superiority of umbilical Doppler for fetal distress in the first stage of labor over fluid volume and NST and superiority to NST for second-stage fetal distress.

The apparent trend in observed superiority is interesting, not the least because both NST and fluid volume assessment are the de facto clinical standards for monitoring prolonged pregnancies. A large-scale study of this observation would have not only scientific interest but also possible clinical value.

## Middle Cerebral Artery Doppler Velocimetry

Redistribution of fetal cardiac output with an enhanced flow to the brain is an important finding in IUGR due to placental insufficiency. This phenomenon, called the "brain-sparing effect," is recognizable on Doppler interrogation [18]. A few investigators have studied whether a similar phenomenon occurs in prolonged pregnancy. Battaglia et al. [7] used reduction in the time-averaged mean Doppler velocity changes in the fetal descending thoracic aorta to identify those at increased risk for complications including oligohydramnios and cesarean section for fetal distress. There was no significant difference observed in the middle artery RI between groups with normal and decreased aortic mean velocity. This suggested no significant alteration of cerebral flow velocity even in compromised post-term fetuses. Anteby et al. [13], in contrast, found decreased middle cerebral artery PI in fetuses  $> 41$  weeks who developed moderate to severe variable decelerations in labor. Decreased middle cerebral artery vascular resistance was demonstrated in the study by Weiner et al. [19], of post-term pregnancies manifesting compromise. The middle cerebral artery PI was significantly lower in 16 post-term fetuses with oligohydramnios defined as AFI  $\leq 5$  cm compared with 104 with normal fluid. The findings are consistent with preferential perfusion of the brain at the expense of the kidney result-

ing in oligohydramnios. Bar-Hava et al. [20] found no such difference in the middle cerebral artery RI when a group of 15 post-term fetuses with oligohydramnios was compared with 42 with normal fluid volume defined as amniotic fluid indexes  $>5$  cm. As mentioned previously, the study by Devine et al. [17] found cerebral redistribution defined as middle cerebral artery umbilical artery Doppler ratio  $<1.05$  to be reduced in compromised post-term pregnancies. This ratio was found to be a significant predictor, with 80.0% sensitivity and 94.9% specificity for the detection of adverse outcomes in such fetuses. Zimmerman et al. [14] did not find significant differences in the middle cerebral Doppler RI values when subgroups of post-term patients with complications such as low Apgar scores, low cord pH, postmaturity syndrome, or thick meconium, among others, were compared with a normal group. No power analysis was performed to determine adequacy of the sample size. It is likely based on numbers presented that the study was underpowered for these analyses. Selam et al. [21] studied the middle cerebral artery PI in 10 post-term cases with amniotic fluid index  $>5$  cm compared with 25 cases with normal fluid. The middle cerebral artery PI was significantly lower in the post-term group with oligohydramnios (median value 0.89 vs 1.33, respectively;  $p=0.004$ ). The placental-cerebral ratio derived as umbilical to middle cerebral PI value was significantly higher in the oligohydramnios vs normal fluid group (median value 0.88 vs 0.67, respectively;  $p=0.027$ ). This supports the notion that cardiovascular redistribution occurs in pregnancies complicated by oligohydramnios.

The study by Brar et al. [22] also found reduced cerebral placental (umbilical) S/D ratios in 19 post-term patients with abnormal antepartum test defined as either an abnormal NST or amniotic fluid index  $<5$  cm compared with a group of 26 with normal test results. Cerebral to placental resistance in the compromised group was  $1.1 \pm 0.3$  vs  $1.8 \pm 0.3$  in normal ( $p < 0.05$ ).

## Aortic Blood Flow Doppler

Rightmire and Campbell [5] measured the time-averaged mean velocity in the thoracic aorta in 35 pregnancies  $\geq 42$  weeks. Mean Doppler velocities, corresponding to blood flow, diminished with prolongation of gestation beyond term. Although the 8 fetuses with compromised outcome had lower mean velocities than other postdates pregnancies, the difference did not achieve significance. The authors speculated that the decreasing velocities resulted from hypovolemia and hemoconcentration (hyperviscosity) in the compromised fetuses.

Battaglia et al. [7] found a “generally high predictive value” of decreased mean descending thoracic aorta Doppler velocity for various outcomes such as oligohydramnios, meconium staining, and abnormal NST. Aortic Doppler had an 80% sensitivity, 78% specificity, 33% PPV, and 78% NPV for cesarean done for fetal distress. Reduced mean aortic velocity correlated with shorter interval to delivery and preceded an abnormal NST by greater than 36 h on average.

In the study by Malcus et al. [9], there was no significant reduction in mean fetal descending aortic Doppler velocity with advanced gestation in prolonged pregnancies. This is in contrast to that reported by Rightmire and Campbell [5]. There were no significant differences found in aortic Doppler PI in 23 cases experiencing asphyxia defined by low Apgar or arterial cord pH  $<7.10$  compared with 23 with normal outcome in the study by Malcus et al. [9]. Power analysis was not used to help to explain the lack of significance observed. Anteby et al. [13] found a negative correlation between the mean time-averaged aortic blood flow Doppler velocity and adverse perinatal outcome in their study of 71 women  $>41$  weeks. Time-averaged velocity of the descending thoracic aorta was significantly decreased in cases with meconium, moderate to severe variable decelerations and operative delivery for fetal distress compared with their unaffected peers. Olofsson et al. [23] compared mean thoracic aortic Doppler velocities and estimated aortic blood flow using vessel diameter measurements in 34 women delivered after 43 weeks compared with 32 controls delivered  $<40$  weeks. Mean aortic velocity and relative volume flow was significantly lower in the post-term group vs controls. When study cases experiencing complications, such as oligohydramnios, meconium, fetal distress, and birth asphyxia, were excluded, there was no significant difference in aortic flow values between normal prolonged gestation cases and controls. This finding suggests that the differences initially observed between prolonged gestation and controls was due to compromised cases with altered aortic Doppler flow indices.

Weiner et al. [19] found no significant difference between the abdominal aorta PI values when term patients were compared with post-term cases  $>41$  weeks who had either normal or reduced amniotic fluid volume. The 16 post-term cases with low AFI ( $<5$  cm) had significantly worse perinatal outcome including cesarean section for fetal distress, NICU admission, and 5-min Apgar score  $<7$  when compared with the post-term group with normal fluid volume.

The cumbersome and time-consuming nature of fetal aortic Doppler measurements combined with equivocal reports reviewed above would militate against its use in clinical care. Furthermore, variabil-

ity in technique and defined outcomes once again limits our ability to arrive at definitive conclusions. There does, however, appear to be some observable changes in aortic Doppler indices in compromised prolonged gestations with reduced velocity, possibly indicating a degree of compromise.

## Aorta and Pulmonary Artery Doppler

Hemodynamic changes in cardiac function have been described in growth-restricted fetuses. Weiner et al. [24] suggested that abnormal cardiac Doppler precedes the occurrence of abnormal fetal heart rate (FHR) pattern in these fetuses. These authors [19] also investigated the aorta and pulmonary outflow tracts by Doppler ultrasound in uncomplicated prolonged pregnancies to determine if changes of cardiac function can cause the development of oligohydramnios and the occurrence of an abnormal FHR pattern. They found that both the aortic peak velocity and the estimated aortic blood flow calculated using vessel diameter measurements correlated significantly with both the amniotic fluid index and the FHR pattern. On the other hand, the pulmonary peak velocity and estimated outflow volume correlated with the FHR pattern only; thus, left cardiac output was reduced in post-term pregnancies with oligohydramnios and both left and right output were reduced in the presence of abnormal fetal heart rate. It is well known that the left cardiac output is directed mainly to the brain. It is possible that reduced renal perfusion occurred in association with the lower left cardiac output directed mainly to the brain, leading to oliguria and oligohydramnios.

## Renal Artery Doppler

Doppler velocimetry of the renal artery, while of limited practical value in the day-to-day management of prolonged pregnancies, has the potential to shed light on the mechanism of fetal deterioration. A limited number of studies have been published in this area. Arduini et al. [25] compared the Doppler changes in the fetal renal artery in IUGR and post-term fetuses to determine whether the mechanisms of fetal compromise were the same. Changes in the renal PI in 114 IUGR and 97 post-term fetuses >42 weeks were compared. In each population the relationship between renal PI and fluid volume categorized as adequate reduced or oligohydramnios was evaluated. The renal PI in IUGR fetuses was significantly increased above normal. This increase was most marked in the oligohydramnios group. This contrasted with findings

in the post-term fetuses where there were no significant differences in renal artery PI compared with normative data. Furthermore, there was no correlation between renal Doppler and amniotic fluid volume. The authors concluded that while IUGR results have classic utero-placental insufficiency with redistribution of fetal cardiac output, a different mechanism occurred in prolonged gestation. Specifically, it was noted that animal studies demonstrated increased sensitivity of the fetal kidney to vasopressin with advancing gestation. Vasopressin promotes reabsorption of water by the kidney resulting in reduced urine volume [26]. Arduini et al. [25] suggested that this might be the mechanism of oligohydramnios in prolonged human pregnancies. Veille et al. [27] compared the renal artery S/D in 33 patients with normal amniotic fluid volume vs 17 with oligohydramnios defined as AFI  $\leq 5$  cm. The mean gestational age in the normal group and the group with low amniotic fluid volume was 41.3 weeks; however, the number of cases that were post-term was not given. Despite the fact that there was no difference in the umbilical artery S/D (normal fluid group  $2.36 \pm 0.05$  vs oligohydramnios group  $2.24 \pm 0.05$ ;  $p = \text{NS}$ ), the renal S/D was significantly higher in the oligohydramnios group (renal S/D:  $6.5 \pm 0.3$  vs  $7.8 \pm 0.4$ ;  $p < 0.009$ ). Overall, there was a significant negative correlation between AFI and fetal renal S/D ( $Y = -0.435$ ,  $p = 0.01$ ). This study suggested that the reduction in amniotic fluid volume was indeed secondary to reduced renal perfusion and conflicts with the findings of Arduini et al. [25]. The number of cases with IUGR in the Veille et al. study [27] was not given, whereas IUGR cases were excluded from consideration among the post-term fetuses in the study of Arduini et al. [25]. Along with the differences in the gestational age of inclusion the prolonged pregnancy groups of the two studies may not be comparable.

Bar-Hava et al. [20] compared renal and umbilical artery RI in 57 post-term pregnancies >41 weeks. Fifteen patients had oligohydramnios (AFI < 5), while the other 42 had normal fluid volume and served as controls. There were no differences in either the umbilical ( $0.51 \pm 0.1$  vs  $0.052 \pm 0.06$ ) or renal ( $0.71 \pm 0.08$  vs  $0.73 \pm 0.05$ ) artery RI values between oligohydramnios and control groups, respectively. Power analysis done by the authors reportedly confirmed the adequacy of the patient numbers. They therefore did not find evidence of renal blood flow redistribution in post-term pregnancies with oligohydramnios.

Studies in laboratory animals [28] indicate that angle-independent Doppler indices, such as S/D, PI, and RI, correlate poorly with actual blood flow measured by more direct methods. Direct velocity measurements, such as peak systolic (PSV) and end-diastolic velocities (EDV), were found to correlate more closely

with actual volume flow. Oz et al. [29] studied renal artery RI, PSV, and EDV in 147 patients >41 weeks; of these, 21 (14.3%) had oligohydramnios. Adverse outcome was defined as cesarean for fetal distress, 5-min Apgar <7, prolonged NICU stay, or perinatal death. The renal artery RI was significantly higher in the oligohydramnios group (0.884 vs 0.860;  $p < 0.05$ ).

Interestingly, renal artery Doppler EDV below the mean for gestation significantly increased the risk of oligohydramnios: RR (95% CI) 1.5 (1.1, 2.0). This finding suggested that the changes in EDV accounted for the different RI values. Reduced renal EDV would reflect increased renal vascular resistance. This study provided the most specific evidence as to the mechanism of oligohydramnios in prolonged pregnancies.

A smaller study of 38 patients >41 weeks was performed by Selam et al. [21]. They compared the renal artery RI in 10 oligohydramnios cases (AFI <5 cm) with 28 cases with normal fluid. An increase in the renal artery PI was observed. Differences in study design, inclusion, and exclusion criteria and different outcomes of interest account for some of the variability in the studies conclusions. It is possible that more than one mechanism accounts for oligohydramnios in prolonged pregnancies. At this point we are unable to explain why a different mechanism might predominate in different patients.

## Uterine and Uteroplacental Artery Doppler

As reported for placental insufficiency in IUGR fetuses, it is possible that a decrease in uteroplacental flow could also occur as a consequence of prolonged pregnancy. Several studies, therefore, have been undertaken to investigate whether Doppler waveform analysis of uteroplacental circulations could have a role in the identification of at-risk fetuses in post-date pregnancies. Uterine arteries, uterine-arcuate arteries, and radial spiral arteries have been assessed with Doppler ultrasonography by investigators in different studies.

A study on 82 pregnancies of at least 287 days gestation found normal Doppler findings in uterine arteries but a significant reduction of time-averaged mean velocity in the descending aorta was associated with oligohydramnios, meconium-stained fluid, abnormal NST, and cesarean delivery for fetal distress [7].

The prospective study of Malcus et al. [9] involving 102 women with more than 294 completed gestational days found similar Doppler PIs in the uterine artery compared with values at term. The study found that abnormal flow velocity waveforms in the uterine artery had no significant relationship to fetal asphyx-

ia defined as the presence of umbilical artery pH  $\leq 7.10$  and/or an Apgar score <7 at 1 or 5 min and/or operative delivery for fetal distress.

Uterine-arcuate arteries were assessed by continuous-wave Doppler ultrasound in 75 pregnancies of at least 41 weeks' gestation and systolic-diastolic ratio (S/D) and RI were calculated by Fischer et al. [8]. There was no significant difference in the mean uterine-arcuate artery S/D or resistance index between pregnancies with normal and abnormal perinatal outcome.

In the study by Weiner et al. [12] uterine artery blood flow velocity waveforms were measured transvaginally in 142 post-term pregnancies combined with umbilical artery Doppler and antepartum tests, namely, NST and estimation of amniotic fluid volume. The authors concluded that in post-term pregnancies Doppler velocimetry alone (either the uterine or the umbilical artery) did not by itself improve the ability to predict abnormal outcome but may increase the ability to predict the compromised fetus when combined with additional antepartum tests.

Zimmerman et al. [14] measured Doppler waveforms in the uteroplacental arteries in the region of placental implantation in a total of 153 prolonged pregnancies. The uteroplacental arteries were localized within the myometrium close to the placental bed. These corresponded anatomically to the radial-spiral arteries and RI values were calculated. The investigators showed that Doppler resistance indices in the uteroplacental arteries in the region of placental implantation did not change significantly with increasing gestation from 41 to 43 weeks' gestation and sonographic grading of placenta maturity was also not related to vascular resistance in the uteroplacental arteries nor to fetal outcome. Finally, they did not find any correlation between uteroplacental RIs and perinatal outcome in post-term pregnancy.

Some data are available for very prolonged pregnancies beyond 43 weeks' gestation. In a study population of 44 women proceeding to 43 completed weeks' gestation, perinatal complications were not associated with an increased uteroplacental vascular resistance [15].

Taken together, the results of these studies indicate that there is no major alteration to maternal uteroplacental flow in those prolonged pregnancies that are destined to be complicated by fetal compromise. The underlying mechanism of fetal complication in post-date pregnancies therefore appears different from the uteroplacental insufficiency responsible for IUGR occurring at earlier gestational ages. Even if placental histological modifications are present in post-date pregnancies, they do not appear to result in major changes in Doppler flow velocity in the uteroplacental circulation. Indeed, whether or not such changes con-

sistent with placental senescence even exist has been called into question [30]. We can therefore conclude that uterine artery and uteroplacental Doppler, when used for the routine assessment of prolonged pregnancies, do not predict fetuses that will subsequently develop perinatal complications.

## Conclusion

A comprehensive review of Doppler velocimetry revealed significant variability in the design and conduct of these studies. Areas of variability include differences in ultrasound machines used, Doppler modality (continuous wave vs pulsed Doppler), Doppler indices used, and definition of prolonged pregnancy and precision of pregnancy dating. The Doppler technique requires experience and precision that are difficult to ensure and maintain across different trials. The extreme variability observed is likely to overwhelm any small or moderate correlation between Doppler measurements and outcomes, should they exist. The generally small size of the study samples and the near universal lack of power analysis for studies with negative results represent significant additional hurdles. Properly designed and sufficiently powered trials would therefore still be of benefit. An interesting empirical observation was that umbilical Doppler velocimetry appeared to better predict outcome in prolonged pregnancy when compared with the standard antenatal tests such as NST and fluid volume assessment. This is certainly an observation that merits further investigation.

# Doppler Velocimetry for Fetal Surveillance: Adverse Perinatal Outcome and Fetal Hypoxia

Dev Maulik, Reinaldo Figueroa

The primary objective of fetal surveillance is to detect fetal compromise arising from nutritive and respiratory deficiencies. A variety of obstetric complications, including fetal growth restriction and hypertension, may expose the fetus to such risks. There is emerging evidence that the growth-restricted human fetus suffers from chronic hypoxia and acidosis. Although an immense amount of information is available on acute and subacute fetal respiratory deficit, the mechanism of chronic nutritional and respiratory deficiency in the fetus has remained relatively ill-understood.

Encountering unfavorable circumstances, the fetus appears to mobilize a spectrum of compensatory responses, including preferential preservation of fetal growth over placental growth, changes in fetal movement pattern, and eventual deceleration of the fetal growth rate (Fig. 24.1). In the face of deepening deprivation, compensation gives way to decompensation.

It has also been shown that a central component of the fetal homeostatic response involves flow redistribution, which favors the vital organs (i.e., brain, heart, adrenals), whereas flow to muscle, viscera, skin, and other less critical tissues and organs declines [1]. Underlying this phenomenon are the diverse changes in impedance in these vascular systems.

The introduction of Doppler velocimetry has not only enabled us to investigate this phenomenon in the human fetus but it has opened up the potential of its use for detecting fetal compromise. A significant amount of information exists on the diagnostic efficacy of the Doppler method for identifying the fetus with adverse outcome as defined by various clinical parameters. What constitutes adverse perinatal outcome, however, is a highly controversial and problematic issue. It is well recognized that many of these

**Fig. 24.1.** Summary of fetal sequential response to progressive stress. Note that the depicted sequence is an approximation; the actual course may vary depending on the characteristics of the chronic deprivation and the individual fetal ability to cope

clinical indicators do not necessarily reflect chronic respiratory or nutritive deficit of the fetus. It is important therefore to consider the efficacy of fetal Doppler velocimetry also with regard to detecting fetal hypoxia or asphyxia, although it may not prognosticate the long-term neurologic outcome of the infant.

This chapter provides a general review of the efficacy of fetal Doppler velocimetry for predicting adverse perinatal outcome and identifying fetal hypoxia and acidosis in high-risk and unselected pregnancies. The efficacy of the method in relation to specific pregnancy disorders is considered in other dedicated chapters in this book.

## Doppler Velocimetry and Adverse Perinatal Outcome

This section presents a critical appraisal of the effectiveness of fetal Doppler velocimetry for identifying the fetus at risk. During this inquiry it is important to ascertain whether the technique is used in complicated pregnancies or in an unselected obstetric population. Although such risk categorization is merely a relative distinction of high or low prevalence of adverse outcome in population, it significantly influences the efficacy measures of a test. Thus for a given diagnostic test, the efficacy is greater among patients with a high prevalence of the disorder than among those with a low prevalence. The efficacy of the Doppler technique should therefore be appraised according to the risk category of the study population.

**Table 24.1.** Diagnostic efficacy of umbilical Doppler velocimetry for high-risk pregnancies

## Diagnostic Efficacy of Doppler Velocimetry Among High-Risk Pregnancies

The efficacy of fetal Doppler investigations for predicting adverse perinatal outcome in complicated pregnancies has been widely investigated. A selection of these studies is summarized in Table 24.1, some of which are also discussed later.

Most studies indicated that the Doppler results were efficacious for identifying the fetus at risk in complicated pregnancies. There are, however, wide variations in the performance of the technique, with the sensitivity ranging from 21% to more than 90% and the specificity from 63% to 97%. This range may not be surprising, as the studies were heterogeneous in several ways, including the population selection criteria, the method of using Doppler surveillance (e.g., the frequency of examination), the diagnostic threshold value of the test result, and the outcome parameters. As is evident, the investigators were not uniform in their selection criteria of an adverse perinatal outcome, which included fetal smallness for gestational age (SGA), operative delivery for fetal distress, Apgar score, the need for admission to the neonatal intensive care unit (NICU), and various other

conditions. These variations are not surprising as the criteria for morbid perinatal outcome remain controversial. Many of the traditional measures of morbidity are now known to be of little significance for long-term prognosis of the infant. Despite these limitations, traditional measures of perinatal morbidity have not yet been replaced by any more insightful alternatives.

In addition, some of these studies were deficient in their experimental approach. For example, many investigators did not employ a blind technique, which might have compromised the studies' validity as the clinicians' preconceived notion about the efficacy of the test would inevitably introduce bias. If the physician was already favorably disposed toward the test, the results could be erroneously affirmative; on the other hand, the chances of obtaining false-negative results would increase if the physician had no confidence in the test. Thus blind evaluations significantly enhance the validity of the study results. In one of the first studies reported on the diagnostic efficacy of Doppler velocimetry, the investigators [2] did not state whether the clinicians were blind to the Doppler results. Moreover, in one of the largest studies on Doppler efficacy, which also included a nonstress test (NST) and biophysical

**Fig. 24.2.** Principle of receiver operating characteristic (ROC) curve analysis for assessing the efficacy of a diagnostic test. *D(-)* disease-free, *D(+)* diseased, *T(-)* test negative, *T(+)* test positive, *TP* true positive, *FP* true negative. *Top*: Distribution pattern of the diseased and disease-free populations along the test value represented by the *horizontal line* in the middle of each panel. *Bottom*: ROC curves. Note that with a useless test there is an equal chance of being diseased or disease-free at any given value of the test (*A1*); the corresponding curve (*A2*) is the *diagonal* from the *lower left* to the *upper right corner*. In contrast, a perfect test completely discriminates between the two populations (*B1*). The *arrow* points to the most discriminatory value of

the test. The corresponding ROC curve (*B2*) is represented by the *left and upper margins* of the graph with no false positives. The *upper left corner* corresponds to only true-positive and no false-positive results and therefore represents the absolute discriminatory value of the test. A useful, but less than perfect, test predominantly separates the two populations with some degree of overlap that contributes to the false-positive and false-negative results (*C1*). The *arrow*, as in the previous case, points to the most discriminatory value of the test. The ROC curve covers an area (*black shaded*) that is a measure of the test's overall efficacy (*C2*). The test value nearest to the *upper left corner* is the most efficacious

profile [3], the clinicians had ready access to the Doppler and other fetal monitoring results, which obviously compromised the reliability of the conclusions drawn from this investigation.

Despite such limitations, most investigators have confirmed that fetal Doppler velocimetry is an effective method for identifying fetal jeopardy in high-risk pregnancies with the significant exception of postdatism, for which it may not be a reliable discriminator of fetal status (see Chap. 23 for an in-depth discussion).

This affirmative conclusion remains valid irrespective of whether the study utilized the Bayesian or signal analytic approach or both. The Bayesian approach determines the probabilistic measures of efficacy, such as the sensitivity, specificity, or predictive values, at a given test value. The signal analysis method measures the overall discriminatory performance of a test from its true- and false-positive rates for all available values and assists in determining its optimal threshold for a particular application. This technique is also known as the receiver operating characteristic (ROC) method [4] and is explained in Fig. 24.2. In addition to these two techniques, the kappa index [5] has been used. The kappa index measures the degree of concordance between the test result and the diagnosis beyond chance; the value of this index has been utilized to assess the magnitude of the test's efficacy [6]. A kappa index more than 0.8 is regarded as near perfect, at 0.6–0.8 as “substantial”, at 0.4–0.6 as moderate, and less than 0.4 as fair to poor.

These analytic techniques were utilized by Maulik et al. [7] to evaluate the diagnostic efficacy of the umbilical arterial systolic/diastolic (S/D) ratio for predicting adverse perinatal outcome. As indicated, the study was blind, so that those responsible for clinical management of the patient did not have access to the Doppler results. A free-standing continuous-wave Doppler device with a 4-MHz transducer and a fast Fourier analyzer was used. The criteria for abnormal perinatal outcome included (1) SGA at birth (<10th percentile); (2) 5-min Apgar score <7; (3) umbilical cord arterial pH below 7.2; (4) fetal distress during labor (late and severe variable deceleration, subnormal short-term variability, and fetal scalp pH <7.20); (5) presence of thick meconium; and (6) NICU admission. The ROC curve assisted in determining the optimal cutoff value of the S/D ratio (demonstrated in Fig. 24.3). The ROC analysis indicated that this test had an impressive but less than perfect capability of discriminating between an adverse and a normal outcome. Ratios of 2.9 and 3.0 exhibited the maximum inherent discriminatory power: The former of the two values exhibited greater sensitivity, and the latter, which is the more prevalent standard, showed greater specificity and a higher kappa index (Table 24.2). Furthermore, when fetal SGA status was excluded

**Fig. 24.3.** Receiver operating characteristic curve of the umbilical arterial systolic/diastolic (S/D) ratio. Note that the S/D ratio cutoff point (2.9) closest to the upper left corner of the graph has the best ability to discriminate between the normal and abnormal outcome groups. **Table 24.2.** Test performance values for various systolic/diastolic ratio cutoff points (from [7] with permission)

Cutoff point	Sensitivity	Specificity	PPV	NPV	KI
2.5	0.93	0.53	0.47	0.94	0.36
2.9	0.83	0.87	0.74	0.92	0.68
3.0	0.79	0.93	0.83	0.91	0.73
3.5	0.35	0.99	0.93	0.77	0.41

PPV, positive predictive value; NPV, negative predictive value; KI, kappa index.

from the outcome, the S/D ratio had the best diagnostic efficacy; in contrast, when small fetal size was the only outcome criterion, the test demonstrated the worst efficacy. This result further confirms that the umbilical arterial Doppler indices are more capable of identifying fetal compromise than small fetal size.

### Fetal Doppler Velocimetry, Nonstress Test, and Biophysical Profile: Comparative Efficacy for Predicting Adverse Perinatal Outcome

When appraising the diagnostic efficacy of fetal Doppler, an important consideration is to compare it with

that of the currently utilized fetal surveillance procedures. This section presents the comparative effectiveness of these modalities in relation to the prediction of adverse perinatal outcome. Other relevant aspects of this issue (i.e., the prediction of fetal asphyxia and the sequence of occurrence of abnormal tests) are discussed later in the chapter.

The effectiveness of the umbilical arterial A/B (S/D) ratio for predicting adverse outcome was investigated by Trudinger et al. [2] in 170 high-risk patients. The parameters of fetal compromise included birth weight below the 10th percentile or an Apgar score of less than 7 at 5 min. The fetal heart rate was assessed in terms of reactivity and a modified Fischer score. In this study, the umbilical arterial S/D ratio appeared to be more sensitive, but less specific, than electronic fetal heart rate monitoring. Farmakides et al. [8] investigated the diagnostic efficacy of the NST and the umbilical arterial S/D ratio in 140 pregnancies. The measures of outcome included intrauterine growth restriction (IUGR), fetal distress, cesarean section for fetal distress, and admission to the NICU. Fetuses with a normal NST but abnormal S/D ratio had an outcome worse than those with an abnormal NST and a normal S/D ratio; those for whom both tests were abnormal experienced the worst outcome.

Further corroboration came from Arduini et al. [9], who noted in a cross-sectional study involving 1,000 unselected pregnancies at 36–40 weeks' gestation that umbilical velocimetry was more effective than NST for identifying fetuses at risk of adverse outcome (cesarean section for fetal distress, lower birth weight, 5-min Apgar score <7, admission to the NICU). The relative strengths of the individual and combined use of the various tests were investigated by Hastie et al. [10] in 50 pregnant patients. These investigators observed that the repeat nonreactive NST was highly sensitive (92%) and the S/D ratio highly specific (83%); they therefore suggested the effectiveness of combining the two tests for predicting adverse perinatal outcome. The suggestion of a combined approach also came from Nordstrom et al. [11], who determined the umbilical arterial S/D ratio and biophysical profile in 69 high-risk pregnancies within 10 days preceding the delivery. Intrapartum fetal distress and SGA occurred in 43% of the infants. The S/D ratio demonstrated a higher sensitivity (37%), specificity (92%), positive predictive value (PPV) (79%), and negative predictive value (NPV) (66%) than the biophysical profile (27%, 82%, 53%, and 59%, respectively).

These observational studies, though highly informative, do not provide evidence for a greater effectiveness of any of the tests in regard to altering outcome. Such conclusions can be achieved only by randomized trials. This issue is discussed in Chap. 26.

## Fetal Doppler Sonography and Neurodevelopmental Outcome

As indicated above, the currently utilized immediate measures of outcome may not effectively prognosticate the long-term effects of in utero fetal compromise on subsequent neurologic development. This point is particularly relevant when assessing the efficacy of antepartum surveillance, which is a relatively difficult area of investigation. Not surprisingly, there are few studies in this area, and those published so far are contradictory. Maršál and Ley [12] in their long-term investigation found a significant correlation between the abnormalities of fetal aortic Doppler waveforms and deficient neurologic development of the infant assessed at 7 years of age. Similarly, Fourn et al. [13] measured the ratio of antegrade to retrograde velocity integrals in the aortic isthmus of 44 fetuses with abnormal umbilical artery Doppler velocimetry and studied the neurodevelopmental condition of the children between the ages of 2 and 4 years. The investigators found a significant correlation between the flow patterns in the fetal aortic isthmus and neurodevelopmental deficit, with a relative risk of 2.05 (95% CI 1.49–2.83) when predominantly retrograde flow was observed in the fetal aortic isthmus. These findings are significant and require corroboration. In a group of fetuses from high-risk pregnancies delivered before 34 weeks Todd et al. [14] found that when compared with umbilical Doppler velocimetry, antepartum fetal heart rate monitoring was more strongly associated with poor cognitive function of the infant at 2 years of age. Obviously, additional investigations are required before any definitive conclusions can be reached on this issue.

## Efficacy of Doppler Sonography for Screening Low-Risk and Unselected Pregnancies

Although the diagnostic efficacy of the Doppler technique in a high-risk population is encouraging, its performance in a low-risk population is disappointing, as indicated by several studies summarized below.

In a prospective study involving 2,097 singleton pregnancies, Beattie and Dornan [15] evaluated the capability of umbilical arterial Doppler indices [pulsatility index (PI), S/D ratio, resistance index (RI)] to detect fetal growth restriction and perinatal compromise. It was noted that the indices did not adequately predict any of the parameters of adverse perinatal outcome. It is noteworthy, however, that elevated Doppler indices were the only abnormal findings in three cases of unexplained fetal death in this population. Moreover, although the investigators did not find the indices to be useful for timing the death,

there were no indications that these fetuses underwent adequate surveillance after the abnormal Doppler findings, as up to 6 weeks transpired between the abnormal findings and the fetal death. There is an important methodologic issue related to the Doppler examination technique. The high-pass filter, which screens out low frequency components of the Doppler signal, was set at 200 Hz, thereby increasing the odds of a false-positive diagnosis of an absent end-diastolic velocity. Regrettably, such an inappropriately high setting of the high-pass filter has been used by many other investigators, which may have compromised the validity of their results. Despite these limitations, the main finding that Doppler insonation of the umbilical arteries may not be efficacious in a low-risk population has been corroborated by others [16–18].

Hanretty and coworkers [16] investigated the association between the uteroplacental and umbilical arteries and the obstetric outcome in unselected pregnant mothers. Only the results of the umbilical Doppler studies are discussed here. Their study utilized a prospective blind design and the populations of 326 women at 26–30 weeks' gestation and 356 women at 34–36 weeks' gestation. There was a significant ( $p < 0.05$ – $0.002$ ) decrease in the birth weight of fetuses with an abnormal umbilical artery S/D ratio at either gestation. There were no statistically significant differences between the groups in relation to other obstetric outcomes, including antepartum admission, preeclampsia, preterm delivery, antepartum and intrapartum cesarean section, Apgar score, and NICU admission.

Newnham and associates [17] evaluated the umbilical arterial S/D ratio as a screening tool in a prospective double-blind study of 535 pregnancies at medium risk for fetal compromise. Ultrasound biometry and Doppler measurements were performed at 18, 24, 28, and 34 weeks' gestation. Umbilical artery S/D ratios at 24, 28, and 34 weeks' gestation were found to be predictive of IUGR. This predictive capability was enhanced in the growth-restricted fetuses in whom hypoxia developed but was weak when umbilical artery S/D ratios were evaluated as primary screening tests for fetal hypoxia. The results confirm a role for Doppler-determined S/D ratios in the evaluation of high-risk pregnancies but do not support a role as primary screening tests in low-risk obstetric populations.

Sijmons and colleagues [18] conducted a prospective blind assessment of the efficacy of umbilical arterial PI screening for predicting infants with SGA (birth weight  $< 2.3$ rd and 10th percentile) and a low ponderal index ( $< 3$ rd and 10th percentile). The population consisted of 400 women at 28 and 34 weeks' gestation attending a university tertiary medical cen-

ter. The prevalence of the outcome varied between 3.3% and 22.1%. For the different outcome parameters, the test sensitivity ranged from 6.9% to 41.7%, specificity from 91.5% to 99.7%, the PPV from 10.0% to 52.9%, and the NPV from 79.1% to 97.8%.

## Doppler Velocimetry and Fetal Hypoxia-Asphyxia

In this section we examine the efficacy of Doppler velocimetry of the various fetal circulations to detect fetal hypoxia and acidosis.

### Fetal Asphyxia and Umbilical and Aortic Doppler Indices

A number of clinical studies have been reported on the efficacy of umbilical arterial and aortic Doppler measurements for detecting fetal hypoxia and asphyxia (Table 24.3). The studies employed two distinct approaches for assessing fetal asphyxia. In four studies, umbilical cord blood sampling was performed at the time of elective cesarean section. Blood gases measured in this manner, however, may not reflect the antepartum acid-base status of the fetus. In the remaining five studies, blood gases in fetal blood samples were determined by cordocentesis. Most studies used Doppler assessment of the umbilical artery, although one used the aortic mean velocity and another added aortic and carotid Doppler assessments. In three studies the efficacy of umbilical arterial Doppler and biophysical profile was compared, and one included a comparison with fetal heart rate monitoring. All studies measured pH, most determined the  $PO_2$ , and some also measured  $PCO_2$  and lactate. There was also a considerable variability in the patient populations, ranging from those with sonographic diagnosis of fetal growth compromise to those without recognized risks. Most investigators found a significant association between fetal acid-base compromise and Doppler indices from the umbilical and aortic circulations. As expected, the higher the risk category of the pregnancy, the greater the association of the Doppler results with fetal asphyxia. The association between fetal hypoxia and the umbilical artery Doppler index was less impressive. These studies are discussed below according to whether the investigations were restricted to the Doppler method or included other methods of fetal surveillance.

### Efficacy of Doppler Method

Soothill et al. [19] were the first to use cordocentesis to assess the efficacy of fetal Doppler velocimetry for reflecting fetal oxygenation and acidosis. Umbilical ve-

**Table 24.3.** Association between fetal Doppler results and fetal blood gases

Study, first author	No. of patients	Patient risk category	Cord blood sampling	Doppler assessment	Acid-base parameters	Association correlation
Soothill [19]	29	SGA	Cordocentesis	Aortic MV	pH, PO <sub>2</sub> , PCO <sub>2</sub>	Present

Pardi [22] <sup>b</sup>	21	SGA	Cordocentesis	UA PI	pH, PO <sub>2</sub> , PCO <sub>2</sub> , lactate	Present
Yoon [25] <sup>a</sup>	24	High risk	Cordocentesis	UA PI	pH, PO <sub>2</sub> , PCO <sub>2</sub>	Present

SGA, small for gestational age; AGA, appropriate for gestational age; C/S, cesarean section; UA, umbilical artery; AEDV, absent end-diastolic velocity; MV, mean velocity; PI, pulsatility index; RI, resistance index; S/D, systolic/diastolic ratio.

<sup>a</sup> Studies compared the Doppler method with the biophysical profile.

<sup>b</sup> Study compared fetal heart rate monitoring with the Doppler method.

nous blood PO<sub>2</sub>, PCO<sub>2</sub>, pH, and plasma lactate were measured in 29 fetuses with growth restriction (abdominal circumference <5th percentile for gestational age). A duplex Doppler device was used to determine the mean velocity of aortic blood flow, which demonstrated significant negative correlations with the severity of fetal hypoxia ( $r = -0.73$ ,  $p < 0.0001$ ), hypercapnia ( $r = -0.48$ ,  $p < 0.02$ ), and hyperlactemia ( $r = -0.54$ ,  $p < 0.005$ ) and a positive correlation with fetal venous acidemia ( $r = 0.58$ ,  $p < 0.001$ ). These investigators subsequently demonstrated the efficacy of the continuous-wave Doppler interrogation, a simpler, more cost-effective technique for indirectly reflecting fetal blood gas status [20]. Umbilical venous blood gases were determined by cordocentesis in 59 fetuses with abdominal circumferences below the 5th percentile for gestational age who also suffered from the absence of umbilical artery end-diastolic flow. In 88% of the cases the blood gases were abnormal; 42% were hypoxic, 37% were asphyxiated, and 9% were acidotic. Furthermore, there was poor correlation between the degree of fetal smallness and the acidosis or severity of hypoxia.

Additional support for the efficacy of umbilical artery Doppler indices for detecting fetal hypoxia and acidosis has come from other investigators. Ferrazzi et al. [21] used cord blood sampling at cesarean section on 14 high-risk pregnant patients, 10 of whom also underwent cordocentesis. A significant relation was found between the umbilical artery PI and the fetal blood pH, PCO<sub>2</sub>, and lactate concentrations. Um-

bilical venous oxygen content failed to show this association. A noteworthy observation was the sharp rise in umbilical venous lactate concentration when the umbilical arterial PI exceeded 1.5. Tyrrell et al. [22] observed a significant association between the absence of end-diastolic flow in the umbilical artery and hypoxia and acidosis. The absent end-diastolic velocity detected hypoxia with a sensitivity of 78%, specificity 98%, PPV 88%, and NPV 98%. Similarly, acidosis was detected with a sensitivity of 90%, specificity 92%, PPV 53%, and NPV 100%. When umbilical artery Doppler sonography revealed the presence of the end-diastolic velocity, an S/D ratio elevated beyond 4.5 was diagnostic of hypoxia (sensitivity 89%, specificity 97%, PPV 40%, NPV 98%) and acidosis (sensitivity 100%, specificity 88%, PPV 20%, NPV 100%). Although the authors were confident about the method's diagnostic efficacy for both fetal hypoxia and acidosis, it should be noted that the umbilical arterial response was greater with acidosis than with hypoxia.

### Comparative Efficacy of Doppler Velocimetry and Other Methods of Fetal Surveillance

The diagnostic efficacy of umbilical arterial Doppler velocimetry has been compared with that of other modalities of antepartum fetal surveillance. Pardi and colleagues [23] studied SGA fetuses (abdominal circumference <5th percentile) regarding the umbilical

artery PI and by cardiotocography to detect cordocentesis-derived fetal blood gas abnormalities. Fetuses with normal cardiotocography and a normal PI did not demonstrate hypoxia or acidemia. In contrast, when both tests were abnormal, two-thirds of the fetuses had lactic acidosis, low blood oxygen content, and low pH values. These observations indicate that the combination of Doppler indices and cardiotocography is a powerful tool for identifying asphyxia in the SGA fetus. Use of this approach should improve management of this condition by identifying the infants who are not only small but also compromised, which in turn should promote more timely intervention and at the same time minimize unnecessary procedures.

More extensive investigations exist regarding the comparative efficacy of Doppler velocimetry and the biophysical profile in recognizing fetal asphyxia. Among these studies the report by Vintzileos and co-investigators [24] is the only one that contradicts the rest of the investigations discussed in this chapter. They found no association between the Doppler results and cord arterial and venous pH. Fetal biophysical assessment was made and the umbilical artery S/D ratio determined in 62 patients with pregnancy complications (mostly preeclampsia or SGA) within 3 h of delivery by cesarean section, which was performed before the onset of labor. Cord blood gases were measured on samples collected immediately after delivery of the baby. The relation between the cord arterial and venous pH and the biophysical profile score and NST were statistically significant ( $p < 0.05$ – $< 0.0005$ ), whereas that between the S/D ratio and cord arterial or venous pH was not significant. Furthermore, the NST had the best sensitivity (100%) and NPV (100%). The fetal biophysical profile had the best specificity (91%), PPV (62%), and overall efficiency (90%). The S/D ratio had the lowest sensitivity (66%), specificity (42%), PPV (16%), NPV (88%), and overall efficiency (45%). The authors concluded that the umbilical arterial S/D ratio, as determined by continuous-wave Doppler velocimetry, is inferior to the biophysical profile and the NST, and it has no value for antepartum surveillance for fetal acidosis.

These findings, however, were contradicted by Yoon et al., who used both approaches of cord blood sampling: collection from the cord vessels at cesarean section or from the umbilical vein by antepartum cordocentesis. In the first study [25] the comparative efficacy of Doppler umbilical velocimetry and the biophysical profile for identifying fetal acidosis was investigated in 105 singleton pregnancies in which umbilical blood gases were determined at cesarean section performed before the onset of labor. The biophysical profile and Doppler velocimetry showed comparable effectiveness for detecting fetal acidosis.

Patients with abnormal Doppler results showed a significantly higher prevalence of fetal acidosis, and all the fetuses with abnormal Doppler results were either acidotic or growth-restricted. Upon recognizing the limited validity of cord blood gases sampled at cesarean section for reflecting antepartum fetal acid-base status, the investigators conducted a second study [26], which used cordocentesis to assess fetal acidemia, hypoxemia, and hypercarbia in 24 patients (at 26–40 weeks' gestation). Umbilical arterial PI was determined using pulsed Doppler equipment. The prevalence of fetal acidemia (pH at 2 SD below the mean for gestational age) was 41.7%. A statistically significant relation was noted between the change in umbilical artery PI and fetal acidemia ( $p < 0.001$ ) and hypercarbia ( $p < 0.001$ ) but not hypoxemia ( $p > 0.1$ ). Similarly, a significant relation was noted between the biophysical profile score and fetal acidemia ( $p < 0.001$ ) and hypercarbia ( $p < 0.005$ ) but not hypoxemia ( $p > 0.1$ ). Stepwise multiple logistic regression and ROC analyses demonstrated that umbilical artery Doppler velocimetry was a better predictor for acidemia and hypercarbia than the biophysical profile score.

### Fetal Asphyxia and Cerebral Doppler Sonography

In contrast to the umbilical artery Doppler indices, the cerebral artery Doppler indices demonstrate a consistent relation with fetal hypoxia. The human fetal cerebral circulation is uniquely sensitive to a decline in  $PO_2$  and a rise in  $PCO_2$ . As hypoxia develops, vasodilation and a concomitant fall in the middle cerebral arterial Doppler index occur. When hypoxia becomes severe, the Doppler index tends to rise, suggesting increasing cerebral vascular impedance, which is probably caused by cerebral edema. It is also apparent that the umbilical artery Doppler indices are sensitive to acidosis but not to the partly compensated respiratory acidosis.

Bilardo et al. [27] performed multiple ultrasound biometric and pulsed Doppler measurements in 41 SGA and 10 appropriate-for-gestational-age (AGA) fetuses at 19–37 weeks' gestation. Fetal asphyxia was assessed from umbilical venous blood sampled by cordocentesis. In addition to the  $PO_2$ ,  $PCO_2$ , and pH measurements, an asphyxia index was formulated from the three blood gas parameters by principal component analysis. Of the various ultrasonographic biometric and Doppler parameters, those encompassing the hemodynamic changes in the vascular supply to the fetal brain (internal carotid) and abdominal viscera (aorta) were the best predictors of fetal asphyxia. A more specific study on the middle cerebral artery PI and fetal oxygenation [28], which utilized

cordocentesis for fetal blood sampling, showed a significant quadratic relation between fetal hypoxemia and the degree of reduction in the PI. The maximum fall in PI occurred when the fetal  $PO_2$  was 2–4 SD below the normal mean for gestation. When the oxygen deficit increased, the PI tended to rise. The authors speculated that this increase reflected the development of fetal brain edema.

The fetal cerebral and umbilical circulatory responses to hypoxia, hypercapnia, and acidosis were investigated by Chiba and Murakami [29] in 17 SGA fetuses. Cordocentesis was performed to determine umbilical venous blood gases and pH. The fetal circulatory response was evaluated by gestation-adjusted RI values from the middle cerebral and umbilical arteries. The middle cerebral artery demonstrated decreased impedance in the presence of hypoxia and acidosis. In contrast, the umbilical artery impedance increased with acidosis but was insensitive to hypoxia and hypercapnia. These observations were corroborated by Akalin-Sel et al. [30], who found a low  $PO_2$  and pH and a high  $PCO_2$  in the umbilical venous blood sampled by cordocentesis from the SGA fetuses compared to the gestation-related normal values. The cerebral circulation was responsive to hypoxia and hypercapnia, whereas the aortic and umbilical circulations were responsive to hypercapnia and acidosis but not to hypoxia. Decreased impedance in the cerebral arterial system was associated with increased impedance in the aortic, umbilical, and uteroplacental arteries.

These findings have significant clinical implications for managing high-risk pregnancies. Although some animal studies suggest that fetal Doppler velocimetry may not be efficacious for identifying fetal asphyxia, it may not be applicable to the human situation, as indicated by the results of clinical research summarized above. Obviously, the fetal cardiovascular response to chronic and progressive hypoxia and acidosis is complex. Doppler investigation helps us to elucidate this phenomenon and may contribute to improving the perinatal outcome. The differential response of the umbilical and cerebral hemodynamics to hypoxia and acidosis may be utilized to sequence the progression of fetal compromise, which may significantly enhance the diagnostic efficacy of the Doppler technique. Moreover, integration of the current modes of fetal surveillance, such as antepartum cardiotocography or biophysical profile scoring with the Doppler mode, offers exciting possibilities for improving the clinical value of this diagnostic approach.

## Sequence of Changes in Fetal Surveillance Parameters with Progressive Antepartum Fetal Compromise

Although comparisons have been made between Doppler velocimetry and other prevalent modes of fetal surveillance, no single testing modality should be regarded as the exclusive choice for fetal surveillance, as these tests reveal different aspects of fetal pathophysiology, often in a complementary manner. Obviously, more work is needed to determine the optimal integration of the various surveillance methods for improving the perinatal outcome in a cost-effective manner: It is important to establish the sequence in which the various signs of fetal compromise manifest during surveillance of the fetus at risk. It is known that not all of these signs appear simultaneously. We have witnessed a variable chronology of falling cerebral Doppler indices, rising umbilical arterial Doppler indices, eventual disappearance of the end-diastolic flow, and the occurrence of ominous cardiotocographic patterns. It is also critical to examine the prognostic significance of the pattern of these occurrences. A few studies have systematically addressed this issue.

Arduini et al. [31] followed 36 SGA fetuses with an abnormal elevation of the umbilical and middle cerebral artery PI ratios (>95th percentile) until the onset of antepartum late deceleration of the fetal heart rate. Comprehensive Doppler evaluation of the fetal circulation was performed along with fetal cardiotocographic examination. Statistically significant changes in PI occurred in all the vessels (umbilical artery, descending aorta, renal artery, internal carotid artery, middle cerebral artery). The most significant fall in the middle cerebral PI occurred 2 weeks before the onset of late deceleration, indicating the maximum compensatory vasodilatory response of the cerebral circulation. In contrast, significant increases in the peripheral and umbilical PI occurred close to the onset of abnormal fetal heart rate patterns. James et al. [32] evaluated the chronology of abnormalities of: (1) umbilical artery Doppler results; (2) fetal growth as indicated by ultrasound measurement of the fetal abdominal circumference; and (3) biophysical profile score. The retrospective study of 103 fetuses at risk of chronic fetal asphyxia revealed that the umbilical artery Doppler result deteriorated first, followed by the abdominal circumference, and then the biophysical profile score. Whereas an abnormality of one of these parameters in isolation did not result in any adverse consequences, abnormality of all three ultrasonographic features led to the worst outcome.

A prospective longitudinal investigation was conducted by Ribbert et al. [33] that included the follow-

ing indicators of fetal well-being: fetal heart rate variability, body movements, breathing movements, and Doppler hemodynamic evaluation of the umbilical and internal carotid arteries. The study population consisted of 19 SGA fetuses who eventually required delivery by cesarean section because of fetal distress. In 14 of 19 fetuses, abnormal velocity waveforms were present from the beginning of the study. The heart rate variability was initially marginal but declined further during the last 2 days preceding delivery. Decreased body and breathing movements occurred subsequently and less frequently. The worst outcome was in fetuses with reversed end-diastolic velocities and a rapid fall in the variability. The authors concluded that with the progressive decline of the fetal condition fetal test abnormalities occur in the following sequence: Abnormal velocity waveform patterns occur first followed by a progressive decrease in the heart rate variability; fetal general body and breathing movements are the last to decline.

Weiner et al. [34], studying hemodynamic changes in the middle cerebral artery and the aortic and pulmonary outflow tracts, correlated these changes with the computerized fetal heart rate pattern in fetuses with absent end-diastolic velocity in the umbilical artery. They observed that with progressive deterioration of the fetal status the cerebral circulation loses its autonomic reactivity first, followed within a few days by a similar response in the heart, as shown by the decreased fetal heart rate variability. This study is discussed in greater detail in Chap. 25.

A prospective longitudinal study was conducted by Hecher et al. [35] that included short-term variation of the fetal heart rate, PIs of fetal arterial and venous waveforms, and the amniotic fluid index. The study population included 110 singleton pregnancies with growth-restricted fetuses after 24 weeks of gestation and was divided into two groups: pregnancies delivered at 32 weeks or less and pregnancies delivered after 32 weeks. The first variables to become abnormal were the amniotic fluid index and the umbilical artery PI. Abnormalities of the middle cerebral artery, aorta, fetal heart rate short-term variation, ductus venosus, and inferior vena cava then followed. The decrease in PI of the middle cerebral artery followed the abnormalities in the umbilical PI, and became progressively abnormal until delivery in the pregnancies delivered before 32 weeks. In pregnancies delivered after 32 weeks the authors found a normalization of the middle cerebral artery PI before abnormalities in the fetal heart rate. In the pregnancies delivered before 32 weeks of gestation, the increase in the ductus venosus PI and the decrease in short-term variation were more pronounced than the changes in the other variables and became abnormal a few days before delivery. In addition, perinatal mortality was

significantly higher if the short-term variation and ductus venosus PI were abnormal compared to only one or neither being abnormal.

Baschat et al. [36] examined longitudinally 44 growth-restricted fetuses with elevated umbilical artery PI ( $>2$  standard deviations above mean) and birth weight below the 10th percentile who required delivery for abnormal scores in the biophysical profile. Fetal well-being was assessed serially using all five components of the biophysical profile and concurrent Doppler evaluations of the umbilical artery, middle cerebral artery, ductus venosus, inferior vena cava, and free umbilical vein. The majority of the fetuses did not have reactivity of the fetal heart rate. The investigators observed significant deterioration of the biophysical profile and Doppler studies between the first examination and time of delivery. First, there was a change in the Doppler variables. In 42 (95.5%) fetuses one or more of the Doppler variables were abnormal. The umbilical artery and ductus venosus PI abnormalities progressed rapidly a median of 4 days before the biophysical profile worsened. Fetal breathing movement began to decline 2–3 days before delivery, followed by a decrease in the amniotic fluid volume. Loss of fetal movement and tone were observed on the day of delivery. Additionally, in 31 fetuses deterioration in the Doppler parameters was complete 23 h before a worsening of the biophysical profile, while in 11 fetuses deterioration of the Doppler parameters and the biophysical profile occurred simultaneously.

The above studies indicate that Doppler velocimetry and existing fetal monitoring techniques can be integrated to provide greater pathophysiologic insight into the mechanism of progressive fetal decompensation. Such integration may provide a rational, effective alternative to the current standards of fetal surveillance.

## Summary

There is ample evidence that Doppler indices from the fetal circulation can reliably predict adverse perinatal outcome in an obstetric patient population with a high prevalence of complications, such as fetal growth restriction and hypertension. This efficacy is not evident, however, in populations with a low prevalence of pregnancy complications. It is also apparent that fetal Doppler indices are capable of reflecting fetal respiratory deficiency with varying degrees of efficiency. The umbilical arterial Doppler indices are more sensitive to asphyxia than to hypoxia, whereas cerebral Doppler indices demonstrate significant sensitivity to hypoxia. Compared to fetal heart rate monitoring and the biophysical profile, umbilical artery

Doppler velocimetry shows mostly similar and often superior efficacy. Furthermore, progressive fetal deterioration manifests in sequential abnormalities of the various fetal assessment parameters, starting with middle cerebral artery vasodilation and eventual progression to disappearance of the fetal heart rate variability, late deceleration, and the absence or reversal of the end-diastolic velocity in the umbilical artery. Evidently, no single testing modality should be regarded as the exclusive choice for fetal surveillance, as these tests reveal different aspects of fetal pathophysiology, often in a complementary manner. Clearly, more work is needed to determine the optimal integration of the various surveillance methods for improving perinatal outcome in a cost-effective manner.

# Absent End-Diastolic Velocity in the Umbilical Artery and Its Clinical Significance

Dev Maulik, Reinaldo Figueroa

Among the characteristics of the umbilical arterial Doppler waveform, the end-diastolic velocity is of primary hemodynamic and clinical significance. As discussed in Chap. 10, the end-diastolic velocity demonstrates an impressive continuous increase throughout the gestation which is attributable to an ever-increasing decline of the fetoplacental flow impedance. It results in a concomitant decrease in the pulsatility of the waveform and is reflected in the Doppler indices such as the systolic/diastolic (S/D) ratio and the resistance index (RI), both of which progressively decline with the advancing gestation. These changes are prognostically reassuring. In contrast, any decline in the end-diastolic velocity with the consequently rising Doppler indices indicates rising impedance in the fetoplacental vascular bed and signifies a worsening

prognosis. With the further increase of impedance, the end-diastolic velocity eventually becomes absent. Such a development, though rare, is ominous and results in a profoundly adverse perinatal outcome. An example of absent end-diastolic velocity (AEDV) is shown in Fig. 25.1. Occasionally, further hemodynamic deterioration occurs, resulting in reversal of the end-diastolic velocity (Fig. 25.2). The impressive amount of information [1–26] now available on the clinical significance of the absent and reversed end-diastolic velocity in the umbilical artery is appraised in this chapter.

**Fig. 25.1.** Example of absent end-diastolic velocity in the umbilical artery. *Top:* Color Doppler-directed pulsed Doppler interrogation of the umbilical vessels. *Bottom:* umbilical arterial Doppler waveforms. Note that there is no noticeable loss of low frequency shift information, as the high-pass filter was set at 50 Hz

**Fig. 25.2.** Progressive disappearance of the end-diastolic frequency shift in the umbilical arterial Doppler waveforms from a pregnancy complicated with severe fetal growth restriction at 33 weeks' gestation. *Top left:* Presence of the end-diastolic frequency shift, although the Doppler indices were high for the gestational age (systolic/diastolic ratio 5; resistance index 0.8). *Top right:* Absence of the end-diastolic frequency shift. *Bottom left:* Spontaneous deceleration with prolongation of the diastolic phase and the appearance of umbilical venous pulsation. *Bottom right:* Progression to the reversal of the end-diastolic frequency shift

**Table 25.1.** Incidence of absent and reversed end-diastolic velocity in high- and low-risk populations

Study, first author	No. of patients	Risk category	Doppler type	High-pass filter (Hz)	AEDV	
					No.	%
Johnstone [7]	380	High	PW, CW	150	24	6.30
Beattie [27]	2,097	Low	CW	200	6	0.29
Huneke [14]	226	High	CW	200	18	8.00
Malcolm [15]	1,000	High	PW	100	25	2.50
Wenstrom [17]	450	High	PW	100	22	4.90
Weiss [19]	2,400	Unselected	PW	50	51	2.10
Battaglia [23] <sup>a</sup>	46	Very high	PW	100	26	56.20
Pattinson [22]	342	Very high	PW, CW	150	120	34.50
				200		
Rizzo [25]	6,134	High	PW	100	192	3.10
Karsdorp [24] <sup>a</sup>	459	Very high	?PW	Lowest	245	53.40

CW, continuous wave; PW, pulsed wave; AEDV, absent end-diastolic velocity.

<sup>a</sup>Fetuses with congenital anomalies and dyskaryosis were clearly excluded. The other studies either included these fetuses or are unclear about it.

## Incidence

The frequency with which absent or reversed end-diastolic velocity (AREDV) is encountered in the umbilical artery varies according to the risk category of the obstetric population, the time of gestation at which the observation is made, and the Doppler examination technique. For high-risk pregnancies the incidence varies from 2.1% to 56.0% (Table 25.1). Such a wide range may be explained by the differing definitions of high-risk pregnancy used by the investigators and by the level of the high-pass filter used. For example, the basis for high-risk categorization of a pregnancy may range from clearly defined clinical criteria, such as hypertension, to ill-defined groupings of various clinical conditions. In contrast to that in the high-risk population, the incidence of AREDV may be as low as 0.29% in an obstetric population with a low prevalence of pregnancy complications. The following two examples illustrate this point. In probably the largest reported series on AREDV, Karsdorp et al. [24] used well-defined criteria for selecting the population for a multicenter study. Only patients with hypertension or fetal growth restriction (or both) were included. Hypertension was defined as a diastolic pressure of 110 mmHg by a single measurement or 90 mmHg by two or more measurements. Also included were patients with hypertension plus proteinuria; the latter was defined as urinary protein loss of more than 300 mg in 24 h. Intrauterine growth restriction (IUGR) was defined as the abdominal circumference measuring less than the 5th percentile for gestational age based on local population-specific nomograms. The lowest possible high-pass filter threshold was used. Of the 459 patients selected

in this manner, 245 developed AREDV, for an incidence of 53.4%. In comparison, Beattie and Dornan [27] found that only 6 of 2,097 singleton pregnancies developed AREDV for an incidence of 0.29%. The actual rate might even be lower if we consider that the high-pass filter setting was 200 Hz, which is relatively high for umbilical arterial Doppler insonation.

## Technical Considerations

As alluded to above and discussed elsewhere in this book, the procedure used for Doppler measurement may affect the measured magnitude of the end-diastolic frequency shift. It is apparent from the basic principles of the Doppler shift that shifted frequencies can only be underestimated, not overestimated. There are two technical sources of this problem: (1) the threshold setting of the high-pass filter; and (2) the angle of insonation between the Doppler beam and the flow axis. The high-pass filter (see Chap. 3) eliminates from the Doppler signal the low-frequency/high-amplitude frequency component and is used to remove signals generated by movement of the vascular wall or other adjacent tissues. This filter, however, also removes low-frequency components generated from the slow-moving blood flow as encountered during the end-diastolic phase of the cardiac cycle. Thus end-diastolic frequencies are removed from the umbilical Doppler waveform. A relatively high setting of the filter therefore leads to a false diagnosis of AEDV. It is strongly recommended that the high-pass filter should be at the lowest possible setting, which may not exceed 100 Hz. The second consideration is related to the angle of insonation, which is inversely related to the magnitude of the es-

timated Doppler shift because of the cosine function of the angle in the Doppler equation (see Chap. 2). A larger angle therefore leads to a lower frequency measurement, which leads to disappearance of the end-diastolic frequency even in the presence of end-diastolic flow.

## Absent End-Diastolic Velocity and Adverse Perinatal Outcome

There is an ominous association between the AREDV in the umbilical artery and adverse perinatal outcome (Table 25.2). The latter includes not only morbid states, such as fetal growth restriction, developmental anomalies, and abnormal chromosomes, but also a substantial increase in perinatal deaths. In addition, there is a significant association with pregnancy complications, such as hypertensive disease of pregnancy and oligohydramnios.

### Perinatal Mortality

One of the most remarkable features of umbilical arterial absent and reverse flow is the catastrophic increase of deaths of fetuses in utero and of neonates. From a total of 1,126 cases of AREDV reviewed in this chapter, 193 were stillborn and 312 died during the neonatal period. These data translate into a 170/1,000 stillbirth rate and 280/1,000 neonatal mortality rate, respectively – hence a 450/1,000 perinatal mortality rate. Most deaths are attributable to obstetric complications, such as growth restriction and hypertension with the underlying pathology of chronic in utero respiratory and nutritional deprivation, but they also may be attributed to the higher frequency of anomalies and aneuploidy encountered in these infants, as well as prematurity. It is difficult to correct the mortality figures for congenital malformations and chromosomal abnormalities, as most studies do not explicitly report this information. However, it appears that the corrected perinatal mortality is approximately 340/1,000 births. When the end-diastolic flow in the umbilical artery is reversed, the outcome is abysmal. The European Multicenter Study observed that 98% of such infants required NICU admission, and the odds ratio for perinatal mortality was 10.6 when compared to those with positive end-diastolic velocity. The reverse flow therefore indicates severe fetal decompensation and, if unattended, eventually leads to an agonal pattern and fetal death. An example is presented in Fig. 25.3.

**Table 25.2.** Absent and reverse end-diastolic velocity in the umbilical artery and adverse perinatal outcome

Perinatal outcome	Mean	Range
Death (%)	45	17–100
Gestational age (weeks)	31.6	29–33
Birth weight (g)	1,056	910–1,481
Small-for-gestational age (%)	68	53–100
Cesarean section for fetal distress (%)	73	24–100
Apgar score <7 at 5 min (%)	26	7–69
Admission to neonatal intensive care unit (%)	84	77–97
Congenital anomalies (%)	10	0–24
Aneuploidy (%)	6.4	0–18

**Fig. 25.3.** Umbilical arterial Doppler velocimetry showing an agonal pattern. Note that reverse end-diastolic velocity was present for most of the cardiac cycle (60%–70%). This pattern signifies that fetoplacental perfusion, which is normally present for the duration of the cardiac cycle, was seen in this case for only a fraction of that time

### Perinatal Morbidity

Not only is there a high rate of perinatal loss, the surviving fetuses and infants demonstrate signs of profound compromise, with a marked increase in the incidence of various measures of morbidity (Table 25.2). One of the main complications of AREDV is a high frequency of fetal anatomic malformations and aneuploidy. In addition, there is a great preponderance of preterm births and low birth weight infants, which are mostly attributable to fetal or maternal complications mandating early intervention. Thus there is a three- to fourfold increase in the number of cesarean deliveries because of fetal distress. These infants are of low birth weight because they are not only preterm but also suffer from growth deficit.

There is a much higher frequency of fetal acidosis, ominous cardiotocographic findings, low Apgar score, and the need for NICU admission. Furthermore, the combination of fetal asphyxia and prematurity exposes the fetus to the additional danger of end-organ damage, such as necrotizing enterocolitis and cerebral hemorrhage.

### ***Congenital Malformation and Chromosomal Abnormalities***

There is a preponderance of congenital malformations and abnormal chromosomes in fetuses afflicted with umbilical arterial AREDV. Cumulative data, as summarized in Table 25.2, demonstrate that one in ten fetuses with AREDV have anatomic maldevelopment. There is heterogeneity, however, in the reported incidence. In studies with small populations the frequency may be in excess of one in five. On the other hand, not all studies encountered fetal anomalies associated with AREDV that frequently. Pattinson and associates [22], in a reported series of 120 AREDV infants, observed no anomalies independent of aneuploidy. The largest series of malformations in relation to umbilical arterial AREDV was reported by Rizzo and colleagues [25], who found 25 fetuses with anomalies among 192 with AREDV; of these anomalies, 14 were associated with aneuploidy.

The AREDV-associated anomalies involve most organ systems (Table 25.3), although anomalies of the cardiovascular system are encountered most frequently. Isolated and multiple malformations are en-

**Table 25.3.** Absent end-diastolic velocity and congenital malformations

Dysplasia

countered with equal frequency, and most cases of multiple anomalies are seen with aneuploidy. Hence most cases with normal chromosomes have isolated malformations, whereas most cases of aneuploidy are associated with multiple malformations.

The frequency of chromosomal abnormalities is 1 in 16. Autosomal trisomy dominates, with trisomy 18 being the most frequently encountered aneuploidy. The relative distribution of various chromosomal anomalies in AREDV fetuses is shown in Fig. 25.4. The risk factors for chromosomal aberrations include (1) an absence of obstetric complications, such as gestational hypertension or preeclampsia; (2) the presence of fetal malformations; and (3) the appearance of absent end-diastolic velocity (AEDV) at an early gestational age. Although these fetuses are severely growth-restricted, there is no difference in the pattern of growth compromise between those with abnormal chromosomes and those without. Snijders and associates [28] studied a population of 458 growth-restricted fetuses and observed that the fetuses with chromosomal abnormalities had a higher mean head-circumference/abdominal circumference ratio than fetuses with a normal karyotype. More specifically, Rizzo and associates [25], in their investigation of fetuses with AEDV, found no significant difference in head/abdomen circumference between those with abnormal karyotype and those with a normal karyotype. This finding is contrary to the conventional wisdom, which holds that fetuses with chromosomal aberrations suffer from symmetric growth compromise.

Many of these infants also tend to develop abnormal fetal heart rate patterns during labor, which may lead to cesarean delivery unless the fetal karyotype is known. The mechanism of increased fetoplacental impedance is not fully understood. The work of Rochelson and colleagues [29], however, shed considerable light on this phenomenon. A quantitative morphometric analysis of placentas revealed a significant reduction in the small muscular artery count and the small muscular artery/villus ratio. Abnormal Doppler

**Fig. 25.4.** Relative frequency of the various chromosomal abnormalities associated with umbilical arterial absent end-diastolic velocity

waveforms correlated closely with reduced small muscular artery counts. It is apparent that aneuploidy adversely affects fetoplacental vascularization, which results in increased fetoplacental circulatory impedance and may contribute to fetal growth restriction.

Recently, Doppler flow studies in the umbilical artery were performed in first trimester fetuses. Borrell and colleagues [30] screened 2,970 pregnancies at 10–14 weeks' gestation and observed 11 cases of reversed end-diastolic flow for an incidence of 0.4%. Seven of the 11 fetuses had an autosomal trisomy and two other fetuses had a congenital heart defect.

Earlier, Martinez and associates [31] had prospectively recorded the umbilical artery pulsatility index (PI) in 1,785 pregnancies before undergoing chorionic villus sampling or genetic amniocentesis. They had shown that fetuses with trisomy 18 had an elevated PI. The PI was measured transvaginally for pregnancies from 10 to 13 weeks and transabdominally for pregnancies from 14 to 18 weeks. Seven of the ten fetuses with trisomy 18 had an elevated PI above the 95th percentile; nine fetuses had an elevated PI above the 90th percentile. PI as a marker for trisomy 18 had good sensitivity (70%–90%), specificity (>90%), and negative predictive value (99%) but a poor positive predictive value (5%–7%). Reversed end-diastolic flow was detected in two cases, both of which had trisomy 18.

### ***Intrauterine Growth Restriction***

The strength of the relation between AREDV and fetal growth compromise depends on the stringency of the definition of growth restriction. A small-for-gestational-age (SGA) fetus is not necessarily growth-restricted, as fetal “smallness” may also be constitutional in nature. It is also probable that a fetus who fails to realize its full growth potential may not necessarily be SGA. Indeed, the terms IUGR and SGA demonstrate diagnostic uncertainty and lack prognostic reliability. Being SGA does not necessarily indicate a compromised outcome. Despite these ambiguities, fetuses experiencing a substantial defined growth failure often suffer from in utero asphyxia and its adverse consequences. These fetuses also have Doppler evidence of increasing fetoplacental arterial impedance. Thus 50% or more of the fetuses with AREDV demonstrate a growth disturbance (Table 25.2). A similar proportion of fetuses with sonographic evidence of growth restriction develop AREDV. Thus Battaglia and associates [23] noted that 57% of the fetuses identified as being growth restricted by serial ultrasound measurements developed AEDV. Similarly, Pattinson and colleagues [22] observed that 48% of the fetuses suspected of severe growth restriction in their series developed umbilical

arterial AREDV. It is noteworthy that pregnancies complicated by both growth restriction and hypertension demonstrate a greater propensity for developing AREDV than those with either growth restriction or hypertension [24].

### ***Fetal Asphyxia and Hypoxia***

Fetal asphyxia and hypoxia can largely be attributed to fetal exposure to chronic hypoxic and asphyxial insult. The significant association between abnormal umbilical arterial Doppler indices and fetal hypoxia and acidosis is discussed in Chap. 24. It is apparent that the umbilical hemodynamics are affected more by asphyxia or acidosis and less by hypoxia. One of the most impressive pieces of evidence has been provided by Nicolaides and associates [32], who measured umbilical venous blood gases by cordocentesis in 59 fetuses suspected of growth restriction (abdominal circumference below the 5th percentile for gestational age). These fetuses also demonstrated absent umbilical arterial end-diastolic flow. In 88% of the cases the blood gases were abnormal; 42% of the fetuses were hypoxic, 37% asphyxiated, and 9% acidotic. Furthermore, there was a poor correlation between the degree of fetal smallness and acidosis or severity of hypoxia. Other investigators [33] have also observed this efficacy of absent end-diastolic flow and fetal acidosis. The AEDV identified acidosis with a sensitivity of 90%, specificity 92%, positive predictive value (PPV) 53%, and negative predictive value (NPV) 100%.

It is important to note that not all fetuses with AREDV are hypoxic or acidotic. Normal fetal blood gas values, however, do not ensure fetal well-being. Several investigators have noted progressive fetal deterioration and adverse perinatal outcome in fetuses with AREDV despite normal fetal acid-base status as determined by cordocentesis [34, 35]. It appears that progressive fetal hemodynamic decline, as manifested by umbilical arterial AREDV, is not necessarily related to fetal asphyxia and presents a serious threat to the fetus independent of fetal hypoxia or acidosis.

### ***Cerebral Hemorrhage***

One of the major concerns regarding chronic intrauterine asphyxia is its effect on the fetal brain. Although the risk of fetal brain damage due to prematurity and birth asphyxia has been well investigated, the role of antepartum asphyxia in fetal neurologic damage due to hypoxemic ischemic injury requires elucidation. One of the gross lesions from such injury is cerebral hemorrhage, which has been reported in association with AREDV. The main question is whether this association is independent of the preterm birth of these infants.

**Table 25.4.** Umbilical arterial absence of end-diastolic velocity and cerebral hemorrhage

Study, first author	Cerebral hemorrhage		<i>p</i>
	Control group	AREDV group	
Weiss [19] <sup>a</sup>	3/47 (6%)	7/47 (15%)	>0.05
Pattinson [21] <sup>a</sup>	3/16 (19%)	4/16 (25%)	>0.05
Karsdorp [24] <sup>b</sup>	1/124 (1%)	27/168 (16%)	<0.02

<sup>a</sup> Case-control study, matched for gestational age.

<sup>b</sup> Corrected for gestational age by multiple logistic regression.

Weiss and associates [19] conducted a case-control study, comparing 47 fetuses with AREDV of the umbilical artery to 47 control fetuses matched for gestational age and with normal umbilical artery flow velocity waveforms. Fetuses with AREDV showed an increased incidence of cerebral hemorrhage (Table 25.4), but it was not statistically significant. Pattinson and associates [21] also performed a case-control study that showed no difference in cerebral hemorrhage between the 16 matched pairs of fetuses with the presence or absence of umbilical artery end-diastolic velocity. Both of the above findings were refuted by the much larger European Community Multicenter Study [24], which found a significantly increased incidence of severe cerebral hemorrhage in the fetuses with AREDV (Table 25.4). Although it was not a case-control study, the contribution of prematurity was corrected by multiple logistic regression. The odds for cerebral hemorrhage increased by 2.6 when the end-diastolic velocity was absent and by 4.8 when the velocity was reversed. It appears that in a pregnancy complicated with fetal growth restriction or hypotension (or both) AREDV may be associated with an increased risk of fetal cerebral hemorrhage. Such hemorrhagic complication may be related to hypoxic ischemic injury induced by antepartum asphyxial insult and may be causally related to reperfusion. This consideration is important when critically examining the role of Doppler velocimetry of the fetal circulation as an indicator for antepartum asphyxia-related gross brain injury. Obviously, more work is needed in this area to clarify these issues.

### **Necrotizing Enterocolitis**

Several investigators have reported on the increased risk of necrotizing enterocolitis in neonates who had suffered in utero from AREDV of the umbilical artery or the aorta. This serious complication is typically seen in premature neonates who experienced perinatal asphyxia, often secondary to the respiratory distress syndrome caused by pulmonic immaturity. Most infants with AREDV are delivered before 32 weeks

(Table 25.2) and are therefore more apt to develop these complications independent of the existence of AREDV.

The issue is again whether AREDV contributes to this complication independent of prematurity. Hackett and colleagues [4] investigated 82 consecutive cases of fetal growth restriction and identified 29 fetuses with an absence of end-diastolic frequencies in the fetal aorta. These fetuses were significantly more growth-restricted ( $p < 0.001$ ), delivered earlier ( $p < 0.001$ ), and were more apt to suffer perinatal death ( $p < 0.05$ ), necrotizing enterocolitis ( $p < 0.01$ ), or hemorrhage ( $p < 0.05$ ). Malcolm and coinvestigators [15] studied 25 high-risk pregnancies with AREDV in the umbilical artery and observed a highly significant increased risk of necrotizing enterocolitis in the morphologically normal fetuses (53%) compared with the controls (6%), who demonstrated umbilical artery end-diastolic flow in utero. This increased risk appeared to be independent of the degree of growth restriction, prematurity, or perinatal asphyxia. These findings were supported by those of McDonnell and colleagues [36], who noted that the infants who had AREDV were started on enteral feeds later, were more likely to receive parenteral nutrition, and developed necrotizing enterocolitis more frequently than a gestationally matched control group.

The conclusion that AREDV may increase the risk of developing necrotizing enterocolitis independent of prematurity, however, was not supported by Karsdorp and associates [24] in their European multicenter research project. Although proportionately more infants with AREDV developed necrotizing enterocolitis, the difference was not statistically significant ( $p = 0.20$ ). Moreover, when corrected for gestational age, the absence or reversal of umbilical arterial end-diastolic flow did not influence the risk of respiratory distress syndrome or necrotizing enterocolitis of the neonate.

Other investigators have not confirmed the findings of Hackett [4] and Malcolm [15]. Kirsten and colleagues [37] evaluated 242 infants born to women with severe early preeclampsia (before 34 weeks' gestation). Sixty-eight (28%) of these infants had AEDV while 131 (54%) had normal umbilical artery Doppler flow velocities. Twenty infants developed definite (grade 2) and advanced (grade 3) necrotizing enterocolitis and 21 infants had suspected (grade 1) necrotizing enterocolitis. None of the infants with definite necrotizing enterocolitis had AEDV. In addition, the prevalence of suspected necrotizing enterocolitis between the infants with AEDV and the infants with normal umbilical artery Doppler flow studies was similar (48% versus 43%). Kirsten and associates postulated that the suspected necrotizing enterocolitis could have been a disturbance of the motility of the gastrointestinal tract as a result of the preeclampsia

or the administration of magnesium sulfate to the mother and not necessarily necrotizing enterocolitis. Suspected necrotizing enterocolitis is a clinical diagnosis and, in the majority of cases, the condition improves with conservative management.

### **Hematologic Changes**

Neonates with AREDV during fetal life are apt to develop thrombocytopenia and anemia. They may have a low platelet count at birth and are more likely to become significantly thrombocytopenic during the first week of life [36]. They are also at increased risk of being anemic. It has also been reported [24] that the infants with absent or reversed end-diastolic velocity had odds ratios of 3.0 and 6.1, respectively, for developing anemia compared to a control group of infants. The latter were growth-restricted and their mothers had hypertension, but they had umbilical arterial end-diastolic forward flow. The reason for developing anemia independent of prematurity and other known complications remains to be determined [24].

Baschat and colleagues [38] have also shown that AREDV in growth-restricted fetuses is associated with an increased risk of neonatal thrombocytopenia. In a study comparing 67 fetuses with elevated PI (more than two standard deviations above the mean) to 48 fetuses with AREDV, 22 of the 48 fetuses with AREDV had thrombocytopenia ( $<100,000 \text{ mm}^3$ ) compared to 3 of the 67 fetuses in the control group. Neonates with AREDV had a relative risk of 10.3 or a tenfold increase in the incidence of thrombocytopenia when compared to the control group. In addition, neonates with AREDV had a higher nucleated red blood cell count than the control group. High numbers of nucleated red blood cells in the umbilical cord have been associated with hypoxemia during intrauterine life and subsequent neurologic impairment.

Similarly, Axt-Flidner and coinvestigators [39] reported an increased number of nucleated red blood cells in the umbilical artery at birth in growth-restricted neonates with AREDV during fetal life when compared to neonates with elevated Doppler studies. Moreover, the nucleated red blood cells persisted in the neonatal circulation for a longer period of time in the neonates with AREDV. Nucleated red blood cells are immature erythrocytes. They are seen in variable numbers in the newborn circulation. Although an increased number of nucleated red blood cells has been attributed to increased erythropoiesis in the fetal liver as a result of chronic hypoxemia, these studies [38, 39] have shown that the neonates with a higher number of nucleated red blood cells have lower hematocrits, hemoglobin levels, and platelet counts than the other neonates studied.

### **Hypoglycemia**

Infants with AREDV become hypoglycemic more frequently, and it cannot be fully attributable to preterm gestational age or IUGR. The odds for developing hypoglycemia is 5.0 compared to growth-compromised fetuses without AREDV [24]. The reason for this metabolic problem remains unclear.

### **Neurodevelopmental Sequelae**

Any examination of the efficacy of umbilical arterial AREDV for fetal prognostication must go beyond looking for gross cerebral lesions (e.g., hemorrhage) and encompass immediate and long-term neurologic performance. Furthermore, it is imperative that neurologic outcome measures should be extended to include not only moderate to severe neurologic deficits but also more subtle compromises in cognitive and motor performance. Although there is a paucity of information in this area, a few preliminary reports are available concerning the neurodevelopmental significance of AREDV. Weiss and associates [19] observed in their case-control study (see above) an increase in abnormal neurologic signs in the AREDV group. The pediatric neurologic assessment was blinded to the fetal Doppler results. The adverse signs included persistent hyperreflexia, hypo- or hypertonia, seizures, and cerebral palsy. Fourteen fetuses in the index group (30%) and three fetuses in the control group (6%) demonstrated abnormal neurologic signs at the time of discharge. The results were statistically significant ( $p < 0.006$ ).

In a more comprehensive and long-term investigation, Valcamonico and associates [40] conducted a cohort study in a group of 31 fetuses with IUGR and AREDV in the umbilical artery and 40 growth-restricted fetuses with detectable diastolic flow in the umbilical artery divided into two control groups. The survivors of the perinatal period were followed for a mean of 18 months (range 12–24 months). Twenty surviving neonates with AREDV demonstrated a greater risk of permanent neurologic sequelae (35% versus 0% and 12%) than the two control groups. Although the results suggest that growth-compromised fetuses with AREDV are at a significant risk of sustaining long-term permanent neurologic damage, it may be premature to draw a definitive conclusion on the neurodevelopmental significance of AREDV. This hesitation is based on such observations as those of Pillai and James [41], who performed serial behavioral observations in four severely growth-restricted singleton fetuses who had persistent AREDV for 2–9 weeks. Comparison with 45 low-risk singleton fetuses at comparable gestations revealed no significant differences in the development of behavioral cycles, the proportion of time spent in quiet cycles, or the

amount of fetal breathing. The heart rate pattern remained normal in all the fetuses. Kirsten and associates [42a] evaluated the neurodevelopmental outcome of a group of infants of 242 women with severe early preeclampsia (<34 weeks). Sixty-eight of these women had neonates with AEDV in fetal life. In total, 193 infants, 51 with AEDV, survived to hospital discharge and were evaluated every 6 months until 48 months of age. In all, 126 infants were assessed at 24 months of age. The infants with AEDV scored significantly lower in the performance subscale compared to the infants who had normal or elevated umbilical artery flow studies. In total, 157 infants were assessed at 48 months of age. No differences were noted in developmental quotients, verbal and nonverbal quotients, or in any of the nonverbal intelligence subscales based on umbilical artery flow velocities. Multiple regression analysis showed that socioeconomic status was significantly associated with lower developmental quotients. Cerebral palsy was identified in four of the infants evaluated; AEDV was not associated with cerebral palsy. The mean developmental quotient at 24 and at 48 months of age was not associated with AEDV. It appears that prenatal neurobehavioral development is not necessarily compromised even by long-term AREDV. Although the above investigations did not utilize similar or even comparable methods of neurologic assessment, it is obvious that additional in-depth and long-term investigations are necessary to reconcile these apparently contradictory findings and to elucidate their implications for clinical management.

See Chap. 12 for further discussions on Doppler ultrasound and neurological outcomes.

## Maternal Hypertension and Absent End-Diastolic Velocity

The most frequent maternal complications seen in conjunction with AREDV are the various types of hypertensive disorders encountered during pregnancy, with a preponderance of primary preeclampsia and preeclampsia superimposed on chronic hypertensive disease. The frequency with which hypertension is associated with AREDV varies from 40% to 70%. On the other hand, the proportion of hypertensive mothers who develop umbilical artery AREDV may be as high as 36% [22]. It is noteworthy that when pregnancy is complicated with hypertension alone the risk of developing AREDV is significantly lower than when fetal growth restriction complicates hypertension. This risk was quantified by Karsdorp and his colleagues [24], who noted that in comparison with hypertension the odds ratio for developing AREDV was 3.1 with growth restriction alone and 7.4 when hypertension was complicated by growth restriction.

Other maternal disorders associated with the development of AREDV in the umbilical artery include systemic lupus erythematosus and diabetes mellitus of long duration with vasculopathy. Most such cases are also complicated by fetal growth restriction or hypertension.

## Reappearance of End-Diastolic Velocity

Once AREDV develops in the umbilical artery, it is usually regarded as a nonreversible phenomenon during the course of progressive fetal decompensation. Several investigators, however, have reported apparent improvement of the hemodynamic situation, as indicated by reappearance of forward flow during the umbilical artery end-diastolic phase. Hanretty and colleagues [42b] were among the first to report the reappearance in a case report where the mother was treated for hypertension. Subsequently, Brar and Platt [10] reported improvement of the end-diastolic velocity in 5 of 31 cases of AREDV followed closely during hospitalization. The improved fetuses had better perinatal outcome than those with continuing AREDV. This observation received support from others. Sengupta and associates [16] used prospective conservative management (bed rest and fetal surveillance) in pregnancies complicated by AREDV and found those who improved had a better outcome. Bell and associates [20] used retrospective data analysis and also found improved outcome. The above three studies noted the reappearance of end-diastolic velocity in 19.0%–51.5% cases of AREDV and a consequent increase in the diagnosis-delivery interval by 11–37 days, gestational age by 2–4 weeks, and birth weight by 400–1,400 g. These results, particularly the frequency of reappearance and the impressive improvements in the perinatal outcome noted in one of the studies [20], are remarkable, are not encountered in common experience, and require corroboration.

The study design of Karsdorp and associates [43] differed from those described above. Theirs was a controlled intervention study with seven patients in each arm. The study group received daily volume expansion in addition to management by bed rest and antihypertensive medications, which were also used in the control group. The Doppler waveform improved in the volume-expansion group, which demonstrated statistically significant improved survival (five of seven in the study and one of seven in the control group,  $p < 0.05$ ). There were no significant differences between the groups with regard to birth weight or gestational age. Although the results are encouraging, this investigation should be regarded as preliminary because of the lack of randomization and

**Fig. 25.5.** Doppler sonogram of the umbilical artery showing transient absence and reversal of end-diastolic velocity followed by prompt recovery of a discordant twin

the small sample size. As the authors suggested, randomized trials should be conducted to confirm their observations.

It should be recognized that the appearance of AREDV does not necessarily lead to immediate fetal demise. Days to weeks may pass before the emergence of other ominous signs of fetal jeopardy necessitating delivery. In some cases the end-diastolic velocity returns, and the fetal risk is diminished, although it is highly unlikely that this occurrence is as frequent as some investigators have reported. On rare occasions, apparently normal waveforms may change to the ominous pattern of disappearance and reversal of the end-diastolic flow, returning quickly to the previous pattern; we observed this pattern in a discordant twin (Fig. 25.5). Although the hemodynamic mechanism of this phenomenon remains to be elucidated, the fetus eventually developed persistent AREDV.

Variable end-diastolic velocity in the umbilical artery of a donor fetus with twin-twin transfusion syndrome has been documented [44]. The umbilical artery end-diastolic velocity in the donor fluctuated between positive, absent, and reversed. Eventually the fetus was delivered at 28 weeks because of fetal distress of the donor. A velamentous cord insertion, suspected during the ultrasound evaluation, was confirmed. The significance of finding variable end-diastolic velocity is unknown at this time.

Finally, it should be emphasized that for reliable assessment of the end-diastolic velocity an appropriate Doppler procedure must be used, ensuring a low filter setting and a consistent sampling site in the cord if a pulsed-wave duplex system is used. The use of a high, inconsistent filter setting or different sampling sites can lead to erroneous diagnosis of disappearance and reappearance of the end-diastolic frequency.

## AREDV and Other Emergent Signs of Fetal Compromise

The homeostatic significance of absent end-diastolic velocity in relation to alterations in other components of the fetal circulation and other parameters of fetal well-being needs clarification. Some of these issues, particularly those related to the diagnostic efficacy of fetal Doppler indices, are discussed in Chap. 24. Although some degree of overlap is inevitable, the focus of this chapter is specifically on the umbilical arterial AREDV. Reports provide considerable insight in this area. Teyssier et al. [45] observed in an animal model a hierarchic sequence in the decline of the end-diastolic flow when fetoplacental vascular resistance increased; flow in the aortic isthmus was affected first, followed by flow in the descending aorta and the umbilical artery. Preliminary clinical observations tend to confirm this sequence [46].

Bekedam and associates [13] performed longitudinal measurements of the umbilical arterial PI in 29 growth-restricted fetuses with antepartum late heart rate decelerations. In 17 of these fetuses (59%), AEDV preceded the occurrence of decelerations, with a median interval of 12 days. Arduini and colleagues [47] evaluated 37 fetuses without structural and chromosomal abnormalities regarding the various maternal and fetal factors that affect the time interval between the occurrence of AEDV in the umbilical artery and either the development of abnormal fetal heart rate patterns or delivery. The interval between the first occurrence of umbilical arterial AEDV and delivery ranged from 1 to 26 days. Multivariate analysis revealed that gestational age, the presence of hypertension, and the appearance of umbilical venous pulsation are the principal determinants of this time interval. Finally, Weiner and associates [48] studied hemodynamic changes in the middle cerebral artery and the aortic and pulmonic outflow tracts, correlating these changes with the computerized fetal heart rate pattern in fetuses with AREDV in the umbilical artery. They observed that when the middle cerebral artery began to lose its compensatory vasodilatation other ominous fetal cardiovascular signs emerged, including decreases in the left cardiac output ( $p < 0.05$ ) and the fetal heart rate long-term variability ( $< 30$  ms) and the occurrence of repetitive fetal heart rate decelerations. These observations contribute to elucidation of the evolving cardiovascular responses to progressive fetal decompensation and should lead to the development of more effective fetal surveillance and clinical intervention.

Recently, Williams and associates [49] conducted a prospective randomized study where women who had been referred to their antepartum fetal testing unit because of perceived increased fetal risk were ran-

domized to either umbilical artery Doppler studies or nonstress testing as a screening test of fetal well-being. In this investigation, normal studies were repeated with the same technique as initially assigned. Women with umbilical artery S/D ratios over the 90th percentile or equivocal nonstress testing were subjected to an additional test, the amniotic fluid index. When the amniotic fluid index was below the 5th percentile, the S/D ratio had AREDV, or when the nonstress test was abnormal, induction and delivery were recommended. More women in the Doppler group than in the nonstress group underwent induction of labor (4.8% versus 1.9%,  $p < 0.005$ ). The main outcome variable studied was the presence of peripartum morbidity and was measured by the cesarean delivery rate for fetal distress in labor. The incidence of cesarean delivery for fetal distress was lower in the Doppler group compared with the nonstress group (4.6% versus 8.7%,  $p < 0.006$ ). The women with hypertension and intrauterine growth restriction sustained the greatest reduction in cesarean delivery for fetal distress. The neonatal morbidity between the two groups was similar.

Some investigators have obtained more information from the umbilical artery waveforms in cases of reverse end-diastolic flow. This has been done to try to improve the timing of the delivery and to predict the outcome of the pregnancy. Brodzki and associates [50] measured the highest amplitude and the area below the maximum velocity curve of forward and reverse flow; and they also measured the duration of forward and reverse flow in 44 fetuses with reverse end-diastolic flow. They calculated three ratios: (1) the ratio of the highest amplitude of the forward and reverse flow, (2) the ratio of the area of the forward and reverse flow, and (3) the ratio of the duration of the forward and reverse flow. Then, they established cut-off values for each ratio for the prediction of perinatal death. The ratio of the highest amplitude of the forward and reverse flow and the ratio of the area of forward and reverse flow had the best capacity to predict perinatal death. They found that survivors had higher ratios than the nonsurvivors did. In addition, more fetuses with ratios below the established cut-off values had pulsations in the venous system. The calculation of these ratios may provide additional information when these fetuses are evaluated.

## Summary

It is apparent from cumulative experience that the end-diagnostic component of the umbilical arterial Doppler waveform is of crucial importance for fetal prognostication. AREDV is known to be associated with an unusually adverse perinatal outcome. Most

remarkably, these infants suffer from high perinatal mortality and morbidity rates and demonstrate an increased frequency of malformations and chromosomal abnormalities, with a predominance of trisomies 13, 18, and 21. Most infants with AREDV require intensive care. Furthermore, the risk of cerebral hemorrhage, anemia, and hypoglycemia is increased. It has been observed, however, that absent end-diastolic flow may improve, although often only transiently, and that weeks or more may elapse before the fetus shows additional evidence of compromise. Obviously, the presence of absent end-diastolic flow should warn the physician of significantly increased fetal risk. Appropriate surveillance measures should be immediately undertaken. If the pregnancy is significantly preterm, consideration for delivery should include additional signs of fetal compromise. A more aggressive approach should be taken to ensure fetal maturity. If fetal anomalies are present or AEDV cannot be explained by pregnancy complications such as preeclampsia, then fetal karyotype should also be determined to rule out lethal aneuploidies. Although the benefits of emergency delivery for this phenomenon remain controversial, randomized clinical trials have shown improved outcome from intervention in pregnancies with absent end-diastolic velocity. This subject is discussed comprehensively in Chap. 26.

# Doppler Velocimetry for Fetal Surveillance: Randomized Clinical Trials and Implications for Practice

Dev Maulik, Reinaldo Figueroa

The cumulative clinical evidence indicates that Doppler velocimetry of the fetal circulation is an effective tool for recognizing fetal compromise in high-risk pregnancies. It has prompted many to propose its introduction as a standard for fetal surveillance. However, such enthusiasm must be tempered by a critical appraisal of the efficacy and benefits of the technique. Introduction of a new diagnostic test involves the sequential and often parallel research process of generating evidence that transforms the promises of a new technique into an effective diagnostic tool that delivers measurable benefits (Fig. 26.1).

The process begins with recognition of the potential of a new technology to measure a clinically relevant variable, followed by demonstration of the feasibility of using the technology. This phase is followed by the collection and analysis of normative data on the test, which includes determining the physiologic variations in the test value and establishing its range under normal circumstances. Any possible association between the test and the disease process is then investigated. The next step involves studying the diagnostic efficacy of the test for discriminating between the diseased and nondiseased states. Often a test is introduced into clinical practice at this stage based on the affirmative demonstration of its diagnostic efficacy. However, the diagnostic efficacy may

not translate into any tangible benefit for the patient. Indeed, a new test may not be more beneficial than the existing tests; its introduction may unnecessarily increase the cost of care, and it may even be detrimental. It is imperative therefore to demonstrate without bias that utilization of the test improves clinical outcome, which can be accomplished by randomized clinical trials. It is regrettable that most modalities of fetal surveillance in current practice are not based on such evidence.

It is encouraging to note that with regard to Doppler velocimetry for fetal surveillance, 21 clinical trials [1–21] have been fully reported from 1987 until 2003 in the peer-reviewed literature. In addition, during that period limited information was available on five published or presented randomized trials comprising two review articles [2, 22] and three abstracts [23–25]. All the studies evaluated umbilical arterial velocimetry; a few also used uterine arterial velocimetry. There have been ongoing meta-analyses of these studies as they became available first in the Oxford Perinatal Database and subsequently in the Cochrane Center electronic publications. The initial comprehensive meta-analysis by Alfirevic and Neilson [26] was published in 1995. Since that initial meta-analysis the data have been re-analyzed various times evaluating high- and low-risk pregnancies separately, or evaluating high-risk pregnancies with well-defined candidates (IUGR, hypertension) [27–31]. The original studies are comprehensively reviewed here, and the implications of their findings on the clinical practice of high-risk obstetrics are discussed. The review process included both the traditional and meta-analytic approaches.

**Fig. 26.1.** Steps for developing a new diagnostic test, from the feasibility study to the introduction to clinical practice

## Doppler Randomized Trials: A Summary

The essential features of the 21 published randomized trials are listed in Table 26.1 and are summarized below both individually and as a group. The sequence is according to the chronology of their publication.

Trudinger and associates [1] were the first to report a randomized trial on umbilical arterial Doppler velocimetry. The aim was to assess the impact of

**Table 26.1.** Randomized trials of Doppler ultrasonography for fetal surveillance

First Author, Year (Reference)	Population	Doppler Index*	Doppler in Controls	Treatment Protocol	Clinical Benefits**

using this approach for identifying potential fetal compromise on the timing of delivery and obstetric intervention. Despite the randomization, more patients were assigned to the control group ( $n=167$ ) than to the study group ( $n=133$ ). The Doppler results were revealed for the study group, and no specific management protocol was assigned to the providers. Information on the incidence of absent end-diastolic velocity (AEDV) is not given in this paper. A significant reduction was noted in the incidence of intrapartum fetal distress after spontaneous onset of labor (study group 0.8%, control group 4.9%,  $p<0.05$ ) and of emergency cesarean section (study group 13%, control group 23%,  $p<0.05$ ).

MacParland and Pierce [2] reported briefly a randomized trial in a review article involving 509 patients. The complete study was not published. The preliminary report showed improved outcomes. However, serious allegations on the credibility of one of the authors led to the exclusion of the study from any further considerations.

Tyrrell et al. [3] described a randomized comparison of the effect of routine versus highly selected use

of umbilical and uterine arterial Doppler ultrasonography and the biophysical profile on gestational age at delivery, the rate of obstetric intervention, and short-term neonatal morbidity in 500 pregnant women (study group 250, control group 250) at risk for fetal growth restriction and fetal death. The investigators used a modified version of the biophysical profile and devised a scoring system for the Doppler result incorporating the umbilical arterial systolic/diastolic (S/D) ratio and the uterine arterial resistance index (RI). The test results were available to the physician apparently with no defined intervention protocol. The study group mothers underwent a total of 902 biophysical profiles and Doppler measurements, which were performed in 12 patients in the control group (4.8%). AEDV in the umbilical artery was found in only 2.7% of all the measurements in the study group. A persistently abnormal biophysical score was always associated with umbilical arterial AEDV. Main outcome measures were gestational age at delivery, obstetric intervention rates, and short-term neonatal morbidity. The mean gestational age at induction of labor and the intervention rates were similar in the

two groups. However, in the study group a significant decrease was noted in low 5-min Apgar scores [odds ratio (OR) 0.24; 95% confidence interval (CI) 0.06–0.86] and serious neonatal morbidity (OR 0.12, CI 0.02–0.98). The authors concluded that access to Doppler velocimetry improves the efficacy of fetal surveillance.

Hofmeyr and associates [4] conducted a randomized trial of umbilical arterial Doppler velocimetry in 897 women (Doppler group 438, control group 459). The objective was to determine the impact of Doppler assessment on reducing the need for fetal heart rate (FHR) monitoring and on the time required for fetal testing. In the study group initial assessment was by umbilical arterial resistance index (RI) determination, and in the fetal heart rate (FHR) group it was done by computerized FHR analysis. In the Doppler group 66% underwent FHR monitoring, whereas 39% of the control (FHR) group underwent Doppler velocimetry. The study design permitted such additional evaluation using the nonallocated method based on broad criteria of fetal risk. The study group and the control group were found to be comparable. It was observed that the primary Doppler screening did not reduce the time needed for fetal assessment. There were no significant differences in perinatal outcome between the groups, except that emergency cesarean sections were less frequent in the Doppler group than in the control group (14% versus 20%,  $p < 0.05$ ; OR 0.69, CI 0.49–0.98).

Newnham and associates [5] investigated whether the introduction of umbilical and uterine Doppler assessment into an ultrasonography department of a tertiary level hospital reduces neonatal morbidity and improves obstetric management. The population consisted of 505 women (study group 254, control group 251) with pregnancy complications referred for fetal ultrasonographic investigation during the third trimester. Results were revealed to patients and clinicians. The main outcome measure was the duration of neonatal stay in the hospital; other measures of the perinatal outcome included the number of examinations, the type of FHR monitoring, obstetric interventions, frequency of fetal distress, birth weight, Apgar score, and the need for neonatal intensive care. Umbilical arterial Doppler revealed a 2.9% incidence of AEDV; noteworthy is the high-pass filter setting of 280 Hz, which is considered too high and might have generated false-positive results. The introduction of Doppler waveform studies did not reduce neonatal morbidity and therefore did not change the duration of neonatal hospitalization. Compared to the control group, the Doppler group showed an increase in the 1-min Apgar score (32% versus 22%, respectively) and 5-min Apgar score (3.3% versus 2.6%, respectively), but these differences were not significant. The

study group patients had fewer contraction stress tests and less likelihood of antepartum fetal distress; they were, however, more prone to fetal distress after induction of labor leading to emergency cesarean section. Again, none of these differences was significant.

Davies et al. [7] reported a randomized trial in a general obstetric population to assess the effect on primary management and outcome of routine Doppler velocimetry. The study group of 1,246 patients were allocated to routine umbilical and uterine artery Doppler ultrasound examinations, which were done first at 19–22 weeks' gestation and monthly thereafter if the pregnancy was considered high risk ( $n = 192$ ) or once at 32 weeks if considered low risk ( $n = 1,054$ ). The control group consisted of 1,229 women who received standard, antenatal care without Doppler testing. Doppler sonography was performed in 1.2% of the control group. The frequency of AEDV was low (0.1%). The study and control groups were comparable in terms of the frequency of antenatal admissions, cardiotocographs, gestational age at delivery, mode of delivery, frequency of deliveries with fetal distress, the need for resuscitation, and admission to the neonatal intensive care unit (NICU). The authors failed to demonstrate any improvement in neonatal outcome after routine Doppler ultrasound screening of a general obstetric population. However, the Doppler group experienced significantly more perinatal deaths. Abnormal umbilical arterial Doppler results occurred in 1 of 11 normally formed stillborn infants and in none of the four normally formed neonates who died after 24 weeks' gestation. Although the incidence of stillbirths was increased in the Doppler group, the difference from controls was not significant [16 versus 9; relative risk (RR) 1.75, 95% CI 0.78–3.95]. When corrected for malformations, the perinatal death rate was significantly higher in the Doppler group (16 versus 4; RR 3.95, 95% CI 1.32–11.77). This factor obviously remains a matter of concern and requires clarification. Interestingly, this trial is the only randomized one where such an adverse effect was observed.

In a Swedish multicenter trial, Almstrom and associates [6, 23] compared umbilical arterial Doppler velocimetry with antepartum cardiotocography (CTG) in 426 pregnant women (Doppler group 214, CTG group 212) with fetuses found to be small for gestational age (SGA) ( $< 2$ SD) on ultrasound examination at 31 weeks' gestation or later. The objective was to investigate whether the Doppler technique was superior to CTG reducing fetal mortality in these pregnancies. This study had a predefined protocol that was described in the report. In the control group, 16 (7.5%) had abnormal CTG. In the study group, 4 (1.8%) had blood flow class III (AEDV). Interestingly, 14% of the Doppler group also underwent CTG. Com-

pared to the CTG group, the Doppler group experienced significant decreases in antepartum hospitalization (31% versus 46%,  $p < 0.01$ ), induction of labor (10% versus 22%,  $p < 0.01$ ), and emergency cesarean section for fetal distress (5.1% versus 14.2%,  $p < 0.01$ ). There were no perinatal deaths in the Doppler group, but there were two stillbirths and one neonatal death in the CTG group. One stillbirth was due to placental abruption. The second intrauterine death occurred at 35 weeks' gestation following a normal CTG; there was no apparent cause, and the fetal weight was 27% below the norm. The authors concluded that umbilical arterial Doppler velocimetry is a more effective fetal surveillance tool for SGA fetuses than antepartum FHR monitoring.

Mason and associates [8] performed a randomized trial on 2,016 low-risk primigravid women (Doppler group 1,015, control group 1,001) to determine the effect of routine pregnancy screening with umbilical arterial Doppler testing on obstetric intervention rates and short-term neonatal morbidity. The incidence of abnormal Doppler results was low (1.7%); that of AEDV was only 0.3%. In the control group, 42 women (3.9%) underwent Doppler examination. The investigators observed no significant differences between the control and study groups for any of the outcomes measured. There was only one perinatal death in the study, which occurred in the Doppler group; the pregnancy was complicated by spontaneous rupture of membranes at 34 weeks, fetal bradycardia for which cesarean section was performed, tight nuchal cord, and grade 3 intraventricular hemorrhage. This study demonstrated no beneficial or detrimental effect of routine Doppler ultrasound screening of low-risk women.

Johnstone and coinvestigators [9] performed a randomized controlled trial on 2,289 pregnant mothers (Doppler group 1,114, control group 1,175). The objective was to assess the effect of clinicians' access to umbilical Doppler results in obstetric practice. Continuous-wave Doppler studies of the umbilical artery were performed and the results made immediately available to clinicians. The outcome measures included perinatal mortality, Apgar score, and admission to the NICU. Fetal surveillance included cardiography, biophysical profile, and ultrasound biometry. Doppler was performed in three patients (0.26%) in the control group. Obstetric interventions measured were admission to hospital, induction of labor, and cesarean section. The treatment and control groups were well matched and showed no appreciable differences in perinatal outcome, obstetric intervention, or use of fetal monitoring. However, use of Doppler in the high-risk subgroup led to greater use of FHR monitoring ( $p = 0.007$ ). There were no significant differences in the perinatal mortality between the

groups. The results indicated that obstetricians do not use the test to modify their risk assessment or therefore the need for fetal surveillance.

Newnham and colleagues [10] used a randomized trial to investigate the effects of frequent ultrasound imaging and Doppler velocimetry during pregnancy. The principal outcome parameters were the duration of neonatal hospital stay and the rate of preterm births. The population comprised 2,834 women with single pregnancies at 16–20 weeks' gestation attending the ultrasonography department. The study group consisted of 1,415 who underwent ultrasound imaging and continuous-wave Doppler studies at 18, 24, 28, 34, and 38 weeks' gestation. The control group of 1,419 women underwent single ultrasound imaging at 18 weeks. The only difference between the two groups was a significantly higher incidence of SGA fetuses in the intensively studied group, when expressed as birth weight in the 10th percentile (RR 1.35; CI 1.09–16.7) and birth weight in the 3rd percentile (RR 1.65; CI 1.09–2.49). Although it is possible that this finding was a chance effect, it is also plausible that frequent exposure to ultrasound may have influenced fetal growth. In terms of the efficacy of the Doppler examination, because the study group had frequent sonographic biometry in addition to the Doppler testing it is difficult to distinguish the influence of biometric assessments from those of the Doppler examination.

Whittle and associates [13] performed a randomized trial of Doppler sonography in a nonselected population of 2,986 women (Doppler group 1,642, control group 1,344) to investigate the impact of umbilical arterial Doppler velocimetry screening on obstetric outcome in a nonselected population of mixed low-risk and high-risk pregnancies. The main outcome measure was perinatal mortality corrected for malformations. The eligibility for entry into the study was physicians' concerns regarding "fetal well-being." Subgroup analysis was performed on those with hypertension and suspected growth restriction. The Doppler results were made available only for the study group. There were no significant differences between groups regarding antenatal admissions to hospital, preterm deliveries, rate of cesarean section, admission to the neonatal unit, or need for assisted ventilation. The results of the subgroup analysis were similar. Fewer stillbirths occurred in the Doppler group but the difference did not reach significance (8 versus 3; OR 0.34, CI 0.10–1.07).

Omtzigt et al. [11, 32] conducted a randomized trial of umbilical Doppler velocimetry in a nonselected hospital population of 1,598 (control group 789, study group 809). More than 40% were at high risk. The objective was to investigate the effect of Doppler velocimetry on the rate and duration of maternal hospital admission, obstetric management, and

perinatal outcome. In the study group, umbilical arterial Doppler investigation was conducted only when indicated (46%). Abnormal pulsatility index (PI) values prompted intensified fetal monitoring. AEDV was observed in 3.5% of the patients. This study not only had a predefined protocol, it was described in the report and is discussed in detail later in this chapter. The study group demonstrated a significant reduction in perinatal mortality of normally formed fetuses and infants weighing 500 g or more (RR 0.33, CI 0.13–0.82) compared to the control group. As the neonatal mortality rate did not differ between the groups, the reduction in perinatal mortality was attributable to the use of umbilical arterial Doppler surveillance and not to any delay in the timing of fetal death. Neonatal seizure activity was noted in two infants in the control group and none in the Doppler group, but the difference was not statistically significant.

Pattinson et al. [12] investigated the effect of Doppler fetal surveillance in a randomized trial of pregnant women of more than 27 weeks' gestation with hypertensive disease or suspected SGA fetuses. The outcome measures were perinatal mortality and morbidity, antenatal hospitalization, maternal intervention, admission to the NICU, and hospitalization until discharge from the neonatal wards. Doppler velocimetry was performed in all patients, but the results were revealed only for the study group. The groups were clinically comparable. Physicians received management guidelines for patients with AEDV. Twenty patients (9.4%) developed AEDV in the umbilical artery; all were SGA fetuses. Among the SGA patients (study group 61, control group 63), there was one perinatal death in the study group (neonatal death related to respiratory distress syndrome) and six perinatal deaths in the control group (five stillbirths and one neonatal death). None of the infants who had end-diastolic velocity in the umbilical artery died. The reduction of stillbirths in the Doppler group was significant ( $p=0.029$ ; OR 0.13, CI 0.02–0.78). For those with SGA fetuses with end-diastolic velocity, the women in the Doppler group spent significantly fewer days in the hospital before delivery (median stay 0 versus 2 days,  $p=0.05$ ) and tended to have fewer maternal interventions (27% versus 43%; OR 0.49, CI 0.20–1.25), cesarean sections (13% versus 27%; OR 0.43, CI 0.14 and 1.32), and NICU stay (median stay 1.5 versus 4.0 days,  $p<0.05$ ). There were no differences in outcome when the end-diastolic velocity was present in conjunction with hypertension. There was one neonatal death in the Doppler group of this subset of patients, and it was related to maternal trauma. The study demonstrated the benefit of intervention because of the knowledge of Doppler velocimetry in patients with AEDV and in those with SGA even with end-diastolic velocity in the umbilical artery.

Nienhuis and associates performed a randomized trial to investigate whether hospitalization can safely be averted if the umbilical artery Doppler results were normal in women with singleton pregnancies and suspected fetal growth restriction (FGR) [14]. In the study group (74 patients), strong recommendations were made against hospitalization for suspected FGR if the Doppler findings were normal. In the control group (76 patients), the Doppler results were not revealed and the participants received the standard management. The endpoints included duration and frequency of hospitalization, perinatal outcome, neurological development, and postnatal growth. The duration but not the frequency of hospitalization was significantly shorter in the study group than in the control group. No significant differences were noted in the other outcome measures. The authors concluded that normal umbilical artery Doppler findings in suspected cases of IUGR may justify ambulatory management.

A collaborative multicenter French study investigated the efficacy of routine umbilical artery Doppler between 28 and 34 weeks of gestation in a low risk population of 4,187 women who were randomly assigned to the study and the control groups [15]. Apart from a significant increase in the frequency of subsequent ultrasonographic and Doppler examinations no significant differences were noted in the outcome. Although perinatal mortality was three times lower in the Doppler group (3 versus 9), this difference failed to achieve significance (OR 0.33; 95% CI 0.06–1.33).

Haley and coworkers [16] conducted a randomized trial on 150 mothers with the prenatal diagnosis of FGR. The objective was to compare the efficacy of umbilical artery Doppler sonography with that of fetal heart rate monitoring on resources utilization. In comparison with the fetal monitoring group, the Doppler group had the average hospital inpatient stay reduced from 2.5 days to 1.1 days ( $p=0.036$ ). Moreover, there was a reduction in monitoring frequency and fewer hospital prenatal ambulatory visits.

Ott and associates conducted a randomized trial to investigate the efficacy of the addition of the middle cerebral to umbilical artery systolic/diastolic ratios to the modified biophysical profile in 665 high risk pregnant patients [17]. The study group received the Doppler test in addition to the standard management of modified biophysical profile for fetal surveillance whereas the control group received only the standard management. Although no significant differences in the outcome were noted, a significant decline in cesarean deliveries in the Doppler tested patients was noted in a subgroup of patients at risk for uteroplacental insufficiency.

McCowan and colleagues performed a pilot randomized trial in 167 pregnant women between 24

and 36 weeks' gestation with small for gestational age fetuses to study whether the frequency of fetal surveillance could be safely reduced in the cases with normal umbilical artery Doppler [18]. In comparison with those who had fortnightly surveillance, those undergoing twice-weekly fetal surveillance were delivered 4 days earlier (264 vs 268 days;  $p=0.04$ ) and were more likely to have labor induced ( $n=70$ , 82%, vs  $n=54$ , 66%;  $p=0.02$ ). There were no differences in the neonatal outcome between the groups. Given the small sample size associated with preliminary nature of the study the authors prudently advised a larger trial for a more definitive recommendation.

Williams and associates [19] conducted a prospective randomized study where 1,360 at risk women at  $\geq 32$  weeks of gestation were randomized to either umbilical artery Doppler studies or nonstress testing. Women with umbilical artery S/D ratios  $> 90^{\text{th}}$  percentile or equivocal nonstress testing had the amniotic fluid index determined. Induction of labor and delivery were recommended when the amniotic fluid index was  $< 5^{\text{th}}$  percentile, the S/D ratio had ARDV or when the nonstress test was abnormal. In comparison with the control group, the Doppler group had more frequent induction of labor (4.8% versus 1.9%;  $p < 0.005$ ), and lower incidence of cesarean section for fetal distress (4.6% versus 8.7%,  $p < 0.006$ ). Those with hypertension (1.5% versus 13.6%) and FGR (2.4% versus 8.8%) experienced the greatest reduction in cesarean section for fetal distress. The neonatal morbidity between the two groups was similar.

A multicenter randomized controlled trial, the Growth Restriction Intervention Trial (GRIT), compared two strategies: the consequences of delivering within 48 hours for steroid administration (immediate delivery) with delaying for as long as the fetal status permitted to foster maturity (delay until the obstetrician is no longer uncertain) [20]. The population consisted of high risk pregnancies between 24 and 36 weeks. Over 90% of the population was complicated with fetal growth restriction. Cesarean deliveries were more frequent in the immediate delivery group (91%) compared to the delay group (79%) (OR 2.7, 95% CI 1.6–4.5). While there were more stillbirths in the delay group, more neonatal deaths were recorded in the immediate delivery group. However, the study failed to resolve the issue of optimal timing as no significant differences were noted in the deaths before discharge from the hospital between the two groups (10% in the immediate group versus 9% in the delay group).

In a continuation of the study for long term outcomes, death or disability at or beyond 2 years of age were investigated. Disability was assessed by Griffith's developmental quotient and the presence of severe motor or perceptual compromise [33]. No important

differences in mortality or in the developmental assessment were seen. However, most of the difference in disability was observed in gestations below 31 weeks of gestation at randomization: 14 (13%) immediate versus five (5%) delayed deliveries. This prompted the investigators to caution against delivering before 30 weeks of gestation.

In the only randomized trial performed exclusively in twin gestations, Giles and coinvestigators [21] assigned randomly 526 women to receive either the standard sonographic biometry assessment or standard assessment and umbilical artery Doppler ultrasound at 25 weeks and again at 30 and 35 weeks. More intense fetal surveillance was instituted in the presence of any indicators of fetal compromise. No differences in the outcome was noted between the two groups although both groups showed a lower than expected fetal mortality probably resulting from the more intense fetal surveillance in general.

## Doppler Randomized Trials: Cumulative Summary

The 21 studies described above encompass a total population of 25,279 pregnant mothers.

There was considerable clinical heterogeneity among the studies, including the characteristics of the population, study objectives and a predetermined measure of the primary outcome, Doppler sonographic technique, and management protocol.

## Population Characteristics

Despite the risk categorization, there was no uniformity among the studies regarding their observed high-risk attributes. There were five trials conducted on populations of unselected pregnant mothers. Although presumed to be representative of the low-risk general obstetric population, not all of these studies appeared to be so qualified, as their site included university-based tertiary medical centers, which tend to attract complicated cases. This point is exemplified by the Utrecht study [11, 32], which was conducted on unselected cases but was found to include approximately 50% high-risk mothers. This study also had a perinatal mortality rate of 2.7%, which was higher than that of five studies in the high-risk group. Similarly, this study also had a 3.5% incidence of AEDV in comparison with an incidence of 1.9%–4.4% in the high-risk group. There is also some degree of heterogeneity in the stated objectives of the trials.

## Objective and Primary Outcome

Considerable variation was also noted in the purpose of the trials and the measures of the primary outcome. Many of the studies measured various outcomes related to pregnancy management, fetal surveillance, management of labor and delivery, and perinatal morbidity and mortality. Lack of uniformity, however, was apparent with regard to the specific criteria of these measures. Among the rest, the objective of one was to assess physicians' use of Doppler information [9], and that of the other was to evaluate the effect of Doppler testing on the time required for fetal assessment [3]. Only half the studies reported a predetermined, specific primary outcome measure.

## Doppler Sonographic Technique and Research Design

Although it may be difficult to expect a significant degree of dissimilarity in the instrumentation and procedure for Doppler interrogation of the umbilical arteries, there are some aspects of the method that can become critical sources of variance in results. They include the Doppler mode and the high-pass filter, a high level of which may produce false identification of AEDV. Many studies utilized continuous-wave Doppler ultrasound, while others used pulsed-wave Doppler mode, or did not specify the type of Doppler setup used for the study. One trial [12] utilized a 280-Hz high-pass filter setting; interestingly, this study reported the highest occurrence of AEDV. Five studies did not state the filter setting, and the rest utilized a threshold of 50–100 Hz. With regard to the use of Doppler sonography in the trial design, four studies [1, 4, 13, 32] used a Doppler technique in all patients, but the results were revealed to the obstetric care providers only for the study group. There is no measure, however, of the success rate for concealing Doppler information for the control group. In three studies [2, 3, 10] Doppler sonography was used in the control group in a selective manner, which was not uniform among the studies. In the remainder of the trials, Doppler sonography was not supposed to be performed in the control group of patients, although this "rule" was not universally implemented.

## Management Protocol

Management protocol probably represents the most problematic source of clinical heterogeneity in these trials. Only seven of the studies had predefined treatment protocols [6, 11, 12]. The rest had limited or no set protocol for management; the results were given to the care providers, and it was anticipated that they

would exercise their experience and knowledge to make the best use of this information. Others may have had some guidelines, but it was not apparent in the paper. This drawback severely limits the utility of these trials for formulating any evidence-based fetal surveillance policy utilizing Doppler ultrasonography.

## Doppler Randomized Trials: Meta-Analysis

### Meta-Analysis: Brief Introduction

Although the traditional review of the published clinical trials of Doppler velocimetry as presented above is informative, it does not help to arrive at a definitive conclusion regarding its efficacy, nor does it provide us with a reasonable basis for developing a management plan. Even if Doppler sonography is highly effective, a traditional review fails to give us a measure of the magnitude of benefit that may result from its use in clinical practice for fetal surveillance. These problems can be significantly mitigated by performing a more systematic review by aggregating and statistically analyzing data from the various trials to derive a valid quantitative conclusion. The process is called meta-analysis, a term coined by Glass [34] to distinguish it from the primary analysis, which is the original process of analyzing the information from an individual research study, and from the secondary analysis, which is reanalysis of the original data to address new research questions. The concept is not entirely new, as quantitative statistical synthesis of past research data was described by several eminent statisticians decades before the origin of the term meta-analysis [35–37].

The technique has been used widely for systematic review of scientific research in the social sciences and was applied extensively later to clinical research in medicine. As the number of clinical trials has mushroomed, the need to depart from the more traditional subjective, often inconclusive review process has grown. The application of this type of quantitative systematic review of published data has been slow in the field of obstetrics. One of the key elements for popularizing this approach in obstetrics and gynecology has been the effort of the Oxford Perinatal Data Group and its inheritor, the Cochrane Perinatal Collaboration in the United Kingdom. An in-depth discussion of meta-analysis is beyond the scope of this chapter, but a brief review, specifically relevant to Doppler trials, is included here. It should be noted that this concise discussion is limited to the meta-analysis of experimental studies, such as randomized clinical trials, and excludes meta-analysis of non-experimental investigations or observational studies,

**Table 26.2.** Steps of conducting a meta-analysis

1. Formulate the research question.
2. Define the protocol for meta-analysis.
3. Define the criteria for selection of the target trials.
4. Comprehensive search and retrieval of information on trials.
5. Independent selection of trials as per the defined criteria.
6. Extract relevant information from the trials.
7. Aggregate the study results.
8. Analyze the data.
9. Interpret the results.
10. Report the results.

which is not only a highly controversial issue but is not relevant to the Doppler clinical trials.

Meta-analysis is often regarded in a simplistic manner as a semiautomated process of collecting and feeding data from available past research into a computer program, which then provides simple quantitative aggregate measures of an effect. In reality, however, a proper meta-analysis consists of a rigorously systematic approach (Table 26.2). Moreover, it is important to consider the various methods of meta-analysis, which are based primarily on their manner of dealing with the heterogeneity of the studies included in the review.

The advantages and limitations of meta-analysis are summarized in Table 26.3. As mentioned earlier, the technique offers a vast improvement over the traditional review, which often is not comprehensive, does not produce a quantitative analysis of the existing information, and is highly susceptible to subjective biases. Moreover, the traditional review process cannot compensate for the loss of power of individual studies of inadequate sample size, nor is it subject to systematic updating, which is possible with a meta-analysis. Meta-analysis can offer great benefit when designing appropriate future trials based on the questions generated by the systematic review process so the limitations of the past trials are addressed. Moreover, if a well-conducted meta-analytic process demonstrates a significant benefit of a new diagnostic and therapeutic intervention, it may be introduced into clinical practice in a timely fashion without going through additional essentially redundant trials, thereby saving time and resources. Such a scenario highlights one of the principal beneficial contributions of the systematic review. Finally, meta-analysis is not a static process. As information on additional trials on a subject becomes progressively available, the results can be systematically and continuously updated and conclusions revised.

Meta-analysis, however, is not a panacea for all the inadequacies of individual trials; nor is it a replace-

**Table 26.3.** Advantages and limitations of meta-analysis

<b>Advantages</b>
Provides a systematic quantitative review of all available data
Provides a quantitative estimation of the effect of a treatment from the cumulative data
Amplifies the statistical power of individual studies
Significantly less subjective and less biased than the traditional reviews
Assists in directing future research based on the strengths and weaknesses of all reviewed studies
Prevents redundant studies and saves resources
Allows continuous updating of the systematically reviewed information
<b>Limitations</b>
Retrospective analysis – limited by the quality of the constituent studies
Heterogeneity of the studies meta-analyzed – the “apples and oranges” issue
Pooling of many mediocre or poor studies does not necessarily yield better results
Oversimplifies the complex but critical etiologic and therapeutic relations
Obscures the reasons for the effect variability
Not entirely objective: publication bias, selection bias

ment for a large, well-designed, well-conducted primary clinical trial of sufficient power. Some of its essential attributes are often the potential sources of its limitations. It attempts to encompass all data within the scope of the defined objectives of the review process and the predetermined inclusion criteria for the trials. Indeed, to be comprehensive, the current recommendation is to enter all available information including abstracts, review articles, and unpublished data so subjective problems such as publication bias are minimized or eliminated. This approach, however, appears to be too nondiscriminatory, as data from potentially poorly conducted trials and unreliable sources are included. Meta-analysis is essentially a retrospective process limited by the quality of its constituent trials, which has given rise to the metaphoric criticism of meta-analysis as an alchemic process of converting “tons of garbage to a single diamond.” There are scoring systems for assessing the quality of clinical trials, but these systems are often subjective, the score values may not be appropriately weighted, and there may be no clear guideline for dealing with the studies of low scores.

The validity of meta-analytic inference has been questioned on the basis of heterogeneity of constituent studies. The traditional response when dealing with heterogeneity has been to consider the objective of meta-analytic generalization. Glass [34] discussed

this point metaphorically as the “apples and oranges” issue; if the objective is to generalize the apples and oranges to fruit, heterogeneity should not make much of a difference. The current trend, however, is not only to apply statistical methodology to minimize the impact of heterogeneity on the validity of the meta-analytic inference but also to analyze the sources of such heterogeneity in order to understand and improve therapeutic effectiveness.

There are several statistical methods for conducting meta-analysis. Traditionally, the method for deriving the average estimate of the effect size has been to use one of the fixed-effects models, which takes into account intrastudy but not interstudy variance. This model was developed by Mantel and Haentzel [38] and was subsequently modified by Yusuf et al. [39]. There is strong support for the use of this model for meta-analysis from many investigators [40, 41]. When the fixed-effects model is used, a separate statistical test (e.g. the  $\chi^2$  distribution) is usually performed to determine if the variations in the results can be explained by chance. However, it is a relatively insensitive tool to test for homogeneity [42]. Although the fixed-effects model is the most widely used method for meta-analysis in the medical field, there has been significant criticism of its exclusive use. The alternative method, the random-effects model, originally suggested by Cochran [43] and subsequently developed by DerSimonian and Laird [44], deals with study-to-study variations in the analytic process of generating the aggregate effect and the confidence intervals. There has been substantial support for this approach, particularly when one is aiming to apply the meta-analytic inference to the future application of the treatment rather than to the past trials under investigation [45, 46].

An in-depth discussion of statistical methodology for meta-analysis is well beyond the scope of this chapter. However, the choice between the fixed-effects model and the random-effects model is pertinent when considering the meta-analysis of Doppler trials. The issue here is more that of “oranges and tangerines” than of “apples and oranges”. To be sure, there is great controversy among statisticians regarding the choice between the two models. The choice may be guided by the basic assumptions of these models. The fixed-effects model assumes that results of the analysis are applicable to the studies already performed and included in the systematic review process, whereas the random-effects model assumes that the results are applicable to all such studies in the future. Furthermore, if the studies are sufficiently homogeneous, the results do not differ between the models; however, the random effects model yields conservative results with wider confidence intervals. A pragmatic approach is first to avoid aggregating

obviously dissimilar studies and, in the absence of apparent heterogeneity, to use and report both models. If this practice reveals heterogeneity, one should systematically investigate its underlying reason. With this background information on meta-analysis, let us examine now its application to the Doppler trials.

## Doppler Meta-Analysis

Alfirevic and Neilson [47] reported a meta-analysis of published and unpublished randomized Doppler trials in high-risk pregnancies. Of the 12 studies included, six were peer-reviewed original publications, two were unpublished (personal communication), two appeared to be abstracts published in conference proceedings, and two were review articles. The trials were subjected to a quality assessment program proposed by Chalmers and associates [48] and were found to be eligible for inclusion in the systematic review process. This report suggested a significant reduction in the perinatal deaths of normally formed fetuses consequent to the use of umbilical arterial Doppler surveillance (Fig. 26.2). The odds of perinatal mortality declined by 38%. A significant decrease was also noted in the number of antepartum admissions to the hospital (44%), inductions of labor (20%), and cesarean sections for fetal distress (52%). Moreover, significant declines were observed in elective delivery, intrapartum fetal distress, and hypoxic encephalopathy on post hoc analyses (Fig. 26.3). Obviously, the last group of benefits require additional investigation. It should also be noted that a meta-analysis does not replace the value of a randomized clinical trial based on a sufficient sample size. Depending on the choice of the outcome parameter and the effect size, it probably requires thousands of patients involving multiple centers. It would be a challenge to organize and obtain sufficient resources for a trial of this magnitude.

Noting that the statistical method utilized in this meta-analysis was based on the fixed-effects model, we undertook a random-effects model approach as described by DerSimonian and Laird [44] to reanalyze the data pertaining to perinatal deaths as collated by Alfirevic and Neilson [26]. The data are presented in Table 26.4, which confirms the results from the fixed-effects model analysis. The random-effects model analysis suggests that the use of umbilical artery Doppler velocimetry for fetal surveillance of complicated pregnancies may lead to a 36% decline in perinatal death (CI -54% to -10%). This figure is reassuring, although one may have reservations about the inclusion and exclusion criteria used in the Alfirevic and Neilson meta-analysis. Further refinement of our assessment of the benefits of Doppler velocimetry may be obtained by reexamining some of these issues.

**Fig. 26.2.** Proportional effect of Doppler ultrasonography on the number of dead babies (stillbirths and neonates) when used for high-risk pregnancies. (Reprinted from [26] with permission)

**Fig. 26.3.** Effects of Doppler ultrasonography on perinatal outcome in high-risk pregnancies. Post hoc analysis (Reprinted from [26] with permission)

Since the first systematic review of Alfirevic and Neilson [26] subsequent systematic reviews have been performed. Divon performed a meta-analysis of eight published and peer-reviewed randomized trials of 6,838 patients [27]. Umbilical artery Doppler studies significantly decreased perinatal mortality (OR 0.66, CI 0.46–0.94). Divon concluded that there were enough data to show the benefit of umbilical artery Doppler velocimetry in high-risk patients and meta-analysis

of additional randomized controlled trials was unlikely to change these results.

In 1996, Neilson and Alfirevic [28] reviewed 11 randomized controlled trials of 7,000 high-risk pregnancies. The study by MacParland and Pearce [2] was removed from this meta-analysis because the veracity of the data presented was put into question. The use of Doppler ultrasound was associated with a trend toward a reduction in perinatal deaths (OR 0.71, 95%

CI 0.50–1.01) especially in pregnancies complicated by hypertension or presumed impaired fetal growth. In addition, there were fewer inductions of labor (OR 0.83, 95% CI 0.74–0.93) and fewer hospital admissions (OR 0.56, 95% CI 0.43–0.72) without adverse perinatal effects. Moreover, there was no difference for fetal distress in labor (OR 0.81, 95% CI 0.59–1.13) or cesarean deliveries (OR 0.94, 95% CI 0.82–1.06). The investigators concluded that the use of Doppler ultrasound appeared promising in helping to reduce perinatal deaths.

Westergaard and colleagues [29] reanalyzed randomized controlled trials on the use of umbilical artery Doppler velocimetry in 8,633 high-risk pregnancies in order to determine which high-risk pregnancies benefit from the use of Doppler velocimetry. They divided 13 randomized controlled trials (including two unpublished studies) into “well-defined studies,” when there was a strict definition of suspected intrauterine growth restriction or hypertensive disease of pregnancy, and “general risk studies.” The “well-defined studies” showed a significant reduction in antenatal admissions (OR 0.56, 95% CI 0.43–0.72), inductions of labor (OR 0.78, 95% CI 0.63–0.96), elective deliveries (OR 0.73, 95% CI 0.61–0.88), and cesarean deliveries (OR 0.78, 95% CI 0.65–0.94). No significant difference was found in perinatal mortality (OR 0.66, 95% CI 0.36–1.22). The perinatal deaths were audited by a panel of 32 international experts who found that more perinatal deaths in the “well-defined studies” were potentially avoidable by use of Doppler velocimetry (50% controls versus 20% Doppler velocimetry group). The “general risk studies” did not show significant differences in the variables studied. These investigators concluded that only in pregnancies with suspected intrauterine growth re-

striction or hypertensive disease of pregnancy would the use of Doppler velocimetry reduce the number of perinatal deaths and unnecessary obstetric interventions.

Two other meta-analyses of trials of umbilical artery velocimetry in low-risk pregnancies have been performed. Goffinet and colleagues [30] conducted a meta-analysis of four randomized trials of umbilical Doppler in unselected or low-risk pregnancies with a total population of 11,375 women. Three other studies were not included because they did not meet the inclusion criteria or they had methodological problems. Screening Doppler umbilical artery velocimetry did not influence perinatal deaths (overall perinatal deaths OR 0.90, 95% CI 0.50–1.60) or stillbirth (overall stillbirths OR 0.94, 95% CI 0.42–1.98), antenatal hospitalization (OR 1.04, 95% CI 0.95–1.15), obstetric outcome, or perinatal morbidity.

A subsequent meta-analysis of five trials on routine Doppler ultrasound in unselected and low-risk pregnancies with a total population of 14,338 women also concluded that routine Doppler ultrasound examination in low-risk or unselected populations did not confer benefit on mother or infant [31]. Umbilical Doppler examination cannot be recommended as a routine test in low-risk or unselected populations.

Unfortunately, the many systematic reviews of trials on the effect of umbilical artery Doppler velocimetry have been based on essentially the same 12 trials that were evaluated in the first meta-analysis by Alfirevic and Neilson [26] with some modifications. Thornton has been critical of this pattern of repeated analysis, and believes that “repeated analysis of the same data set can at best only generate hypotheses for future researchers to test” [49]. He suggested the need for trials of the effect of umbilical artery Doppler velocimetry where there is a clearly defined group and a defined delivery timing policy to follow. Alternatively, trials with well-defined groups and different delivery timing policies should be addressed.

It is of interest to note that none of the existing modalities of fetal surveillance are based on affirmative evidence derived from clinical trials and systematic meta-analytic reviews. The benefit of the antepartum nonstress test was investigated in four randomized clinical trials [50–53]. None of the studies demonstrated any benefit. Moreover, a meta-analysis of these studies failed to show any benefit (Table 26.5). No randomized trial has ever been reported for the contraction stress test. There were two quasi-randomized trials on the fetal biophysical profile in the 1980s [55, 56]; neither demonstrated any difference in outcome after use of the test. Subsequent meta-analytic review also showed no benefit [57]. Two additional trials [58, 59] on the biophysical profile published in the 1990s were included in the meta-analysis by Al-

**Table 26.5.** Meta-analysis of randomized trials of antepartum nonstress cardiocardiography for fetal surveillance [54]

	Cardio-tocography	Control	Odds ratio (95% CI)
Delivery by cesarean	183/795	170/784	1.07 (0.84–1.36)
Fetal distress	172/631	140/613	1.27 (0.98–1.65)
Low Apgar score	38/380	38/369	0.91 (0.56–1.47)
Abnormal neonatal neurological signs	26/597	25/586	1.00 (0.57–1.77)
Admission to special care nursery	100/453	88/430	1.11 (0.80–1.54)
Perinatal deaths excl. lethal malformations	12/651	4/628	2.65 (0.99–7.12)

**Table 26.6.** Meta-analysis of controlled trials of biophysical profile for fetal surveillance [60]

	Biophysical profile	Control	Odds ratio (95% CI)
Perinatal mortality	13/1,405	11/1,434	1.30 (0.59–2.92)
Corrected perinatal mortality	3/1,122	2/1,058	1.42 (0.25–8.20)
Apgar score <7 after 5 min	37/1,400	32/1,428	1.21 (0.75–1.96)
Birthweight <10th percentile	9/279	17/373	0.71 (0.32–1.56)
Intrapartum fetal distress	14/279	25/373	0.74 (0.39–1.43)

firevic and Neilson [60]. These investigators concluded that the evidence was insufficient to evaluate the use of the biophysical profile as a test of fetal well-being in high-risk pregnancies (Table 26.6).

## Management of High-Risk Pregnancy: A Proposal Based on Clinical Trials

If Doppler velocimetry is beneficial as a fetal surveillance tool, what is the optimal mode of its application for managing the fetus at risk? Regrettably, it is difficult to use the above reports to develop and recommend a specific management plan, as most of the trials did not seem to have any defined protocol to translate the Doppler surveillance findings into a clear plan for intervention.

A general approach can be developed from the studies reporting a management protocol and demon-

strating an improved outcome after using the Doppler method [6, 11, 12]. The general approach may be described as follows. When the Doppler index remains within the normal limits or does not progressively rise, weekly testing should suffice. The nonstress test or the biophysical profile should be used either as a backup test or performed in conjunction with the Doppler. The latter approach is often used as a multimodal test for fetal well-being. If the fetal and maternal conditions remain assuring, allow the pregnancy to continue to maturity and assess the patient for delivery. In the presence of sonographically confirmed growth compromise, the pregnancy may not be allowed to become postdated.

A high or increasing Doppler index warrants more intense fetal surveillance consisting of weekly umbilical arterial Doppler, and once- or twice-weekly nonstress test and biophysical profile as warranted by the clinical condition until fetal maturity. If these tests indicate fetal compromise, or absent end-diastolic velocity develops, the likelihood of poor prenatal outcome is increased and urgent clinical response is indicated. The patient should be hospitalized and the management individualized depending on gestational age and fetal status.

The optimal timing for delivery in a preterm pregnancy with fetal growth restriction still remains uncertain. As discussed previously, the issue of a defined delivery timing policy for the compromised preterm fetus has been recently tested in the GRIT study, which failed to resolve the issue [19].

However, thanks to the recent impressive advances in neonatal care, a distinction can be made regarding the risks of prematurity between pregnancies beyond and before the 32nd completed week of gestation. In gestations less than 32 completed weeks, the absence of end-diastolic flow in the umbilical artery should prompt consideration for immediate delivery. Other ominous findings prompting delivery include (a) cessation of fetal growth on successive ultrasound examinations; (b) umbilical arterial absent or reversed end-diastolic flow; (c) nonreassuring fetal heart rate patterns including nonreactive nonstress test, poor fetal heart rate baseline variability, persistent variable or late decelerations; (d) oligohydramnios; and (e) biophysical profile score  $\leq 4$ .

When absent end-diastolic flow develops in a preterm pregnancy (<32 weeks) with a significant risk of fetal lung immaturity, further assurance of fetal well-being is sought by daily surveillance with umbilical arterial Doppler sonography, nonstress test, and biophysical profile. Steroids should be administered to enhance fetal lung maturity. Delivery is indicated regardless of maturity when a single or combination of tests indicate imminent fetal danger (as described above) and the fetal risk from a hostile intrauterine

environment is judged to be greater than that from pulmonary immaturity.

It should be noted that this management approach does not provide an answer for every contingency that may develop. The physician must individualize the care in the light of the myriad variations in the clinical situation. This recommendation should be used as a pragmatic guideline that integrates the new modality with the existing standards of fetal surveillance. As new evidence accumulates and our experience grows, these guidelines may contribute to the emergence of more effective standards of practice. Obviously, this plan of management requires refinement in the future so the issue of cost-effective integration of the various modalities of fetal monitoring in appropriate sequence and frequency may be addressed. Moreover, the utility of in-depth hemodynamic information, such as the middle cerebral arterial Doppler index and the cerebroplacental ratio, requires further investigation.

## Conclusion

The development of Doppler sonography has made it feasible to assess the fetal and uteroplacental circulations. Numerous studies have established a significant association between abnormal Doppler indices and the various pregnancy disorders and adverse perinatal outcomes. Most clinical investigations suggest that, in high-risk pregnancies, umbilical arterial Doppler indices may be efficacious for predicting perinatal problems including fetal death. Many randomized trials on Doppler velocimetry have yielded positive results. Furthermore, systematic reviews of the trials by meta-analysis demonstrate a significant reduction in preventable fetal deaths. The current evidence mandates that Doppler velocimetry of the umbilical artery should be an integral component of fetal surveillance in pregnancies complicated with fetal growth restriction or preeclampsia. Obviously, no single testing modality should be regarded as the exclusive choice for fetal surveillance, as these tests reveal different aspects of fetal pathophysiology, often in a complementary manner.

# Doppler Investigation of the Fetal Inferior Vena Cava

Yoshihide Chiba, Toru Kanzaki, Zeev Weiner

Inferior vena cava (IVC) flow velocity waveforms represent both right atrial function and the blood flow pattern within the venous tree of the lower fetal body. Flow velocity waveforms obtained close to the venous entrance into the right atrium reflect mostly right atrial activity. Therefore the information obtained by studying blood flow patterns within the IVC includes (1) whether there is normal atrial filling; (2) detection of a fetal arrhythmia and the resulting blood flow pattern; and (3) estimation of hemodynamic disturbances in severely compromised fetuses.

In this chapter we describe the normal pattern of IVC blood flow and the various components of the IVC flow velocity waveforms. Typical alterations of the IVC flow velocity waveforms in hydropic fetuses, fetuses with arrhythmias, and severely compromised fetuses are discussed. Finally, special attention is devoted to the significance of umbilical vein pulsations.

## Normal Blood Flow Pattern in Fetal IVC

A Doppler waveform in a fetal IVC under normal sinus rhythm shows a pulsating pattern synchronized

with cardiac motions. There are three components in a cardiac cycle: the monophasic blood flow retrograding from the right atrium to the inferior vena cava, the initial forward flow, and the second forward flow. The reverse flow occurs during atrial contraction. The initial forward flow coincides with atrial diastole and ventricular systole, and the second forward flow coincides with ventricular diastole (Fig. 27.1) [1, 2].

Fetal movements, particularly fetal breathing movements, influence the blood flow, changing the pattern not only in the IVC but also in the umbilical vein. Blood flow in the IVC has a complicated pattern during fetal breathing movements [3].

Many studies have reported that blood flow in an adult vena cava has a pulsating pattern synchronized with cardiac movements [4–8]. The cause of each component of the blood flow in an adult vena cava has been analyzed from the viewpoint of the atrial pressure [7–9], with the conclusion that the cause of reverse flow is an increase in atrial pressure due to contraction of the right atrium. The cause of systole forward flow is controversial. Some authors have estimated it only for atrial dilatation [4, 5]. However, others have suggested that the cause of the forward flow is movement of the tricuspid annulus toward the

**Fig. 27.1.** Time relation of venous return in the inferior vena cava with a cardiac cycle. A reverse flow, *Sf* initial forward flow, *Df* second forward flow

apex at ventricular systole [9–11]. Some have suggested that both factors are responsible [6, 8, 12]. The cause of diastole forward flow is the decreased atrial pressure due to rapid ventricular filling.

Generally the blood flow pattern in the fetal IVC is similar to that in the adult, as is the cause. We believe, in addition, that the pressure of the left atrium and movement of the mitral annulus may influence flow in the fetal vena cava.

Changes of the IVC flow velocity waveforms throughout gestation were studied by Huisman et al. [13] and Wladimiroff et al. [14]. These authors described a significant increase in time-averaged velocity and a significant decrease in percent reverse flow with advancing gestational age. Such changes, which could be seen as early as 11–16 weeks' gestation, corresponded with the increasing peak E wave/A wave ratio. We may conclude therefore that the changes in the IVC flow velocity waveforms observed during pregnancy represent increased cardiac compliance during this period. Rizzo et al. studied the blood flow pattern in the umbilical vein during early gestation [15]. They reported pulsations in the umbilical vein in all cases until 8 weeks' gestation, after which the pulsations disappeared progressively until 13 weeks' gestation. The presence of umbilical venous pulsations correlated with reverse flow within the IVC during atrial contractions.

## Doppler Evaluation of Preload Condition in the Fetal Vena Cava and the Umbilical Vein

Among 101 cases of nonimmune hydrops, 30 cases were complicated structural heart diseases. The prognosis of such cardiogenic hydrops is poor: the mortality was 86.7% [16]. To determine the best timing for delivery and the indications for intrauterine therapy of the fetus, one must understand the cardiac functions of the fetus with nonimmune hydrops.

The subjects for our study of cardiac function were divided into three groups according to diagnosis [3, 17]. The first group comprised those with structural heart disease associated with hydrops; the second had structural heart disease without hydrops; and the third contained those with hydrops but without heart disease.

We evaluated four parameters to establish the cardiac function of the three pathologic groups and that of normal fetuses. The first parameter, the cardiothoracic area ratio (CTAR), was the simplest and easiest to understand. The CTAR measures the dimensions of the heart with a four-chamber view. The next pa-

rameter was heart contractility, measured by Pombo's method. The third parameter was measurement of the peak systolic blood flow velocity in the descending aorta ( $U_{max}$ ). The final parameter was the Doppler blood flow pattern in the IVC. We knew that fetuses with congenital heart disease associated with hydrops have high velocity of atrial reverse flow in the IVC, and based on that we defined two new indices, the preload index (PLI), which is calculated from the Doppler shift of the atrial reverse flow and that of systolic forward flow in a fetal IVC. During the evaluation of fetal cardiac functions using these four parameters, the PLI showed the highest sensitivity and specificity for the cardiogenic hydrops fetus versus the normal fetus. It also showed good resolution between the cardiogenic hydrops fetus and the fetus with structural heart disease not associated with hydrops.

### Preload Index

The blood flow pattern in an IVC with normal sinus rhythm showed a pulsating pattern synchronized with the cardiac cycle. The Doppler waveform of the IVC includes three components: reverse flow (A), which occurs during atrial contraction; an initial forward flow (Sf), which coincides with atrial diastole and ventricular systole; and a second forward flow (Df), which is seen with ventricular diastole. A new index, the preload index (PLI), is defined as  $PLI = A/Sf$ . The PLI is independent of the angle between the Doppler beam incidence and the blood flow (Fig. 27.2) [3].

**Fig. 27.2.** Definition of the preload index (PLI). A blood flow from the right atrium occurring at atrial contraction, Sf blood flow into the right atrium coinciding with ventricular systole, Df blood flow into the right atrium coinciding with ventricular diastole

**Fig. 27.3.** Chronological change of the preload index (PLI) after 20 weeks of gestation. (With permission from [18])

**Fig. 27.4.** Preload index (PLI) among controls and those with fetal disease. Group 1, hydrops associated with heart disease ( $n=9$ ); group 2, structural heart disease without hydrops ( $n=8$ ); group 3, hydrops without heart disease ( $n=11$ )

### Normal Fetuses

The PLI value of normal fetuses ranged from 0 to 0.37 (median 0.13). The PLI gradually decreased after 20 weeks (Fig. 27.3) [18]. The decrease was so slight after 24 weeks of gestation that the influence of age can be ignored on any analysis done beyond 24 weeks of pregnancy [3].

### Fetuses with Hydrops and Heart Disease

The PLI values in the three groups of fetuses with disease are compared in Fig. 27.4. The PLI values for those with hydrops associated with heart disease (group 1) are significantly higher than those for normals and for the group with heart disease without hydrops (group 2). PLI values for group 1 ranged from 0.52 to 1.05. All PLI values in this group with cardiogenic hydrops were more than 0.5. PLI values

**Fig. 27.5.** An example of hyper preload condition. Higher preload index (PLI) in the recipient of twin-to-twin transfusion syndrome (TTTS)

for the third group (those with hydrops without heart disease) were in a wide range, from 0 to 1.08. According to the results of our studies [3, 17], cardiogenic hydrops is associated with less contractility of the heart, lower flow velocity in the descending aorta, and a significantly higher PLI in the IVC.

Another study has shown that umbilical venous pressure is higher in the presence of hydrops fetalis [19]. Thus it is logical to assume that excessive preload is present in the fetus with cardiogenic hydrops. Half of the fetuses with hydrops without heart disease had a higher PLI in our study. It is again reasonable to assume, then, that they might have secondary cardiac dysfunction, as their hydrops is not primarily cardiogenic. Thus we have assigned them a new designation: secondary cardiogenic hydrops (Fig. 27.5).

**Blood Flow Change During Fetal Therapy**

A high PLI in fetuses showing pleural effusion is always decreased in value by aspiration of the pleural effusion (Figs. 27.6, 27.7). This phenomenon suggests shunting surgery for hydrothorax (Fig. 27.8). In Japan between 1996 and 1999, 28 cases of hydrothorax underwent shunting surgery. In 20 of the 28 cases, surgery was judged effective by the committee on perinatal medicine of the Japan Society of Obstetrics and Gynecology [20].

**Blood Flow Dynamics in Fetal Central Veins During Labor**

Our studies of venous blood flow during labor support the suggestion that high preload influences blood flow of the fetal central vein [22]. For example, during the recovering period from cord compression or during late deceleration, we recognize high reverse flow in the IVC. It is speculated that blood flow vol-

**Fig. 27.6.** Following aspiration of hydrothorax, the preload index (PLI) decreased from 1.40 to 0.67, the thoracic pressure also decreased from 25 mmHg to 9 mmHg. (With permission from [19])

**Fig. 27.7.** Change in preload index (PLI) by the aspiration of hydrothorax, before and after

ume increases the total cardiac output during the recovering period due to cord compression. During late deceleration the blood flow volume may be relatively higher than the cardiac output. Pulsation of blood flow was observed in the umbilical vein under the same conditions during the recovering period from cord compression or during late deceleration (Fig. 27.9).

**Fig. 27.8 a, b.** Fetal therapy for hydrothorax using a double basket catheter. **a** During shunting surgery under ultrasound guidance and **b** immediately after birth

### IVC Blood Flow at an Early Stage of Pregnancy

The high preload may present at an early stage of gestation in a normal fetus, an observation supported by our findings [23]. A statistical analysis was performed on the Doppler waveforms in the IVC during early pregnancy, as well as in the umbilical artery, middle cerebral artery, and descending aorta [23]. This study shows that the PLI values significantly increased from 9 to 12 weeks of gestation ( $p < 0.05$ ). The PLI values decreased gradually after 13 weeks' gestation ( $p < 0.05$ ) (Fig. 27.10). This study also shows that the resistance indices of the umbilical artery began to decrease at almost the same age (12 weeks' gestation). There was no end-diastolic component before 11 weeks of pregnancy (Fig. 27.11). It is logical to assume that at 12 weeks of pregnancy the compliance of the placental circulation may begin to decrease and the venous blood flow may tentatively increase [24].

### Abnormal IVC Blood Flow Patterns with Fetal Arrhythmias

Many studies of the IVC in human adults [4–8] have contributed to our understanding of the mechanisms that cause variations of flow in a fetal vena cava. We have reported the characteristic blood flows associated with fetal arrhythmias elsewhere [1].

**Fig. 27.9.** Flow changes with fetal breathing movements before cord compression but begins to decrease with compression. Then, during the period of recovery from cord compression, blood flow pulsation is synchronized with cardiac motion, shown by the fetal electrocardiogram

**Fig. 27.10.** Dynamics of preload index (PLI) from 9 to 20 weeks of normal pregnancy. IVC inferior vena cava

**Fig. 27.11.** Changes of resistance index (RI) from 9 to 20 weeks of normal pregnancy. UmbA umbilical artery

**Fig. 27.12.** Biphasic forward flow immediately after the dominant reverse flow in a case of premature atrial contraction of the fetus

### Blood Flow Pattern of Premature Contractions

During premature atrial contractions (PACs), the systolic forward flow is suddenly interrupted by the reverse flow of the atrial contraction with a higher velocity than usual. The higher reverse flow is designated dominant A. The forward flow after dominant A has a biphasic pattern, with each phase corresponding to ventricular systole and diastole (Fig. 27.12) [1].

With premature ventricular contractions (PVCs), the dominant reverse flow suddenly interrupts the diastolic forward flow. This dominant reverse flow coincides with premature ventricular systole. The subsequent forward flow is monophasic, representing diastolic forward flow [1].

### Bradycardic Arrhythmia

With bigeminy of a blocked PAC, the usual reverse flow (A) and dominant reverse flow (dominant A) appear alternately. The time from the preceding flow A to the dominant A is shorter than that from dominant A to the next flow A (Fig. 27.13) [1].

With complete atrioventricular block, reverse flow (including both normal reverse or flow and dominant reverse flow) appears regularly. The reverse flow coincides with the atrial contraction. Dominant reverse flow appears when an atrial contraction occurs during ventricular systole. The forward flow takes variable forms depending on the time relation between the P wave and the QRS complex on the fetal electrocardiogram (ECG) (Fig. 27.14) [1].

### Tachyarrhythmias

With atrial flutters and 2:1 conduction, reverse flow appears twice as often as the QRS complex on the ECG. When the fetal ECG is not monitored, the Doppler waveform in a descending aorta may help to determine the rate of appearance of ventricular systole (Fig. 27.15) [1]. With supraventricular tachycardia,

**Fig. 27.13.** Blood flow in an inferior vena cava during fetal bigeminy of a blocked premature atrial contraction

**Fig. 27.14.** Blood flow patterns of an inferior vena cava (IVC) and a descending aorta (D Ao) in a case of fetal complete atrioventricular block

**Fig. 27.15.** Blood flow in an inferior vena cava (IVC) of a case of fetal atrial flutter with 2:1 conduction

**Fig. 27.16.** Blood flow in an inferior vena cava (IVC) in a case of fetal supraventricular tachycardia

the blood flow pattern in an IVC is almost same as the normal sinus rhythm (Fig. 27.16).

### Determination of Fetal Therapy According to the Type of Tachycardia

Some types of fetal tachycardia can be diagnosed by the Doppler waveform at the IVC. However, some conditions were difficult to diagnose, for example, Wolff-Parkinson-White Syndrome. It is necessary to establish the etiology of the tachycardia when we select an antiarrhythmic drug. We require a precise diagnosis to consider the type of intrauterine fetal therapy. We previously published some reports regarding the differential diagnosis of fetal tachycardia by magnetocardiography and direct fetal electrocardiography (Fig. 27.17) [25–29].

**Fig. 27.17.** Averaged fetal magnetocardiography of Wolff-Parkinson-White syndrome of the fetus

### IVC and Umbilical Vein Blood Flow Patterns in High-Risk Fetuses

The occurrence of umbilical venous pulsations in abnormal and normal pregnancies has been described by several authors. Nakai et al. [30], Indik et al. [31], and Gudmundsson et al. [32] reported pulsatile flow in the umbilical vein with changes in the IVC blood flow pattern in hydropic fetuses. Arduini et al. [33] found that fetuses with absent end-diastolic velocity in the umbilical artery who present with umbilical venous pulsations deteriorate rapidly. In their study, fetuses with umbilical venous pulsations developed abnormal fetal heart rate patterns within a shorter time than did fetuses with normal umbilical venous flow.

As already mentioned, umbilical venous pulsations can be observed in normal pregnancies during the first trimester, and Nakai et al. [22] found such pulsations during the third trimester in normal fetuses. They concluded that umbilical venous pulsations in normal fetuses are due to pulsations of the umbilical artery. Their theory was supported by the fact that umbilical venous pulsations in normal fetuses were observed only transiently and only in the free loop of the umbilical vein.

We conclude that an abnormal blood flow pattern in the venous system represents hemodynamic deterioration in severely compromised fetuses.

# Ductus Venosus

Torvid Kiserud

The ductus venosus (venous duct, ductus Arantii) is one of the three physiological shunts responsible for the circulatory adaptation to intrauterine life. It is attributed to Giulio Cesare Aranzi (1530–1589), but the first written account dates back to his contemporary Vesalius in 1561 [1]. Its function was long recognized [2, 3] but of hardly any clinical importance until ultrasound techniques were introduced [4–6]. It is now widely used as an important part of the hemodynamic assessment of the fetus [7] and has been suggested for diagnostic use after birth as well [8].

## Anatomy and Development

The ductus venosus is a thin, slightly trumpet-shaped vessel connecting the intra-abdominal umbilical vein with the inferior vena cava (IVC; Fig. 28.1). Its inlet, the isthmus, is on average 0.7 mm at 18 weeks and 1.7 mm at 40 weeks of gestation [9–11]. It leaves the umbilical vein (portal sinus) in a cranial and dorsal direction and reaches the IVC at the level of the hepatic venous confluence shortly below the atria. This section of the IVC is shaped as a funnel [12] but expands predominantly to the left side to receive blood from the ductus venosus and the left hepatic veins [13, 14]. Although variations in direction have been reported, the ductus venosus approaches the IVC at a fairly steep angle (on average  $48^\circ$ ) [13]. In early pregnancy the ductus tends to be a straight continuation of the umbilical vein (Fig. 28.2). In late pregnancy a curvature after the isthmus is commonly observed. The relationship to the left and medial hepatic veins is close and sometimes their inlets into the IVC cannot be separated from that of the ductus venosus [15].

Topographically and functionally, the ductus venosus appears to be connected to the foramen ovale in the primate [16], fetal lamb [17, 18], and in the human fetus [2, 5, 19–21]. In the fetal sheep there is a valvular membrane that directs blood from the ductus venosus into the fairly long thoracic IVC to reach the foramen ovale [3]. Although this pattern is commonly presented in anatomical sketches of the human anatomy, it is quite different from the true human to-

pography. The thoracic IVC is short or non-existent in the human fetus and there is no valve developed at the ductus venosus outlet, the effect being that the ductus venosus projects the blood flow directly towards the foramen ovale from a short distance and is less dependent on laminar flow arrangement to avoid extensive blending with low oxygenated blood from the abdominal IVC [13].

During early gestation, the ductus venosus is formed as a confluence of hepatic sinuses, then devel-

**Fig. 28.1.** Anterior anatomical view with the liver divided to expose the trumpet-shaped ductus venosus (DV) at 39 weeks of gestation. The DV leaves the abdominal portion of the umbilical vein (UV) in the direction of the foramen ovale (FO). The direction is slightly to the left of the abdominal inferior vena cava (IVC), which expands predominantly to the left side (arrow) as it reaches the liver confluence. This expansion represents also a continuation of the ductus venosus permitting umbilical blood to reach the FO without extensive blending with deoxygenated blood from the IVC. RL right lobe of the liver. (From [14])

ops into a separate channel [22–25], and is regularly recognized with ultrasound color Doppler in embryos of 8 weeks of gestation. Ultrasound visualization and volume flow calculations indicate that the ductus venosus has a more prominent role during early pregnancy than near term [11, 26].

A sphincter has been suggested to operate at the inlet [22, 27–30]. The scarcity of muscular and neuronal elements in the human ductus venosus have raised doubts as to whether such sphincter exists [21, 31–33]. Adrenergic nerves have been traced in the inlet area [34]. An  $\alpha$ -adrenergic constriction and a  $\beta$ -adrenergic relaxation have been reported [33, 35, 36]. Both a prostaglandin and a peroxidase P-450 mechanism have been suggested to function in the ductus venosus in the same way as described for the ductus arteriosus [37–40]. The mechanisms could be responsible for the patency during fetal life and its closure in postnatal life; however, in contrast to the ductus arteriosus, oxygen does not seem to trigger the obliteration of the ductus venosus [41]. Recent studies indicate that it is the entire length of the ductus venosus that is active during regulation [33, 42, 43] and that the regulatory mechanism is less sensitive to

adrenergic stimuli than the portal venous branches in the liver tissue [33].

## Physiological Background

### Via Sinistra

The ductus venosus is an important part of the via sinistra, a classical concept still valid at present (Fig. 28.3). As a direct connection between the umbilical vein and the central venous system, it has the capacity to shunt well-oxygenated blood directly into the central circulation and feed the left atrium

**Fig. 28.2.** Inferior and posterior view of the umbilical vein (UV), portal sinus (PS), and ductus venosus (DV) at 15 weeks' gestation. Note the considerable number of branches present in the area. Due to the preparation the main portal stem is not seen, but is expected to enter near the label for the right portal vein (RPV). IVC inferior vena cava, LPV *i* inferior left portal vein, LPV *s* superior left portal vein. (From [20])

**Fig. 28.3.** Fetal circulatory pathways showing the three shunts, ductus arteriosus (DA), ductus venosus (DV), and the foramen ovale (FO). The via sinistra (red) directs blood from the umbilical vein (UV) through the DV and FO to reach the left atrium (LA), left ventricle (LV), and ascending aorta (AO) thus supplying the coronary and cerebral circuit with well-oxygenated blood before joining with the via dextra (blue) in the descending AO. The via dextra receives deoxygenated blood from the abdominal inferior vena cava (IVC) and superior vena cava (SVC) directed to the right atrium (RA), right ventricle (RV), and pulmonary trunk (PA) bypassing the pulmonary circuit through the DA. Splanchnic blood from the main portal stem (MP) is provided to the right liver lobe after blending with umbilical blood that reaches the right portal branch (RP) through the left branch (LP). CCA common carotid arteries, FOV foramen ovale valve, LHV left hepatic vein, MHV medial hepatic vein, PV pulmonary vein, RHV right hepatic vein. (Slightly redrawn from [11])

**Fig. 28.4.** Ductus venosus blood flow (ml/min per kg) in 193 low-risk fetuses presented with 10th, 50th, and 90th percentiles. The relative flow appears more prominent at mid-gestation than during the third trimester. (From [11])

**Table 28.1.** The fraction of umbilical blood shunted through the ductus venosus during the second half of the human pregnancy [11]

Gestational age (weeks)	Number	Degree of ductus venosus shunting (%)	
		50th percentile	(10th; 90th percentiles)
18–19	34	28	(14; 65)
20–24	45	25	(10; 44)
25–28	34	22	(10; 44)
29–32	32	19	(9; 46)
33–36	21	20	(10; 31)
37–41	27	23	(7; 38)

through the foramen ovale, thus ensuring oxygenated blood to the coronary and cerebral circuit. Animal studies have shown that around 50% of the umbilical blood bypassed the liver through the ductus venosus [16, 17, 44, 45]. In human fetuses it is around 30% at 20 weeks and 20% at 30–40 weeks of gestation when measured by Doppler ultrasound techniques [11, 26]; thus, the shunting through the ductus venosus seems more prominent at mid-gestation than at term (Fig. 28.4; Table 28.1).

During experimental hypoxemia and hypovolemia, the ductus venosus flow is maintained [16, 44, 46–49]; however, since the flow to the liver is reduced, it implies that the fraction of umbilical blood directed through the ductus venosus increases to 70% [16, 44, 46–50]. A similar effect seems to be present in growth-restricted human fetuses [50].

The size of the foramen ovale, the position, and the direction of the ductus venosus, and its high kinetic energy, are suggested to play a role to reduce degree of blending with de-oxygenated blood in the IVC and to force open the foramen ovale valve [13, 14]. Since the oxygen extraction in the liver tissue is

low, causing a reduction in saturation of 10–15% [51, 52], the hepatic venous blood flow from the left liver constitutes another important source of oxygenated blood directed towards the foramen ovale. In total, it is an abundant volume of oxygenated blood that predominantly fills the foramen ovale but additionally spills over to the right side. The result is a notably small difference in oxygen saturation between the left and the right ventricle, 10% under experimental conditions increasing to 12% during hypoxemic insults [3, 53].

### Umbilical Liver Perfusion

Another aspect of the ductus venosus function is its role in the fetal liver circulation. Since 20%–30% of the umbilical blood is shunted through the ductus, it implies that 70%–80% of the umbilical blood perfuses the liver as the first organ in the fetus [11]. The pattern indicates the importance of the fetal liver during intrauterine development. Recent studies indicate that blood flow in the fetal liver regulates fetal growth (Fig. 28.5) [54, 55], and that this blood flow depends on external factors such as maternal nutritional state and dietary habits, at least during late pregnancy [56]. In addition to an active regulation of the ductus venosus influencing the distribution of umbilical blood to the liver, both passive regulation (blood pressure and viscosity) [17, 57, 58] and active regulation (vessel constriction) [33, 59, 60] tune the portal liver blood flow. This makes the liver a very delicate watershed area regulated at low pressures. In the long run, umbilical liver flow has a high priority in maintaining growth and development. During acute challenges (i.e., hypoxemia or hypovolemia) short-term responses with increased shunting through the ductus venosus ensures survival. If such challenges are main-

**Fig. 28.5.** Experimentally occluded ductus venosus in fetal lambs leads to an increased umbilical flow through the liver, increased signs of proliferative activity (*right ordinate*), and increased liver growth (*left ordinate*). (From [54])

tained over a longer period, adaptational mechanisms come into play, reducing the metabolic requirements, and the circulatory redistribution partially returns to normal patterns [61, 62].

### Portal Watershed Area

Since blood from the umbilical vein and blood from the main portal stem both supply the liver, there is a watershed area in the liver between the two sources in the right liver. Conventionally umbilical blood supplies the left liver, the ductus venosus, and flows through the left portal branch to join with the blood from the main portal stem as the blood flows into the right portal branch (Fig. 28.3); thus, in the human fetus under physiological conditions in late pregnancy, the left half of the liver receives pure umbilical blood while the right half receives a 50% mixture of umbilical and splanchnic blood [26, 63]; however, during hypovolemia this distributional pattern is shifted to the left. During experimental hemorrhage, less umbilical blood is provided to keep up the pressure in the portal system with the perfusion of the liver and ductus venosus. An increasing component of splanchnic blood from the main portal stem fills up the left portal branch and an increasing proportion of the ductus venosus blood flow will be of splanchnic origin [44, 47, 48]. The phenomenon of shift of the watershed to the left has been observed in the human fetus as well [64, 65], but with no proof that the underlying cause was hypovolemia.

### Porto-Caval Pressure Gradient

The position between the umbilical vein (i.e., portal sinus) and the IVC makes the blood flow in the ductus venosus an important indicator of the porto-caval pressure gradient that perfuses the liver tissue [10, 66]. The absolute blood velocity has been suggested as a marker of fetal portal hypertension seen during fetal liver diseases (e.g., lymphoproliferative infiltration, virus infections, mitochondrial diseases). The simplified Bernoulli equation is suggested for the estimation of the pressure gradient [10] ( $\Delta p$ ; in mm Hg) based on the maximum trace of the ductus venosus blood velocity ( $V_{DV}$ ) and the velocity in the umbilical vein ( $V_{UV}$ ) measured in m/s:

$$\Delta p = 4((V_{DV})^2 - (V_{UV})^2)$$

It has been estimated that the energy dissipation at the isthmus does not exceed 30%, which makes the calculation a fairly reliable pressure estimate [67, 68] in spite of the possible pressure regain expected to occur during velocity retardation as the blood approaches the heart. Up to now, the diagnostic possibilities of this concept have not been explored to any extent.

**Fig. 28.6.** Pressure difference between the lungs and abdomen during fetal respiratory activity at 39 weeks of gestation. It is based on the assumption that the close proximity to the diaphragm makes the ductus venosus blood velocity an indicator of the difference in pressure above and below the liver. The pressure is calculated from the velocities using the simplified Bernoulli equation. (From [10])

### Fetal Respiratory Force

Since the liver and its venous confluence is situated just beneath the diaphragm, the ductus venosus blood flow velocity also reflects the abdomino-thoracic pressure gradient. This gradient varies during fetal respiratory movements and is calculated to reach more than 20 mmHg during maximal excursions (Fig. 28.6). The estimations are based on the Bernoulli equation in the same manner as above. The low velocities in the umbilical vein do not influence the calculations and can be left out. Again, this concept is another example of possible diagnostic ductus venosus examination hardly explored.

### Postnatal Physiology

After birth, the ductus venosus is obliterated within 1–3 weeks (Fig. 28.7) [69, 70]. Interestingly, the high blood velocity seen prenatally seems to be maintained during that period [70], reflecting the fact that the portal perfusion pressure for the liver circulation is maintained. Observations of prematurely born neonates show that the ductus remains patent longer than in infants born at term [71, 72]. The hypothesis that a patent ductus venosus represents a bypass of the liver in the first weeks of postnatal life to the extent that it influences the clearance rate has been addressed by assessing the galactose concentration in prematurely born neonates [73]. No effect of the patent ductus was found, but the degree of shunting in the ductus venosus was not quantified. The ductus

**Fig. 28.7.** Distribution of closing times of the ductus venosus in healthy neonates. The bars represent the percentage closure per day and the curve represents the fitted log-logistic distribution. (From [70])

venosus stays open longer also in infants with congenital heart defects or persistent pulmonary hypertension [8], and the waveforms in these cases resemble those seen in abnormal cases prenatally; thus, the ductus venosus velocimetry has been suggested as a diagnostic adjuvant during the first weeks of postnatal life as well.

## Ultrasound Imaging and Insonation

A sagittal anterior insonation offers the best visualization of the ductus venosus (Fig. 28.8) [5, 9]. To assess its course and diameters, the perpendicular insonation through the fetal liver suits best. An oblique

**Fig. 28.8.** Sagittal ultrasound insonation shows the ductus venosus (DV) connecting the umbilical vein (UV) to the proximal portion of the inferior vena cava (IVC) in a fetus of 18 weeks' gestation. Note how the continuation of the DV follows the posterior wall of the IVC and the foramen ovale valve (curved arrow) into the left atrium (LA) and behind the atrial septum (AS; arrow). RA right atrium

transverse section may be more convenient in some fetal positions but rarely offers visualization of the entire length of the vessel.

Color Doppler is an indispensable help in identifying the high velocity at the isthmus of the ductus (Fig. 28.9). With modern equipment the identification can be done from any direction but requires an appropriate setting of filters and ranges to distinguish the typical high velocity of the ductus venosus from velocities in neighboring vessels.

For the pulsed Doppler measurements the sagittal anterior or posterior insonation offers the best control of angle. The anterior insonation from below the fetal umbilicus (Fig. 28.9), or the posterior from the level of the chest, gives insonations that hardly require angle correction. If such insonations are not possible, then the oblique transverse section through the fetal abdomen will provide a good visualization of the ductus venosus inlet but less control of the insonation angle. For the measurement of waveforms this should suffice.

Sample volume should be kept wide to ensure the recording of the maximum velocity during the heart cycle. This holds true for the second half of pregnancy; however, during early pregnancy the sample volume has to be reduced to fit with the geometrical details in order to reduce interference of velocities of the umbilical vein, the proximal portion of the ductus, or neighboring veins and arteries. This is particularly important during the atrial contraction phase

**Fig. 28.9.** Color Doppler helps identifying the isthmus inlet of the ductus venosus (DVi). The preferred insonation for Doppler recording is along or between the arrows. Note that the aliasing starts already in the umbilical vein (UV) in front of the inlet, the reason being that the blood starts to accelerate before reaching the isthmus. AO descending aorta, HV middle hepatic vein

since a zero velocity or inverted velocity, which is commonly used for diagnostic purposes [74–79], may be masked.

Angle of insonation and angle correction need particular attention. Transducers commonly used by obstetricians are broad with a flat or curved surface. Compared with sector scanners, these transducers make it harder to achieve an insonation along the ductus venosus with zero or near-zero angle correction. If the recording of absolute velocities has any diagnostic consequence, there is much to gain from getting accustomed to sector scanners so commonly used in cardiology. As mentioned, the sagittal insonation offers the best control of angle, but an oblique transverse interrogation may, in favorable positions, be a good alternative. The angle of insonation should always be documented. In case a curvature has developed centrally to the isthmus, a tangential insonation to this curvature ensures correct insonation and no need of angle correction.

### Normal Ductus Venosus Blood Velocity

Typically, the ductus venosus blood flow has a high velocity during the entire cardiac cycle compared with neighboring veins at the corresponding gestational age (Fig. 28.10) [5, 6, 9, 80–82]. Starting in early pregnancy (e.g., 10 weeks of gestation) the velocity increases until reaching a plateau at 22 weeks [81, 82]. For the rest of the pregnancy the peak velocity ranges between 40 and 85 cm/s (Fig. 28.11) [5, 6, 80, 81]. Some variation in reference ranges is seen,

**Fig. 28.10.** Doppler recording of the blood velocity at the isthmus of the ductus venosus at 33 weeks of gestation. Typically there is high velocity during the entire cardiac cycle with a peak during systole (S), another peak during passive diastolic filling (D), and deflection (white arrow) during atrial contraction (A). The velocity of the interfering umbilical vein is faintly seen between black arrows

probably depending on equipment, insonation techniques, angle correction, and population.

The velocity pattern reflects the cardiac cycle with a peak during systole, another during passive diastolic filling and a nadir during active diastolic filling (atrial contraction; Fig. 28.10). Typically, the nadir during the second half of pregnancy, in contrast to other precordial veins; however, below 15 weeks of gestation, an increasing number of zero or below-zero

**Fig. 28.11.** Cross-sectional reference ranges for the systolic peak velocity (S) in the ductus venosus with the 5th, 50th, and 95th percentile. (From [81])

**Fig. 28.12.** Doppler recording of the blood velocity at the isthmus of the ductus venosus at 32 weeks of gestation shows no pulsation. The phenomenon occurs in 3% of all recordings in low-risk pregnancies. (See Chap. 5 for explanation)

velocities are observed in normal fetuses [14]. Reference ranges have been established for all the components of the wave as well as for the time-averaged maximum velocity during the entire cardiac cycle [5, 80–82]. The time-averaged weighted mean velocity is typically 0.7 of the maximum velocity. The relationship is established by mathematical modeling, and experimental and clinical observations, and is a quite useful information when calculating volume flow [68, 83–86].

It is important to acknowledge the wide normal variation of the waveform. Most reference ranges have not taken that into account, and some have. In 11% of the recording no second velocity peak will be found during the passive diastolic filling [9], and in 3% of all recordings there will be no well-defined nadir visible (Fig. 28.12) [9]. These patterns reflect the wide range of geometrical variation possible in the normal fetus. Squeezing of the ductus venosus outlet or the IVC at the level of the diaphragm will cause an increased wave reflection with less or no pulse wave

transmitted into the ductus venosus resulting in non-pulsatile velocity recording at the isthmus (see Chap. 5) [14, 87]. While this is a fairly common phenomenon in normal fetuses, there are no data on its occurrence in the compromised pregnancy; however, based on experience, it must be rare.

Absolute blood velocity thus has the advantage of directly reflecting both the porto-caval pressure gradient that drives the liver perfusion [10] and the cardiac events that modify the velocity waveform [5]; however, both the type of equipment used by the obstetrician and their tradition of examination technique have made the angle-independent waveform analysis the preferred method compared with the more demanding absolute velocity recording, but not without some loss in diagnostic information.

### Waveform Analysis: Indices

To give an angle-independent evaluation, ratios of various components of the waveform during the heart cycle have been suggested (Table 28.2). Some of these ratios are used also for other fetal veins and in analysis of arterial blood velocities. The indices that include the entire heart cycle are more robust and are thus recommended for general use. The pulsatility index for veins (PIV) [80] is probably the most widely used index (Fig. 28.13).

The waveform reflects cardiac events, i.e., the intra-cardiac pressure variation, which is emitted into the precordial venous system as a pulse wave. As mentioned above, using the waveform as the only analysis of the velocity means disregarding the porto-caval pressure gradient reflected in the absolute

**Fig. 28.13.** Cross-sectional reference ranges for the pulsatility index for veins ( $(S-a)/V_{\text{mean}}$ ). (From [81])

**Table 28.2.** Indices suggested for the waveform analysis of the ductus venosus blood flow velocity. Some of the indices are suggested also for other veins. *A* minimum velocity during atrial contraction (a-wave), *D* peak velocity during ventricular diastole, *S* peak velocity during ventricular systole,  $V_{ta}$  time-averaged maximum velocity

velocity. At a very acute angle of insonation an increased error assessing the lowest velocity during atrial contraction may make the waveform less reliable.

## Interpretation of the Waveform

### The Atrial Contraction Wave

The atrial contraction wave (a-wave) is the single most important part of the waveform from a diagnostic point of view. The augmented atrial contraction wave signifies an increased end-diastolic filling pressure in the heart, which may be induced by an increased distension of the atria leading to an augmented contraction (the Frank-Starling effect) commonly seen in cases with increased preload or congestive heart failure [88–94]. An increased afterload can also lead to a reinforced a-wave (Fig. 28.14) [95–99]. Experimentally imposed hypoxic insult has been shown to cause an increased a-wave in late pregnancy [86, 100, 101], but also at mid-gestation and in early pregnancy [102]. In case of the latter, the effect is believed to be primarily a direct hypoxic effect on the myocardium. In late pregnancy, the effect is predominantly orchestrated via immediate neural responses and secondary endocrine effects on cardiac rhythm and contractility as well as on peripheral vascular impedance [45, 103, 104].

Heart rate is an important determinant for the precordial venous waveforms [92]. A slowing of the heart rate permits a more pronounced venous filling and increased distension of the myocardium resulting

**Fig. 28.14.** A case of progressive placental compromise and growth restriction shows normal ductus venosus blood flow at 18 weeks with a normal a-wave (upper panel). At 24 weeks the augmented a-wave was apparent (middle panel). At 25 weeks a further deterioration was seen with a reversed a-wave and an increasing dichotomy between the systolic and diastolic peak (lower panel)

in augmented atrial contraction. The effect is seen in fetal bradycardic conditions.

An increased venous return causes a more pronounced myocardial distension, and a correspondingly augmented a-wave. Typically, this occurs in the twin–twin transfusion syndrome with one of the fetuses being overloaded through placental communications [105]. Arterio-venous malformations in the placenta, fetal liver, fetal brain, or the increased load due to cystic adenomatoid lung malformations are other examples of conditions causing an increased venous return.

Hyperkinetic circulation, such as in fetal anemia, also increases the preload, and the a-wave [106]. With the deterioration of cardiac function, i.e., congestive heart failure, the sign of augmented a-wave becomes

more marked, with the minimum velocity reaching zero line or below, even in late pregnancy.

Compliance of the heart is reflected in the a-wave. The reduced compliance of the myocardium in cardiomyopathies, myocarditis (e.g., parvovirus B19 infection), hypoxemia, and acidosis is commonly associated with a deepened a-wave (Fig. 28.14). The compliance can also be influenced by extra-cardiac restrictions in the chest (see Chap. 5). Normally, the absence of free air during intrauterine life makes the entire vascular system, including the heart, less compliant than after birth. In addition, increased pressure in the fetal chest (e.g., large tumors, pleural effusions, or tracheal atresia) could lead to further restriction of the cardiac excursions and made visible in the a-wave.

A significant tricuspid or mitral regurgitation, or both, may contribute to a rapidly increasing volume and pressure in the atria thus causing an augmented a-wave.

Timing of the atrial contraction is also an important determinant for the magnitude of the a-wave. The various patterns found in arrhythmias are particularly instructive [107–109]. In its simplest form, the wave of a supraventricular extrasystole may hardly be visible in the ductus venosus Doppler recording, whereas the atrial contraction following the compensatory postictal pause has been given the extra time and load of volume to cause an augmented a-wave. An even more amplified version of the a-wave is seen in cases of atrioventricular block. When the atrial contraction coincides with the ventricular systole, the atrioventricular valves are closed and the compliance correspondingly reduced, the result being a stronger pulse-wave directed into the precordial veins, including the ductus venosus. During tachycardia the timing of the atrial contraction, the size of the atria, whether the atrioventricular valves are open, the momentary degree of filling, the functional condition of the myocardium itself, and probably details of where the contraction starts and how it propagates determine the details of the a-wave [109].

In recent years the a-wave has been the focus in the search for methods of surveillance of patients with placental compromise. Short-time variation of the computerized CTG and the a-wave (or its effect on the pulsatility indices) showed late changes compared with umbilical artery pulsatility and changes in the middle cerebral artery (Fig. 28.15) [110–112]. The sign seems easier to interpret in pregnancies before 32 weeks of gestation than after; thus, it has become a promising method for serial observations in order to determine timing of delivery of the growth-restricted fetus. Since the ductus venosus velocity pattern is an instantaneous reflection of the cardiac function, these changes are probably useful signs in other conditions where the fetus is at risk as well.

**Fig. 28.15.** Serial observations of cases with severe intrauterine growth restriction delivered 32 weeks of gestation. Changes in the pulsatility index of the umbilical and middle cerebral arteries and oligohydramnios are common findings 3–5 weeks before delivery. Alterations in the ductus venosus waveform and short time variation are notable during the last 2 weeks before delivery, indicating that these two parameters may be suitable for the final tuning of time of delivery. (Modified from [20])

### Systolic Wave

Conventionally, the systolic peak during ventricular contraction is smooth and rounded (Fig. 28.16). Changes in myocardial function are reflected also in this part of the cardiac cycle. In conditions of reduced compliance, both of extracardiac and cardiac origin, the downstroke of the velocity becomes more acute (Fig. 28.16). This is particularly apparent during the deterioration seen in placental compromise [7, 113]. Increased afterload combined with an increased degree of hypoxemia and acidosis drives the myocardial function toward less compliance. The visible result is the acute up- and downstroke of the systolic peak and a corresponding dissociation between the systolic and diastolic peak (Fig. 28.16). A similar effect can be achieved by the externally increased pressure on the heart, and thus correspondingly reduced compliance (see Chap. 5). The increased blood volume and atrial pressure caused by a regurgitation of the atrioventricular valves causes an augmented a-wave; however, the more extensive the regurgitation is, the more rapid the atrial filling will be, and the earlier in the heart cycle the impact will come. In cases of Ebstein anomaly this may lead to an early downstroke during ventricular systole.

### Pitfalls

For the beginner, sampling the velocity in a neighboring vein, or including interference from the IVC or other vessels, may falsely give the impression of an abnormal ductus venosus recording. The velocity in the hepatic veins tends to be more acute and, partic-

**Fig. 28.16.** Conventionally, the systolic peak (S) is smooth signifying good atrial compliance (*upper panel*). Increased stiffness of the myocardium due to hypoxia and acidosis, such as in advanced placental compromise, results in a rapid downstroke (*arrow*) of the S (*lower panel*). Typically the waveform is transformed into acute velocity changes and a dissociation between S and diastolic peak (D). The augmented a-wave (A) reaching below zero is a common part of the pattern

ularly during the second trimester, the veins have a zero or reversed velocity during atrial contraction. Before leaping to a conclusion, it is prudent to reproduce the recording in a renewed insonation. It is also helpful to know that the augmented pulsatility in the ductus venosus commonly has a corresponding pulsatile flow in the umbilical vein. If the insonation makes the identification of the ductus venosus less certain, the pulsatility and a-wave should be checked in more accessible precordial veins such as the IVC or hepatic veins.

The pulsatile flow in the left portal vein is the mirror image of the ductus venosus waveform [64]. One of the consequences is that the a-wave occurs not as a nadir but as a peak (see Chap. 5). The simultaneous sampling of the ductus venosus inlet and the left portal vein could then cause a masking of the true nadir in the ductus venosus. Masking may also be the case during simultaneous sampling at the isthmus of the ductus venosus and the umbilical vein where the pulsatility usually is less pronounced. This is a common problem in early pregnancy.

Local changes of no pathological significance may influence the waveform. The fetal position may be such a factor. A fetus bending forward, particularly in the extreme situations of oligohydramnios, may squeeze the IVC, the outlet, or the entire length of the ductus venosus to the extent that most of the wave is reflected and the recorded wave at the inlet has lost pulsation (see Chap. 5). In 3% of pregnancies this normal phenomenon may be observed. Usually, a change in fetal position within the next minutes is accompanied with the restoration of pulsatile flow velocity.

A normal ductus venosus does not exclude abnormal physiology. All the factors determining the waveform should be taken into consideration when interpreting the velocity recording, e.g., a metabolic error of the myocardium may not necessarily be reflected in an abnormal waveform in the ductus venosus if the heart has compensated for the increased stiffness of the muscle by increasing the cardiac volume and thus improving the compliance.

Increased vascular resistance in the fetal liver tissue may cause portal hypertension and ascites. Examining exclusively the waveform of the ductus venosus using indices may not reveal any abnormality since the waveform predominantly reflects cardiac function. It is a common error not to notice the absolute velocities, which may exceed 1 m/s and signify portal hypertension in such cases [66].

## Reproducibility

In experienced hands a recording of the ductus venosus blood velocimetry is achieved in almost all women both in early and late pregnancy, even with substandard equipment. The limits of agreement for intra-observer variation are [-13; 12 cm/s] for the systolic peak, and [-15; 12 cm/s] during the a-wave [9]. The reproducibility is better for the indices than for the absolute velocity recordings [81]. That is due to the extra challenge it takes to record absolute velocities at a zero- or low angle of insonation, a less important detail when using the waveform analysis.

Doppler assessment of the ductus venosus during early pregnancy seems to have a reduced reproducibility, particularly for the peak systolic and the nadir during a-wave during transabdominal scanning at 10–14 weeks of gestation. The coefficient of variation for systolic and end-diastolic velocity was 19% and 29%, respectively [114]. The coefficient for the PIV was better, 9%. These results were reproduced in another study but with somewhat better numbers [115].

The normal ranges for absolute velocities were reasonably reproduced in the pioneering studies [5, 9, 80, 81]. When recording Doppler signals without the control of color Doppler, the velocities appeared to be

slightly less, possibly due to less control of the correct insonation angle. For the pulsatility indices there is little variation from study to study.

Fetal movements and respiratory exercise could have a profound impact on the ductus venosus blood flow velocity and should carefully be avoided for the standard evaluation.

## Agenesis of the Ductus Venosus

An increasing number of case reports link agenesis of the ductus venosus to fetal demise, hydrops fetalis, asphyxia, vascular and cardiac anomalies, and chromosomal aberrations [116–125]. This has led to the recommendation of an extended scan if the ductus venosus is not identified. It is likely that agenesis occurs more commonly in connection with chromosomal aberrations and anomalies, but so far there are no statistics to prove it. Some have taken the presence of ductus venosus agenesis in hydrops and intrauterine demise as an indication that a patent ductus venosus is vital for intrauterine development; however, it can be argued that the ductus venosus agenesis was discovered in these fetuses after a primary finding had made an extended ultrasound scan necessary or during post-mortem examination. In a recent study of 203 normal pregnancies one fetus had agenesis [11]. Perinatal outcome was uneventful for this fetus with a birth weight at the 39th percentile and a normal ponderal index.

Experimental occlusion of the ductus venosus in fetal sheep led to increased umbilical vein pressure and hepatic venous flow but otherwise had no impact on regional blood distribution [126]; however, such an occlusion has a considerable impact on liver cell proliferation and IGF-2 production, and thus growth [54, 55].

There is an interesting set of observations of agenesis in fetuses with porto-caval shunts, or similar shunts, draining umbilical venous blood directly to the central veins or heart [125]. These fetuses seem to be in the position of not being able to develop the ductus venosus or to close the ductus as a compensatory mechanism. Many of these fetuses have a hyperkinetic circulation, possibly in an attempt to keep up portal pressure and liver perfusion.

This is not in contradiction to the concept that the ductus venosus is an important fetal shunt. Instead, the story unfolds with the ductus venosus having at least two functions. In the long run, the regulation of the umbilical liver perfusion is crucial for fetal development and growth; however, during acute challenges of hypoxemia or hypovolemia, the priority of the liver is temporarily reduced to permit life-saving maneuvers of maintaining oxygenated blood to the heart

and brain, or as some physiologists have put it: “The fetal dilemma: spare the brain and spoil the liver” [127].

# Doppler Ultrasound Examination of the Fetal Coronary Circulation

Ahmet Alexander Baschat

## Introduction

The coronary circulation provides blood to the myocardium. Matching myocardial blood flow and demand is critical to ensure cardiac function over a wide variety of physiologic and pathologic conditions. For this reason examination of coronary vascular dynamics in various fetal conditions is becoming increasingly relevant to the perinatal medicine specialist. Ultrasound examination of the fetal coronary circulation has become possible through advances in ultrasound technology and a better understanding of human fetal cardiovascular physiology. Although not yet standard clinical practice, continuing trends in ultrasound technology and spreading familiarity with the examination and interpretation is likely to expand clinical applications in the future [1].

Ultrasound examination of the fetal coronary system utilizes gray-scale, zoom and cine-loop techniques and requires optimal spatial and temporal settings of the Doppler modalities. A proper setup of the ultrasound system is therefore a necessary prerequisite. Traditional ultrasound planes used in cardiac scanning are modified to provide the best visualization of the coronary vessels. A comprehensive survey of extracardiac vascular dynamics is often necessary to provide the clinical context for interpretation of intracardiac and coronary flow dynamics. This chapter reviews embryology, functional anatomy, ultrasound technique, and clinical utility of ultrasound evaluation of the fetal coronary circulation.

## Embryology and Functional Anatomy of the Coronary Circulation

Oxygenated blood is delivered to the myocardium through the right coronary artery (RCA) and left coronary artery (LCA) arising from the right anterior and left posterior aortic sinuses, respectively, and the left anterior descending branch (LAD) of the LCA [2, 3]. Venous return from the left ventricle drains mainly through a superficial system through the coronary sinus and anterior cardiac veins carrying ap-

proximately two-thirds of myocardial venous return. The deep system, consisting of arterioluminal vessels, arteriosinusoidal vessels, and thebesian veins, receives the remaining venous return and drains directly into the cardiac chambers [2–4].

In embryonic life endothelial cells migrate from the septum transversarium in the hepatic region of the embryo to form epicardial blood islands which eventually coalesce into vascular networks extending throughout the epicardium and myocardium [5, 6]. Concurrently, the RCA and LCA originate as microvessels that penetrate the outflow tracts and acquire a muscular coat in this process. The primitive coronary arterial circulation is established when main-stem coronary arteries and myocardial vascular channels connect. Venous drainage develops independently of the arterial system and becomes fully functional when the coronary sinus, as a remnant of the left horn of the sinus venosus, becomes incorporated into the inferior wall of the right atrium and thebesian veins gain access to the ventricular cavities. The coronary circulation is completely functional by the fifth to sixth week of embryonic life and ensures myocardial blood supply by the time the embryonic circulation is established.

Coronary vascular development can be modulated by various stimuli. Such stimuli include local oxygen tension, mechanical wall stress, and myocardial and vascular shear forces [6–9]. As a result, the coronary circulation is subject to great anatomic and functional variation that is manifested in several ways. Under physiologic conditions modulation of vascular growth enables matching coronary vascular development to myocardial growth [10]. This ensures a balanced relationship between ventricular mass and vascular density. Prolonged or progressive tissue hypoxemia may lead to an exaggeration of this physiologic process with a subsequent marked increase in vascular cross-sectional area in the coronary circulation [11–14]. Under these circumstances vascular reactivity to physiologic stimuli is also altered, often resulting in amplified responses [15]. Similarly, abnormal intracardiac pressure relationships, such as those found in outflow tract obstructive lesions, may force the development of accessory vascular channels between the

coronary vessels and the ventricular cavity (ventriculo-coronary fistulae) [16]. The plasticity of the coronary circulation is responsible for the variation in myocardial vascular territories and blood flow found in various fetal conditions and illustrates the critical importance of myocardial oxygenation for proper cardiac function.

Myocardial metabolism is almost exclusively aerobic and in the presence of adequate oxygen various substrates, including carbohydrates, glucose, lactate, and lipids, can be metabolized [17–20]. In fetal life, myocardial glycogen stores and lactate oxidation constitute the major sources of energy while fatty acid oxidation rapidly becomes the primary energy source after birth. To maintain metabolism myocardial oxygen extraction is as high as 70%–80% in the resting state. Consequently, a coronary atrioventricular  $O_2$  difference of 14 ml/dl exceeds that of most other vascular beds and allows little further extraction of  $O_2$  unless blood flow is significantly augmented; therefore, coronary blood flow is closely regulated to match myocardial oxygen demands.

The regulation of myocardial perfusion operates at several levels and time frames. The unique parallel arrangement of the fetal circulation allows for delivery of well-oxygenated blood through the ductus venosus to the left ventricle and thus the ascending aorta. In the fetal lamb the coronary circulation receives approximately 8% of the left ventricular output at rest in this manner [21]. This proportion may be higher in the human fetus and may be further altered by modulating the degree of shunting through the ductus venosus [22]. Once blood enters the coronary vessels from the ascending aorta the pressure difference to the right atrium becomes the primary driving force for coronary blood flow. This perfusion pressure is further subjected to changes in vascular tone and extravascular pressure. Autonomic innervation of coronary resistance vessels regulates overall vascular tone [23, 24], but ventricular contractions are the main contributor to extravascular resistance with significant impact on the flow velocity waveform [25–27]. Myocardial perfusion predominantly occurs during diastole when the ventricles relax and pose little extravascular resistance. This diastolic timing of predominant perfusion is unique to the coronary circulation and distinguishes it from other vascular beds in the human body. In the adult, increases above a resting heart rate of 70 beats per minute result in a disproportional shortening of diastole. Fetal heart rates of 120–160 beats per minute place special demands on dynamic vascular mechanisms to regulate myocardial blood flow volume.

Efficiency of myocardial oxygen delivery is further enhanced by active autoregulatory control mechanisms ensuring optimal myocardial blood flow de-

spite fluctuations in arterial perfusion pressure [28, 29]. This is achieved through caliber adjustment of precapillary resistance vessels allowing channeling of blood flow to areas of greatest oxygen demand [30, 31]. With maximal dilatation of these sphincters myocardial blood flow may be elevated four times above basal flow. The increase in blood flow volume that can be achieved under these circumstances is the myocardial blood flow reserve. If myocardial oxygenation cannot be sustained, long-term adaptation with formation of new blood vessels may be invoked thus increasing the myocardial blood flow reserve [32–34]. Such elevated myocardial blood flow reserve allows marked augmentation of blood flow during periods of acutely worsening hypoxemia or increased cardiac work and increases as high as 12 times the basal flow have been reported [15, 35, 36].

## Ultrasound Examination Technique

### Ultrasound Setup

The setup of the ultrasound system is of major importance for successful examination of the fetal coronary arteries. Gray-scale ultrasound, color-, and pulsed-wave Doppler are used in a complementary manner and machine settings need to be optimized to provide the best spatial and temporal resolution. Although visualization of coronary vessels can be achieved using 4-MHz transducers, higher frequencies are likely to improve resolution and therefore detection. The dynamic range of the gray-scale image should be set to an intermediate level that is generally used in cardiac setups. Zoom magnification of the area of interest limits the computing power that needs to be allocated to the generation of the gray-scale image. These two maneuvers will improve the frame repetition rate and should therefore be applied before adding color Doppler imaging. When adding color Doppler imaging the filter should be set to a high degree of motion discrimination and the color box and gate are kept as small as possible to optimize spatial and temporal resolution of this Doppler modality. The lateral dimension of the color box has the greatest impact on computing power and therefore frame rate. The color amplification gain is set to eliminate background noise on the screen. The persistence is set to a low level to minimize frame averaging. The color velocity scale is adjusted to a range that allows visualization of intra- and extracardiac flows without aliasing and suppression of wall-motion artifacts. A useful velocity range for coronary arteries is between 0.3 and 0.7 m/s for coronary arteries and between 0.1 and 0.3 m/s for the coronary sinus. Since initial detection of the coronary arteries relies on col-

or Doppler, these aspects of the setup are essential preliminary steps. Once the coronary vessel is identified using these techniques the transducer position should be adjusted to provide an insonation angle close to  $0^\circ$  prior to obtaining pulsed-wave measurements. The pulsed-wave Doppler gate should be adjusted to exclude other cardiac and extracardiac flows and should be the only active display when measurements are taken. Concurrent activation of multiple image modalities (duplex or triplex mode) drastically increases computing requirements and affects the spatial and temporal resolution of the spectral Doppler waveform.

### Examination of Coronary Arteries

Using gray-scale ultrasound the coronary ostia are discernible in late gestation (Fig. 29.1). Before this time, the size of the main-stem arteries is below 1 mm in diameter and thus frequently below the resolution threshold of current sonographic equipment in the majority of cases [37]. For this reason color and pulsed-wave Doppler ultrasound are necessary to detect and verify coronary artery blood flow. The Doppler examination of the fetal coronary vessels has been adopted from techniques developed for infants and neonates [38]. The main-stem right and left coronary arteries are best examined in a long-axis view of the left ventricular outflow tract and ascending aorta or a precordial short-axis view of the aorta. The LAD branch of the LCA is best identified from an apical short-axis view. In the standard precordial short-axis view the left coronary artery courses forward towards the transducer, whereas the right coronary artery runs more parallel. This view therefore facilitates examination of the LCA. In the lateral, or long-axis, view of the left ventricular outflow tract the RCA is more readily imaged if imaged from the right side of the fetus. In this view it may also be possible to visualize both coronary arteries (Fig. 29.2) [39, 40].

The LAD may be identified scanning from the apical four-chamber view. From this view the transducer is tilted towards the head until the level of the superior cardiac surface and interventricular groove is reached [41]. Cardiac wall motion, high blood flow velocities in the ventricles and ventricular outflow tracts and movement of pericardial fluid can all interfere with the relatively low coronary blood flow velocities on color Doppler imaging. Back and forward motion of pericardial fluid outlining the ventricular walls in particular may be mistaken for a coronary artery [42]. For these reasons identification of coronary artery blood flow by color Doppler imaging should always be followed by verification of the typical waveform pattern by pulsed-wave Doppler to provide assurance that the coronary arteries have indeed been identified.

Spectral Doppler measurement of coronary blood flow velocities is easiest proximally since vessel diameter is greatest and motion during the cardiac cycle is less than distally. After coronary vessels are identified by color Doppler, the pulsed-wave Doppler gate is positioned at the origin of the vessel. The gate may require adjustment to achieve continuous sampling of the waveform allowing for the movement of the aortic root in the cardiac cycle. The coronary artery flow velocity waveform has a biphasic pattern with systolic and diastolic peaks and antegrade flow throughout the cardiac cycle (Fig. 29.3). Predominant diastolic perfusion produces a unique waveform pattern with higher velocities during diastole than systole. In normal fetuses coronary blood flow has been visualized from 29 weeks onwards (median gestational age of  $33 \pm 6$  weeks). The median systolic and diastolic peak blood flow velocities are 0.21 and 0.43 m/s, respectively, and show little change during the latter part of gestation (Figs. 28.4, 28.5) [43]. Gestational age at visualization and coronary artery blood flow velocities are in part determined by the fetal condition (see below).

**Fig. 29.1.** The fetal heart is examined in a short-axis view of the aorta at  $34 \pm 2$  weeks gestation (a) and in a long-axis view of the left ventricular outflow tract at  $35 \pm 5$  weeks' gestation (b). The ostia of the left and right coronary arteries are discernible in a (arrows) in the area of the left posterior and right anterior aortic sinus. (From [87]). In b the ostium of the left coronary artery is discernible (arrow)

**Fig. 29.2.** The origin of the great vessels and the atrioventricular valves shows the course of the left and right coronary arteries (*RCA* and *LCA*, respectively) in relationship to the aorta (*AO*), pulmonary artery (*P*), mitral valve (*MV*), and tricuspid valve (*TV*). The angle of insonation and type of cardiac axis determines the orientation of the coronary arteries on the ultrasound image. Short-axis views facilitate examination of the left coronary artery (**B**) and may enable

visualization of both coronary arteries (**C**) occasionally also allowing demonstration of the origin of the left anterior descending branch (**B, C**). Although the right coronary artery can be examined in the short-axis view (**A**), it is easier to identify this vessel in a right lateral long-axis view of the left ventricular outflow tract (**E**). This view also allows simultaneous visualization of both coronary arteries (**D**)

### Examination of the Coronary Sinus

The larger size of the coronary sinus and its anatomic course greatly facilitate its ultrasound examination [44, 45]. The coronary sinus runs in the atrioventricular groove and enters the right atrium below the level of the foramen ovale just above the valve of the inferior vena cava. Because of its position, apical or basal four-chamber views provide the best opportunity for gray-scale biometry, whereas lateral four-chamber views provide a more favorable insonation angle for color- and spectral Doppler imaging (Figs. 29.6, 29.7).

Gray-scale and M-mode echocardiography have both been used to obtain normative data on the

length and diameter of the coronary sinus. The caliber of the coronary sinus undergoes cyclic changes with the cardiac cycle being smallest at the beginning of diastole and largest in mid-systole with maximal descent of the arteriovenous ring. M-mode echocardiography allows precise documentation of caliber and dynamic changes (Fig. 29.8). The coronary sinus has a maximum diameter ranging from 1 to 3 mm with advancing gestation. The method utilized to obtain these measurements does influence the reference limits [45, 46]. Figures 29.9 and 29.10 show gestational reference ranges for the maximal diastolic and systolic dimensions that were measured using the M-mode technique. Appreciating the phenomenon of variations in coronary sinus diameter may call for

**Fig. 29.3 a-c.** Pulsed-wave Doppler images of the left coronary (LCA), left anterior descending (LAD), and right coronary arteries (RCA) obtained in a 29-week fetus. Of note is

the predominance of blood flow during diastole that is observed in all three vessels. (From [87])

**Fig. 29.4.** The median and 95% confidence interval for the peak systolic velocity (PSV) in the coronary artery of appropriately grown fetuses in relation to gestational age (GA). (From [43])

**Fig. 29.5.** The median and 95% confidence interval for the peak diastolic velocity (PDV) in the coronary artery of appropriately grown fetuses in relation to gestational age (GA). (From [43])

**Fig. 29.6.** The fetal heart shows the course of the coronary sinus in the right lateral four-chamber view. The coronary sinus runs in the atrioventricular groove and opens into the right atrium near the atrioventricular valve, in close proximity to the inferior vena cava (IVC) and foramen ovale (FO). In this imaging plane, the direction of blood flow is towards the transducer beam. (From [47])

**Fig. 29.7.** The fetal heart imaged in the apical four-chamber view shows the left and right ventricles (LV and RV) and the corresponding atria (LA and RA). The coronary sinus runs in the atrioventricular groove parallel to the mitral valve leaflets. The coronary sinus is visualized by tilting the transducer towards the inferior cardiac surface until the valve leaflets disappear. (From [45])

**Fig. 29.8.** The fetal heart imaged in an apical four-chamber view at  $28 \pm 4$  weeks' gestation. The coronary sinus (arrows) can be seen running in the atrioventricular groove between the left ventricle (LV) and atrium. Using the cine-loop technique a difference in diameter between end-sys-

tolic (A) and mid-systolic (B) diameters can be appreciated. M-mode tracing obtained from a normal coronary sinus at 29 weeks' gestation demonstrating fluctuations during systole and diastole (C). The cursors are placed on the anterior and posterior walls of the coronary sinus. (From [45])

**Fig. 29.9.** Individual measurements, and the mean and 95% confidence interval of the maximum systolic diameter of the coronary sinus with respect to gestational age ( $y=0.1373x+1.6072$ ;  $r^2=0.9849$ ). (From [45])

**Fig. 29.10.** Individual measurements, and the mean and 95% confidence interval of the maximum diastolic diameter of the coronary sinus with respect to gestational age ( $y=0.0765x+0.9242$ ;  $r^2=0.9701$ ). (From [45])

**Fig. 29.11.** The fetal heart is imaged in a lateral four-chamber view and coronary sinus blood flow towards the right atrium (RA) is identified with color Doppler imaging (a). Pulsed-wave Doppler shows a triphasic flow profile with a small systolic (S) and a larger diastolic peak (D) followed by brief reversal during atrial contraction (b). (From [87])

verification using this M-mode technique when dilatation of the coronary sinus is suspected.

Color Doppler identification of coronary sinus blood flow is successful in approximately 50% of normal fetuses. During diastole the direction of blood flow from the coronary sinus is towards the right atrium, whereas blood flow across the foramen ovale is directed towards the left atrium (Fig. 29.11) [47]. Despite its straight course, exact placement of the sample volume spectral Doppler measurements is only possible in approximately 10% of fetuses. This low success rate is partly due to lower coronary sinus blood flow velocities and interference caused by in-

tra-atrial blood flows and/or cardiac and atrioventricular valve movement. The coronary sinus flow velocity waveform has a triphasic pattern with systolic and diastolic antegrade flow and occasional reversal during atrial contraction (Fig. 29.11). Similar to the coronary arteries, diastolic forward velocities (median 0.38 m/s) exceed systolic velocities (median 0.18 m/s). These velocities are related to the periods of predominant myocardial blood flow. Methods to relate coronary sinus velocities to myocardial flow reserve have been described in neonates and adults [48, 49], but these are currently not practicable for validation in the human fetus.

## Clinical Applications in Fetuses with Normal Cardiac Anatomy

In fetuses with normal cardiac anatomy disorders are frequently only apparent through alterations in cardiovascular status. Under these circumstances coronary blood flow dynamics may be altered to accommodate changes in myocardial oxygen requirements. Since spectral Doppler of the coronary sinus is rarely achieved, clinical observations revolve primarily around color- and pulsed-wave Doppler characteristics in coronary arterial vessels.

### The "Heart-Sparing Effect" in Fetal Growth Restriction

Severe fetal growth restriction (IUGR) can progress to decompensation of cardiovascular status. Such deterioration can be documented through progressive deterioration of arterial and venous Doppler studies [50]. This progression often accompanies the deterioration of acid-base status from chronic hypoxemia to acidemia [51–54]. Under these circumstances the combination of elevated central venous pressure, elevated afterload, and worsening oxygenation places unique demands on myocardial oxygen balance. Elevated afterload increases myocardial oxygen demand because of an increase in cardiac work. Elevated central venous pressure and aortic pressures decrease the pressure difference across the coronary vascular bed and therefore diminish the driving force for coronary perfusion. The summation of these factors has detrimental effects on coronary perfusion at a time when myocardial oxygen balance and fetal metabolic state are critical. Consequently, adaptive mechanisms need to be evoked in order to maintain myocardial oxygen balance. The necessary augmentation of coronary blood flow can be achieved in two principal ways. One way is to increase the proportion of oxygenated left ventricular output available for myocardial delivery. The second way is through autoregulation-mediated coronary vasodilatation.

Several mechanisms operate in IUGR fetuses that increase the potential delivery of oxygenated blood to the myocardium. Under conditions of elevated placental resistance the relative proportion of left ventricular output increases [55–57]. Decreases in oxygen tension may further increase the proportion of oxygenated umbilical venous blood that is delivered through the ductus venosus to the left side of the heart [58, 59]. Prolonged chronic myocardial hypoxemia allows for angiogenesis and increases in vascular cross-sectional area and therefore myocardial flow reserve. These responses constitute chronic heart sparing in IUGR. When acute worsening of cardio-

vascular status and/or oxygenation is superimposed the only mechanism to significantly augment myocardial blood flow is marked coronary vasodilatation with massive recruitment of coronary vascular reserve. This vascular response is more acute, often occurring over the course of 24 h, and is most consistently associated with severe elevation of precordial venous Doppler indices [60, 61].

The chronic initial phase of heart sparing can be implied by demonstrating certain Doppler abnormalities in the arterial and venous circulations. These include absent or reversed umbilical artery end-diastolic velocity and/or end-diastolic blood flow reversal in the aortic isthmus [62]. In the second trimester the magnitude of coronary blood flow may still be below the visualization threshold of ultrasound equipment; therefore, augmentation of coronary blood flow cannot be documented by spectral Doppler measurement of coronary arteries. With acute worsening of fetal cardiovascular and respiratory status color- and pulsed-wave Doppler measurement of coronary artery blood flow is readily achieved as a reflection of maximal augmentation of coronary blood flow – now exceeding the visualization threshold [40]. In IUGR both diastolic and systolic coronary artery peak blood flow velocities are significantly higher than in appropriately grown fetuses providing additional evidence of blood flow augmentation. There are no associated changes in the coronary sinus diameter as evidence of increased coronary venous return [63]. Since coronary artery blood flow may be visualized in normal and IUGR fetuses at overlapping gestational ages, concurrent examination of the arterial and venous circulations is mandatory to assess fetal status. Clinical management cannot be based on the evaluation of coronary vascular dynamics alone. In IUGR fetuses with abnormal arterial and venous Doppler, heart-sparing prognosis is poor with a high perinatal mortality and a high risk for acidemia and neonatal circulatory insufficiency requiring the highest level of neonatal care.

### Fetal Anemia

Severe fetal anemia can result in reduction of oxygen-carrying capacity and subsequently impaired myocardial oxygenation. Fetal hydrops with tricuspid insufficiency and abnormal precordial venous flow is associated with elevated right-heart pressures and a decline in coronary perfusion pressure. Under these circumstances short-term augmentation of myocardial blood flow of four to five times basal flow can be achieved through autoregulation. Color- and spectral Doppler measurement of coronary artery blood flow velocities has been successful in circumstances of acute fetomaternal hemorrhage, non-immune hy-

**Fig. 29.12.** Systolic and diastolic peak blood flow measurements in three cases of severe fetal anemia. In cases 1 and 3 velocities were obtained in hydropic fetuses prior to transfusion. In case 1 a hematocrit of 9% was corrected to 39.8% and in case 3 from 14% to 42.8%. In the second case of maternal trauma, repeated transfusions were necessary on days 1 and 5 for hematocrit levels of 21% and 24%, respectively. (From [43])

drops, and hemolytic disease [43, 64]. Peak diastolic velocities as high as 1 m/s and peak systolic velocities of 0.5 m/s may be observed, significantly exceeding those observed in any other fetal condition. Blood flow velocities are responsive to maternal oxygen therapy and fetal blood transfusion and fall below the visualization threshold after normalization of the fetal hematocrit (Fig. 29.12). With the development of fetal hydrops, a decrease in coronary sinus dynamics is observed. This finding is analogous to observations in adults with heart failure where coronary sinus caliber changes are attenuated presumably due to elevations in coronary venous pressures [45].

### Ductus Arteriosus Constriction

Constriction of the ductus arteriosus is one of the reported fetal complications of maternal indomethacin therapy for preterm labor. As a conduit for the right ventricle to the systemic circulation, constriction of this vessel raises afterload and therefore cardiac work and oxygen requirement. In severe constriction tricuspid insufficiency and abnormal venous indices may develop. In such severe cases color- and pulsed-wave Doppler of coronary artery blood flow is possible. While the peak velocities are not significantly elevated, the gestational age at visualization is determined by the onset of the clinical condition. With resolution of ductus arteriosus constriction following discontinuation of indomethacin, coronary blood flow could no longer be visualized.

### Other Fetal Conditions

Acute changes in fetal oxygenation and cardiac pre- and afterload also cause arterial and venous redistribution in favor of the organs essential for fetal life. These “heart-, brain-, and adrenal gland-sparing” phenomena have been described in different animal models. The few observations made by Doppler ultrasound in the human fetus support the presence of the same protective mechanisms. Transient “brain- and heart-sparing” phenomena were observed in a 30-week fetus following acute bradycardia after umbilical fetal blood sampling. Sudden visualization of coronary blood flow, “brain-sparing,” and highly pulsatile precordial venous flow persisted for a long period after the 12-min bradycardia [65]. Changes in coronary sinus dynamics have been documented in a fetus with supraventricular tachycardia [45]. It is likely that more observations of alterations in coronary arterial and venous dynamics will be reported as familiarity with the examination technique and advances in ultrasound technology facilitate examination.

### Clinical Applications in Fetal Cardiac Abnormalities

Due to the vascular properties of the coronary arterial circulation abnormalities frequently develop in cardiac lesions that are associated with disturbed intracardiac pressure/volume relationships during organogenesis. Owing to the embryologic development of coronary sinus abnormalities involving this vessel, anomalous central venous drainage (both systemic and/or pulmonary) is frequently present. Ultrasound biometry and assessment of coronary sinus dynamics has clinical relevance and may be the only apparent clue pointing in the direction of such anomalies.

### Ventriculocoronary Connections in the Human Fetus

Ventriculocoronary connections are frequently noted in fetuses and newborns with pulmonary atresia, hypoplastic right ventricle, intact ventricular septum, or restrictive ventricular septal defect [66]. In cases of hypoplastic left heart with aortic atresia, intact ventricular septum and patent mitral valve ventriculocoronary connections may also be present but are less common. The genesis of these vascular abnormalities is discussed above. The abnormal coronary channels may provide a conduit to release intraventricular pressures and may partially avert hypoplasia and fibroelastosis; however, coronary blood flow dynamics may be significantly compromised, impacting on prognosis and approach to postpartum surgical man-

**Fig. 29.13.** The fetal heart is imaged in a lateral “five-chamber” view including the left ventricular outflow tract. A large tortuous vessel is seen originating from the aorta connecting into the right ventricular cavity, which is of moderate size (a). Pulsed-wave Doppler with the gate in the ventriculocoronary fistula shows the characteristic bi-directional flow pattern with systolic flow towards the aorta (below the baseline) and diastolic flow towards the right ventricle (above the baseline; b). (From [16])

agement [67–69]. While coronary perfusion may be well maintained in utero, the situation may change after birth. Right ventricular dependent coronary circulation may occur and result in acute or chronic global myocardial ischemia or infarction due to coronary steal and segmental vascular obstruction. Because of these potential impacts, prenatally detected outflow tract obstructive lesions with relatively preserved ventricular architecture should prompt the search for ventriculocoronary fistula.

Prenatal diagnosis of ventriculocoronary fistula is achieved by demonstration of high-velocity bi-directional flow in the coronary artery by color Doppler flow mapping and verified by pulsed-wave Doppler examination. A severely dilated coronary artery may also be imaged by two-dimensional echocardiogra-

phy. In cases of right ventricular outflow tract obstruction, diastolic flow from the aortic sinus is directed toward the hypoplastic right ventricle. Pressures are reversed during ventricular systole and blood flows from the right ventricle to the aorta (Fig. 29.13) [66, 70, 71].

### Coronary Arteriovenous Fistula in the Human Fetus

Congenital coronary fistulae may occur occasionally if cardiac anatomy is otherwise normal; the majority of these involve a single coronary artery, less often multiple branches. Connections may involve the coronary arterial tree, right atrium, coronary sinus, caval veins, right ventricle, and the pulmonary trunk. Drainage into a low-pressure system can result in a large left-to-right shunt already causing symptoms in childhood such as congestive heart failure, myocardial ischemia from coronary artery steal, right-chamber enlargement, arrhythmia, thrombosis with consecutive embolization, and bacterial endocarditis [72]. In the majority of cases symptoms appear in the second and third decade of life. In a 20-week fetus prenatal detection of an isolated coronary fistula connecting to the right ventricle has been reported with demonstration of a progressive increase in size as well as tortuosity of the fistula during gestation [73]. A similar case with a fistula between the LCA and the right atrium has also been recently described [74]. The shunting blood caused a high-velocity flow in the dilated coronary sinus. In addition to the prenatal findings a persistent left superior vena cava and a small ventricle septum defect were also identified postnatally. Following coil embolization of the coronary fistula further clinical course was reported as uneventful.

### Idiopathic Arterial Calcification in the Human Fetus

The idiopathic arterial calcification has an unknown etiology and is characterized by generalized arterial calcification and stenoses especially of the walls in the arterial trunk of the pulmonary artery and aorta [75, 76]. Most commonly the coronary arteries are also affected, but peripheral arteries of gastrointestinal tract, liver, kidneys, brain, extremities, and placenta may also be involved. Severe myocardial dysfunction may cause severe fetal hydrops, tissue ischemia, and fetal death in the late second or third trimester [77]. In less severe cases, especially in the absence of hydrops, palliative treatment post-partum may be started with steroids and bisphosphonates in order to stop or delay the progression of the disease [78]; however, most infants with idiopathic arterial

calcification die within the first year of life complicated by cardiac and pulmonary failure, severe hypertension, renal infarction, peripheral gangrene, and bowel infarction [76].

### Critical Aortic Stenosis

Critical aortic stenosis in fetal life can be associated with a marked decrease in left ventricular output and reversal of shunting across the foramen ovale. Under these circumstances coronary perfusion pressure is affected by a decrease in arterial pressure and an elevation of right atrial pressure thereby decreasing the driving force across the coronary vascular bed. Concurrently, left ventricular work and therefore myocardial oxygen demand are increased. Development of acute heart sparing has been documented in a fetus presenting with severe left ventricular outflow tract obstruction and non-immune hydrops due to critical aortic stenosis. While these findings were ameliorated initially by transplacental digoxin therapy, visualization of coronary blood flow became visible at 39 weeks coinciding with shunt reversal across the foramen ovale [79].

### Persistent Left Superior Vena Cava

While Doppler examination of the coronary sinus has limited utility in the human fetus, substantial dilatation may result from volume overload from a persistent left superior vena cava draining into the coronary sinus [80–82]. The frequency of a persistence of the left vena cava is 1–2 per 1000 but may be as high as 9% in the presence of congenital heart defects [83]. The degree of dilatation is often marked and lies appreciably above normal reference limits. This dilatation appears to be predominantly related to vascular volume changes and is independent of associated cardiac defects [63]. Other causes of coronary sinus dilatation in the human fetus may be a coronary arteriovenous fistula and anomalous pulmonary vein drainage into the coronary sinus. It is important to note that because of its close proximity to the insertion of the atrioventricular valve, a dilated coronary sinus has been mistaken for an atrial septal defect of ostium primum type and/or an atrioventricular septal defect, respectively [84–86]. Coronary sinus dynamics may be attenuated in fetal conditions associated with elevated right-heart pressures, severe fetal cardiac dysfunction, and hydrops. These alterations in dynamics may indicate elevated coronary sinus pressures or changes in coronary blood flow [45].

# Doppler Interrogation of the Umbilical Venous Flow

Enrico Ferrazzi, Serena Rigano

## Introduction

The first reports about measurements of fetal umbilical venous blood flow in human fetuses go back to the early 1980s. Eik-Nes et al. in 1980 [1], Gill et al. in 1981 [2], and Eik-Nes et al. in 1982 [3] reported measurements obtained on the “intrahepatic” umbilical vein. It was not always certain whether these were sampled before the portal sinus, i.e., the origin of the portal veins. This pioneering era came to an end when Erskine and Ritchie [4] and Giles et al. [5] came to the conclusion that “The results obtained are in keeping with previous studies but indicate that, although the method is relatively simple, determination of absolute blood flow in these vessels has little clinical potential because of inherent measurement inaccuracies.” Fortunately, over more than a decade, these statements on quantitative “measurement inaccuracies” and on “poor clinical potential” in the diagnosis of fetal growth restriction were challenged, among others by Gerson et al. [6], Reed et al. [7], Sutton et al. [8], Schmidt et al. [9], and Challis et al. [10].

In the past 20 years the potential role of the measurement of flow, in the umbilical vein, ductus venosus, and cardiac outflow tract, was perceived as a possible direct insight into the core of pathophysiology, not just how it looks, but how it works; however, the real limitation was set by expensive research ultrasound machines, and by the expertise of research sonologists, until high-technology digital instruments became the standard of quality in commercial ultrasound units.

## Fetal Flow Volume Measurements in the Era of Digital Computing and Imaging

### Sources of Inaccuracies

Even if all other hemodynamic variables were considered negligible, which is not the case, an error of 15% in diameter measurement could determine a ma-

ajor error in the calculation of flow itself since flow is determined according to the following equation:

$$\begin{aligned} \text{UV flow (ml/min)} \\ &= \text{cross-sectional area } (\pi \times \text{radius}^2) (\text{mm}^2) \\ &\quad \times \text{mean velocity (mm/s)} \times 60, \end{aligned}$$

where linear measurements are squared and so is the error. Similar but more complex adjustment should be made for the error in the angle of interrogation of the Doppler beam, which at its best could be corrected on one plane, that of the plane of the image itself, but not within the thickness of the sonographic “slice” of the vessel. The third source of error is determined by the attempt to calculate the true mean velocity. Most sonographic software is designed to extract the mean velocity out of the instantaneous Doppler shift analysis, as an intensity-weighted mean velocity; however, when interrogated peak velocities are relatively slow (14–18 cm/s from 20 to 38 weeks of gestation) the amount of blood flow “cut” by high-pass filters becomes relevant, and in addition to this, each software operates on analog-to-digital conversion of the Doppler shift and on the signal-to-noise ratio which is largely dependent on the gain and on the software itself. The complex issue of precise assessment of mean velocity is also biased by the difference between two-dimensional imaging and three-dimensional reality. The ideal flow model is a perfect parabolic flow evenly distributed in the vessel in which the mean velocity is half that of the peak velocity (mean velocity = peak velocity  $\times$  0.5) measured in the cross-sectional area. Again we must underline that Doppler sample volumes are closer to a bi-dimensional sample volume more than to a whole cross-sectional sample volume. Peak velocity is a simple measurement, and that measured in a two-dimensional and a three-dimensional model are equal. The mean instantaneous velocity could be calculated by a simple coefficient which takes into account the shape of the flow in the cross-sectional area. Unfortunately, the conditions of perfect parabolic flow are seldom met in the umbilical vein. According to Pennati and co-workers [11] one should take into account the fact

that close to the placenta the flow profile is closer to a flat profile in which the mean velocity and peak velocity differs by a coefficient of 0.74, whereas all along the free loops this coefficient is 0.61. This is higher than 0.5 and normative data derived from the formula reported above underestimate true flow by 18%.

### Source of Accuracy

Imaging quality, color imaging quality, and pulsed Doppler velocimetry quality of today's technology are an obvious challenge to these limitations (Fig. 30.1).

In 1999 [12] we checked the intra- and inter-observer coefficients of variation of the umbilical vein diameter, mean velocity, and absolute flow. The diameter was calculated as the mean of three measurements on a magnified section of the cord. The brightest spot at low amplification was assumed as the best marker of true diameter. The brightest ultrasound echoes are in fact those reflected back by orthogonal

surfaces, which can be the case only when the ultrasound plane intersects the vessel at its true maximum diameter (Fig. 30.1). The ultrasound probe was tilted by  $90^\circ$  and the Doppler beam was spotted on the same section of the vessel where the diameter was measured. We considered that it was more reproducible, simpler, and probably more accurate, to assume for the given viscosity of blood, the diameter of the vessel and its length that an ideal parabolic flow truly occurs in those tracts of the umbilical vein where the lumen is linear for at least an approximate length of three times its diameter. The intra-observer coefficients of variation for the vein diameter, mean velocity, and absolute umbilical venous blood were 3.3%, 9.7%, and 10.9%, respectively. The inter-observer variabilities for the same parameters were 2.9%, 7.9%, and 12.7%, respectively. The same results were obtained by Lees and co-workers [13] and proved to be a little better for the intra-observer mean diameter calculated from four measurements of the UV (0.22 mm, respectively). Similar positive findings in reproducibility were reported by Boito et al. [14]. The coefficient of variation for the umbilical vein cross-sectional area was 6.6%, and for the time-averaged velocity it was 10.5%, resulting in a coefficient of variation of 11.9% for volume flow. The mean time required to obtain a complete set of measurements in our study was 3 min. These findings obtained in three different centers provide enough evidence to support the hypothesis that, as far as reproducibility and clinical feasibility are concerned, today's technology is able to achieve accurate measurements of the umbilical vein flow in the human fetus.

### Volume Flow Values and Problems of Standardization

The specific umbilical vein flow we calculated from our findings [12] was  $129 \text{ ml/min kg}^{-1}$  at 20 weeks of gestation and  $104 \text{ ml/min kg}^{-1}$  at 38 weeks of gestation. Boito et al. reported similar, but lower values,  $117.5 \pm 33.6 \text{ ml/min kg}^{-1}$  to  $78.3 \pm 12.4 \text{ ml/min kg}^{-1}$  for the same gestational age span [14].

Di Naro, with a similar methodology, reported values of  $126.0 \pm 23.4 \text{ ml/kg per min}$  at term [15]. Lees and co-workers reported [13], according to their methodology, values as high as  $176 \text{ ml/min kg}^{-1}$ , which are closer to the mean arterial values measured by Kunzel in 1992 ( $143 \text{ mm/kg min}^{-1}$ ) [16]. Actually, Lees et al. [13] was measuring an average of arterial and venous volume flow and Kunzel et al. [16] was measuring mean arterial flow. Accurate hemodynamic modeling of a pulsatile flow is quite complex, mostly because of problems in assessing the time-averaged mean velocity [17]. If we compare our present ( $108 \text{ ml/min kg}^{-1}$  at 32–41 weeks of gestation) we

**Fig. 30.1.** **a** Magnified image of a straight section of the umbilical vein. **b** Magnified image of the color imaging of the umbilical vein. Note how the peak velocities are skewed toward the external wall of the curved vein

appreciate the fact that these mean values are at the same level of umbilical volume flow measured by Eik-Nes in 1982 [3] ( $115 \text{ ml/min kg}^{-1}$ ). The only difference with these “historical” reports is the time required to obtain these measurements, and their reproducibility. Other methodologies had been tested for the same purpose by Kiserud [18] and Chantraine et al. [19]. This latter work represents newer technological possibilities and at the same time reminds us of the quest for standardization of non-invasive flow measurements. We still hold the opinion that given the limitations of Doppler technology, the true mean instantaneous velocity should be derived by the peak velocity times the coefficient derived by the general model of flow. According to Pennati et al. [20] this coefficient should be set at a value of 0.61. This report induced us to revise the values we reported in 1999 [12] just by increasing them by 18%. This means that the volume flow in the umbilical vein at 38 weeks of gestation is  $123 \text{ ml/min kg}^{-1}$  instead of  $104 \text{ ml/min kg}^{-1}$ . In this brief analysis we have met many methodologies that differ from our simple diameter-peak velocity interrogation: off-line measurement of cross-sectional area, software-dependent measurements of time-averaged mean velocity, mean values of venous and arterial flow measurements, and non-Doppler flow measurements. It is quite evident from published methodologies and results that the variability in measurements between centers is not stochastic; rather it is systematic, depending on the different methodologies adopted. So far, the simpler the better is our preferred choice.

### Comparison Between Non-Invasive Doppler Volume Flow Values and Traditional Experimental Studies

The simple “diameter-peak velocity  $\times 0.5$ ” methodology was applied to the two veins of fetal lambs versus historical measurements of flow obtained with invasive technique [12]. Gestational age and fetal weights were not different between the animals studied by Doppler technique ( $129.6 \pm 2.8$  days,  $2.75 \pm 0.26$  kg, respectively) and steady-state data ( $131.6 \pm 4.1$  days,  $2.94 \pm 0.68$ , respectively). Variability between the groups was similar (f test;  $p=0.138$ ). No significant differences were detected between the Doppler and diffusion technique groups for umbilical venous flow ( $210.8 \pm 18.8$  and  $205.7 \pm 38.5 \text{ ml/min kg}^{-1}$ ;  $p=0.881$ ).

A second study was then performed on the same set of seven animals [21]. Ultrasound Doppler and steady-state diffusion technique yielded virtually identical results ( $207 \pm 9$  vs  $208 \pm 7 \text{ ml/min kg}^{-1}$ ). A serendipitous result of that study was that the venous flow in each one of the two veins of the lamb was strictly correlated with the weight of the cotyledons

serving each vein. The accuracy of volume flow measurements was tested by Di Naro and co-workers [15] on human fetuses with different characteristics of the umbilical cord, normal coiled cord, and non-coiled lean cord, assuming and proving that the latter is a less favorable hemodynamic condition for umbilical circulation.

## From Umbilical Flow Volume Measurements to Fetal Pathophysiology

### The Relationship of Umbilical Vein Blood Flow to Growth Parameters in the Human Fetus

According to our reported study, umbilical blood flow increased exponentially throughout pregnancy from  $63 \text{ ml/min}$  at 20 weeks to  $373 \text{ ml/min}$  at 38 weeks [12]. By means of a different methodology, Boito and co-workers reported an increased volume flow from  $33 \text{ ml/min}$  at 20 weeks to  $221 \text{ ml/min}$  at 36 weeks of gestation [14]. When these absolute values are converted into weight-specific values, as reported above, the higher values become lower. In general, the estimation of fetal weight has a possible error of approximately  $\pm 10\%$  in 68% of cases. This error can even be larger in growth-restricted or macrosomic fetuses in which there is a change in the volumetric proportion between head and abdomen. As a result, expressing blood flow per kilogram estimated fetal weight introduces unnecessary errors and may obscure underlying pathophysiology. In contrast, the abdominal circumference as measured by ultrasound has been shown in many studies to serve as an early and sensitive biometric indicator of fetal growth restriction. Reporting data both as weight-specific values and abdominal or head circumference-specific values could help to compare “real measurements,” and hopefully it could better serve the purpose of using flow volume in clinical practice.

### Umbilical Vein Blood Flow and Abnormal Fetal Growth

The next step, which is relatively independent from systematic differences caused by various methodologies, is to observe what is happening under varied intrauterine conditions of the fetus and of the placenta. According to Kiserud and co-workers maternal hypoxemia on 12 pregnant sheep caused significantly reduced maximum and weighted mean blood velocity [22]. According to Padoan and co-workers at the University of Colorado Health Sciences Center, weight-specific umbilical venous flow is significantly reduced in fetal lambs affected by heath stress chronic growth

**Fig. 30.2.** Umbilical venous flow per unit weight ( $\text{ml}/\text{min}/\text{kg}^{-1}$ ). Growth-restricted fetuses with abnormal umbilical arterial pulsatility index (*triangles*). Growth-restricted fetuses with normal umbilical arterial pulsatility index (*circles*). The 2nd, 5th, 95th, and 98th percentiles of normal reference values

restriction compared with normal fetuses of comparable gestational age ( $129.4 \pm 14.8$  vs  $176.4 \pm 13.3$   $\text{ml}/\text{min}/\text{kg}^{-1}$ ;  $p < 0.05$ ) and is correlated to  $p\text{O}_2$  ( $10.9 \pm 1.2$  vs  $19.1 \pm 0.7$ ;  $p < 0.001$ ) [23].

Obviously, when comparing normal fetuses to growth-restricted fetuses, it is important that the flow be related to some index of tissue mass, and not to gestational age, as is the case for qualitative waveform indices in the human “small” fetuses. This can be done by calculating an estimated fetal weight or from some other anthropomorphic measurement directly derived by ultrasound images. In our experience [24] umbilical volume flow in growth-restricted fetuses is reduced on a weight basis (Fig. 30.2). If we consider only those growth-restricted fetuses delivered without ominous heart rate signs (mean gestational age  $32 \pm 4$ ; mean weight  $1265 \pm 424$  g) weight-specific umbilical flow ( $\text{ml}/\text{min}/\text{kg}^{-1}$ ) was significantly lower than controls of comparable gestational age ( $98.4 \pm 19.1$  vs  $117.1 \pm 29.9$ ;  $p < 0.001$ ). A much larger difference was observed when flow measurements were obtained on growth-restricted fetuses with an abnormal heart rate, just before elective delivery (mean gestational age  $29 \pm 3$  weeks; mean weight  $962 \pm 334$  g;  $63.0 \pm 22.1$  vs  $124.0 \pm 30.3$   $\text{ml}/\text{min}/\text{kg}^{-1}$ ;  $p < 0.001$ ). Boito and co-workers reported umbilical volume flows per kilogram fetal weight below the normal range in 21 of 33 growth-restricted fetuses [14]. These findings were replicated by the same group on a second series [25] of 23 growth-restricted fetuses who showed a significant lower weight-specific flow compared with controls ( $59.6$  vs  $104.7$   $\text{ml}/\text{min}/\text{kg}^{-1}$ ;  $p < 0.001$ ).

A broader impact on the understanding of fetal physiology under a condition of growth restriction

**Fig. 30.3.** Longitudinal assessment of umbilical venous flow per unit weight ( $\text{ml}/\text{min}/\text{kg}^{-1}$ ). Growth-restricted fetuses with abnormal umbilical arterial pulsatility index (*full circles*). Growth-restricted fetuses with normal umbilical arterial pulsatility index (*empty circles*). The 2nd, 5th, 50th, 95th, and 98th percentiles of normal reference values

due to poor placental development can be derived by umbilical flow volume measurements when cross-sectional measurements obtained at a late stage of growth restriction, i.e., just before elective premature delivery, are highlighted by longitudinal observation from the early stage of the disease. The findings reported by Rigano and co-workers [26] showed that UV weight-specific flow ( $\text{ml}/\text{min}/\text{kg}^{-1}$ ) was reduced at the time of patient enrolment in 71.4% (15 of 21 IUGR fetuses) of the study population. By the time of delivery, 76.2% of the IUGR fetuses had UV weight-specific flow less than the 10th percentile. Figure 30.3 shows longitudinal umbilical flow volumes in growth-restricted fetuses per unit fetal weight with abnormal umbilical pulsatility index (PI), and with normal umbilical PI. These longitudinal observations suggest that this reduction is present weeks before heart rate abnormalities, this means that fetal-placental flow has its main impact on fetal metabolism. These data were replicated by Di Naro and co-workers [27]. Despite the different methodology and slightly different absolute value, the same message of early reduction was confirmed.

### Diagnostic Usage of Umbilical Vein Blood Flow in Growth-Restricted Fetuses

Differences between normal and growth-restricted fetuses could be more reproducibly assessed if the head or the abdominal circumference were used directly instead of ultrasound assessment of fetal weight. Figure 30.4 shows the same volume flow measurements as Fig. 30.3. In this analysis absolute flow values are

**Fig. 30.4.** Longitudinal assessment of umbilical venous flow per head circumference ( $\text{ml}/\text{min mm}^{-1}$ ). Growth-restricted fetuses with abnormal umbilical arterial pulsatility index (*full circles*). Growth-restricted fetuses with normal umbilical arterial pulsatility index (*empty circles*). The 2nd, 5th, 50th, 95th, and 98th percentiles of normal reference values. *HC* head circumference

normalized by the head circumference ( $\text{ml}/\text{min mm}^{-1}$ ). The advantage of this simplified normalization stems also from the fact that fetal head is an area of preferential distribution of flow and growth in the deprived fetus [28]; therefore, the use of this part of the fetal body as an index of fetal body mass improves the sensitivity of flow assessment in asymmetrically growth-restricted fetuses.

The increase in flow volume throughout gestation in normal fetuses is accounted for mainly by growth of the umbilical fetal vessels. The diameter of the vein increases from 4.1 to 8.3 mm, which would lead to a four-fold increase in cross-sectional area, whereas the velocity increased only 20% from 0.08 m/s at 20 weeks to 0.10 m/s at 38 weeks [12]. When blood velocity and diameter is normalized for fetal mass, an interesting result that can be observed in growth-restricted fetuses is that the diameter in small fetuses is not narrower than that of normal fetuses of comparable mass, whereas the main variable to decrease is blood velocity (Fig. 30.5). According to these data velocity itself could be used as a simple diagnostic test in growth-restricted fetuses. According to fetal sheep experiments [29] pressures and flow velocities are inversely related in the venous in-flow tract from the umbilical vein to the ductus venosus and inferior vena cava, this finding brings in both a diagnostic potential and a pathophysiological variable of interest.

In the same paper by Boito and co-workers, elsewhere quoted [25], a complex set of ultrasound volumetric measurements was performed on the head and

**Fig. 30.5.** Umbilical venous mean velocity per unit head circumference ( $\text{ml}/\text{min mm}^{-1}$ ). Growth-restricted fetuses with abnormal umbilical arterial pulsatility index (*full circles*). Growth-restricted fetuses with normal umbilical arterial pulsatility index (*empty circles*). The 2nd, 5th, 50th, 95th, and 98th percentiles of normal reference values. *HC* head circumference

on the abdomen of restricted and normal fetuses and a significant ( $p < 0.001$ ) inverse relationship was observed between fetal weight-related umbilical venous volume flow and fetal brain/liver volume ratio. The same diagnostic-oriented usage of umbilical venous flow was adopted by Tchirikov and co-workers [30]. In their reported experience the ratio between weight-specific umbilical vein blood volume ( $\text{ml}/\text{min kg}^{-1}$ ) and umbilical artery PI was a better predictor of poor fetal outcome than umbilical arterial PI alone.

## Redistribution of Umbilical Flow in Fetal Liver

Umbilical arterial qualitative velocimetry has probably reached its maximum clinical value. Its usage in fetal medicine is now a key criterion to differentiate severe growth-restricted fetuses from less severe forms and other diseases causing growth restriction. Umbilical volume flow measurements help us to better understand the pathophysiology of growth restriction. What happens under conditions of chronic hypoxia in the human fetus? From animal experimental studies we know that ductal dilatation sustained by the presence of an active sphincter regulation is the hypothesized mechanism allowing the fetal adaptation to the hypoxia [31]. This interpretation was confirmed in a recent experimental study in fetal sheep

by Kiserud and co-workers [32]. Their data showed that induced hypoxemia determined a significant dilatation of the isthmus of DV. In 1998 our group reported the first suggestion of in vivo ductal dilatation in two IUGR human fetuses examined for a prolonged period of time [33] and more recently such findings were confirmed on a larger series of growth-restricted fetuses [11, 34, 35]. Reduction in umbilical vein flow volume and an increase in the ductal shunting determines a severe deprivation of substrate in the right liver lobe initiating a severe organ failure, the prevention of this damage can prove to be of great impact on proper timing of delivery in severe growth-restricted fetuses.

For clinical usage this set of knowledge can be used with a criteria of feasibility: the simpler the better. Since the reduction of flow in the umbilical vein is determined by a reduction in velocity and not by the diameter of the vessel [24], only the measurement of velocity only could be used. If volume flow per unit fetal weight is influenced by errors in weight estimation, why do we not use volume flow per unit head circumference? If we know that the ductal a-wave is determined by dilatation of the inlet [11, 33, 34], the diameter of the ductus only could be checked when qualitative indices change without resorting to complex velocity measurements.

# Doppler Examination of the Fetal Pulmonary Venous Circulation

Rabih Chaoui, Franka Lenz, Kai-Sven Heling

## Introduction

The assessment of the pulmonary venous system in the fetus has evolved dramatically in the past decade due to the routine use of spectral and color Doppler ultrasound. Besides checking the normal connection of pulmonary veins during fetal echocardiography, the interest in these veins has increased recently in order to get insight into the mystery of the pulmonary circulation in the human fetus in vivo. Physiologic conditions and changes during pregnancy have been assessed and have allowed the comparison with data under abnormal conditions. This chapter briefly reviews the clinical value of Doppler assessment of pulmonary veins.

## Visualization of Pulmonary Veins Using Real-Time and Color Doppler Ultrasound

There are four pulmonary veins, inferior and superior on the right and left sides. All these veins enter the left atrium separately and have their own ostium. Using high-resolution real-time equipment and a perpendicular approach to the site of connection, the echolucent veins may then be recognizable in the surrounding gray lung (Fig. 31.1). It is generally difficult to visualize all four pulmonary veins in the fetus, but in the four-chamber view the two inferior veins can be visualized. Pulmonary veins in the fetus have a diameter of approximately 1 mm or less and are therefore difficult to identify routinely on screening ultrasound. This is also the reason why pulmonary volume flow is analyzed quantitatively on the arterial side.

In our examination technique we seek one right pulmonary vein (inferior) along a fictive line prolonging the intra-atrial septum. In real-time this is best visualized from the right transverse or slight dorsoanterior approach (Fig. 31.1). Using color Doppler this vein can be visualized either by an apical approach when (red) flow is seen toward the left atrium at the site where the inter-atrial septum inserts (Fig. 31.2) or by a dorsoanterior approach (flow in blue; Fig. 31.3).

The left pulmonary vein (inferior) is found as a vessel directly pointing toward the foramen ovale flap (Figs. 31.4, 31.5). It can be visualized in real-time when the heart is examined from the left transverse side (Fig. 31.4). Using color Doppler the same plane can be used to visualize flow in blue (Fig. 31.4), or a transverse right side to visualize blood flow in red toward the transducer (Figs. 31.2, 31.5). An apical approach slightly more from the right thoracic side may allow the visualization of two veins from the right and the left coursing into the left atrium (Fig. 31.2). New color Doppler techniques, such as power Doppler ultrasound or dynamic flow, can be very helpful tools in visualizing pulmonary veins especially when insonation angle is more perpendicular to the vessels of interest (Fig. 31.6).

Real-time visualization of the pulmonary veins was facilitated in the past few years by using new contrasting techniques, such as harmonic imaging or compound imaging (SonoCT, CRI, etc.; Figs. 31.1,

**Fig. 31.1.** Third-trimester fetus in dorsoanterior position. One right pulmonary vein (RPV) is visualized as the prolongation of the intraatrial septum. In this case we used harmonics imaging and a 5-MHz transducer. RA right atrium, LA left atrium

**Fig. 31.2.** Apical four-chamber view in color in a 30-week fetus demonstrates both inferior left and right pulmonary veins (*LPV, RPV*) entering the left atrium (*red*). Flow toward the transducer is visualized in *red*. On the left side the superior left pulmonary vein is seen in *blue*. (*LA, RA* left and right atrium, *LV, RV* left and right ventricle)

**Fig. 31.3.** Basal visualization of the heart in a dorsoanterior fetal position. Both inferior and superior right pulmonary veins (*RPV, RPVs*) are seen in *blue* entering the left atrium (*LA*). Note the color presetting as seen on the color bar with +18 cm/s

**Fig. 31.4.** Left approach to the four-chamber view with one left pulmonary vein seen in real-time image (in harmonic mode). The flow is parallel to the insonation angle and this plane is ideal for visualizing pulmonary flow, here seen in *blue*. *LA* left atrium

31.4). When using color Doppler, velocity range should be reduced to a range of 15–25 cm/s (Figs. 31.3, 31.7) with low filter and high persistence as we have described elsewhere [1]. The visualization of pulmonary veins using color Doppler is possible from the late first trimester by optimizing color Doppler presets (Fig. 31.8). Whether this contributes to increased diagnosis accuracy is not yet known. We include this visualization in first trimester mainly in

cases with suspected isomerism or in targeted examination, e.g., when totally anomalous pulmonary venous connection (TAPVC) was present in a previous child.

Usually it is sufficient to identify one pulmonary vein on each side during a routine study [2]. If, however, there is a heart defect detected, it is advisable to demonstrate at least three of the veins [2]. The examiner has, however, to be careful when assuming that

**Fig. 31.5.** Left pulmonary vein is visualized from a right lateral view of the heart. Here also the insonation angle is ideal for a color setting and flow is visualized in red

color Doppler confirmed the correct connection of the veins in a heart defect [3] as explained later in this chapter. In these cases we recommend a combination of color Doppler with pulsed Doppler of the pulmonary vessels, since flow velocity waveforms are often abnormal in TAPVC.

## Pulsed Doppler Ultrasound of Lung Veins

### Physiologic Conditions

Conversely to postnatal life, where whole blood passes through the pulmonary vessels to be oxygenated, the pulmonary circulation in the fetus is only a small part of cardiac output. Whereas animal experiments in fetal sheep found that pulmonary flow is around 8% of combined cardiac output [4], Doppler studies on human fetuses *in vivo* suggested that this flow is larger, being 13% at 20 gestational weeks and increasing to 20%–25% during the last trimester [5].

Doppler studies of volume flow were performed mainly on the arterial side where vessel diameter is easily measurable, whereas Doppler examination of the pulmonary venous system focused mainly on the study of velocity waveform. Pulmonary venous flow patterns in the adult were demonstrated to be influenced by dynamic changes in left atrial pressure created by contraction and relaxation of the atrium and ventricle [6]. Systolic peak (S) is caused by left atrial pressure reduction that results from the relaxation of the left atrium and the downward move of the mitral valve in systole. Diastolic peak (D) is caused by rapid emptying of the left atrium during left ventricular relaxation. During atrial contraction (A) there is a rise in left atrial pressure which causes in the adult a reversed flow into the pulmonary vein, i.e., a negative A-wave [7] which is not present [8, 9] (or occasionally present [10, 11]) in the fetus.

**Fig. 31.6.** *Left:* Power Doppler ultrasound in a lateral four-chamber view. With this technique pulmonary veins and the atria and ventricles are visualized at the same time. *Right:* Dynamic flow is very sensitive and arterial and venous flow are visualized

**Fig. 31.7.** Spectral Doppler of a pulmonary vein with a triphasic envelope characterized by the systolic (S) and diastolic (D) waves, and the A-wave as nadir during the atrial contraction

**Fig. 31.8.** A 13-week fetus examined transvaginally with visualization of a right pulmonary vein (RPV) entering the left atrium (LA). In a previous pregnancy there was a right isomerism with totally anomalous pulmonary venous connection

**Fig. 31.9.** Reference range (individual values, mean and 95% data intervals) for peak systolic velocity in the pulmonary veins plotted against gestational age. (From [9])

The fetal pulmonary vein velocity waveform is therefore very similar to that of the venous duct, with a forward triphasic flow throughout the heart cycle (Fig. 31.7). Parameters of blood flow velocity waveforms have been examined in several studies in recent years and similar results were reported [8–11]. Peak systolic (Fig. 31.9), diastolic velocities (Fig. 31.10), and time velocity integral (TVI) increase significantly during the second half of pregnancy, whereas pulsatility index decreases (Fig. 31.11) [9]. The rise in

**Fig. 31.10.** Reference range (individual values, mean and 95% data intervals) for velocities during atrial contraction in the pulmonary veins plotted against gestational age. (From [9])

**Fig. 31.11.** Reference range (individual values, mean and 95% data intervals) for pulsatility index of the pulmonary veins plotted against gestational age. (From [9] with permission)

peak velocities and TVI is compatible with the increase in pulmonary blood flow during gestation.

Given that the fetal pulmonary vein waveform reflects changes in the left atrium, studies have been performed to analyze indirectly the impact of left atrial pressure changes on the waveform. The pulmonary venous velocity pattern can be influenced by following determinants [12]:

1. Pulmonary volume flow
2. Foramen ovale size and flow
3. Left atrial compliance (size and muscle distensibility)
4. Atrial contraction, end-diastolic pressure (e.g., adrenergic drive, hypoxemia)

5. Left ventricular size and performance
6. Mitral valve size and function (e.g., regurgitation).

### Abnormal Patterns of Flow Velocity Waveforms

If we assume that left atrial pressure is a major determinant of the pulmonary vein velocity waveform, an obstruction of the left atrium should lead to typical changes in the waveform envelope. This was confirmed for fetuses with hypoplastic left heart syndrome, for example, where a distinct reversed flow during atrial contraction was demonstrated (Fig. 31.12) [13–15]. When the mitral valve is closed or severely dysplastic, left atrial blood can only escape during atrial contraction by passing across the foramen ovale from left to right or by returning to the lung. The larger the interatrial communication, the less blood will return into the lung during atrial contraction, and vice versa. Better et al. [14] reported an increase in systolic velocity and a reversal in A-velocity in such fetuses that correlated with the degree of restriction of the atrial septum after birth. This was

**Fig. 31.12.** Three types of an obstructed left atrium as reflected in the pulmonary vein flow velocity waveforms. The *upper wave* is a mild obstruction with a slight reverse A-wave, the *middle wave* is a serious obstruction with a pronounced reversed A-wave. The *lower wave* is severely abnormal and indicates an obstructive left atrium, often associated with thickened pulmonary veins and congestive lungs

supported by a recent observation we reported in two different cases of hypoplastic left heart [15], one showing a wide patent and the other a sealed foramen ovale. In the patent interatrial communication, the pulmonary venous velocity waveform was normal with a positive A-wave. In the sealed foramen ovale, however, the waveform showed a nearly to-and-fro pattern (Fig. 31.12), since all blood flow coming from the lung returns back into the lung. This is associated with congested pulmonary veins. This chronic high pressure leads to vascular damage as observed at autopsy, with arterIALIZATION of pulmonary veins as well as the development of lymphangiectasia of the lung as we observed in other cases.

In a further study we examined changes of the velocity waveforms in other heart anomalies ( $n=96$ ) and were not able to find any changes depending on the heart anomaly, mainly due to the interatrial conditions of obstruction [16].

Besides obstructed left atrium conditions (e.g., hypoplastic left heart, mitral atresia), we also found abnormal waveform patterns in TAPVC. In this severe malformation pulmonary veins are not connected to the left atrium and interestingly velocity waveforms reflect the site of connection. When connecting to a descending channel into the liver, infradiaphragmatic blood flow in the pulmonary veins was shown to be continuous [3]. Connection directly to the right atrium or indirectly via a vertical vein may show pulsations but not with the typical shape of a pulmonary vein [12]; therefore, it has been suggested that the routine use of pulsed Doppler of lung veins may help in diagnosing TAPVC in the fetus.

In summary, it can be emphasized that left atrial obstruction as seen in hypoplastic left heart syndrome or mitral atresia can be associated in most cases with an increased pulsatile flow due to the reversal of flow during atrial contraction. A to-and-fro pattern is suggestive for a sealed foramen ovale and associated with severe impairment of lung development, showing a poor prognosis. Flow pulsations are decreased or absent in TAPVC with infradiaphragmatic connection, or show an atypical pattern resembling inferior vena cava or a more dumped pattern in cardiac or supracardiac connections.

### Other Fields of Interest Assessing Pulmonary Vein Doppler

The relationship of pulmonary venous flow with systolic and diastolic cardiac times assessed at the level of the mitral valve are used in cardiology to assess diastolic function. Brezinka and coworkers [17] analyzed this relationship in 28 healthy fetuses in the second half of pregnancy and found that pulmonary venous inflow into the left atrium occurs predomi-

nantly during the filling and ejection phases of the cardiac cycle. Absolute cardiac diastolic and systolic time intervals as well as the distribution of pulmonary venous flow velocity integrals between these cardiac time intervals remained unchanged with advancing gestational age.

Macklon and coworkers [18] examined the influence of fetal behavioral states on venous blood flow velocity waveforms in ten normally grown fetuses at term. The examinations were performed either during quiet (state 1F) or active (state 2F) sleep. Whereas no changes were observed on the arterial side, venous pulmonary blood flow velocity waveforms demonstrated a significant increase in time-averaged peak diastolic and end-diastolic velocity during active sleep, suggesting an increase of pressure gradient between the pulmonary venous system and the left atrium in these behavioral states.

DeVore and Horenstein [19] described a new technique for the evaluation of fetal arrhythmia by simultaneous recording of the intraparenchymal pulmonary artery and vein. Since both vessels are adjacent to each other within the lung showing opposite flow directions, a simultaneous spectral Doppler sampling will demonstrate waveforms on both sides of the baseline (Fig. 31.13): the peak of the pulmonary artery reflects the ventricular systole, whereas the atrial

**Fig. 31.13.** Simultaneous pulmonary artery and vein Doppler tracing in a normal fetus. Sampling is performed in lung parenchyma where peripheral pulmonary artery and veins are adjacent to each other. Peak velocity on the arterial side indicates systole (S) and is observed on the venous side as well. The nadir on the venous side indicates the atrial contraction (A)

**Fig. 31.14.** Simultaneous pulmonary artery and vein Doppler tracing in a fetus with ectopic beat. The ectopic beat originating from the atrium is seen as a notching on the venous side with a reversal flow

contraction is identified by an interruption or a nadir in venous flow (Fig. 31.13). Using this technique the examiner is able to easily assess qualitatively the relationship of atrial to ventricular contraction and to quantify the arteriovenous time as well. The method seems to be helpful in differentiating arrhythmias (Figs. 31.14, 31.15).

## Malformations of Pulmonary Veins and Their Diagnosis

### Embryology in Summary

Understanding embryologic development facilitates the comprehension of different anomalies involving the pulmonary system.

Embryology of the fetal venous system is complex and has been reviewed several times in the past few years [20–22] to facilitate the understanding of detected (mainly intrahepatic) venous anomalies by the use of color Doppler. The development of the pulmonary vein system is better examined, since the anomalies are known entities in pediatric cardiology.

The sinus venosus is incorporated at the end of the fourth week into the posterior wall of the right and left atria. The right part of the sinus venosus encircles the superior and inferior vena cava and becomes part of the dorsal wall of the right atrium. The left part becomes remnant and builds the coronary sinus of the left atrium.

Separately from the development of the left atrium, the pulmonary veins develop as part of the splanchnic venous bed. During further development pulmonary veins differentiate into the individual veins but still connect to the systemic venous circulation. At a certain stage these pulmonary veins connect to the left atrium where a “common” pulmonary vein arises as a bud and they lose their connection to the central circulation. It is still debated whether the pulmonary veins from the lung connect with the bud resulting from the invagination of the dorsal wall of the left atrium or with remnants of the coronary sinus [23].

**Fig. 31.15.** Simultaneous pulmonary artery and vein Doppler tracing in a fetus with second-degree arteriovenous block in connective disease of the mother. For every second atrial contraction there is one ventricular systole recorded

## Anomalies of the Pulmonary Venous Connections

Failure of the meeting of the common pulmonary vein and its splanchnic components results in various forms of anomalous venous connections. In the case of a complete failure to connect there is a total bilateral anomalous pulmonary venous connection. This is the embryologic persistence of the connection to the systemic veins, since this remains the only pathway for lung blood to return to the heart. According to their site of connection, there are four forms of TAPVC: at supracardiac, cardiac, and infracardiac levels, and mixed connections [2]. In partial anomalous venous drainage there is a failing of one, two, or three pulmonary veins to connect to the common pulmonary vein and the vein(s) remain connected to a systemic vein, either the superior caval, the brachiocephalic vein, or the coronary sinus. The right pulmonary veins are more often involved than the left.

The postnatal hemodynamic consequence of anomalous pulmonary venous connection is that oxygenated blood from the lung reaches directly or indirectly together with the systemic veins into the right instead of the left atrium. If arterialized blood does not reach the left atrium, the neonate may present with cyanosis. The obstruction can be at cardiac level, if the atrial communication is small, or at more proximal stages either at the level of the pulmonary veins themselves, within the course of the confluence or at their connection with a systemic vein [2]. The most severe form of obstruction is assumed to be the infradiaphragmatic connection. When a TAPVC with obstruction is present, the clinical presentation is very early and severe after birth, whereas later clinical appearance is observed in cases with no obstruction and may present first late in childhood in cases with partial anomalous pulmonary venous connection (PAPVC).

### Prenatal Diagnosis of Anomalous Pulmonary Venous Connection

Total or partial anomalous pulmonary venous connections occur in 2% of all live births. They can occur as an isolated incidence or as a part of complex heart anomalies, mainly right atrial isomerism (asplenia syndrome; see review in [24]). Despite the “theoretical” ease of visualization of pulmonary veins during fetal echocardiography, diagnosis of TAPVC has been, however, reported prenatally only in case reports or very small series [3, 25]. In large series on fetal echocardiography this condition was among the missed diagnoses; therefore, clues for diagnosis are probably indirect signs, on one hand, and the tar-

geted examination for this condition when typical associated heart anomalies are suspected, on the other [25]. The diagnosis can be assisted by the use of pulsed Doppler sampling of the pulmonary veins [25].

The diagnosis of partial anomalous pulmonary vein connection is very difficult prenatally but can occasionally be made. We focus on the total anomalous venous connections. The prenatal clues for diagnosis depend mainly on the site of connection and we discuss it according to this classification.

### Supracardiac TAPVC

Supracardiac TAPVC is the most common form of anomalous connection. In most cases the four pulmonary veins form a confluence posterior to the left atrium and connect via a vertical vein (which is the embryologic left persistent superior vena cava) to the brachiocephalic vein, which drains into the superior vena cava (Fig. 31.16). This condition is rarely detected by visualizing the confluence behind the left atrium, but by visualizing the left persistent superior vena cava as a fourth vessel in the three-vessel-trachea view in the upper thorax (Fig. 31.17, right). Since an LVCS is a common anomaly seen in the fetus as well, the differentiation from an isolated LVCS is mandatory. This is achieved by means of color Doppler (Fig. 31.17). In isolated LVCS, blood from the jugular vein continues via the LVCS toward the heart, which means that flow in the LVCS goes in the direction of the heart. In supracardiac TAPVC with connection to LVCS blood flow goes the opposite way,

**Fig. 31.16.** Supracardiac total anomalous pulmonary vein connection. Lung veins are connecting to a left persistent superior vena cava (LSVC) which drains the blood to the anomalous vein and then to the right superior vena cava (SVC). Blood flow in the left vena cava is toward the head and the right superior vena cava in the opposite direction (compare with Fig. 31.17). (Courtesy of Philippe Jeanty from [www.thefetus.net](http://www.thefetus.net))

**Fig. 31.17.** Supracardiac totally anomalous pulmonary venous connection (TAPVC). *Left:* Longitudinal view of the upper left thorax with a left persistent superior vena cava (LSVC) with blood flow is seen with a perfusion toward the fetal head (*in red*). *Right:* In the three-vessel view the pulmonary trunk is ante-grade perfused (*blue*), and the aorta is hypoplastic and cannot be seen. On both sides of the pulmonary trunk the left persistent (LSVC) and right SVC are perfused in opposite directions which is typical for a supracardiac TAPVC

upward toward the upper thorax (Fig. 31.17, left). A longitudinal visualization of the LVCS may therefore help enormously (Fig. 31.17, left). Furthermore, blood flow in the innominate vein appears increased compared with other conditions, since in addition to blood coming from the left side of the upper extremity, blood flow of the lungs will pass through it. Even by using a cardiac setting of color Doppler with high velocities, the innominate vein will appear very clearly with high flow. Pulsed Doppler of pulmonary veins may be of help in these conditions, especially in cases with obstruction of these veins.

The supracardiac type of TAPVC connecting directly to the superior vena cava is difficult to detect unless the superior vena cava is dilated.

A common feature in both conditions could be the discrepant size of the right and left heart [25]. In supracardiac and cardiac TAPVC the left side of the heart is more narrow due to lack of blood flow to the left and the right side is dilated due to the increased flow; therefore, it has to be borne in mind that conditions suspicious for size discrepancy, such as right ventricular dysfunction suggesting tricuspid insufficiency or aortic coarctation, should be suspicious for supracardiac or cardiac TAPVC as well.

### Cardiac TAPVC

In cardiac TAPVC pulmonary veins connect directly to the coronary sinus, which becomes dilated, or less commonly the connection is directly into the posterior wall of the right atrium (Fig. 31.18).

The first condition can be detected when a dilated coronary sinus is found. Generally, the best plane to visualize a coronary sinus is a cross section just below the four-chamber view as we recently described

in an article on normal and abnormally dilated coronary sinus [26].

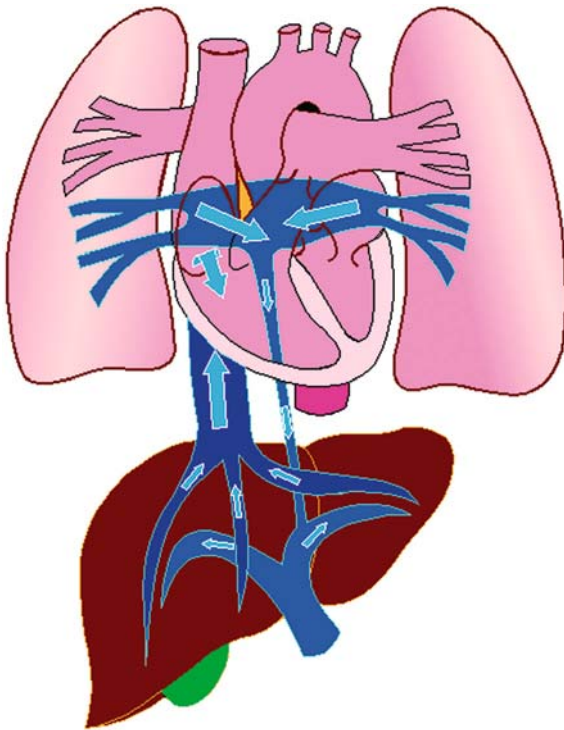

The direct connection of pulmonary veins with the right atrium can be visualized by means of color Doppler or power Doppler (Fig. 31.19). This is rarely detected primarily on screening ultrasound but mainly when there is a suspicious sign. The two clues for suspicion are either the small size of the left side of the heart compared with the right or the presence of right atrial isomerism (asplenia) as detected from upper abdomen anatomy (juxtaposition of aorta and inferior vena cava) [24]. In Fig. 31.19 one can recognize the sampling vein behind the right atrium where the pulmonary veins drain. Pulsed Doppler demonstrates the continuous rather than the typical pulsatile flow.

**Fig. 31.18.** Cardiac TAPVC. All pulmonary veins are connected to the right atrium. (Courtesy of Philippe Jeanty from [www.Thefetus.net](http://www.Thefetus.net))

**Fig. 31.19.** Cardiac TAPVC in a fetus with right isomerism. *Left:* Pulmonary veins drain into the right atrium (RA) after coursing behind the left atrium (LA; compare with Fig. 31.18). *Right:* Color Doppler shows the vessel behind the left atrium with a course toward the right atrium (blue with sample volume). Spectral Doppler demonstrates the continuous flow instead of the pulsatile flow

**Fig. 31.20.** Infracardiac (or infradiaphragmatic) TAPVC shows the four pulmonary veins draining into a vertical vein which courses across the diaphragm and ends in the liver vasculature. (Courtesy of Philippe Jeanty from www.Thefetus.net)

### Infracardiac TAPVC

In infracardiac TAPVC the four pulmonary veins form a confluence which is localized behind the atria. This confluence is connected to an anomalous descending vein which passes the diaphragm accompa-

nying the esophagus and drains into the portal veins in most cases but occasionally into the hepatic veins or into the ductus venosus (Fig. 31.20). In isolated cases a discrepant size of the ventricles is not typical and the main suspicion can only be made in cases with right isomerism. The confluence and the descending veins are, according to our experience, so tiny that on real-time and color Doppler examination they appear to be part of the left atrium and are not easily recognizable.

Three diagnostic clues can be of help:

1. The proper use of color Doppler by changing the settings in order to visualize the proper connection of the veins may help in detecting the confluence (Fig. 31.21). Interestingly, in contrast to normal connecting pulmonary veins, where a certain distance is found between the connecting sites of the right and the left inferior pulmonary veins, in this condition the veins connect in the same place – the confluence vein (Fig. 31.21).
2. Pulsed Doppler of pulmonary veins shows a continuous flow [3] as demonstrated in Fig. 31.22.
3. Of further help is the longitudinal view of the upper abdomen and heart using color Doppler, which can demonstrate a vessel with the opposite color to the hepatic veins and entering the liver from cranially (Fig. 31.23). At a time where in IUGR conditions and most cardiac anomalies the ductus venosus is examined routinely, the examiner could shift the transducer slightly to the left and the right to recognize such an abnormal vessel. This should of course not be confused with the hepatic artery showing an increased flow in fetuses with severe IUGR, which is again easy to differentiate by means of pulsed Doppler.

**Fig. 31.21.** Infracardiac TAPVC. *Left:* At first sight analysis of pulmonary venous connection may suggest a normal connection. *Right:* Increasing velocity range demonstrates that both veins are draining into a vessel behind the atrium (*arrows*). In another plane this vein is seen crossing the diaphragm (see Fig. 31.23)

**Fig. 31.22.** Infracardiac TAPVC. Spectral Doppler of the intrathoracic vein shows a continuous flow instead of the pulsatile flow as sign of an abnormal connection (compare with Figs. 31.7 and 31.19)

### *Rare Anomalies of the Pulmonary Veins*

Other anomalies of the pulmonary venous system are the presence of arteriovenous fistulae within the lung. In the past few years there have been some case reports of such conditions leading prenatally to volume overload [27, 28]. The hint for detection was sonolucent echoes in the lung showing a high turbulent flow on color Doppler (Fig. 31.24). Another rare condition is the direct connection of the pulmonary artery branch directly to the left atrium bypassing the vein as we described in a case report within a series of different cases of cardiomegaly [29].

**Fig. 31.23.** Infracardiac TAPVC. Longitudinal view of abdomen and thorax. *Left:* The vertical vein is seen behind the heart and crossing the diaphragm (*Diaph;* *arrows*). *Right:* Color Doppler shows direction of flow toward the liver. Directly in front of the spine the descending aorta is seen (*arrows*), and ventral of the vein one hepatic vein (*HV*) is seen (*arrow*)

**Fig. 31.24.** Arteriovenous fistula in the lung. *Left:* In real-time a dilated right pulmonary vein (*RPV*) is seen draining into the left atrium (*LA*). *Right:* Color Doppler shows the turbulent flow typical for the high perfusion in the fistula

# Introduction to Fetal Doppler Echocardiography

Dev Maulik

## Introduction

Evaluation of the fetal heart constitutes one of the critical areas of prenatal diagnosis. Advances in diagnostic medical ultrasound continue to be of central importance in this progress. Of the various ultrasound modes, two-dimensional (2D) real-time high-resolution imaging forms the technical foundation for echocardiographic assessment of the anatomic integrity of the fetal heart. The diagnostic capabilities of the procedure are substantially extended by the incorporation of other echocardiographic modalities such as the color Doppler and the M-mode ultrasound [1–7]. Since the publication of the first edition of this book, significant advances have continued in this field. Of particular interest is the development of three-dimensional (3D) echocardiography and the tissue Doppler mode [8–10]. Table 32.1 summarizes these developments. A brief review of tissue Doppler is included in this chapter, whereas 3D echocardiography is reviewed in Chap. 34.

**Table 32.1.**

Fetal echo mode	First author	Reference
M-mode	Winsberg	[1]
Two-dimensional echo	Allan et al.	[3]
	Kleinman et al.	[4]
Duplex M-mode	DeVore et al.	[5]
Duplex pulse-wave Doppler	Maulik et al.	[6]
Tissue Doppler	Harada et al.	[21]
Color flow Doppler	Maulik et al.	[10]
Three-dimensional fetal echocardiography – Two-dimensional image integration	Sklansky et al.	[8]
Three-dimensional fetal echocardiography – spatiotemporal image correlation	DeVore et al.	[9]
Real-time three-dimensional fetal echocardiography – two-dimensional phased array	Maulik et al.	[10]

An essential component of this progress is the impressive development of Doppler echocardiography in clinical practice. Maulik and co-workers were the first to describe the use of the duplex Doppler method for characterizing normal and abnormal flow patterns in the fetal cardiac chambers and outflow tracts [6, 11]. Subsequent work has established the utility of these techniques in clinical practice for both physiologic and diagnostic evaluation [6, 12–16]. The color and spectral pulsed-wave Doppler modalities allow assessment of normal and abnormal cardiac flow patterns, and extend the diagnostic information generated by the 2D and M-mode echocardiographic methods. Spectral pulsed Doppler offers range resolution, allows evaluation of flow velocities in specific target locations, and when used as a duplex system, the method allows assessment of circulatory dynamics in specific intracardiac locations and outflow tracts of the fetal heart. The technique of Doppler color flow mapping significantly enhances our ability to investigate cardiac hemodynamics by depicting color-coded 2D flow velocity distribution in cardiac chambers and great vessels.

In this chapter we review the basic principles of Doppler echocardiography as applied to the hemodynamic assessment of the fetal heart.

## Choice of Equipment for Doppler Echocardiography

### General Considerations

The diagnostic utility of fetal echocardiographic imaging depends on the capabilities of the ultrasound device for producing high-resolution images, the experience and skill of the sonographer, and patient characteristics pertaining to the quality and ease of imaging (Fig. 32.1). The imagability is determined by fetal position, fetal movements (breathing, movement, hiccup), gestational age, maternal movement, and maternal body habitus. Obviously, use of a superior imaging device assists in minimizing the adverse effects of many of these unfavorable circumstances on the quality and diagnostic utility of the echocardiography.

**Fig. 32.1.** Factors affecting the quality of diagnostic information derived from fetal cardiac imaging

graphic information, but the utility of a device significantly depends on the skill of the operator in generating the diagnostic information and the skill of the diagnostician in interpreting that information. For reliable and confident fetal echocardiographic assessment, it is crucial to ensure not only the adequacy of the instrumentation but also the sufficiency of training and skill of the provider.

## Ultrasound System

The basic principles of duplex pulsed-wave Doppler and color flow Doppler instrumentation have been described in Chaps. 3 and 6. Here the relevant issues specifically related to fetal echocardiographic application are briefly discussed. The desirable configuration of an ultrasound device for fetal echocardiographic examination consists of a multiplex system. Several ultrasound modalities comprise such a system, including high-quality 2D imaging and other sonographic techniques. These devices enable the sonographer to perform with reasonable confidence comprehensive structural and functional assessments of the fetal heart. When choosing a device, critical consideration should be given to the quality of the resolution of 2D imaging and the transducer features appropriate for the needs of fetal echocardiographic examination. As with any other field of medical ultrasound imaging, an appropriate archival system is selected so images and reports can be saved and retrieved in a reliable manner.

Integration of 2D imaging with Doppler sonography offers some unique challenges, and the various approaches to their solution are reflected in the device's features. For example, high-resolution imaging requires a high-frequency transducer; in contrast, Doppler signals are weaker than the pulse echocardiographic specular reflections of imaging and require a low-frequency transducer for optimal sensitivity. The introduction of multifrequency transducers offers an innovative solution, as higher imaging resolution can be achieved at higher frequency, whereas Doppler sensitivity is improved using a lower frequency. Because of the angle dependence of Doppler

signals, the optimal imaging plane is often not consistent with the optimal Doppler plane. Beam steering capability of the array transducers may assist in these circumstances. Careful consideration of these factors helps the operator select the appropriate device for fetal echocardiographic application.

The choice of transducer frequencies appropriate for fetal echocardiographic examination should be individualized to achieve the best possible resolution for a given depth of the scanning target. The higher the frequency of the incident beam, the greater the spatial (axial) resolution and the lower the depth of penetration. Depending on the maternal habitus, gestational age, and fetal position, the fetal heart often lies deep from the maternal abdominal surface. Although a 5-MHz transducer produces a higher resolution image of the fetal heart, it may not be able to reach such depth. In this circumstance, a 3-MHz transducer may be necessary. As mentioned previously, multifrequency transducers offer a convenient solution.

Consideration should also be given to the type of transducer appropriate for fetal cardiac evaluation (discussed in detail in Chaps. 3 and 6). It is generally recognized that electronic-array design offers significant advantages. Both convex sequential-array and phased-array transducers may be used for fetal echocardiographic applications. For most obstetric applications, including fetal cardiac evaluation, convex sequential transducers are often preferred, as they provide uniform high resolution in the image plane. However, phased-array devices may be helpful when fetal orientation limits acoustic access to the fetal heart.

## Preparation for Echocardiographic Examination

It is imperative that the mother be informed prior to examination in a clear and considerate manner about the reason for fetal cardiac evaluation, as well as about the procedure, efficacy, and limitations of fetal echocardiography. The findings should be explained at the conclusion of the examination. The family may participate in this session at the mother's discretion. The overall approach should be multidisciplinary, involving the obstetrician, maternal-fetal medicine specialist, pediatric cardiologist, and neonatologist. The counseling procedure should be documented.

The examination is performed with the patient lying in a semirecumbent left lateral position on a comfortable, secure examination table. The examination often must be conducted with the mother in the supine position, in which case care is taken to limit the duration of the procedure to avoid supine hypo-

**Fig. 32.2.** Steps of fetal echocardiographic examination and integration of the various ultrasonographic modalities

tension. Maternal positional change may be helpful if echocardiographic access to the fetal heart is suboptimal in a given position.

## Method of Fetal Doppler Echocardiography

The procedure for fetal Doppler echocardiography consists of the following steps (Fig. 32.2).

1. Preliminary scan to determine fetal orientation and situs
2. Systematic evaluation of fetal cardiac anatomy by 2D imaging of the heart in the various echocardiographic planes
3. Assessment of cardiac structure and function with spectral and color flow Doppler modes using the guidance of 2D imaging
4. Additional assessment of cardiac structure and function with M-mode echocardiography combined with color flow Doppler mode using the guidance of 2D imaging.

### Preliminary Examination

General ultrasound imaging of the fetus is performed initially, during which fetal orientation is determined and the fetal cephalic and caudal ends, extremities, and spine are identified. This preliminary step allows determination of the right and left sides of the fetus. Scanning the thoracic region leads to ready identification of the fetal heart. At this stage, fetal visceral orientation, also known as fetal situs, is determined by noting the location of the following landmarks in the transverse cross-sectional image of the fetal upper abdomen (Fig. 32.3): (1) The fetal stomach is on the left side. (2) The abdominal aortic cross section is seen as a circular, pulsating structure on the left, anterolateral to the spine; the aorta can be confirmed by spectral pulsed-wave Doppler interrogation, which

**Fig. 32.3.** Determination of fetal situs from the sonogram of the fetal abdominal cross section. The aorta (AO) lies anterior and to the left of the spine (SP). The inferior vena cava (IVC) is anterior and to the right of the aorta. The stomach (ST) is visible on the left side as an echo-lucent space

clearly demonstrates the distinctive aortic velocity waves. (3) The inferior vena caval cross section is identifiable as an ellipsoidal structure on the right, anterolateral to the spine but at a plane anterior to the aortic location. Its identity can be confirmed from the characteristic Doppler waveforms obtained by pulsed-wave Doppler interrogation. It should be noted that the inferior vena caval location assists in recognizing the morphologic right atrium.

The normal visceral and vascular positions described above are known as situs solitus. An abnormal viscerovascular arrangement can be either situs inversus or situs ambiguus. In the former, the viscerovascular arrangement becomes the mirror image of that encountered in situs solitus, so the stomach is on the right side, the aorta is on the right side at a posterior plane to that of the inferior vena cava, and the inferior vena cava is on the left side. With situs ambiguus, more complex abnormalities prevail.

### General Approach to Fetal Cardiac Imaging

After the preliminary examination, systematic 2D echocardiographic imaging is performed to evaluate the various components of the fetal cardiac anatomy. This examination is usually conducted using a dynamic “free-flow” technique. The available sonographic windows to the fetal heart are often limited because of an unfavorable fetal position. It is recommended that a standardized approach based on traditional echocardiographic planes be adopted for the fetal examination while maintaining a dynamic scanning approach (Table 32.2). This disciplined approach expedites the learning process and ensures the quality

**Table 32.2.** Echocardiographic planes

and reliability of the procedure for general application. The views of the fetal heart at various echocardiographic planes are described below. These views offer a comprehensive evaluation of the fetal heart, although they do not constitute all the available approaches to cardiac imaging. The minimal information to be derived from the 2D fetal echocardiographic examination is listed in Table 32.3.

### Four-Chamber View

As the fetal heart lies horizontally in the thorax, a cross-sectional scan of the fetal thorax just above the level of the diaphragm reveals the four-chamber view of the fetal heart (Fig. 32.4). It is an apical four-chamber view when the fetal spine is posterior, as encountered in the occipitoposterior position (Fig. 32.5A). When the fetus is in the occipitoanterior position with

**Fig. 32.4.** Method for obtaining an apical four-chamber view of the fetal heart. *Far left:* Orientation of the transducer plane in relation to the fetal thorax. *Bottom left:* Echocardiographic plane in relation to the fetal heart

the fetal spine directed anteriorly, the cardiac apex is directed toward the maternal spine and the base faces the maternal anterior (Fig. 32.5B). This position constitutes the basal four-chamber view. When the fetus lies on its side in the occipitolateral position, the lateral four-chamber view is visualized with the cardiac apex directed laterally (Fig. 32.5C).

The four-chamber view is one of the most important approaches for fetal cardiac assessment. It is readily obtainable, does not require in-depth expertise in the echocardiographic technique, and yields an immense body of information regarding the functional integrity of the fetal heart. Although it constitutes an essential component of the screening examination of the fetus, it should be clearly recognized that this view in itself is not sufficient for ruling out fetal cardiac malformations and cannot act as a surrogate for comprehensive systematic sonographic examination of the fetal heart.

The four-chamber view allows assessment of the following components of the fetal cardiac anatomy: atria, interatrial septum, foramen ovale and its valve, eustachean valve, tricuspid and mitral valves, ventricles, and interventricular septum. The right and left ventricles appear to be of comparable size. The right ventricle is nearer the anterior abdominal wall, whereas the left ventricle faces the posterolateral abdominal wall and is nearer the spine. The septomarginal trabeculum, or moderator band, can be seen near the apex in contiguity with the interventricular septum. The right ventricular cavity is irregular, whereas the left cavity is smooth. The tricuspid and mitral orifices and the respective valves are clearly imaged in this plane. The former is situated more toward the apex than the latter. The right and left atria appear to be of similar size. The superior and inferior vena caval entry into the right atrium and the pulmonary venous entry into the left atrium may also be seen in this or a similar plane. The interatrial septum can be visualized separating the at-

ria, although the apical or basal four-chamber view may not offer the best acoustic exposure for the septum, which may be better imaged in the lateral four-chamber view. The foramen ovale can be visualized in the septum, and its valve can be seen in the left atrial cavity. The pulmonary veins entering the left atrium may be identified in the image.

### ***Pulmonic and Aortic Outflow Tracts: Long-Axis Crossover Views***

From the four-chamber plane, rotational movement of the transducer of approximately  $45^\circ$  (clockwise with the fetal spine posterior and counterclockwise

**Fig. 32.8.** Two-dimensional echocardiogram of the fetal heart. *Left:* Long-axis view of the left ventricular outflow. *AO* aorta, *LA* left atrium, *LV* left ventricle, *RV* right ventricle.

*Right:* Long-axis views of the right ventricular outflow. *PA* main pulmonary artery, *LV* left ventricle, *RV* right ventricle

with the spine anterior) along its central axis with slight fanning motion cephalad toward the left shoulder of the fetus reveals the left parasternal long-axis view of the left ventricle and the aortic outflow tract (Fig. 32.6). The transition from the four-chamber plane to this view is swift, requiring only minimal transducer manipulation. Further slight rotation and fanning motion of the beam in the longitudinal plane in the left parasternal area reveals the right ventricle and the pulmonic outflow tract (Fig. 32.7).

These views allow assessment of the right and left ventricular outflow tracts (Fig. 32.8). Particularly noteworthy is the aortic-pulmonary crossover relationship, which is characteristic of normal cardiac anatomy. Absence of this feature is pathognomonic of great artery transposition.

### Parasternal Short-Axis View

Ventricular short-axis views may be obtained by rotating the transducer approximately 90° from the four-chamber view and moving the beam plane perpendicular to and along the long axis of the ventricles, starting at the cardiac apex and concluding at the cardiac base (Fig. 32.9). This maneuver generates cross-sectional images of the ventricles at the apex, midcavity, atrioventricular junctions, and the root of the great vessels (aortic short-axis pulmonic outflow view). These approaches allow assessment of the ventricles, the mitral and tricuspid valves and orifices, and the ventricular outflow tracts, especially the pulmonary arteries (Fig. 32.10).

**Fig. 32.9.** Method for obtaining ventricular short-axis (parasternal) view of the fetal heart at the level of the cardiac base and the origin of the great arteries. *Far left:* Orientation of the transducer plane in relation to the fetal thorax. *Middle:* Echocardiographic plane in relation to the fetal heart. *PA* pulmonary artery, *PV* pulmonary valve, *RV* right ventricle, *TV* tricuspid valve, *IVC* inferior vena cava, *LA* left atrium, *RA* right atrium

### Ductal and Aortic Arch: Long-Axis View

From the four-chamber plane, the transducer should be rotated (clockwise with fetal spine posterior) to align the imaging plane to the left of the fetal midline sagittal plane (Fig. 32.11). This maneuver reveals the long-axis view of the pulmonic artery-ductal arch (Fig. 32.12). With fine manipulation and slight tilting motion of the transducer, the imaging plane can be projected slightly oblique in reference to the sagittal plane, traversing from the right anterior thorax to the left of the fetal spine with an occipitoposterior position (Fig. 32.13), or from the left of the spine to the right

anterior thorax with an occipitoanterior position. This maneuver reveals the aortic arch (Fig. 32.14).

### Spectral Doppler Sonographic Examination

Whereas 2D imaging provides information on the structural integrity of the fetal heart, the addition of Doppler ultrasonography provides information on the cardiac circulatory state, which may reflect the presence of fetal cardiac disease. Thus Doppler ultrasonography may be of adjunctive diagnostic value. Spectral Doppler sonographic interrogation of the fetal heart can be performed only with a pulsed-wave duplex Doppler technique in which imaging provides guidance for the Doppler sample volume placement. Continuous-wave Doppler ultrasonography has lim-

**Fig. 32.13.** Method for obtaining the aortic arch view of the fetal heart. *Far left:* Orientation of the transducer plane in relation to the fetal thorax. *Middle:* Echocardiographic plane in relation to the fetal heart

ited use for assessing fetal cardiac flow because it lacks range discrimination.

Once a detailed anatomic examination of the heart has been performed, the Doppler cursor is moved across the plane of the 2D cardiac image, and the Doppler sample volume is then placed at the desired intracardiac or outflow locations. The ultrasound mode is then changed to pulsed-wave spectral Doppler sonography and the frequency shift signals are obtained (Fig. 32.15). Because of fetal movement and consequent unpredictable changes in the fetal posi-

**Fig. 32.14.** Two-dimensional echocardiogram of the fetal heart depicting the aortic arch. Note the tight curvature of the aortic arch and the origin of the arteries supplying the head and neck. tion, repeated verification of the location of the Doppler sample volume is essential. Various approaches may be used, including (1) display of a frozen 2D image that is updated at predetermined intervals, verifying the Doppler sample volume location; (2) interpolation techniques that produce a 2D image during a

short interval during which spectra are interpolated; and (3) time-sharing algorithms that produce simultaneous display of spectral Doppler images and 2D images by sharing the available pulses during a given time interval between the two modes. Unfortunately, all of these approaches have trade-offs and therefore do not provide an ideal solution.

Finally, duplex pulsed-wave Doppler ultrasonography can be used to determine fetal cardiac output. The principle of this technique is briefly described later in the chapter.

### Color Doppler Flow Mapping

The introduction of color Doppler echocardiographic technique represents one of the major advances in noninvasive cardiac diagnosis [17, 18]. Fetal cardiac hemodynamics have been imaged using the color mapping technique [19]. The depiction of Doppler mean frequency shifts by 2D flow mapping requires a balanced compromise between spatial resolution, Doppler accuracy, and temporal resolution. The normal range of the fetal cardiac cycle is 0.375–0.545 s (corresponding to a heart rate of 120–160 bpm). This degree of rapidity of fetal cardiac events necessitates an adequate processing speed to maintain temporal resolution. The small size and deep location of the fetal heart and the inability to ensure its favorable orientation impose further restrictions on obtaining adequate signals.

With Doppler color flow mapping for a given sector size, the more numerous the scan lines, the better the spatial resolution of the color (see Chap. 6). Furthermore, the more profuse the samples per scan line, the more accurate the mean velocity estimation. However, increasing the scan lines and sample points

**Fig. 32.15.** Spectral Doppler interrogation. *Left panel:* Pulmonary outflow. The Doppler path is indicated by the *cursor line*. The Doppler sample volume (*horizontal lines*) is placed in the outflow tract. *Right panel:* Spectral Doppler waveforms from the ductus. As the flow is towards the transducer, the waveforms deflect upward from the baseline

leads to greater processing time, which in turn leads to a slower frame rate and therefore a consequent loss of temporal resolution, especially in a hyperdynamic situation with a shorter cardiac cycle as is encountered in the fetus. The small size of the fetal heart compensates for this problem to some extent by allowing an adequate anatomic exposure with a relatively smaller scan area. Limiting the scanned area of interrogation can substantially improve both color sensitivity and temporal resolution. Another important consideration is the device's ability to distinguish between the various types of motion detected by the Doppler mode within the interrogated area. Doppler shift signals are generated not only by blood flow but also by tissue motions, such as fetal cardiac wall movements or during fetal breathing, which result in color artifacts. Although these artifacts can be eliminated by a high-pass filter, the latter also eliminates low-velocity flow information. Many devices now minimize this problem by utilizing advanced filtering technology that processes multiple parameters including velocity and amplitude. These issues are discussed in detail in Chap. 6.

The methodology is similar to the pulsed-wave Doppler technique described above. Appropriate 2D views of the fetal heart are first obtained by 2D echocardiography. The mode of operation is then changed to color Doppler sonography, which results in the depiction of 2D color-coded flow patterns superimposed on real-time gray-scale images of the heart. Manipulation of the transducer allows interrogation of various cardiac chambers, orifices, and outflow tracts. The presence of the color flow patterns facilitates identification of cardiac anatomy, particularly of those components that often are not amenable to ready recognition by 2D echocardiographic imaging. This method, however, has limitations for fetal application, some of which have been briefly discussed above. An additional problem may arise from the relatively high-velocity fetal cardiac wall movement, which results in color artifacts of "ghosting". This problem can be eliminated by increasing the high-pass filter, but this step also eliminates low-velocity flow components. The problem is compounded if the fetal position is such that the fetal heart is oriented perpendicular to the beam axis. In this situation, because of the high angle, Doppler frequency shifts are significantly attenuated. In contrast, the ventricular wall movement is in the beam axis, thus enhancing ghosting. Finally, color flow depiction in high-velocity flow areas such as the ductus arteriosus, aortic root, or pulmonary root frequently demonstrates velocity ambiguity or the Nyquist effect, so color directionality of the flow is depicted as reversed.

## Spectral and Color Doppler M-Mode Echocardiography

The designation M-mode represents motion mode, or time-motion mode, as it displays unidimensional moving images of tissues and organs. A single line of ultrasound is transmitted, and the echoes returning from the tissue reflectors along the line of transmission are displayed in the intensity modulation mode. If the display is now swept across, the motion changes in the image are displayed or recorded as a function of time (Fig. 32.16, see color insert). It is customary to display and record M-mode images with the vertical axis representing the tissue depth from the transducer and the horizontal axis representing the time. Usually the former is marked at 1-cm intervals and the latter at 0.5-s intervals. Both spectral and color Doppler sonography can be used in conjunction with M-mode sonography. For fetal applications it is obvious that duplex mode sonography must be used so the M-mode cursor can be precisely aligned with the target. Such a combined approach can offer substantial benefit when identifying abnormal hemodynamics with high temporal accuracy. Maulik et al. [10] demonstrated the utility of using spectral pulsed-wave Doppler sonography with M-mode sonography when they reported fetal tricuspid regurgitation. With the Doppler color M-mode

**Fig. 32.16.** Color M-mode echocardiogram of the fetal heart. *Top:* Color Doppler image of the apical four-chamber view with the M-line cursor passing through the right ventricle (RV) and right atrium (RA). LV left ventricle, RV right ventricle. *Bottom:* color M-mode tracing. The atrioventricular flow across the tricuspid orifice is depicted in red. Note the motion of the tricuspid valve. The *down* arrows show the valve leaflets prior to their opening at the beginning of the ventricular diastole. The *up* arrow indicates the moderator band movement

technique, multigated Doppler sampling is performed on a single scan line, which is sampled 1,000 times a second, and the unidimensional tissue and color flow images are scrolled (usually from right to left on the video screen) and therefore displayed as a function of time. Because of the high sampling rate from a single line, the color M-mode technique provides a high Doppler sonographic sensitivity and temporal resolution and allows reliable timing of the flow with the events of the cardiac cycle. For these reasons, color M-mode sonographic technique is useful for fetal echocardiographic examination.

### Tissue Doppler Echocardiography

Tissue Doppler sonography comprises processing and analyzing Doppler frequency shift generated by tissue movement. The physical and technical principles of tissue Doppler imaging of the heart are similar to those of Doppler sonography of blood flow with the exception of the approach to filtering. Doppler insonation of the heart generates signals from cardiac blood flow and myocardial movement. However, the Doppler signals generated by blood flow are of substantially lower amplitude and higher frequency than

those from myocardial movement. In depicting flow, the high-pass filter system eliminates the high-amplitude and low-frequency myocardial Doppler signals so that only flow signals are displayed. In contrast, tissue Doppler echocardiography utilizes filtering that eliminates the low-amplitude high-frequency flow signals permitting tissue Doppler signals being displayed (Fig. 32.17). There are three types of tissue Doppler: pulse-wave tissue Doppler mode, color flow tissue Doppler mode, and color tissue Doppler M-mode.

In the adult, tissue Doppler echocardiography has been used for assessing cardiac systolic and diastolic functions [20–22]. Such assessments can be performed by measuring myocardial velocity, myocardial velocity gradient, myocardial strain, and strain rate. Myocardial strain is its deformation during systole and diastole. Strain implies differential velocities in the cardiac wall and does not reflect overall movement of the heart including its translational motion within the thorax in relation to the other structures. Detailed reviews of these concepts may be found elsewhere [23].

More recently the feasibility of tissue Doppler sonography for fetal cardiac assessment has been reported. Harada and associates measured motion

**Fig. 32.17.** Tissue Doppler velocity waveforms from the right ventricular wall below the parietal insertion of the tricuspid valve. The sampling site is indicated by the *horizontal arrow* pointing to the Doppler sample volume (*two horizontal lines*).

The diastolic and systolic velocity waveforms are indicated on the *lower panel*. *A* indicates arterial systole and *E* indicates end diastole. *RA* right atrium, *LA* left atrium, *MV* mitral valve, *TV* tricuspid valve, *RV* right ventricle, *LV* left ventricle

velocities of the left ventricular posterior wall, right ventricular anterior wall, and interventricular septum along the longitudinal axis in normal fetuses aged 19–38 weeks' gestation and observed gestational age-specific increases in the peak myocardial velocities during early diastole and atrial contraction in the left and the right ventricular walls [24]. The authors speculated that such changes in tissue Doppler velocities may indicate maturational changes in the diastolic function. Tutschek and colleagues performed fetal tissue Doppler echocardiography with a high-resolution ultrasound system by changing the Doppler settings optimized for low-velocity motion assessment and observed increasing longitudinal contraction velocities of the fetal heart with the progression of gestation [25].

The limitations of the technique include angle dependency which may compromise the accuracy of measuring myocardial motion. Moreover, translational movements of the heart within the thorax will also generate Doppler shift. However, this effect can be reduced by restricting the velocity measurements within the cardiac wall rather than in relation to the transducer. Such assessments include determination of myocardial velocity gradient and myocardial strain rate imaging as briefly noted above.

Tissue Doppler echocardiography offers a potentially powerful tool for assessing fetal cardiac function in utero. Future studies will demonstrate to what

extent this potential will be realized for both investigational and clinical use of this technique.

## Doppler Depiction of Fetal Cardiac Circulation

Color flow mapping and directed pulsed-wave spectral Doppler sonography allow characterization of normal and abnormal fetal cardiac flow dynamics,

**Fig. 32.18.** Color Doppler flow mapping of the inferior vena caval (IVC) inflow into the right atrium (RA) and then to the left atrium (LA) through the foramen ovale (arrow)

**Fig. 32.19.** Spectral Doppler interrogation of the inferior vena caval flow. *Right:* Color flow imaging of the inferior vena cava and placement of the Doppler sample volume. *Left:* Inferior vena caval Doppler waveforms. Note the triphasic waveform, two positive peaks (down arrows) and a

negative peak (up arrow), reflecting the events of the cardiac cycle. The first positive peak coincides with ventricular systole and the second positive peak with ventricular diastole. The negative peak is associated with atrial systole

which may assist in the diagnosis of congenital cardiac disease. Doppler examination thus supplements 2D echocardiographic findings. The technique and Doppler flow characteristics of fetal cardiac hemodynamics are described below.

### Atrial Flow

Doppler flow mapping of atrial circulatory dynamics using a color flow duplex system offers an impressive depiction of the atrial flow. The flow from the inferior vena cava into the atria can be clearly visualized (Fig. 32.18). Spectral Doppler waveforms from this vessel exhibit a triphasic flow pattern (Fig. 32.19). Doppler investigation of vena caval hemodynamics is presented in Chap. 27. The superior vena caval flow entering the right atrium can be visualized separately from the inferior vena caval return. These two inflows become confluent in the right atrial chamber. Regarding the left atrial inflow, the pulmonary veins can be investigated using color and spectral Doppler systems. The left pulmonary veins are more readily accessible. Doppler waveforms from the pulmonary veins reflect atrial and ventricular cycles (Fig. 32.20).

Spectral Doppler investigation of fetal atrial hemodynamics may be conducted in apical and lateral four-chamber and other views. Such interrogation demonstrates complex flow patterns (Fig. 32.21) consistent with multiple inflows in the atria, two outflows of the right atrium, and a single outflow of the left at-

**Fig. 32.20.** Doppler interrogation of pulmonary venous return. *Top:* Lateral four-chamber view of the fetal heart, with the Doppler sample volume placed at the upper left pulmonary vein. *Bottom:* Pulmonary venous Doppler waveforms. The trough coincides with atrial systole

rium. A higher Doppler frequency shift is observed in the right atrium than in the left atrium. This description of the Doppler flow characteristics of the atria further elucidates the previously reported observations in previable human fetuses using acute radioangiographic studies [26] and in fetal sheep [27].

**Fig. 32.21 a, b.** Doppler waveforms from the atria. *a Top panel* shows interrogation of the right atrium. *Bottom panel* shows the complex pattern of the right atrial Doppler waves.

*b Top panel* shows the complex interrogation of the left atrium. *Bottom panel* shows the complex pattern of the left atrial Doppler waves. *RA* right atrium, *LA* left atrium

**Fig. 32.22.** Doppler insonation of the foramen ovale flow. *Top:* Placement of the Doppler sample volume at the foramen ovale. *RA* right atrium, *LA* left atrium. *Bottom:* Interatrial Doppler waves. *FO* foramen ovale, *a* ventricular peak systole, *b* ventricular end-systole, *c* atrial passive filling, *d* atrial systole

### Interatrial Flow

The foramen ovale valve movement is associated with changes in the Doppler frequency shift in the left atrium; a higher frequency shift is observed when the valve is open than when it is closed [5]. Flow across the foramen ovale is optimally investigated with the lateral four-chamber view or a short-axis view, which allows angle-appropriate alignment of the Doppler cursor with flow direction across the foramen. Spectral Doppler investigation of the flow across the foramen shows a biphasic flow velocity pattern (Fig. 32.22). Ventricular systole is associated with a sharp rise in the frequency shift, reaching a peak coinciding with peak systole, following which the shift decelerates to a nadir at end-systole. With passive atrial filling the shift rises again, reaching a second peak that is lower than the first peak. This phase is followed by a rapid decline that coincides with atrial systole. These changes are influenced by the fetal behavioral state. The ventricular end-systolic and atrial passive filling phases demonstrate a significantly higher-frequency shift when the fetus actively sleeps (state 2F) than when it sleeps quietly (state 1F). It is reflective of flow redistribution and increased right-to-left shunt during active sleep.

### Tricuspid and Mitral Flow

The color Doppler flow technique vividly portrays the flow patterns across the atrioventricular flow channels (Fig. 32.23). Color imaging may facilitate acquisition of the Doppler signals from the various areas of the atrioventricular flow jets.

**Fig. 32.23.** Color Doppler echocardiogram of the mitral and tricuspid flow. The fetal heart is viewed in the apical (oblique) four-chamber plane. As flow is directed toward the transducer, it is coded in red. *RA* right ventricle, *LV* left ventricle, *IVS* interventricular septum, *RA* right atrium, *LA* left atrium, *IAS* interatrial septum, *SP* fetal spine

Spectral Doppler insonation demonstrates a biphasic flow pattern across the tricuspid and mitral orifices, reflecting the contributions of ventricular relaxation and atrial contractions to the atrioventricular flow. The peak flow velocity due to contraction of the atrium (A wave) is significantly greater than the peak flow velocity caused by ventricular diastole (E wave) (Fig. 32.24A). However, in the left heart, the A wave is less than, equal to, or only marginally greater than the E wave (Fig. 32.24B). These findings suggest a physiologically lower compliance of the right ventricle than of the left ventricle and are similar to the pulsed-wave Doppler echocardiographic observations in neonates and infants.

Takahashi et al. [14] investigated mitral and tricuspid flows using pulsed-wave Doppler sonography in 23 fetuses of 30–38 weeks gestational age. They noted that the peak velocity across the mitral orifice was  $52.1 \pm 9.9$  cm/s (mean  $\pm$  SD) and that across the tricuspid orifice was  $56.1 \pm 8.7$  cm/s. They also reported that the velocity patterns of the right ventricle and left ventricle inflow demonstrated two peaks consistent with the rapid filling phase and the atrial contraction phase, and the peak velocity of the atrial contraction phase was slightly greater than that of the rapid filling phase. Kenny et al. [28] investigated E and A waves comprehensively in 80 normal human fetuses at 19–40 weeks' gestation. They identified clearly defined E and A waves from the tricuspid orifice in 48% of the fetuses and from the mitral orifice in 60%. The ratio for both atrioventricular orifices increased during gestation.

These gestational age-related changes in the atrioventricular flow velocities were confirmed by Reed et

**Fig. 32.24 a, b.** Doppler interrogation of the tricuspid and mitral flow. **a** Top panel presents the Doppler echocardiogram in the apical four-chamber plane. Note the location of the Doppler sample volume in the right ventricular chamber just distal to the tricuspid orifice. Bottom panel presents the biphasic tricuspid Doppler waveforms. E peak velocity related to forward flow during the ventricular diastole, A peak velocity related to forward flow during the atrial systole. **b** Doppler interrogation of the mitral flow. Top panel shows the Doppler echogram of the fetal heart in the apical four-chamber plane. Note the location of the Doppler sample volume in the left ventricular chamber just distal to the mitral orifice. Bottom panel presents the biphasic mitral Doppler waveforms. E peak velocity related to forward flow during the ventricular diastole, A peak velocity related to forward flow during atrial systole

al. [19] and Rizzo et al. [29]. The latter group prospectively studied 125 normally grown fetuses and 35 small-for-gestational-age (SGA) fetuses longitudinally at 27–42 weeks' gestation. In normal fetuses the ratio between the E velocity (early passive ventricular fill-

ing) and the A velocity (active ventricular filling during atrial contraction) increased progressively and significantly ( $p < 0.01$ ) during pregnancy in both transmitral and transtricuspid waveforms, approaching 1.0 at term. These changes suggest progressive structural and functional maturation of the ventricles resulting in age-related increases in myocardial compliance. Romero et al. [30] studied the pressure-volume relation in fetal, neonatal, and adult hearts and demonstrated low compliance of the fetal heart. These changes may also be related to the known fetal hemodynamic changes with the progression of gestation, including the significant fall in fetoplacental vascular impedance [30].

**Fig. 32.25. a** Right ventricular outflow tract is shown in the aortic short axis plane of the fetal heart. Note aliasing in the outflow tracts. **b** Left ventricular outflow is shown in the oblique long axis view of the fetal heart. The lighter color at the beginning of the aorta is indicative of higher velocity. The arrows depict flow direction. AO aorta, IVS interventricular septum, DA ductus arteriosus, LV left ventricle, RV right ventricle, LVOT left ventricular outflow tract, MV mitral valve, PA pulmonary artery, RPA right pulmonary artery, SP fetal spine

## Pulmonary and Aortic Outflows

The right and left ventricular outflow can be imaged in the ventricular long-axis plane (Fig. 32.25). This plane allows clear assessment of the aortic-pulmonary cross-over relation (Fig. 32.26). Color flow imaging facilitates recognition of this important normal characteristic of the heart. The main pulmonary arterial flow can be conveniently seen in the parasternal short-axis plane at the base of the heart, which demonstrates the aortic cross section surrounded by the right atrium, right ventricle and pulmonary trunk, and right pulmonary

**Fig. 32.26.** Color Doppler imaging of the cross over relation between the origins of the great arteries. SP fetal spine, LV left ventricle, RV right ventricle, IVS interventricular septum, RVOT right ventricular outflow, LVOT left ventricular outflow

**Fig. 32.27.** Color Doppler echocardiogram of the aortic arch. Note the tighter curve of the arch and the change in the color depiction of flow, reflecting the changes in the flow direction in relation to the transducer. The curved arrow indicates flow direction at the root of the aorta. Vertical arrow indicates root of aorta. AA aortic arch, LV left ventricle, DTA descending thoracic aorta

**Fig. 32.28.** Color Doppler echocardiogram of the ductal arch. Note the wider curve of the arch and color aliasing at the ductal level. DA ductus arteriosus, PA pulmonary artery, RV right ventricle, S fetal spine

artery. The orientation of the main pulmonary artery in this plane often facilitates alignment of the Doppler beam along the pulmonary blood flow axis, ensuring an optimal angle of insonation. Aortic and pulmonary arterial hemodynamics can also be readily investigated in the aortic arch (Fig. 32.27) and ductal arch (Fig. 32.28) planes, respectively. Doppler frequency shift waveforms from the main pulmonary artery are characterized by rapidly accelerating and decelerating slopes, with sharp peaks during right ventricular systole (Fig. 32.29). In comparison with the maximal aortic velocity wave, however, the immediate postpeak deceleration slope is less acute in the pulmonary waveform. The peak velocity values from the pulmonary artery and the aorta, measured longitudinally in 27 normal pregnancies from 18 weeks to term, are presented in Table 32.4 (D. Maulik and P. Ciston, unpublished data).

In a longitudinal study, Rizzo et al. [31] showed significant increases in the pulmonic peak velocity ( $p \leq 0.001$ ) and in the aortic peak velocity ( $p \leq 0.05$ ) during early pregnancy between the end of the first trimester (11–13 weeks) and midgestation (20 weeks). Hata et al. [32] performed a cross-sectional investigation of 54 normal fetuses at 16–40 weeks of pregnancy and noted increases in transpulmonic peak velocity ( $r = 0.39$ ,  $p < 0.05$ ) and transaortic peak velocity ( $r = 0.61$ ,  $p < 0.001$ ) throughout the gestation. The transpulmonary peak velocity/transaortic peak velocity ratio was 1:1 in 45% of the instances. In contrast, Reed et al. [33], in a cross-sectional study of 87 fetuses at 17–41 weeks' gestation, did not note any changes in the peak aortic velocity with advancing gestational age ( $p < 0.001$ ). Moreover, peak Doppler flow velocities were greater in the aorta than in the pulmonary artery ( $p < 0.001$ ).

Imaging by Doppler color flow mapping in the main pulmonary artery produces a graphic depiction

**Fig. 32.29.** Spectral Doppler waveforms from the pulmonary artery (a) and aorta (b). Both waves show rapid accelerations. The deceleration slope of the pulmonary artery, however, is slightly less steep than that of the aorta

**Table 32.4.** Peak velocity in fetal pulmonary artery and aorta

Site	Peak velocity (cm/s) at three gestational ages (mean ± SD)		
	18–23 weeks	24–31 weeks	32–40 weeks
Pulmonary artery	51 ± 7	59 ± 9	61 ± 11
Aorta	55 ± 10	63 ± 12	73 ± 11

of the pulmonic flow entering the descending thoracic aorta via the ductus arteriosus (Fig. 32.15). With color Doppler imaging the flow in the ductus arteriosus often appears to be of higher intensity because of the greater velocity of ductal flow. In our experience, color Doppler sonography assists in quickly identifying the ductus and confidently aligning the Doppler beam along the direction of pulmonary flow.

**Fig. 32.30.** Doppler depiction of the fetal cardiac circulation during the early first trimester. *Top:* Embryo and flow of the primitive heart. *Bottom:* Simultaneous interrogation of the atrioventricular flow and ventricular outflow

### Doppler Echocardiography During Early Pregnancy

Although it has been customary to initiate fetal echocardiography at 16–20 weeks’ gestation, advances in imaging resolution and color Doppler sonography and the introduction of transvaginal sonography have made it possible to image cardiac hemodynamics in the embryonic heart during the first trimester. These developments have raised the possibility of early echocardiographic diagnosis in certain cases of congenital heart disease. Figure 32.30 shows the spectral Doppler interrogation of the embryonic heart and the atrioventricular and great arterial Doppler waveform. Preliminary experience has demonstrated that transvaginal echocardiography is feasible [34]. This approach may prove useful in the future.

### Determination of Fetal Cardiac Output

The theoretic basis, technical implementation, and limitations of Doppler sonographic flow quantification are discussed in Chap. 4. The methodology for fetal cardiac output measurement was first described by Maulik et al. [5]. Briefly, the stroke volume is determined by integrating the temporal average velocity (also known as the time-velocity integral) across the valvular orifice or vascular lumen with the cross-sectional area of the vascular tract. The cardiac output is obtained by multiplying the stroke volume by the fetal heart rate. The combined cardiac output is the sum of the right and left cardiac outputs. The various measures of the fetal cardiac output are presented in

**Table 32.5.** Measures of fetal cardiac output

Stroke volume (ml) = temporal mean velocity (cm/s) × cross-sectional area (cm <sup>2</sup> )
Cardiac or ventricular output (ml/min) = stroke volume (ml) × fetal heart rate (bpm)
Left cardiac output = cardiac output measured at the aortic or mitral orifice
Right cardiac output = cardiac output measured at the pulmonic or tricuspid orifice
Combined cardiac output (ml/min) = sum of the right and left cardiac outputs

Table 32.5. In the fetus the right and the left sides of the heart work in parallel. Therefore fetal cardiac output must be determined separately for each side. The measurements may be performed either at the root of the great vessels [5, 29, 35, 36] or across the atrioventricular orifices [31, 38]. The right heart output may be measured either across the tricuspid orifice or at the root of the main pulmonary artery just distal to the pulmonary semilunar valves (Fig. 32.31). Similarly, the left cardiac output may be measured across the mitral orifice or at the root of the aorta immediately distal to the aortic semilunar valves. The precision of the technique in terms of reproducibility depends on the site of measurement, the parameters measured, the imagability of the patient in a given instance, and operator skill. In our experience, the roots of the great vessels provide a more reliable measure than the atrioventricular channels. Groenenberg et al. [38] investigated this question and noted high reproducibility of peak systolic velocity and average velocity measured in the ductus arteriosus, pulmonary artery, and ascending aorta. The coefficients of variation between tests within individual patients were less than or equal to 7%.

### Cardiac Output: Normative Data

Maulik et al. [5], in a preliminary report, noted a right ventricular output range of 148 ml/min in a 28-week fetus to 451 ml/min in a near-term fetus. Reed et al. [37] observed a tricuspid flow rate of  $307 \pm 30 \text{ ml} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$  and a mitral flow rate of  $232 \pm 25 \text{ ml} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$  in fetuses of 26–30 weeks gestational age. In a comprehensive longitudinal study, De Smedt and coworkers [39] performed echocardiographic examinations on 28 normal fetuses at 4-week intervals from 15–18 weeks to term. The fetal cardiac output was measured from the tricuspid and mitral orifices. They observed that with advancing gestation the mean temporal blood flow velocities increased linearly, whereas the area of blood flow and calcu-

**Fig. 32.31.** Doppler characterization of pulmonary artery (PA) flow and measurement of right ventricular stroke volume in a normal fetus. *Top:* Doppler sample volume, indicated by a short transverse bar (*oblique arrow*), was placed along an M-line cursor in the midlumen of the PA imaged by two-dimensional echocardiography. Maximal inner PA diameter (*d*) (*horizontal arrows*) at the level of the Doppler sample volume measured 0.9 cm. The cross-sectional area at this level was calculated as  $0.636 \text{ cm}^2$  ( $3.14 d^2/4$ ). *PV* pulmonary valve. *Bottom:* Doppler frequency shifts (*D*) obtained from the PA. Deflection above the baseline (*B*) represents flow toward the transducer and that below the baseline denotes flow away from the transducer. As would be expected, the predominant flow is directed away from the transducer toward the distal PA and is characterized by sharp peaks with rapidly accelerating and decelerating slopes. The maximal area under the flow curve for one cardiac cycle was measured in kilohertz-seconds (vertical distance between the two horizontal arrows =  $0.5 \text{ kHz}$ ) and was converted to the maximum velocity curve area ( $\text{s} \cdot \text{cm}/\text{s} \cdot \text{kHz}$ ) (*A*) using the instrument calibration factor  $K = 25.667 \text{ cm}/\text{s} \cdot \text{kHz}$ . Multiplying *A* by the PA cross-sectional area gave a stroke volume of 3.76 ml. Cardiac output was then calculated by multiplying the stroke volume by the fetal heart rate. The *vertical lines* represent 1-s time markers. *M* M-mode tracing, *E* maternal electrocardiogram

lated right and left ventricular output increased exponentially. The combined ventricular output at term was noted to be 1,735 ml/min and  $553 \pm 153 \text{ ml} \cdot \text{kg}^{-1} \cdot \text{min}^{-1}$  when corrected for sonographically estimated fetal weight.

## Right Heart Versus Left Heart Dominance

It has been shown in the ovine fetal model that right ventricular output is twice that of the left [40]. Maulik et al. [5] noted evidence of human fetal right ventricular dominance in a preliminary report. Subsequently, De Smedt et al. [39] demonstrated in a comprehensive longitudinal study that the right ventricular output was significantly higher than that of the left ventricle, and the right/left ventricular output ratio decreased from  $1.34 \pm 0.28$  (standard deviation) at 15 weeks to  $1.08 \pm 0.28$  at 40 weeks.

## Limitations of Cardiac Output Measurement

As discussed in Chap. 4, the Doppler approach for volume flow measurement is based on a few assumptions, such as the velocity profile of the flow and the uniformity of insonation, which may compromise the reliability of the measurement. Furthermore, the results are subject to significant error also because of the inherent imprecision when measuring vascular diameter and the angle of insonation. Of these measurements, the former is the more significant source of imprecision in the cardiac output measurement. Of the two sites for such measurements, the atrioventricular (mitral and tricuspid) orifices may be more difficult to measure in a consistent manner. Nevertheless, some investigators prefer these sites instead of the roots of the great vessels. The problems contributing to imprecision are compounded because of the deep location, small size, and unfavorable orientation of the fetal heart. For these reasons absolute volumetric flow determination in the fetal heart has been of little practical value for clinical application, although it has been a valuable research tool for extending our knowledge of the physiology and pathology of fetal cardiac function.

## Summary

The introduction and the continuing advances in fetal Doppler echocardiography have enhanced our understanding of the hemodynamic function of the fetal heart and extended our knowledge of the aberrations of this function in various cardiac disorders. The latter include congenital cardiac malformations, cardiac rhythm disturbances, and fetal heart failure. Many of these conditions in the context of Doppler sonography are discussed elsewhere in this text. It is apparent that the addition of the Doppler modality significantly enhances the diagnostic information that can be obtained from sonographic imaging of the fetal heart, and color and spectral Doppler echocardiography has now become an essential component of the fetal cardiac examination. In order to ensure the reliability of the technique it is

imperative, however, that one should be thoroughly familiar with the instrumentation and rigorously trained in its application. When used appropriately, Doppler echocardiography remains a unique and powerful tool for fetal assessment in health and disease.

# Doppler Echocardiography for Managing Congenital Cardiac Disease

Dev Maulik

## Introduction

Fetal cardiac development is regulated by various genetic and environmental influences. Aberrations in these developmental mechanisms result in structural and functional abnormalities of the fetal heart. There has been a greater recognition of the need for antepartum diagnosis of these disorders in recent years. Perinatal diagnosis and management of congenital cardiac disease in conjunction with advances in pediatric cardiac surgery has led to remarkable improvements in the outcome in these infants. An essential component of this approach is the reliable prenatal diagnosis, which permits planning and implementation of appropriate perinatal management. Although high-resolution two-dimensional (2D) dynamic imaging remains the foundation of fetal echocardiographic assessment, the Doppler modality constitutes an essential component of this process by providing hemodynamic insight into the morphologic and functional aberrations of the fetal heart. With the advent of real-time three-dimensional (3D) echocardiography, there are exciting possibilities for prenatal cardiac assessment including Doppler echocardiography.

In the previous chapter, we reviewed the scope and technique of Doppler echocardiography and normative information on fetal cardiac hemodynamics, while the next chapter, which is a new addition to this edition, deals with real-time 3D echocardiography of the human fetus. In this chapter, we review the risk factors for congenital cardiac disease, the common indications for fetal cardiac evaluation, and the application of Doppler echocardiography in managing malformations and dysrhythmias of the fetal heart.

## Risk Factors and Indications for Fetal Cardiac Evaluation

Congenital cardiac disease, as diagnosed clinically, has a prevalence of approximately 8 cases per 1,000 live births [1]. The rate of critical cardiac malformations requiring early therapeutic and surgical inter-

vention has been reported to be 3.5 per 1,000 live births [2]. The risk of cardiac malformations is increased in many conditions (Table 33.1). When these risk factors are present, prenatal counseling and diag-

### Familial

History of congenital cardiac disease  
Genetic syndromes (Mendelian)  
Noonan  
Tuberous sclerosis  
Marfan  
Holt-Oran  
TAR (thrombocytopenia with absent radii)

### Maternal

Congenital heart disease  
Teratogenic exposure  
Anticonvulsants – phenytoin, trimethadione, valproic acid  
Lithium  
Amphetamines  
Retinoic acid  
Alcohol  
Nonteratogenic exposure  
Indomethacin  
Maternal infection  
Viral – rubella, cytomegalovirus, coxsackievirus, mumps  
Parasitic – toxoplasmosis  
Metabolic disease  
Diabetes mellitus  
Phenylketonuria  
Autoimmune disease  
Obstetrical  
Polyhydramnios

### Fetal

Suspicion of cardiac malformation in basic fetal scan  
Abnormal fetal cardiac rhythm  
Extracardiac malformation  
Increased nuchal translucency  
Chromosomal disorders  
Down's syndrome  
Trisomy 13, 18  
Turner's syndrome  
Genetic syndromes  
Fetal growth restriction  
Nonimmune hydrops  
Situs inversus and ambiguous

**Table 33.2.** Approximate risk of cardiac anomalies for selected high risk conditions

Anomaly	Risk (%)
Isolated cardiac anomalies (multifactorial)	
Overall	3–5
Mother	10
Father	3–5
Sibling	3
Left heart anomalies	10–15
Environmental	
Maternal rubella infection	35
Pregestational diabetes	3–5
Phenylketonuria (phenylalanine > 16 mg/dl)	18
Alcohol consumption	25–30
Trimethadone	15–30
Retinoic acid	4

Overall	25
Marfan syndrome	60–80
Holt-Oram syndrome	100
Chromosomal	
Overall	25
Trisomy 21	50
Trisomy 18	100

Data are derived from the literature.

nostic procedures should be offered to the mother. Recently, increased nuchal translucency at 10–14 weeks of gestation in chromosomally normal fetuses has emerged as an indication because of its association with cardiac malformations. The extent of this association varies between 7% and 9% [3, 4]. Controversy, however, exists on whether polymorphisms of 5,10-methylenetetrahydrofolate reductase (MTHFR) lead to a higher risk of congenital cardiac defect [5, 6], and it therefore remains uncertain whether this abnormality should indicate fetal cardiac evaluation. Although a precise measure of the increased risk is not available for all the conditions listed in Table 33.1, a summary of risk quantification for selected conditions is presented in Table 33.2. Such information should be an essential part of informed counseling of patients. More detailed information may be obtained from the standard texts on pediatric cardiology. Fetal echocardiography is indicated whenever a higher probability of fetal cardiac malformation exists. It is also indicated for the precise diagnosis and follow-up of fetal cardiac arrhythmias and fetal heart failure. Furthermore, a suspicious fetal cardiac image during general obstetrical ultrasonography mandates more focused assessment. In many centers, a non-reassuring fetal cardiac image is the most common reason for echocardiographic referral. Frequency of these indications varies from center to center. Common indications for fetal echocardiography are listed in Table 33.3.

**Table 33.3.** Indications for fetal echocardiographic assessment

■ Non-reassuring fetal cardiac image during obstetrical sonography
■ Extracardiac malformations
■ Fetal cardiac arrhythmia
■ Increased nuchal translucency
■ Insulin-dependent diabetes mellitus in pregnancy
■ History of congenital cardiac disease
■ Teratogenic exposure
■ Maternal viral infection
■ Nonimmune hydrops
■ Nonlethal aneuploidy

## Benefits of Fetal Echocardiographic Assessment

Fetal echocardiographic examination allows prenatal diagnosis of congenital heart disease so that appropriate perinatal management can be planned and implemented. An accurate diagnosis of the cardiac lesion will obviously lead to more reliable prognostication and informed management choices. The process involves participation by a multidisciplinary perinatal cardiology team which should include primary obstetricians, maternal-fetal medicine specialists, neonatologists, pediatric cardiologists, cardiac surgeons, and other relevant support personnel. In addition, the parents must be an integral part of this process so that they are appropriately counseled regarding the fetal condition and prognosis, and are able to participate in the decision-making process. In early gestation, severe cardiac anomalies with poor prognosis may prompt the parents to opt for a termination of pregnancy. If this is not an option, a multidisciplinary medical team can develop optimal plans for surveillance, delivery, and perinatal intervention. Table 33.4 summarizes the prognostic factors for survival. Depending on the complexity of the fetal cardiac problem, the site for delivery and neonatal management can be carefully selected. This is particularly important as not all medical centers may have adequate medical or surgical resources to deal effectively with the complexities of congenital heart disease. In this context, one should also note that recent progress in surgical management of certain malformations has improved the chances of survival in cases previously considered hopeless [7]. The reported mortality rate following pediatric cardiac surgery in one of the prominent centers is given in Table 33.5. As noted during the 32nd Bethesda Conference, “Care Of The Adult With Congenital Heart Disease”, the survival rate has continued to improve over the last few decades and the estimated cumulative survivors of con-

**Table 33.4.** Survival after surgery in the presence of congenital heart disease: Boston Children's Hospital

Anomaly	Time of surgery	Early mortality %	Late mortality %
AV canal defect	1976–1987	2.9

genital heart disease to the year 2000 in the United States approached almost 800,000 [8]. An additional emerging benefit of prenatal diagnosis of congenital heart disease may be the potential for in utero intervention for congenital structural cardiac disease, which has been investigated in animal models [9, 10]. Preliminary anecdotal accounts of human fetal cardiac interventions have been reported in the medical press [11]. Although they are still experimental approaches at present, future advances may transform these approaches into clinical realities. Obviously fetal echocardiography including Doppler sonography will continue to play a critical role in any such development. This is further discussed below.

## Utility of Fetal Doppler Echocardiographic Assessment

The importance of Doppler echocardiography lies in the fact that it allows noninvasive assessment of cardiovascular hemodynamic function. Both modalities of Doppler ultrasound offer significant advantages in supplementing the diagnostic information obtained from the 2D echocardiography. However, the operators should be appropriately trained to use the device optimally. The advantages and disadvantages of Doppler echocardiography are summarized in Table 33.6.

**Table 33.6.** Advantages and disadvantages of spectral and color Doppler echocardiography

Advantages
Corroborates anatomic diagnosis
Defines normal and abnormal cardiac hemodynamics
Provides functional definition of a cardiac lesion
Elucidates complex malformations
Potentially reduces imaging time
Disadvantages
More expensive instrumentation although increasingly less expensive
Requires personnel with advanced skills

Spectral Doppler insonation, used in conjunction with the other ultrasound modalities, allows the measurement of peak or mean velocity, which may be utilized to define the normal and the abnormal blood flow characteristics. Almost two decades ago, the diagnostic potential of duplex spectral pulsed Doppler and color Doppler echocardiography was demonstrated in recognizing fetal cardiac abnormalities such as pulmonary arterial aneurysm and tricuspid regurgitation [12, 13]. As reviewed in this chapter, numerous extensive investigations subsequently confirmed the utility of these approaches. Chiba and associates [14] noted the usefulness of color flow mapping for identifying congenital cardiac malformations in 107 high-risk mothers, about a third of whom had cardiac disease. Fetal cardiac malformations were present in 19 cases and included complex disorders. Coppel and associates [15] used color Doppler in 45 of 48 fetuses with cardiac anomalies and noted that color flow mapping was essential for making correct anatomical diagnoses in almost a third of the cases. Over time, the technique has proved useful in defining structural, functional, and hemodynamic anomalies of the fetal heart. Color Doppler facilitates the recognition of anomalies, especially when they are not clearly defined in 2D imaging, and may reduce the examination time. Furthermore, spectral and color Doppler modes are essential for identifying abnormal flow patterns associated with valvular incompetence or stenotic lesions of the vascular channels.

## In Utero Evolution of Cardiac Malformations

Experience with fetal echocardiographic examination over the years has revealed the dynamics of in utero evolution of fetal cardiac disease [16]. In addition to the structural defects, functional changes in the fetal heart can also be observed secondary to various disorders including viral infection and rhythm disturbances. Allan and associates were one of the first groups [17] to

report in utero worsening of cardiac anomalies; they observed discrete coarctation with a normal aortic arch noted first at 21 weeks deteriorating to a markedly hypoplastic aortic arch by 34 weeks. Subsequently, a multiplicity of reports appeared. These include (a) development or progression of pulmonary stenosis in the fetus with advancing gestation [18–21]; (b) development of dilated cardiomyopathy later in pregnancy when no abnormalities were observed at 20 weeks [22]; (c) development of left heart hypoplasia syndrome despite normal echocardiographic scan in early pregnancy [23–25]; (d) intrauterine closure of foramen ovale [26]; and (e) development of right ventricular hypoplasia [27]. In contrast to deterioration, there are infrequent reports of improvement of cardiac lesions in utero; these include: (a) improvement of left heart hypoplasia because of progressive growth of the left heart during gestation [21]; and (b) in utero closure of ventricular septal defect [28]. There are important practical implications of these observations. It is apparent that cardiac assessment performed at midpregnancy may not ensure the absence of cardiac malformation later in pregnancy or at birth. In a pregnancy at a higher risk of cardiac malformation, it may be prudent to repeat the examination at mid third trimester. However, the cost-effectiveness of a policy of cardiac scanning twice during pregnancy in all cases referred for fetal echocardiographic assessment remains undetermined.

## Doppler Characterization of Congenital Cardiac Malformations

Doppler echocardiographic examination constitutes a component of the overall assessment of the fetal heart. This integrated approach is described in Chap. 32. Doppler ultrasonography provides a range of hemodynamic information (see Chap. 4) that should be interpreted in terms of normal and abnormal cardiac function and anatomy. An understanding of the morphologic correlates of abnormal cardiac Doppler flow patterns is helpful for diagnosing congenital heart disease. These correlates are discussed below and summarized in Table 33.7.

1. *Absence of flow in expected locations.* As discussed in Chap. 4, some of the primary hemodynamic information offered by Doppler insonation regards the presence or absence of flow. The reliability of this function depends on the instrumental characteristics and setting and on the circumstances of the examination. For example, the transducer frequency, gain setting, and angle of insonation affect the ability of the operator to identify and reliably conclude that there is or is not flow. Thus one may spuriously fail to note flow even when it exists because of an unfavorable angle or low gain. Similarly, low-flow states may not

**Table 33.7.** Anatomic correlates of Doppler hemodynamic information

Hemodynamic information	Anatomic correlates
Presence of normal flow in expected location	Corroborative of normal anatomic image
Presence of flow in an unexpected location	Anatomic lesions: septal defects, aneurysms
Absence of flow in an expected location	Nonfunctioning chamber; hypoplasia; severe vascular stenosis
Abnormally high-velocity flow	Stenotic lesion, functional constriction
Abnormal flow direction	Regurgitant flow – valvular incompetence; redirected flow in vascular lesion

**Fig. 33.1.** Doppler color flow mapping of left ventricular dilation preceding hypoplastic change. *LV* left ventricle, *RV* right ventricle. Color Doppler shows flow in *RV* extending to the ventricular apex. In contrast, flow could not be demonstrated in most of the *LV* chamber, which shows marked dilation and poor contractility. This condition developed into left ventricular hypoplasia

be identified unless the device is optimized for such function. Assuming that these factors have been taken into consideration, color and spectral Doppler demonstration of the absence of flow in an expected location is helpful for diagnosing an existing or evolving cardiac problem. The most remarkable example is the absence of flow in one of the ventricles, which in conjunction with the observation (by 2D imaging) of the absence of an echo-lucent space in the ventricle is diagnostic of left or right ventricular hypoplasia (see below). We have also seen examples of progressive ventricular developmental failure starting as a dilated ventricular chamber with no discernible flow culminating in left ventricular hypoplasia (Fig. 33.1). There are other instances where Doppler depiction of the absence of flow is suggestive of structural anomalies

**Fig. 33.2.** Fetal Doppler echocardiographic examination of tetralogy of Fallot and aneurysmal dilatation of the main pulmonary artery. The large echo-free space present on the left of the aorta on real-time two-dimensional examination (*left*) was demonstrated by pulsed Doppler to be vascular in nature, as pulsatile flow similar to that obtained in the pulmonary artery could be demonstrated within it

(*right*). This Doppler finding helped to make a confident diagnosis of aneurysmal dilatation of the main pulmonary artery. *Arrow* indicates the location of the Doppler sample volume. *A* aorta, *B* Doppler baseline, *F* Doppler waveforms, *L* left branch of the pulmonary artery, *RV* right ventricle. (Reprinted from [12] with permission)

of the heart. Thus the diagnosis of tricuspid atresia may be facilitated by color Doppler insonation demonstrating no recognizable flow across the tricuspid orifice [13].

2. *Presence of flow in unexpected locations.* Visualizing flow in an expected or an unexpected vascular location may significantly enhance our ability to identify and define congenital cardiac lesions. Identifying the presence of flow in an expected location may be helpful for establishing structural integrity when the imaging appearance is uncertain. The color or spectral Doppler recognition of flow in an unexpected location may, on the other hand, assist in diagnosing a malformation. For example, the demonstration of spectral Doppler flow patterns in a large echo-lucent area adjacent to the aorta helped us to make the prenatal diagnosis of pulmonary arterial aneurysm [2] (Fig. 33.2). Similarly, demonstration of a flow jet across the interventricular septum indicates a septal defect. It should be noted, however, that large defects may be recognizable by imaging alone without the added benefit of color Doppler flow depiction, whereas small defects may not be recognizable even by color flow mapping unless there is a demonstrable flow jet through the septal defect. As the right and left ventricular intracavitary pressures are approximately equal in the fetus, there is no flow across the defect unless there are additional malformations, such as outflow tract stenosis altering the interventricular pressure equilibrium. The presence of a flow jet across a ventricular septal defect (VSD) therefore should alert the observer about the existence of ad-

ditional cardiac lesions. Although atrial septal defects (ASDs) are more difficult to recognize in the fetus, large defects are easily identifiable by the clear demonstration of confluence of flow between the two atria without a visible intervening septal structure (see below).

3. *Abnormal flow direction.* Spectral Doppler depiction of directionality of flow offers a unique opportunity to detect abnormal cardiac hemodynamics. Demonstration of aberrant flow patterns, such as regurgitant flow across a valvular orifice or abnormal flow direction in a vessel, significantly enhances our ability to define fetal cardiac lesions (Fig. 33.3). Atrioventricular regurgitant flow has been identified using spectral and color Doppler [2, 7, 27]. Isolated semilunar valve incompetence of the pulmonary trunk or the aorta is rare and is often difficult to detect, even when present in association with other cardiac anomalies.

Doppler echocardiography can significantly assist in assessing the severity of valvular incompetence. Several approaches have been described in relation to pediatric and adult echocardiographic applications. They include assessment of: (1) the duration of the regurgitant flow in relation to the cardiac cycle; (2) the magnitude of the length of the regurgitant jet into the atrial cavity as measured by pulsed-wave Doppler interrogation; and (3) measurement of the regurgitant jet as a proportion of the area of the atrial cavity.

If the regurgitant flow is minimal and occupies only a fraction of the total duration of the cardiac cycle, it may be considered relatively benign in the absence of associated cardiac anomalies. Pansystolic

**Fig. 33.3.** Spectral Doppler depiction of severe tricuspid regurgitation in a case of Ebstein's anomaly. *Top:* Doppler echocardiogram shows placement of the Doppler sample volume in the regurgitant jet in the dilated right atrial chamber immediately proximal to the tricuspid valve. *Bottom:* Spectral Doppler waveforms showing regurgitant jet projecting downward from the baseline

leakage, on the other hand, signifies severe incompetence. The length of jet backflowing into the atrial cavity has been used as an indicator of the severity of the atrioventricular valvular incompetence. This technique, however, is not reliable, as the pulsed-wave Doppler interrogation may not fully recognize the direction and extent of the regurgitant flow jet in the atrial chamber. Color Doppler flow mapping of the jet area in relation to the atrial area has been shown to correspond well to angiographic grading in adults with cardiac lesions [29, 30].

There is a paucity of reports on the utilization of these techniques in the fetus. Gembruch and colleagues [31] reported on the prenatal diagnosis of 14 cases of atrioventricular (A-V) canal malformation (A-V septal defect) utilizing 2D imaging and color and spectral Doppler sonography. In nine fetuses the A-V regurgitant jet area was compared with the atrial area using planimetry. Hydropic fetuses exhibited a proportionately larger jet area and pansystolic insufficiency. Analysis of the regurgitant jet has also been used to assess ventricular function for fetal prognostication. Tulzer and associates [32] investigated right ventricular function in 20 fetuses with pansystolic tricuspid regurgitation associated with either indomethacin-induced ductal constriction (10 cases) or nonimmune hydrops fetalis (10 cases). They determined right ventricular pressure rise over time ( $dP/dt$ ) from spectral Doppler tracing of the regurgitation jet (Fig. 33.4). Color Doppler-directed continuous-wave Doppler sonography was used. The right ventricular shortening fraction (RVSF), determined by

**Fig. 33.4.** From a tricuspid regurgitation Doppler tracing (TR). The time interval ( $dt$ ) is measured on the TR upstroke between 50 cm/s (correlating to a 1 mmHg gradient between the right ventricle and right atrium) and 150 cm/s (correlating to a 9 mmHg gradient).  $dp$  pressure. (Reprinted from [32], with permission)

M-mode echocardiography, did not correlate with the  $dP/dt$ . It was observed that right ventricular  $dP/dt$  values were consistently lower in the nonimmune hydrops group (Fig. 33.5). Similarly RVSF values were lower in the nonimmune hydrops group. All fetuses with indomethacin-induced ductal constriction recovered completely within 48 h of medication cessation and survived. In contrast, three fetuses with nonimmune hydrops who died had a significantly higher right ventricular  $dP/dt$  than those who survived ( $275 \pm 140$  versus  $718 \pm 151$  mmHg/s;  $p < 0.01$ ). This study demonstrated the potential utility of echocar-

diographic assessment of the fetal cardiac function as a tool of prognostication.

Demonstration of abnormal direction of blood flow in the central vascular channels may assist in defining complex cardiac lesions. For example, the presence of reverse flow in the ductus arteriosus in cases where the pulmonary outflow is difficult to image is diagnostic of pulmonary atresia. Chiba and associates [14] reported the utility of color flow mapping, including the depiction of abnormal flow directionality for identifying intricate malformations.

4. *High velocity and turbulent flow.* Abnormal magnitude of flow velocity is pathognomonic of cardiac pathology. As a general principle, flow velocity is increased in the alternative flow paths as they accommodate the flow diverted from hypoplastic chambers and atretic flow channels. Thus with tricuspid atresia flow velocity is increased in the mitral orifice and the aorta. In contrast, flow velocities across the atretic channels and in the hypoplastic chambers are absent or decreased (during the initial phase of the lesion). With fetal congenital heart block, the aortic and pulmonic flow velocity and flow are significantly increased. Stenotic lesions present a different problem. If there are no alternative circulatory paths, inflow in a vascular system equals outflow.

## Doppler Echocardiographic Assessment of Specific Cardiac Anomalies

Color flow and spectral Doppler modes can substantially assist 2D echocardiography in defining various congenital cardiac malformations. This section pre-

sents the Doppler characterization of anomalous hemodynamic patterns for commonly encountered congenital heart diseases in the fetus. The categorization used here is imperfect and somewhat arbitrary, as many of these conditions are characterized by multiple lesions. Furthermore, this review is brief, as a comprehensive discussion of these conditions is beyond the scope of this chapter.

### Cardiac Position

Anomalies of the cardiac position are rare. Fetal cardiac malposition may be intrathoracic or extrathoracic. Intrathoracic malposition may result from (1) secondary displacement of the heart due to a thoracic mass or fluid collection, which may lead to pseudo-dextrocardia; or (2) visceral malrotation resulting in dextrocardia. Extrathoracic malposition results from defective development of the anterior thoracic wall or the diaphragm causing ectopia cordis. Although these conditions are recognized by 2D echocardiography, color and spectral Doppler modes assist in defining altered vascular connections and associated cardiac malformations.

### Intrathoracic Cardiac Displacement

The most common malposition of the heart is probably related to a mediastinal shift caused by a space-occupying intrathoracic lesion such as a left diaphragmatic hernia (Fig. 33.6). With this condition, although the heart is displaced to the right hemithorax, the cardiac apex remains oriented to the left.

**Fig. 33.6.** Color Doppler depiction of pseudo dextrocardia secondary to left diaphragmatic hernia. SP fetal spine, L left, R right. The fetal heart is located on the right side of the thorax; its normal position on the left is occupied by the stomach. Note that despite the left displacement the cardiac apex remains directed to the left.

**Fig. 33.7.** Color Doppler imaging of dextrocardia. *Left:* Intrathoracic displacement of the fetal heart to the right with the cardiac apex directed to the right. The fetal heart exhibited ventricular inversion, left ventricular hypoplasia,

and transposition of the great arteries. *Right:* The situs was solitus as indicated by the normal orientation of the inferior vena cava (IVC), aorta (AO), and other viscera

tion of the primary thoracic abnormality, cardiac displacement and levo-orientation, and normal visceral situs. Dextrocardia is a rare anomaly (Fig. 33.7). A detailed discussion of the features is not relevant here. The condition is diagnosed by echocardiographic examination demonstrating the presence of the heart on the right side of the fetal thorax. The direction of the cardiac apex in dextrocardia is toward the right. The condition should be distinguished from the situation in which the heart is displaced to the right because of a diaphragmatic hernia, left pleural effusion, or a mediastinal mass. Although 2D imaging is sufficient for recognizing the malposition, color and spectral Doppler echocardiography may assist in defining abnormalities of ventricular organization or ventriculoarterial connection, which are commonly encountered with dextrocardia [33]. The most common abnormal connection is the complete and corrected transposition of the great arteries. In addition, abnormalities of visceral situs are seen, including situs inversus, incomplete visceral lateralization, and atrial isomerism syndromes.

### Extrathoracic Cardiac Displacement

Ectopia cordis may be thoracic, abdominal, or cervical; the thoracic type is encountered most frequently. The characteristics include cephalad orientation of the cardiac apex, a sternal defect, varying degrees of deficiency of the pericardium, diminished intrathoracic space, and omphalocele [34]. Intracardiac anomalies are frequent, as are associated anomalies that involve the central nervous system, skeletal system, and ventral wall. Although the condition can be

**Fig. 33.8.** Ectopia cordis with omphalocele. Note the hypoechogenicity of the fetal heart

identified by 2D sonographic imaging, detailed identification of the intracardiac anatomy may be difficult because of poor echogenicity of the cardiac structures, and color Doppler may be of significant assistance. An example of ectopia cordis is shown in Fig. 33.8. The image also demonstrated the presence of an anterior abdominal wall defect associated with an omphalocele. Defining cardiac structural integrity was difficult with 2D echocardiographic examination; Doppler color flow images, however, suggested a uni-ventricular chamber, which was confirmed at autopsy after pregnancy termination.

**Fig. 33.9.** Color Doppler depiction of an ostium secundum atrial septal defect. It is noteworthy that the condition may not be distinguishable from physiologic flow through the foramen ovale

## Atrial, Atrioventricular, and Ventricular Anomalies

### Atrial Septal Defects

Recognition of defects in the interatrial septum is challenging as physiologic flow exists across the foramen ovale, the septum is less echogenic than the interventricular septum, and the valve of the foramen ovale is not always recognizable. The ASD may be located (1) in the fossa ovalis in the central septum, where it is known as an ostium secundum defect; (2) in the upper septum, where it is known as a sinus venosus defect, often associated with anomalous venous return; and (3) in the posterior septum, where it is known as an inferior vena caval defect. Of the three, the ostium secundum defect is the most common and the inferior vena caval defect the least common. It is difficult to identify an ASD unless the deficiency is a large one. Figure 33.9 shows a large ostium secundum defect that was almost indistinguishable from the normal foramen ovale, except the valve of the foramen could not be seen even with careful high-resolution imaging.

### Atrioventricular Septal Defect

In contrast to the deficiencies of the ASD, defects involving the atrioventricular septum (AVSDs) are more easily identifiable in the fetus because of their large size and associated structural and hemodynamic anomalies. Various known as A-V canal defect, endocardial cushion defect, and ostium primum defect, the AVSD is characterized by complete absence of the interatrial septum and the presence of a common A-V orifice (Fig. 33.10). The A-V flow direction is regulated by a five-leaflet valve. Occasionally there are two A-V orifices separated by a straddling A-V valve, known as

**Fig. 33.10.** Color flow depiction of atrioventricular septal defect. The image is a two-dimensional frame from a real-time three-dimensional duplex color flow image. Note the flow across the ventricular septal defect (*horizontal arrow*). The interatrial septum is absent and the flow in the common atrial cavity is turbulent. External simulated fetal heart rate gating (G) was used to combine the sub-volumes. RV right ventricle, LV left ventricle, IVS interventricular septum, CA common atrium, CAVV common atrioventricular valve

the double-outlet atrium. AVSD variations exist in which the malalignment of the septum may lead to right or left atrial outflow obstruction. Hemodynamic abnormalities associated with AVSD may be recognizable by prenatal Doppler echocardiographic examination. Of specific relevance is the A-V flow regurgitation caused by the valvular incompetence. The condition has a high association with trisomy 21: Approximately 80% of infants with AVSD have trisomy 21 and approximately 40% of infants with Down syndrome suffer from AVSD [35]. Therefore when fetal echocardiographic examination leads to the prenatal diagnosis of AVSD, fetal karyotyping should be offered.

### Ventricular Septal Defect

The VSD is the most frequently occurring congenital cardiac lesion, accounting for about one-third of all cardiovascular malformations [36]. An isolated VSD carries an excellent prognosis, and most VSDs close spontaneously within 5 years of life [37]. Prenatal diagnosis of the defect depends on the size of the defect and the presence of associated cardiac malformations causing hemodynamic disturbance. However, isolated VSDs of moderate or small size may not be easily recognizable during Doppler echocardiographic examination, as they are not associated with detect-

**Fig. 33.11.** Color flow depiction of ventricular septal defect. Flow away from the transducer is coded in *blue* and toward the transducer in *red*. able flow shunting between the ventricles (which may be attributable to the pressure equilibrium that presumably exists between the two ventricles in the fetus). The presence of obstructive lesions in conjunction with a VSD alters this equilibrium, and shunting may be seen across a defect that itself may not be detectable by 2D imaging. Figure 33.11 demonstrates a flow jet from the left ventricle to the right ventricle across a defect in the membranous part of the interventricular septum in a fetus with aortic stenosis.

### **Tricuspid and Mitral Valvular Incompetence**

The conditions associated with intracardiac regurgitant flow are listed in Table 33.8. Significant tricuspid regurgitation is associated with structural and functional cardiac pathology. Approximately 9% of infants with cardiac malformations demonstrate tricuspid incompetence [15]. Congenital tricuspid regurgitation is seen mostly in association with other malformations of the fetal heart, including Ebstein's anomaly and AVSD. Hornberger and associates [38] reported 27 fetuses with significant tricuspid regurgitation and tricuspid valvular disease: 17 with Ebstein's anomaly and 7 with poorly developed dysplastic, normally inserted valves. The perinatal outcome was severely compromised, with 48% stillborn and 35% dying during the neonatal period. We have encountered an occasional fetus with mild tricuspid regurgitation without demonstrable cardiac pathology. Figure 33.12 illustrates the Doppler echocardiographic demonstra-

**Fig. 33.12.** Fetal Doppler color flow mapping. Apical right ventricular two-chamber view. tion of tricuspid regurgitation in the presence of apparently normal cardiac anatomy [13]. This observation was consistent with the postnatal findings. Martin and colleagues [39] observed tricuspid regurgitation in 3% of normal children. "Physiologic tricuspid regurgitation" has been reported in adults, especially in women with intense athletic training (93% of long distance runners and 57% of women with moderate athletic training) [40].

In contrast to tricuspid regurgitation, congenital mitral regurgitation is not encountered in healthy subjects. Its presence implies that there are mostly

**Fig. 33.13 A,B.** Duplex pulsed Doppler echocardiographic demonstration of mitral and tricuspid regurgitation in a fetus with cardiomyopathy. **A Top:** Apical four-chamber view of the fetal heart with the Doppler sample volume placed at the mitral orifice. **A Bottom:** Mitral waveforms with flow from the left atrium to the left ventricle as upward deflections and the regurgitant flow as downward deflections (arrows). **B Top:** Apical four-chamber view of the fetal heart with the Doppler sample volume placed at the tricuspid orifice. **B Bottom:** Tricuspid Doppler waveforms. complex and occasionally isolated cardiac structural malformations or cardiomyopathy (Table 33.8). Figure 33.13 shows mitral and tricuspid regurgitation in a fetus with cardiomyopathy.

### ***Ebstein's Anomaly***

An uncommon malformation, Ebstein's anomaly is identifiable in the fetus with relative ease by 2D and Doppler echocardiographic scans. The defining malformation is apical displacement of the tricuspid valve leaflets from the annulus, affecting the septal and posterior leaflets and occasionally the anterosuperior leaflet. In addition to the displacement, the valves are dysplastic and have varying degrees of dis-

tal attachment [41]. As a result of valvular displacement, the superior or proximal part of the right ventricular chamber is incorporated into the functional right atrial chamber. This situation is known as atrialization of the right ventricle. The inferior or distal part of the ventricular chamber retains the pumping role. The tricuspid valves also demonstrate incompetence of varying severity, and the resulting regurgitant flow contributes to the right atrial dilation. These features are recognizable by 2D imaging and can be corroborated by Doppler insonation. The latter is essential for detecting and assessing the severity of valvular incompetence (Fig. 33.14). There are associated anomalies of the heart, the prenatal diagnosis of which may be facilitated by use of Doppler sonog-

Note the impressive regurgitant flow projecting retrograde into the right atrium across the thickened tricuspid valve

raphy. They include ASD, pulmonary stenosis, absence of semilunar valves resulting in regurgitant flow, AVSD, and other malformations. The prognosis depends on the severity of the malformations. Severe dysplasia and abnormal distal tethering directly contribute to the functional and hemodynamic abnormalities. In general, neonatal survival has been poor. Advances in pediatric cardiac surgery have contributed to the relatively improved outcome.

### Hypoplastic Left Heart Syndrome

Hypoplastic left heart syndrome is characterized by a hypoplastic or completely obliterated left ventricular chamber, mitral atresia, and aortic valvular atresia or

**Fig. 33.15 A-C.** Fetal echocardiogram shows the sonographic characteristics of the hypoplastic left heart syndrome. LA left atrium, RA right atrium, LV left ventricle, RV right ventricle. **A** Lateral four-chamber view of the fetal heart shows virtual absence of the left ventricular chamber and a small left atrial chamber. Flow in the right heart extends from the atrium to the apex of the ventricle. **B** M-mode depiction of the hypoplastic left atrium, a relatively enlarged right atrium (left), and a grossly hypoplastic left ventricle. **C** Top left: Doppler sample volume in the ventricle just distal to the valve. **C** Bottom left: Mitral Doppler waveform. **C** Top right: Doppler interrogation of the tricuspid flow. **C** Bottom right: Tricuspid Doppler waveforms

stenosis. The left atrium is small, with the foramen ovale usually patent. The right ventricle and atrium are enlarged because of hypertrophy and dilation. The condition may evolve with advancing gestation, so early echocardiographic examination may not detect the problem. Although 2D and M-mode echocardiographic examination can establish the diagnosis, addition of color and spectral Doppler interrogation is invaluable for defining the malformation (Fig. 33.15). The cause of left heart hypoplasia is obscure, but it is noteworthy that a similar malformation can be created in animals by decreasing the interatrial blood flow. Such an aberrant hemodynamic phenomenon may be responsible in the human fetus because of the secondary effect of aortic atresia or herniation of the foramen ovale valve. Once the lesion is developed, the right ventricle supplies the lower body and lungs through the pulmonary trunk, pulmonary arteries, ductus, and descending aorta. Retrograde flow with a right-to-left shunt across the transverse aortic arch supplies the subclavian-innominate system and the coronary arteries. This altered flow pattern may be recognized by careful color flow mapping. Without surgical intervention the condition is fatal during neonatal life. Progress in pediatric cardiac surgery, especially introduction of the Norwood procedure staged with the Fontan operation [42], has substantially improved the outcome (Table 33.4). Because the condition is associated with neonatal crisis and the staged surgical repair requires prior preparation, prenatal diagnosis is essential for developing an appropriate, timely management plan.

### ***Pulmonary Atresia, Intact Ventricular Septum, Right Heart Hypoplasia Syndrome***

Pulmonary atresia with an intact ventricular septum and right heart hypoplasia is a common variant of pulmonary atresia/intact ventricular septum syndrome and is related to the atretic condition of the tricuspid valve. The latter is associated with underdevelopment of the right ventricular chamber. In the absence of atresia, the tricuspid valve is incompetent and the right ventricular chamber, instead of being hypoplastic, becomes enlarged. The right atrium shows varying degrees of hypertrophy and dilation and often demonstrates a secundum-type septal defect. Hemodynamic adjustment includes diversion of flow from the right atrium to the left atrium and retrograde flow via the ductus into the pulmonary vessels. Echocardiographic diagnosis, in most cases, can be performed with relative ease by demonstrating the diminutive right ventricular cavity with scant or absent flow (Fig. 33.16). In addition, pulmonary vascular atresia may be recognized in the long-axis and arch views. The prognosis without intervention is

**Fig. 33.16 A, B.** B-mode and Color Doppler flow depiction of hypoplastic left heart. B-mode gray-scale echocardiogram. **A** Diminutive left atrium (LA) and left ventricle (LV). This is re-confirmed by color flow depiction of markedly decreased atrioventricular flow on the left side. **B** The right atrium (RA) and the right ventricle (RV) demonstrate compensatory increase in size and flow. Flow away from the transducer is coded in *blue* and toward the transducer in *red*

poor, although the outcome has improved with the introduction of medical management with prostaglandin to maintain ductal patency and advanced surgical interventions, such as balloon atrial septostomy and systemic-to-pulmonary artery anastomosis.

## **Outflow Tract Anomalies**

### ***Tetralogy of Fallot***

The tetralogy of Fallot involves a perimembranous VSD, pulmonic stenosis, aortic root overriding the ventricular septum, and a hypertrophic right ventricle. The anomalous development is attributable to

anteroposterior deviation of the infundibular septum. The severity and spectrum of anomalies vary. The pulmonic outflow, for example, may be atretic, stenotic, or aneurysmic; the latter is associated with an absent pulmonary valve and constitutes a major variant of the classic tetralogy. Similarly, the locations of the septal defect and the nature of aortic overriding may vary. Most of these problems, along with an accompanying anomalous circulation, are recognizable by 2D spectral Doppler and color flow Doppler echocardiography (Fig. 33.17). Note that right ventricular hypertrophy may not be apparent during the fetal echocardiographic examination, probably due to the delayed development of this problem. Other cardiac anomalies that may be seen in association with this condition include right aortic arch, ASD and AVSD, subaortic stenosis, and anomalous venous communications.

**Fig. 33.17A,B.** Color Doppler flow depiction of tetralogy of Fallot. Flow away from the transducer is coded in blue and toward the transducer in red. **A** Flow across the ventricular septal defect (VSD) is indicated by the upward arrow. The aortic outflow (AO) illustrates significant increase in aortic dimension (4.6 mm) in comparison with the pulmonary outflow (1.9 mm) shown in **B**. Flow is seen moving retrograde (upward arrow) from the ductus arteriosus (DA) into the pulmonary artery (PA). RV right ventricle

One should be cautious when distinguishing tetralogy of Fallot from truncus arteriosus with VSD; although such distinction can be made in the neonate by demonstrating the origin of the pulmonary arteries from the truncus, the fetal diagnosis is more challenging.

### Transposition of Great Arteries

Great artery transposition is characterized by an anomalous A-V connection, with the aorta arising from the right ventricle and the pulmonary trunk arising from the left ventricle. The condition is also known as complete transposition. The most likely pathogenic mechanism is the aberrant growth and absorption of the conotruncus [43]. The most common form of abnormal spatial relation between the great vessel shows the aorta lying anterior and to the right of the pulmonary root. This configuration is also known as the dextro, or D, transposition. The echocardiographic diagnosis in the fetus consists of demonstrating the absence of the normal crossover relation between the aorta and the pulmonary trunk (discussed in Chap. 32). Care must be taken when differentiating the condition from double-outlet right ventricle by following the outflow from the identified ventricles into their respective outflow tracts and defining the spatial relations of the latter. Color Doppler echocardiographic examination is especially helpful for elucidating this aberrant relation (Fig. 33.18). In utero the parallel nature of the fetal right and left heart circulations ensures that there is no significant fetal risk from the altered hemodynamics. The neonatal prognosis has substantially improved with the progress in surgical care of congenital cardiac malformations. Associated cardiac malformations, such as subpulmonary stenosis, significantly influence both the short- and long-term outcomes.

**Fig. 33.18.** Transposition of the great arteries. Color flow image shows the parallel course of the right and left ventricular outflow tracts (RVOFT and LVOFT)

**Fig. 33.19.** Color Doppler image shows truncus arteriosus. *OFT* outflow tract, *RV* right ventricle, *LV* left ventricle

### Persistent Truncus Arteriosus

Persistent truncus arteriosus is characterized by the presence of only one great artery carrying outflow from both ventricles. Variations in the condition exist in relation to the presence or absence of a septal defect and the point of origin of the pulmonary arteries. The malformation is probably caused by abnormal conotruncal development. Echocardiographic diagnosis in the fetus depends on the demonstration of a single arterial outflow overriding the ventricular septum (Fig. 33.19). The condition must be differentiated from Fallot's tetralogy by imaging the origin of the pulmonary arteries arising from the truncus. The anomaly may lead to fetal cardiac failure; serial echocardiographic monitoring therefore is recommended for a timely diagnosis. The prognosis remains relatively poor because of the high risk of congestive cardiac failure and high primary mortality associated with the surgical correction during the neonatal period.

## Fetal Cardiac Arrhythmias

The incidence of fetal cardiac arrhythmias is approximately 1%–2% [44]. Most are isolated extrasystoles; supraventricular tachycardia is the most common tachyarrhythmia. Our experience with the relative frequency of the various dysrhythmic conditions referred for echocardiographic evaluation during a 5-year period is summarized in Table 33.9. These data are consistent with those in published reports. Although initial recognition may occur during electronic monitoring of the fetal heart rate, fetal echocardiography is essential for the definitive diagnosis and assessment of cardiac structure and function. This section briefly describes the mostly commonly encountered fetal cardiac arrhythmias (i.e., premature atrial contractions, supraventricular paroxysmal tachycardia, and congenital heart block) in which Dop-

**Table 33.9.** Relative frequency of fetal arrhythmias (174 cases)

Color flow mapping demonstration of regurgitant or turbulent flow
Color M-mode demonstration of regurgitant or turbulent flow
Structural assessment
Color flow mapping, supplemental to two-dimensional echocardiography

pler sonography plays a useful role as a diagnostic and surveillance tool. These three conditions constitute 98% of all rhythm disturbances seen in the fetus.

### General Principles

M-mode echocardiography is the most important ultrasound modality for establishing the nature of an abnormal rhythm. M-mode sonography allows simultaneous determination of the atrial and ventricular rates, so the nature of the rhythm disorder may be ascertained. It may be best accomplished by aligning the M-line cursor across the atrium and ventricle – provided the fetal position permits such alignment (see below). As shown in Table 33.10, spectral and color flow Doppler sonography also are of substantial utility for assessing this condition.

Duplex pulsed-wave spectral Doppler insonation allows individual and simultaneous determination of the atrial and ventricular contraction rates. A Doppler wa-

**Fig. 33.20.** Echocardiogram shows simultaneous interrogation of the mitral flow (MF) and aortic outflow (AO). Top: Placement of the Doppler sample in the left ventricular chamber just distal to the tricuspid orifice encompassing the mitral flow and aortic outflow. LA left atrium, LV left ventricle

veform from any fetal artery reflects the ventricular rhythm. On the other hand, insonation of the inferior vena cava or pulmonary vein and of the tricuspid or mitral flow tracts will yield the atrial rhythm. The use of Doppler velocimetry of the inferior vena cava for assessing fetal arrhythmia is discussed in Chap. 27.

To assess the synchronicity of the atrial and ventricular rhythms, Doppler sample volume can be placed and extended to encompass both atrial and ventricular flows. It is accomplished by placing the sample volume appropriately in the ventricular chamber and extending it to include the atrial flow into the ventricle and the ventricular outflow. The tricuspid or mitral waveform reveals the atrial rhythm, and the pulmonary or aortic outflow indicates the ventricular rhythm (Fig. 33.20). An alternative approach, described by Chan and colleagues [45], involves placing the Doppler sample volume in the lower abdomen to encompass the aorta and the inferior vena cava, generating the ventricular and atrial rates, respectively. In this location the two vessels lie in close proximity and therefore are accessible to interrogation by an extended sample volume.

In addition to rhythm determination, Doppler echocardiographic modalities allow assessment of hemodynamic changes associated with an abnormal rhythm. Moreover, color Doppler echocardiography is supplemental to 2D imaging for identifying any associated cardiac structural malformations. This point is clinically important, as the presence of malformations in conjunction with arrhythmia signifies a worse prognosis.

Spectral Doppler may be particularly helpful for elucidating the hemodynamic pathophysiology of fetal cardiac arrhythmias. In our initial report [46] we noted that during an ectopic beat the right ventricular stroke

volume may be reduced by 60%. Subsequent investigations have substantially expanded the application of Doppler sonography for studying the hemodynamic effects of fetal cardiac arrhythmia. Lingman and Maršál [47] observed that the systolic rising slope and peak value of the maximum aortic velocity were significantly increased during the first beat after the compensatory pause in fetuses with supraventricular extrasystole; this observation confirmed the Frank-Starling phenomenon in the fetus and was corroborated by Reed and co-workers [48], who reported cardiac Doppler flow changes during fetal arrhythmias in 54 fetuses with gestational ages of 21–41 weeks. During the postextrasystolic beats, time velocity integrals rose by 43% across the tricuspid orifice and 41% across the mitral orifice. Kanzaki and associates [49] investigated fetal cardiac arrhythmia with pulsed-wave Doppler sonography and observed characteristic inferior vena caval flow patterns with each arrhythmic condition. These patterns could be explained by the atrial and ventricular contraction characteristics. Furthermore, inferior vena caval flow components during sinus rhythm could be explained by the events of the cardiac cycle. Distinctive flow velocity patterns were observed for each arrhythmic condition. The most remarkable finding with all the arrhythmic conditions was the high-velocity reverse flow caused by atrial systole with closed tricuspid valve or tricuspid regurgitation. This subject is discussed in depth in Chap. 27.

### Premature Atrial Contractions

As indicated in Table 33.9, premature atrial contractions (PACs) are the most common form of fetal cardiac arrhythmia. The condition is also known as at-

rial premature complexes. Although essentially benign in nature, approximately 1 in 200 to 1 in 300 PACs may convert to supraventricular tachycardia, which is a serious condition for the fetus. The essential electrophysiologic basis for the origin of PACs consists in early depolarization of latent pacemaker cells in the atrium, thereby forming an ectopic focus (Fig. 33.21). Often the cause remains obscure, although the condition may be secondary to a variety of circumstances including maternal ingestion of stimulants such as caffeine.

The fetal diagnosis is made by demonstrating premature contractions originating in the atrium, which is best accomplished by simultaneous M-mode echocardiography of the atrium and ventricle (Fig. 33.22). As all arterial systems are driven by ventricular activity, spectral Doppler interrogation of any fetal artery

**Fig. 33.21.** Electrophysiology of premature atrial contractions. SA sinoatrial, AV atrioventricular

reflects premature ventricular contractions. This point is demonstrated by Doppler waveforms from the pulmonary trunk or the umbilical artery (Fig. 33.23). The Doppler waveform not only demonstrates the premature contractions, it shows compensatory prolongation of the interval before the next cardiac cycle and the increased magnitude of the next Doppler wave. The atrial origin of the extrasystole also can be confirmed by spectral Doppler insonation, as mentioned above. The postextrasystolic increase in the Doppler wave peak systolic frequency is consistent with the presence of the Frank-Starling phenomenon in the fetal heart.

After the initial assessment, subsequent echocardiographic surveillance depends on the frequency of the extrasystoles and the presence of any cardiac malformations. Frequent extrasystoles may predispose to conversion to supraventricular tachyarrhythmia and therefore should be closely observed. Similarly, the presence of any anomaly necessitates more intense echocardiographic evaluation.

### Supraventricular Tachycardia

Supraventricular tachycardia (SVT) is the second most frequently encountered abnormal rhythm in the fetus. As the name implies, there is a sustained increase in the ventricular rate ( $>200$  bpm) due to abnormal electrical activities originating above the ventricular conduction system. The level of tachycardia distinguishes SVT from sinus tachycardia, which is characterized by a fetal heart rate of 160–180 bpm.

There are three main electrophysiologic types of SVT encountered in the fetus: reentrant, automatic, and SVT secondary to atrial tachyarrhythmias. Most cases of SVT in the fetus are of the reentrant variety, which is characterized by sudden onset and remis-

**Fig. 33.22.** Doppler M-mode echocardiogram shows premature atrial contractions (PACs). *Top:* Apical four-chamber view of the fetal heart, with the M-mode cursor intersecting the right atrium, tricuspid orifice and valve, and right ventricle. *Bottom:* Color M-mode recording of a PAC followed by a compensatory pause (*p*)

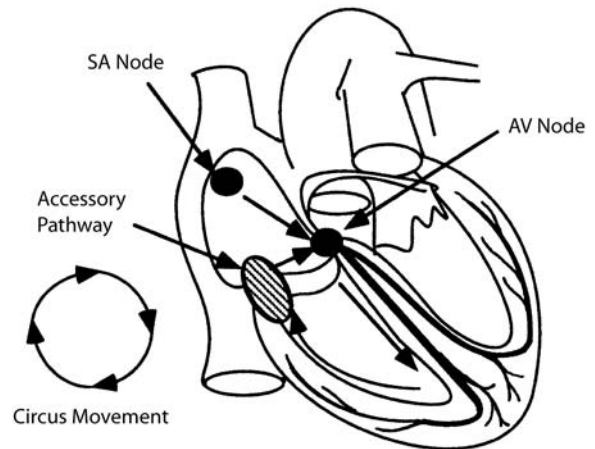

**Fig. 33.23.** Pulmonary arterial Doppler waveforms show a premature cardiac contraction followed by a compensatory pause (arrows). Note the relative increase in the peak velocity of the post-compensatory wave, confirming the existence of the Frank-Starling mechanism in the fetal heart

sion. The mechanism of reentrant tachyarrhythmia consists of circus electric activity encompassing atrial and ventricular conduction systems, most frequently involving an accessory bypass tract. The atrial impulse first is conducted to the A-V node and then into the His-Purkinje system accessory pathway and ventricles. The accessory pathway transmits the impulse from the ventricle to the atrium, thereby completing the reentry circuit (Fig. 33.24). This pattern comprises the most common type of reentrant SVT encountered in the fetus and neonate. When the accessory pathway transmits the impulse in a downward direction (antegrade), Wolff-Parkinson-White syndrome results. For the A-V nodal reentry, the slow tract within the node ( $\alpha$  pathway) conducts the impulse antegradely and the fast track ( $\beta$  pathway) conducts the impulse retrogradely, which then completes the ring-like conduction pathway of the circus movement. Although there are other reentry mechanisms, they are infrequently seen in the fetus. Reentrant SVT is more amenable to therapeutic intervention.

The automatic SVT is caused by the presence of ectopic atrial foci that stimulate the tachyarrhythmic activity of the ventricles. Atrial fibrillation and flutter are related to the atrial circus movement, which produces atrial tachyarrhythmia, a variable transmission of which results in ventricular tachyarrhythmia. These classes of SVT are rare in the fetus and are associated with a worse prognosis than the reentrant variety.

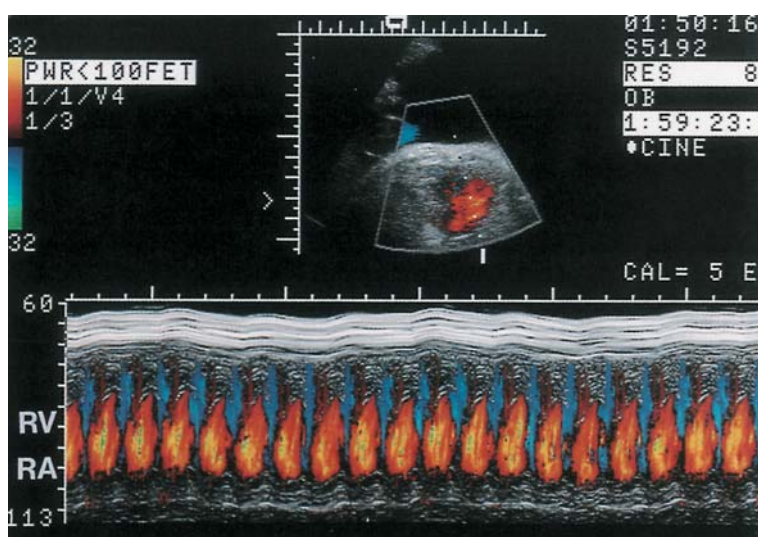

It is noteworthy from the perinatal perspective that fetal SVT is often associated with cardiac malformations, including Ebstein's anomaly, tricuspid atresia, corrected transposition, and cardiomyopathy, although most infants are without any such complications. In addition, viral infections, specifically cytomegalovirus and coxsackie B, have been implicated.

**Fig. 33.24.** Electrophysiology of the reentrant supraventricular tachyarrhythmia involving the accessory bypass tract. SA sinoatrial, AV atrioventricular

The condition is usually recognized during fetal heart rate auscultation or electronic monitoring. The definitive diagnosis is achieved during fetal echocardiographic examination. Duplex imaging-guided M-mode sonography remains the most important modality permitting determination of the atrial and ventricular rates. Figure 33.25 presents a color M-mode demonstration of the atrial contribution to the tachyarrhythmic process. M-mode echocardiography may also be useful for assessing ventricular hypertrophy or dilation and spectral Doppler interrogation for establishing atrial and ventricular rates by the simultaneous interrogation of either the A-V flow and ventricular outflow of the aorta and inferior vena cava (see above). Finally, the importance of a detailed 2D echocardiographic examination cannot be overemphasized, as it allows targeted evaluation of the struc-

**Fig. 33.25.** Color M-mode echocardiogram of the atrioventricular flow in supraventricular tachyarrhythmias. The cardiac rate was approximately 210 bpm. Note the atrial origin of the tachycardia. RA right atrium, RV right ventricle

tural integrity of the fetal heart and recognition of fetal cardiac failure. Color flow mapping significantly facilitates this process.

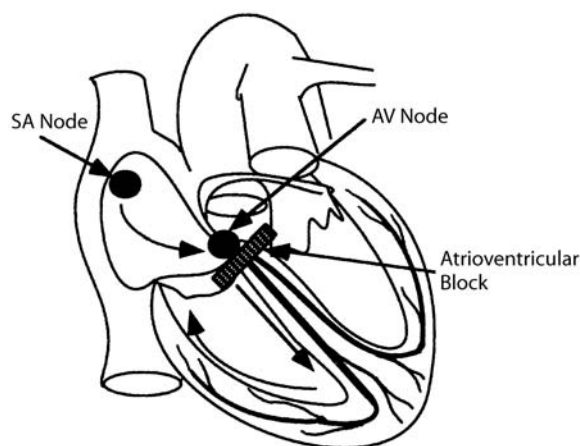

The prognosis of fetal SVT depends on the fetal cardiac status and the obstetric and maternal medical conditions. The prognosis is worse in the presence of (1) any cardiac malformation and its complexity; (2) hydrops signifying fetal cardiac failure; (3) refractoriness to therapy; (4) fetal viral infection; (5) prematurity; or (6) maternal medical complications such as fever or hyperthyroidism.

Antepartum surveillance consists in serial echocardiography to assess progression of the disease (e.g., development of fetal cardiac failure) and to monitor the response to therapy. In the presence of SVT, cardiotocography becomes uninterpretable in terms of recognizing fetal compromise.

### Congenital Complete Heart Block

Congenital complete heart block is characterized by a complete failure of A-V conduction associated with structural malformations or immune complex-mediated injury to the conduction system (Fig. 33.26). The ventricular rate is sustained below 100 bpm, usually at 60–80 bpm. The atrial rhythm is discordant with the ventricular rhythm, and its rate is maintained within the normal range of fetal sinus rhythm for the gestational age (120–160 bpm). Although it is the third most common arrhythmia seen in the fetus, it is still a relatively rare complication, with the reported incidence ranging from 1 in 10,000 to 1 in 20,000 births [50, 51].

From an echocardiographic diagnostic perspective, it is important to note that almost half the cases are associated with congenital malformations of the fetal

**Fig. 33.26.** Electrophysiology of congenital complete heart block. SA sinoatrial, AV atrioventricular

heart. Traditionally, left atrial isomerism and less frequently right atrial isomerism have been implicated. Other malformations include AVSD, outflow tract anomalies such as corrected transposition, or double-outlet right ventricle, many of which cases accompany situs reversal or ambiguity. In most cases without cardiac malformations, maternal autoimmune disease predominates. Specifically, such mothers demonstrate the presence of antibodies against small ribonucleic autoantigens Ro/SS-A and La/SS-B [52]. Transplacental passage of these antibodies from the mother to the fetus and their subsequent cross reaction with fetal cardiac antigens apparently leads to fetal myocarditis, fibrosis, and consequent damage to the cardiac conduction system. It has been demonstrated that anti-La/SS-B, but not anti-Ro/SS-A, antibodies cross react with laminin, the major component

of the cardiac sarcolemmal membrane, suggesting a molecular mechanism for the pathogenesis of the heart block [53]. A high titer of anti-Ro antibody (>1:16) [54] and the concurrent presence of anti-La antibodies increase the risk of congenital heart block.

Compared with other commonly encountered fetal arrhythmias, congenital heart block generally carries a substantially poorer prognosis, with an overall mortality ranging from 50% to 60% [55, 56]. The prognosis is worse when (1) fetal cardiac malformation is present; (2) the ventricular rate is <60 bpm; (3) the atrial rate is below the normal range of the fetal heart rate (<110–120 bpm); and (4) fetal heart failure supervenes as evidenced by the presence of pericardial effusion or hydrops. One of the early reports observed 75% mortality among fetuses with isolated heart block, compared with 15% mortality when the heart block was complicated by cardiac malformations [47].

Although the initial diagnosis is made by auscultation and electronic monitoring of the fetal heart, fetal echocardiography is indispensable for a precise diagnosis. This situation contrasts with that during postnatal life, when electrocardiography is the standard technique for diagnosing arrhythmic conditions. An initial 2D echocardiographic examination is essential for establishing the integrity of the fetal cardiac anatomy and identifying fetal cardiac failure. The 2D echocardiographic examination is also needed for guiding specific M-mode and pulsed-wave Doppler interrogation. M-mode echocardiography is the standard approach for establishing the discordance of the A-V rhythm. It is achieved by simultaneous interrogation and synchronous recording of atrial and ventric-

ular activities. When pericardial effusion is present, M-mode sonography is also useful for assessing any changes in its severity. Finally, Doppler echocardiography is invaluable for recognizing hemodynamic abnormalities such as valvular incompetence, which may complicate these cases. The Doppler mode may also be used to determine A-V rates (see above) and to assess fetal cardiac function in terms of ventricular output, which is illustrated by our reported experience [7]. Figure 33.27, an M-mode recording from a fetus suffering from complete congenital heart block, demonstrates A-V discordance. The M-mode technique was also employed to further assess the pericardial effusion, which was recognized during 2D imaging. Figure 33.28 demonstrates tricuspid incompetence recognized in this case utilizing duplex pulsed-wave Doppler interrogation, which was used in conjunction with M-mode sonography for timing the events of the fetal cardiac cycle. These tests were undertaken prior to the introduction of color flow mapping, which can now be employed for effective elucidation of hemodynamic aberrations. As discussed in Chap. 32, color flow M-mode sonography is particularly useful in this regard. Because of the poor perinatal prognosis, a serial ultrasound examination is required to follow the development and progression of fetal cardiac decompensation. It is noteworthy that the utility of Doppler velocimetry of the umbilical or other fetal arteries is severely limited in this condition because of the undue prolongation of the diastolic phase. M-mode and Doppler echocardiography may be beneficial for intermittent monitoring of the atrial and ventricular rates and for evaluating fetal cardiac status.

**Fig. 33.27.** M-mode echocardiogram shows a relatively rapid left atrial rate of approximately 120 bpm and a ventricular rate of 50 bpm. *Oblique arrows* indicate the contractions of the left atrial wall; *vertical arrows* denote systolic inward motion of the right ventricular wall. ## Summary

Recent years have witnessed significant progress in the technique of fetal echocardiography and perinatal management of fetal cardiac disease. Although 2D cardiac imaging remains the major tool for this evaluation, its diagnostic efficacy is significantly enhanced by the other ultrasound modalities. Specifically, spectral pulsed Doppler, 2D Doppler color flow mapping, and color M-mode provide essential tools for elucidating hemodynamic abnormalities associated with structural and functional congenital cardiac disease. This hemodynamic information plays a crucial role in enhancing the efficacy of investigating these complex problems. It is not surprising, therefore, that Doppler echocardiography now plays such a critical role in the diagnosis, treatment, and surveillance of fetal cardiac disorders. Future developments in this area will certainly encompass 3D Doppler flow evaluation, which has been addressed in Chaps. 7 and 34.

# Four-Dimensional B-Mode and Color Doppler Echocardiography of the Human Fetus

Dev Maulik

## Introduction

Sonographic imaging of the fetal heart remains technically challenging because of the complexities of fetal cardiac structure and function, the dependence of the acoustic access on fetal position and fetal movement. The technique is highly dependent on the operator's skill, requires intense training, and has a steep learning curve. While performing two-dimensional (2D) echocardiography, the operator conceptually recreates the spatial three-dimensional (3D) reality of the fetal heart out of the 2D sonographic images. Although this approach continues to function well, the advantages of four-dimensional (4D) echocardiography, which is 3D imaging in real time, are potentially immense. Three-dimensional images can be created by postprocessing of the digital graphic information generated by sequential 2D imaging; however, when 3D imaging is performed in real time it constitutes 4D imaging. For echocardiography this translates into instantaneous display of the spatial and temporal reality of the heart as the operator performs the scanning. Although the potential of 3D or 4D echocardiography has been appreciated for more than two decades, the actual development of this modality has to overcome significant engineering and computational challenges. Not surprisingly, the early 3D methods did not possess the capability of imaging the fetal heart in real time with acceptable temporal or spatial resolution; however, recent remarkable technological breakthroughs have led to the commercial introduction of true 4D echocardiography instrumentation in adult and pediatric cardiology and have raised the prospect of extending these newer techniques for fetal cardiac assessment. This chapter briefly reviews these recent developments in this field with emphasis on the Doppler mode.

## History of Four-Dimensional Echocardiography

The origins of 3D medical imaging can be traced back three decades with the advances of computed tomography and magnetic resonance imaging. Essen-

tially, the tomographic image slices generated by these modalities are digitally reconstructed to produce 3D images. These developments have revolutionized medical imaging and diagnostics. Even with the continuing advances in technology, these modalities, however, cannot match the versatility of ultrasound for imaging the heart. The development of 3D echocardiography began in the 1970s and 1980s. Pioneering groups of investigators, including Dekker and associates [1], Ghosh and colleagues [2], and others [3], utilized various experimental approaches, which essentially consisted of offline reconstruction of 2D images. Subsequent research and development eventually led to the clinical introduction of systems that utilized offline 3D reconstruction from multiplanar 2D images obtained via transthoracic or transesophageal routes by a rotational method or parallel scanning [4]. A recent remarkable technological accomplishment in this field was the development of matrix phased array which allowed true real-time 4D imaging, introduced first by von Ramm and associates [5] and is discussed later in this chapter.

Regarding the feasibility of 3D fetal echocardiography, initial investigations mostly consisted of 3D reconstruction of sequential 2D images acquired either by free hand scanning combined with position sensors, or by motorized scanning with a one-dimensional linear-transducer array [6]. These approaches did not perform strictly 4D imaging and some form of cardiac gating was necessary to make any sense of the images. Another approach used two ultrasound devices concurrently with one generating 2D grayscale and color Doppler images with 3D spatial movement tracking, whereas the other used umbilical arterial Doppler velocimetry to provide cardiac gating [7]. These laudable pioneering efforts depended on substantial postprocessing to generate the volume data set, were often cumbersome, and suffered from many limitations including poor spatial and temporal resolution.

Subsequent advances have addressed many of these limitations leading to the development of the two distinct current systems; one is based on the recently introduced second-generation matrix 2D phased-array system and represents a significant breakthrough in

true real-time 4D echocardiography of the fetal heart [8]. The other is the motor-driven unidimensional linear-array transducer mentioned above but significantly enhanced with the development of the spatio-temporal image correlation technique [9]. These two approaches are discussed further in this chapter.

### Basic Principles of Three- and Four-Dimensional B-Mode and Doppler Sonography

There are three fundamental sequential steps of 3D sonography: image acquisition; image processing; and image display. Real-time implementation of these sequential processes constitutes 4D sonography (Fig. 34.1).

Three-dimensional images are acquired either by direct scanning with 3D ultrasound beam produced by 2D matrix array transducers or reconstructed from a series of 2D ultrasound images as discussed in the previous section. Color Doppler interrogation which is based on mean Doppler angular frequency shift can be performed in both these approaches; however, the inherent limitations of Doppler sonography, such as angle dependence, are valid in these modalities. Power Doppler can be used without this limitation; however, the loss of flow directional information significantly restricts the utility of this approach. Three-dimensional color Doppler flow depiction can be used to quantify abnormal flow conditions such as regurgitant jets. Potential also exists to quantify volumetric flow. Many of these functions can be performed now to a variable degree with dedicated off-line processing. Future technological advances may permit real-time hemodynamic assessments, including flow quantification, with greater reliability than has been possible up to now.

Three-dimensional image processing requires defining the spatial location of a point in 3D space from the digital graphic information. The unit of 3D spa-

**Fig. 34.2.** Image processing in three-dimensional ultrasound. A pixel is the smallest definable unit of the two-dimensional (2D) image and defines the location in a 2D plane. A voxel is the counterpart of a pixel in three-dimensional (3D) imaging and defines the location in 3D space. X, Y, and Z represent the orthogonal planes of Cartesian co-ordinates for spatial location of a voxel

tial graphic information is known as a voxel. The term stands for volume pixel and constitutes the smallest definable unit of a 3D image. A voxel is the 3D counterpart of a pixel which defines location in a 2D plane. Geometrically, the relative spatial locations of a voxel are represented by the Cartesian co-ordinates x, y, and z (Fig. 34.2). The location is defined by the point's distances from three orthogonal planes determined by these co-ordinates. This is a fundamental concept that is crucial for 3D ultrasound image processing and interpretation. Each voxel can be digitally quantified to represent objective properties such as opacity, density, color, velocity, or even time. The ability to modify the opacity of a voxel is critical for 3D imaging. This is known as opacity transformation which allows visualization of internal morphology of an image which would otherwise be obscured by more opaque surface voxels.

Three-dimensional images can be displayed by (a) surface rendering with identification of various structures, (b) multiplanar reconstruction with dynamic orthogonal display, or (c) as a texture mapped block, such as a pyramidal 3D object, which can be rotated and cropped to reveal internal structures or flow.

Reconstructed 3D images are subject to motion artifacts which may be generated by fetal movements, patient movements including breathing, or inadvertent transducer movement; however, direct 3D imaging employing the 2D matrix transducers is not subject to similar motion artifacts except when two or more images are combined to produce a wide angle view.

### Two-Dimensional Matrix Array

The 2D matrix array technology essentially consists of a phased-array transducer with 3,000 piezoelectric elements all of which transmit and receive ultrasound (Fig. 34.3; Sonos 7500 with X4 transducer, Philips Medical Systems, Andover, Mass.). The enormous vol-

### Steps of 4D Sonography

**3D data acquisition**

**3D image reconstruction**

**3D image display**

**All of the above in real time**

**Fig. 34.1.** Steps of four-dimensional sonography. 3D three dimensional, 4D four dimensional

**Fig. 34.3.** Microscopic view of a matrix array transducer. Each *small square* is an active ultrasound element. The size of a human hair is shown for comparison (*arrows*). (From [9])

ume of data thus generated offer a formidable challenge in real-time processing; however, the system resolves this issue by devising a highly innovative technological solution known as subarray beam forming (Fig. 34.4). The elements are connected via layers of wiring to several custom integrated circuits. The currently marketed device uses many such circuits which are located in the handle of the transducer which itself still remains very modest in size. These circuits perform the initial processing of the ultrasound signals which are then transmitted to the main computer system of the device where further fast processing results in the real-time on-line generation of moving cardiac images. The system allows color Doppler flow depiction in real time in conjunction with the 4D depiction of cardiac anatomy.

**Fig. 34.4.** Graphic depiction of the concept of subarray beam forming

The system generates a 3D pyramid-shaped volumetric sector restricted to an angle of about  $30^{\circ}$ – $50^{\circ}$  (Fig. 34.5). No gating is needed for this volume. A wider pyramidal sector image measuring  $90^{\circ} \times 90^{\circ}$  can also be produced. This is accomplished by swift automatic acquisition and integration of four sectors in real time during consecutive cardiac cycles with each sector measuring approximately  $23 \times 90^{\circ}$ ; however, generation of the extended sector requires some form of cardiac gating which in the adult or pediatric patient is provided by a modified type of electrocardiographic trigger. Although this is not feasible to accomplish in the fetus, an external electronic periodic trigger, which

**Fig. 34.5.** Two-dimensional matrix array: the sector size. **a** On-line 3D scanning. The sector size depends on chosen image resolution or line density, and is about  $30 \times 50^{\circ}$ . **b** Wide-angle scanning. An *arrow sector* is scanned during each of four consecutive heart beats. The four sectors (shown with different color coding) are integrated automatically within a fraction of second. (From [9])

**Fig. 34.6.** Two-dimensional matrix array: the sector size. Pyramid-shaped wide-angle sector image of the fetal heart. Fetal back is toward the apex of the pyramid. Fetal spine can be seen at the right upper corner of the apex. The *arrowhead* points to the foramen ovale. RA right atrium, LA left atrium, RV right ventricle, LV left ventricle. (From [12])

can approximate the fetal heart rate, has been used successfully to produce a reliable full volume data set of the fetal heart (Fig. 34.6) [12].

Brightness and contrast can be adjusted to optimize the 3D image quality. The images can be cropped using the Cartesian co-ordinate x, y, and z planes as well as oblique planes to obtain the 3D perspective.

## Two-Dimensional Matrix Array: Fetal Application of the Technique

The utility of the new system has been shown in adult patients for imaging the coronary arteries and for evaluating mitral stenosis [10, 11]. Preliminary experience in fetal cardiac assessment shows that this technology can provide a comprehensive assessment of cardiac valves, chambers, both atrial and ventricular septal walls, and great vessels [12]. Moreover, unlike real-time 2D echocardiography, both the atrial and the ventricular septal walls as well as the cardiac valves can be visualized as if the examiner is directly facing these structural surfaces in three dimensions in real time (also known as *en face* view) for any abnormalities (Fig. 34.7). Three-dimensional color Doppler allows comprehensive assessment of regurgitant and shunt lesions (Figs. 34.8, 34.9). In normal fetuses, the foramen ovale with right-to-left physiological shunting can be well visualized by 4D color Doppler (Fig. 34.8). In a 36-week-old fetus with complete at-

**Fig. 34.7.** Four-dimensional echocardiography in a fetus with complete atrioventricular septal defect. En face view of the defect (*asterisk*) from the inferior aspect. S ventricular septum. (From [12])

**Fig. 34.8.** Four-dimensional echocardiography in a normal 31-week-old fetus. Color Doppler image shows physiological right-to-left shunting (*arrowhead*). RA right atrium, LA left atrium, RV right ventricle, LV left ventricle, IVC inferior vena cava. (From [12])

trioventricular septal defect, we could fully visualize the septal defect from any desired angulation including en face views (Figs. 34.10, 34.11). Four-dimensional color Doppler allowed depiction of abnormal hemodynamics of the lesion with clarity (Fig. 34.12). Such comprehensive assessment is not possible using real-time 2D echocardiography because of its inability to view the defect using cross sections taken at different levels and angulations.

**Fig. 34.9.** Four-dimensional echocardiography in a fetus with complete atrioventricular septal defect. The pyramidal section has been cropped to show regurgitation (*R*) from the right-sided component of *V*. *AO* aortic cross section. (From [12])

One of the apparent limitations of the technique in our preliminary assessment is the inability to use fetal electrocardiography signals to trigger the volume acquisition which is the approach utilized in assessing the adult heart; however, as mentioned above, a simulated heart rate can be used within the range of the normal fetal heart rate with no visually detectable artifacts. The other potential challenge in any fetal imaging is related to fetal movements which may also interfere with live 3D imaging; however, this is not a significant problem in this system because of the very fast volume acquisition in both B- and color Doppler modes.

### Motorized Curved Linear-Array System and Spatio-Temporal Image Correlation

This is an advanced system essentially based on 3D image reconstruction from sequentially acquired 2D images (Voluson 730 Expert System, General Electric Medical Systems, Kretztechnik, Zipf, Austria). The transducer assembly encases a curved linear array of transducer elements and a motor drive. The drive mechanism allows an automated sweep of the target area to generate 2D images sequentially constituting the volume data set. This method is inherently inadequate for fetal echocardiography because of fetal cardiac motion. Development of the spatio-temporal correlation technology (STIC), however, has resolved this issue.

An integral part of the 3D volume acquisition system, STIC processing, determines the fetal heart rate

**Fig. 34.10.** Four-dimensional echocardiography in a fetus with complete atrioventricular septal defect. **a** Two-dimensional B-mode image of the lesion. The *upper horizontal arrow* shows the ventricular septal defect; the *lower horizontal arrow* shows the absence of the atrial septum. **b** Four-chamber view cropped to show the common atrioventricular valve (*V*) and the defect (*asterisks*). *RA* right atrium, *LA* left atrium, *RV* right ventricle, *LV* left ventricle. (From [12])

from the systolic peaks of the fetal cardiac motion and immediately reorganizes the 2D images with spatial and temporal coherence so that images from the same cardiac cycle are collated together to form a single volume data set for that cardiac cycle (Fig. 34.13). Many such volumes are produced during a single sweep, and the actual number depends on the duration of the sweep and the heart rate. The images can be displayed as orthogonal multiplanar, volume-rendered, or single-plane displays either as cine loops or still images. The images can be gray scale or color B mode, color Doppler, or a combination of B mode and color Doppler with variable translucency, the so-called glass-body display. The

**Fig. 34.11.** Four-dimensional echocardiography in a fetus with complete atrioventricular septal defect. En face view of the defect (*asterisk*) from the right side. Turbulent color flow can be seen across the defect. (From [12])

**Fig. 34.12.** Four-dimensional echocardiography in a fetus with complete atrioventricular septal defect. Four-chamber view cropped to show the color Doppler depiction of shunt across the septal defect. RA right atrium, LA left atrium, RV right ventricle, LV left ventricle. (From [12])

STIC processing is very fast so that the images are produced in real time. Moreover, B-mode resolution has continued to improve. The 3D image volume data set can be archived and reexamined comprehensively later which may improve the efficacy of the prenatal diagnosis of congenital heart defects.

The STIC approach is sensitive to movements. Fetal body movements, or sometimes even fetal breathing, will produce artifacts rendering the images uninterpretable. Maternal breathing or transducer movement may also create this problem.

**Fig. 34.13.** Raw data volume showing a beating fetal heart during a slow 3D sweep. This information is used to calculate the fetal heart rate. (From [8])

## Fetal Echocardiography with STIC Technology

Introduction of this technique represents a significant advance in prenatal cardiac diagnosis. Several investigators have reported the use of this approach for fetal echocardiography [13–15]. These studies demonstrate the feasibility of using the STIC approach to obtain not only the traditional views of the fetal cardiac anatomy but also the ability to view the cardiac structures in an innovative manner. Our own preliminary experience corroborates these reports. A single sweep was able to produce four-chamber and outflow tract images with the color Doppler demonstrating the cross-over relationship between the pulmonary and the aortic outflows (Figs. 34.14, 34.15). It is apparent that this approach and its future evolution

could substantially increase the ease of fetal echocardiography and improve its diagnostic efficacy.

## Conclusion

Development of 4D ultrasound represents a major advance in non-invasive diagnostic technology and its introduction in clinical practice has initiated a significant paradigm shift in medical ultrasound imaging. Four-dimensional echocardiography allows a more comprehensive assessment of the fetal cardiac anatomy and hemodynamics than has been achievable in any of the current or legacy systems. It has the real potential of significantly expanding the scope of in utero diagnosis of congenital heart diseases and other abnormalities of the fetal heart. This is a very new technology and there is a real dearth of investigations critically evaluating its promises and limitations in the fetal application. This is especially relevant for extending its use outside the domain of experts and enthusiasts. At present, traditional 2D B-mode and Doppler sonography will continue to be the standard of practice for fetal cardiac assessment with substantial supplemental assistance from the 4D echocardiography which, however, has the strong potential to become the mainstream approach in the future.

# Doppler Echocardiographic Assessment of Fetal Cardiac Failure

William J. Ott

## Introduction

In the fetus heart failure is the end stage of many pathological events that may lead to significant neonatal morbidity or mortality. In the adult heart failure is defined as “*the pathophysiological state in which an abnormality of cardiac function is responsible for the failure of the heart to pump blood at a rate commensurate with the requirements of the metabolizing tissues and/or to be able to do so only from an elevated filling pressure*” [1, 2]. In many instances this definition also applies to the fetus, but differences in the anatomy and physiology of the fetal heart, when compared with the adult or neonatal heart, may not allow this definition to be fully applicable to the fetus.

## Fetal Cardiac Anatomy and Physiology

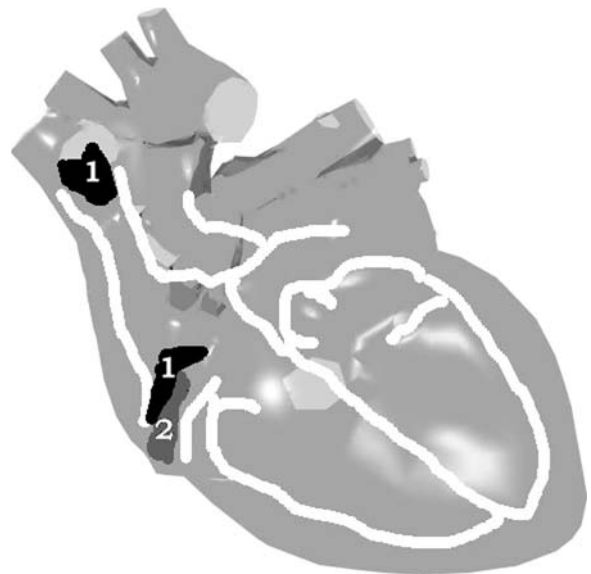

Anatomical and physiological differences between the fetal and neonatal or adult heart call into question the ability to translate the knowledge of the pathophysiological events occurring during heart failure in the adult or neonate to the fetus. In the adult the two ventricular chambers of the heart work in series, with the right ventricle pumping deoxygenated venous blood into the pulmonary circuit and the left ventricle supplying oxygenated blood to the systemic circulation. The fetal heart, however, works in parallel with little of the right ventricular output going to the pulmonary circuit. Figures 35.1–35.3 review the normal fetal intra-cardiac circulation.

Although there is some venous return to the fetal left atria via the pulmonary veins, the majority of venous return to the heart is through the superior and inferior vena cava and associated vessels [3–8]. Deoxygenated blood from the fetal head returns to the right atria from the superior vena cava and directly passes through the tricuspid valve into the right ventricle. Studies in the fetal lamb and other animal models have shown that oxygenated venous blood from the umbilical vein passes through the ductus venosus and preferentially enters the left heart via the foramen ovale [3–

8]. Studies on chronically instrumented fetal lambs have shown that, in physiological conditions, 50%–60% of the umbilical venous blood bypasses the hepatic circulation and enters directly into the inferior vena cava via the ductus venosus [8]. From the inferior vena cava, this highly oxygenated blood preferentially streams through the foramen ovale to the left atrium, left ventricle, and ascending aorta. Figure 35.4 shows venous return in a 22-week fetus. Doppler flow (Fig. 35.4b) shows that, under normal conditions, there is always forward flow throughout the cardiac cycle in the ductus venosus.

Although there may be many anatomical variations in the venous return to the fetal heart, the following general anatomical relationships are noted [9]:

1. The inferior vena cava widens in the proximal portion and enters the atria in a slightly anterior direction. An extension of the inferior vena cava continues into the atria itself as a short tube-like

**Fig. 35.1.** Deoxygenated blood (1) enters the right atrium from the superior and inferior vena cava. Oxygenated blood (2) enters the right atrium primarily from the ductus venosus

**Fig. 35.2.** The oxygenated blood (2) is directed through the foramen ovale into the left atria, while the deoxygenated blood (1) passes into the right ventricle

**Fig. 35.3.** Well-oxygenated blood (2) is then directed out the left ventricular outflow tract to the head and brain; while the deoxygenated blood (1) is directed via the ductus arteriosus down the aorta to the umbilical arteries for oxygenation in the placenta

structure bounded on the right side by the Eustachian valve (or valve of the inferior vena cava) and on the left side by the foramen ovale flap. The atrial septum lies above the middle of the inferior vena cava in a crest-like structure known as the crista dividens (or septum secundum or limbus fossae ovalis). The inferior vena cava/foramen

**Fig. 35.4.** **a** Gray-scale image of parasagittal scan of a 22-week fetus using color Doppler. The aorta and inferior vena cava (IVC) are shown. The *arrow* points to a segment of the ductus venosus as it enters the inferior vena cava just proximal to the right atria. **b** Doppler velocity flow in the ductus venosus of the fetus in **a**. Note the triphasic pattern, but that the flow is always forward throughout the cardiac cycle

ovale complex can be described as a Y-shaped unit with a long branch to the left atrium and a short branch to the right atrium.

2. This anatomical relationship results in two venous pathways for blood return to the fetal heart from the placental and lower body circulations. (a) A right inferior vena cava/right atrium pathway: blood flow from the right hepatic vein and right portion of the proximal inferior vena cava is directed along this pathway. (b) A left ductus venosus/foramen ovale pathway: blood flow from the umbilical sinus, ductus venosus, and left portion of the proximal inferior vena cava is directed along this pathway. The left and medial hepatic

veins connect to this pathway. Blood flow in these two pathways has the proximal inferior vena cava in common but travels in different directions.

These anatomical and physiological relationships result in different pathways for oxygenated and deoxygenated blood returning to the fetal heart. Distal inferior vena cava blood with low oxygen saturation passes through pathway “a” together with the right hepatic venous flow and is directed into the right atria where it joins the deoxygenated blood from the superior vena cava and passes into the right ventricle. Oxygenated blood from the umbilical vein passed through the ductus venosus with some mixing with blood from the left and medial hepatic veins and is directed towards the foramen ovale and the left atria and hence to the left ventricle. These studies in normal human fetuses are, in the main, consistent with previous studies in animal models.

The fetal anatomical shunt of the ductus arteriosus allows the fetal heart to function in parallel rather than in series, as in the adult heart [3]. The deoxygenated blood from the superior vena cava and the “a” pathway blood from the inferior vena cava passes through the tricuspid valve and is ejected out the pulmonary artery. Because of the ductus arteriosus shunt, this poorly oxygenated blood is directed into the descending aorta to the lower carcass, and to the umbilical arteries for oxygenation in the placental circulation. The left ventricle outflow is directed through the ascending aorta to the head and neck to supply the fetal brain with better oxygenated blood derived primarily from the “b” pathway via the foramen ovale. In the normal fetus right ventricular output is significantly greater than the left ventricular output in a ratio of 1.3 to 1.

A detailed evaluation of cardiac anatomy should always be undertaken in cases of suspected fetal heart failure. Normally the two ventricles should be of relatively similar size. Significant differences in ventricular size can be related to structural anomalies (such as hypoplastic left or right heart) or heart failure. Cardiomegaly is a common finding in fetal heart failure. Figure 35.5 shows cardiomegaly in a 24-week fetus with both chronic and acute abruption. An evaluation of cardiac size can be made by comparing the anterior–posterior (AP) and transverse (trans.) diameters of the thorax with the AP and the transverse diameters of the heart in the axial view:

$$\text{Ratio} = \frac{\{[AP(\text{Hrt}) + \text{Trans.}(\text{Hrt})]/2\}}{\{[AP(\text{Th}) + \text{Trans.}(\text{Th})]/2\}}$$

This ratio ranges from 45% to 55% and is independent of gestational age [10]. Using M-mode, measurements of the pulmonary and aortic root diameters

**Fig. 35.5.** Cardiomegaly in a 24-week fetus with acute and chronic abruption

can be obtained. Deng et al. have shown a consistent ratio between the pulmonary and aortic diameters of 1.09 (SD=0.06) with 5th and 95th percentile values of 1.06 and 1.11, respectively [11–13].

## Fetal Cardiac Response to Stress

Because of the anatomical and physiological differences between fetal and adult circulations, the development of heart failure in the fetus may follow slightly different pathways than in the adult. In the adult alterations in myocardial function, and subsequent decrease in cardiac output, can be caused by alterations in one (or a combination) of three basic mechanisms: (a) preload, or ventricular filling pressure; (b) myocardial contractility and heart rate; and (c) afterload or peripheral resistance [1, 2]. Alterations in any of these mechanisms can lead to decreased cardiac output and eventually to cardiac failure.

In the fetus the development of chronic stress and hypoxia results in alterations in fetal cardiovascular function. Both animal experimentation and Doppler evaluation of the human fetus have shown that chronic stress causes an alteration in the right/left heart dominance. During conditions of acute stress the primary fetal response is increased fetal heart rate. During conditions of chronic stress, however, alterations in ventricular function lead to redistribution of cardiac output and preferential perfusion of the fetal brain and coronary arteries.

Rizzo et al. have postulated the theoretical response of the fetal cardiovascular system to increasing fetal stress: a decrease in fetal oxygenation or substrate supply leads to a redistribution of cardiac output, the so-called brain-sparing effect [14]. Eventually the impairment of cardiac function causes an increase in the atrioventricular gradient and an abnormal cardiac filling which causes increased periph-

**Table 35.1.** Causes of heart failure: comparison of adult and fetal causes

Cause	Adult	Fetus
Cardiac arrhythmia	Disorders of arrhythmia	Congenital arrhythmias Maternal collagen vascular disease
Decreased contractility	Metabolic disorders Anoxia/ischemia  Myocarditis	Maternal ketoacidosis Intrauterine growth restriction Myocarditis
Cardiac anomalies	Congenital or acquired	Congenital anomalies
Increased peripheral demand	Myocarditis Systemic infection  Anemia AV shunts	Myocarditis Chorioamnionitis Systemic infection Anemia Fetal tumors Chorioangioma

Decreased venous return	Hemorrhage  Vena cava obstruction	Hemorrhage (abruption, vasa previa, fetomaternal, other) Venous obstruction (tumor, hydrops, other)
Iatrogenic	Drug effects	Indomethacin, tocolytics, others

eral venous pressure and fetal decompensation and cardiac failure. Table 35.1 compares the causes of cardiac failure in the adult with known or postulated causes in the fetus.

## The Scope of Fetal Cardiac Failure

Changes in obstetrical management, the development of new and more accurate methods of fetal surveillance, and a better understanding of the pathogenesis of fetal demise has led to changes in the distribution of the causes of stillbirths. Table 35.2 shows the distribution of stillbirths from a review at the author's institution for the years 1988 through 1992. There were four fetal deaths directly caused by fetal heart failure: one premature closure of the foramen ovale; one case of non-immune hydrops caused by tachyarrhythmia; one case of significant increase in cardiac afterload caused by prune-belly syndrome; and one case of myocardial hypertrophy with heart failure in

a fetus of a diabetic mother. Although only 3% of fetal deaths were directly caused by fetal heart failure, it most likely played a significant role in many other fetal deaths: heart failure was the most likely terminal event in the cases of intrauterine infection (21%), twin–twin transfusion (6%), cord accidents (7%), and acute maternal problems (3%); and may have play a role in many of the cases of placental failure (17%). It is, therefore, likely that fetal heart failure plays a significant role in at least 40%–50% of stillbirths.

## Duplex Doppler Evaluation of the Fetal Cardiovascular System

Evaluation of fetal cardiac status includes measurements of velocity parameters in both peripheral vessels and the heart itself. In peripheral vessels angle-independent indices, such as the pulsatility index, resistance index, and systolic/diastolic (S/D) ratio, are most commonly used. The peripheral vessel most commonly evaluated is the umbilical artery. Changes in the velocity indices in this vessel reflect alterations in placental perfusion that may precede evidence of heart failure in situations of uteroplacental insufficiency. Additional peripheral fetal vessels, such as the aorta, renal arteries, and carotid and middle cerebral

vessels, have also been studied. Alterations in the velocity indices of these vessels, especially in the carotid and cerebral vessels, have been reported to be a sensitive indication of fetal well-being. Velocity measurements at the cardiac level are all absolute values. Measurements of absolute flow velocities require knowledge of the angle of insonation and vessel diameter, each of which maybe difficult to obtain with accuracy. The following formula can be used to calculate volume flow per minute:

Volume flow(ml/min)

$$= \pi/4 \times D^2 \times 1/\cos\theta \times FVI \times HR$$

where D is the diameter (in centimeters) of the vessel studied,  $\theta$  is the angle between the ultrasound beam and the vessel, FVI is the flow velocity integral (area under the velocity waveform), and HR is the heart rate in beats per minute [12]. The error in the estimation of the absolute velocity depends on the magnitude of the angle itself and the diameter of the vessel being interrogated. For angles  $<20^\circ$ , the error is low. With larger angles, the cosine term in the Doppler equation changes the small uncertainty in the measurement of the angle to a large error in velocity equations. In addition, small errors in the measurement of the vessel diameter is magnified by the Doppler equation [12].

The parameters most commonly used to describe the cardiac velocity waveforms are: (a) peak velocity, the maximum velocity at a given moment (e.g., systole, diastole); (b) time-to-peak velocity, or acceleration time, expressed by the time interval between the onset of the waveform and its peak; (c) time-velocity integral, calculated by planimetry of the area underneath the Doppler spectrum; and (d) volume flow (see above) [12]. Velocity flow measurements can be obtained from a number of sites in or near the fetal heart.

### Umbilical Venous Pulsations

During pathologic situations, increased reverse flow in the inferior vena cava may result in venous pulsations in the umbilical vein [14–21]. Indik et al. postulated that it may be possible to distinguish subgroups of fetuses with abnormal umbilical artery S/D ratios by evaluating fetal vena cava flow [21]. They described five sub-groups of fetuses with abnormal umbilical venous pulsations:

1. Tachycardia, which shortens ventricular filling and leads to increased end-diastolic pressure. During atrial contraction the increased end-diastolic pressure causes increased reverse flow in the inferior vena cava.
2. Sinus bradycardia also increases reverse flow by increased ventricular or atrial filling during pro-

longed diastole, leading to increased pressure during atrial contraction.

3. Complete heart block may cause increased reverse caval flow during ventricular systole, most likely due to independent atrial contractions against closed atrioventricular valves.
4. Premature atrial contractions were also noted to cause increased reversed caval flow during the pause following a premature atrial contraction. The mechanism was postulated to be similar to that seen with sinus bradycardia.
5. Abnormal filling of the ventricles is thought to be another etiology for increased reverse flow in the inferior vena cava.

Clinical situations associated with abnormal ventricle filling were congenital heart disease, infants of diabetic mothers, chorioangioma, nonimmune hydrops, and intrauterine growth restriction (IUGR). Umbilical venous pulsations therefore appear to be a significant pathologic event that requires careful fetal evaluation, especially of the fetal cardiovascular system.

### Other Studies

Animal investigations have produced results similar to those seen by Doppler interrogation in the human fetus. Reuss et al. evaluated superior and inferior vena cava and umbilical vein blood flow patterns in fetal sheep using electromagnetic flow transducers [18]. The patterns of velocity flow were similar to those noted above for the human fetus. They were also able to manipulate the circulation of the fetal sheep to study the effects of afterload differences and hypoxia on venous dynamics. Administration of acetylcholine caused a reduction in afterload associated with peripheral vasodilatation, which allowed greater ventricular emptying with increased diastolic peak flow. Hypoxia was associated with an increase in superior vena caval blood flow through the foramen ovale to the left atrium and ventricle. Rizzo et al. postulated the pathophysiological steps leading to changes in biophysical parameters during fetal decompensation [14]: (a) increased resistance in the umbilical artery (S/D ratio); (b) increasing resistance in fetal peripheral vessels with a concomitant decrease in the resistance of vessels in the central nervous system (brain-sparing effect); (c) change in the ratio of right/left ventricular cardiac output with a shift to left ventricular dominance; (d) a decrease in the peak systolic velocities of the outflow tracts with a decrease in combined cardiac output; (e) increase in reverse flow in the inferior vena cava during atrial contractions leading to (f) umbilical venous pulsations and eventually (g) abnormal fetal heart rate tracings.

### Velocity Measurements Across the Atrioventricular Valves

Blood flow across the atrioventricular valves can easily be seen with Doppler sonography (Fig. 35.6) [14, 22–26]. Blood flow velocity can be studied at the level of the mitral or tricuspid valves by placing the Doppler sample volume immediately distal to the valve leaflets in the right or left ventricle. In addition to

**Fig. 35.6.** Gray-scale image of a color Doppler axial scan through the fetal chest at 25 weeks showing flow across the AV valves

obtaining diastolic velocities across the atrioventricular valves, the presence of valvular insufficiency can be ascertained by moving the Doppler gate retrograde through the valve opening. Valvular stenosis has been reported to be associated with increased velocity flow through the affected valve. The waveforms recorded at the level of the mitral and tricuspid valves are characterized by two diastolic peaks: an early ventricular filling peak (E wave) and a second filling peak corresponding to the active ventricular filling phase during atrial contraction (A wave; Figs. 35.7, 35.8). These waveforms can be recorded as early as 12 weeks' gestational age [27].

The ratio between the A and E waves (A/E) is an index of ventricular diastolic function and is related to both cardiac compliance and preload conditions. The A/E ratio shows a significant decrease with advancing gestational age but remains above unity (Figs. 35.7, 35.8). This picture is the converse of that seen in the adult and suggests that ventricular compliance is less in the fetus than the neonate but improves with advancing gestational age. Reed [23] and Reed et al. [25] have shown that in most of the fetuses studied, tricuspid flow velocities during both early and late diastole were greater than those across the mitral valve. This confirms the impression of right heart dominance in the fetus that is seen when evaluating ventricular outflow.

**Fig. 35.7.** Doppler blood flow across the mitral (*left*) and tricuspid (*right*) valves of a 20-week fetus. Note that the A/E ratio is greater than one

**Fig. 35.8.** Doppler blood flow across the mitral (*right*) and tricuspid (*left*) valves of a 34-week fetus. Although the A/E ratio is still greater than one, the ratio is less than that at 20 weeks

There is disagreement in the literature concerning the effects of gestational age on the maximal velocity across the atrioventricular valves. Allan et al. [22] and Reed [23] thought that there was no significant change in maximum or mean velocity flow across the valves throughout gestation, although van der Mooren et al. [26] showed a small but significant increase in velocity parameters with advancing gestational age. The decrease in inferior vena cava reverse flow and the A/E ratio with advancing gestational age is consistent with the increased ventricular compliance seen during that time.

### Ventricular Outflow Velocities

Velocity flow and volume flow measurements have been reported for the right and left ventricular outflows (pulmonary artery and aorta, respectively; shown in Fig. 35.9) [14, 22–26]. The aortic outflow tract can be visualized as it leaves the left ventricle through a slightly rotated, angled four-chamber view, the “five-chamber” view. The pulmonary artery outflow tract as it leaves the right ventricle can be seen from a modified two-chamber view. A number of studies have shown that right cardiac output is greater than left cardiac output throughout gestation, and that beginning at 20 weeks the right/left cardiac output ratio remains constant with a mean value of 1.3, indicating right heart dominance in the human fetus, which has also been reported for the fetal lamb [28, 29].

### Ductus Arteriosus

Ductus arteriosus velocity waveforms can be recorded from a parasagittal short-axis view of the fetus that shows the ductal arch. There is continuous forward flow throughout the cardiac cycle. Ductal peak velocity increases with gestation, and its values represent the highest velocity in fetal circulation occurring under normal conditions. Premature closure of the ductus, which has been reported in patients undergoing indomethacin therapy for premature labor, markedly increases right ventricular afterload and leads to tricuspid regurgitation and eventual cardiac failure. Tulzer et al. confirmed this finding with experimental ductal occlusion in fetal lambs [30].

### Errors in Doppler Blood Flow Velocity Measurements

Doppler velocity flow measurements are prone to error [14, 24]. The most critical factor that affects the accuracy of the measurements is the angle of insonation. Measurement errors increase rapidly if the angle of insonation is greater than  $20^\circ$ . Rizzo et al. reported a coefficient of variation of less than 10% for Doppler velocity flow indices (except for volume flow) when the angle is kept at less than  $20^\circ$  [14]. In addition, the location of the volume flow gate should be frequently checked with duplex or color flow Doppler sonography to confirm the accurate placement of the interrogation site.

**Fig. 35.9.** Doppler blood flow across the aortic (*left*) and pulmonary (*right*) outflow tracts at 24 weeks of gestation

Calculation of volume flow introduces an additional error: measurement of vessel or valve diameter. Because the diameter term is squared in the formula for calculating volume flow, any error in the measurement is significantly magnified. Alverson reported a study of 33 pediatric patients who were scheduled for cardiac catheterization where in the Doppler-calculated volume flow and volume flow measured by the Fick principle during catheterization were directly compared [31]. He demonstrated an excellent correlation between the two methods, with a correlation coefficient ( $r$ ) of 0.981. Fillinger and Schwartz studied Doppler flow measurements in an *in vivo* canine pulsatile flow model and found good correlation between Doppler-calculated and actual flow rates when laminar flow was seen [32]. They expressed caution about the accuracy of Doppler calculations, however, when flow was non-laminar, and they stressed the importance of the angle of insonation. In addition to the above measurement techniques, care must be taken to record velocity flow measurements during periods of fetal rest.

## Clinical Conditions Associated with Fetal Heart Failure

Experience in obstetrical duplex Doppler examinations of the fetus have identified a number of clinical conditions where fetal heart failure is the cause of fetal death or a significant contributor to it.

### Congenital Heart Disease

Structural fetal heart disease is the most common congenital anomaly seen at birth with an incidence of 7–10 per 1,000 live births. Although congenital heart disease is the most common birth defect seen in the neonatal period, there is strong evidence that it is even more common during the fetal period. Two reports have shown that 24% of fetuses with diagnosable congenital heart disease died *in utero*, most likely from fetal heart failure [33, 34].

Ultrasound has been used extensively for the diagnosis and evaluation of structural congenital heart disease [35–42]. Many structural anomalies can be visualized using only conventional ultrasound; however, the use of color flow Doppler can significantly enhance the diagnostic accuracy in suspected congenital heart disease [33, 34, 38, 43–47]. Color Doppler flow studies, coupled with velocity flow measurements,

**Table 35.3.** Changes in Doppler flow velocities with cardiac anomalies. *I* increased, *D* decreased, *A* absent, *U* unchanged, *R* possible regurgitation, *V* variable. (From [45])

Anomaly	Velocity flow			
	Tricuspid valve	Mitral valve	Pulmonary artery	Aorta
Hypoplastic right heart	D	I	D	I
Hypoplastic left heart	I	A	I	A
Tricuspid atresia	A		I	D
Ebstein's anomaly	I or R	I	D	I
Pulmonary atresia	I or R	I	A	I
Tetralogy of Fallot	U	U	D	I
Transposition	U	U	U	U
Double-outlet right ventricle	I	D	V	V
Atrioventricular canal	I or R	I or R	V	V

can (a) confirm the presence or absence of normal flow patterns in cardiac structures, (b) note the presence of abnormal flow patterns such as valvular regurgitation, absence of normal chamber filling (which might be seen in valvular atresia), or increased peak velocity (which may be seen in cases of valvular stenosis), and (c) identify reversal of normal flow direction (such as in the foramen ovale and aortic arch in the case of mitral atresia or in the ductus arteriosus with pulmonary atresia). In cases of fetal ventricular septal defect (VSD), however, there is little flow across the VSD since the pressure gradient between the two ventricles is minimal during intrauterine life. Table 35.3, modified from an article by Reed, shows the alterations in velocity flow that are frequently seen in many cases of congenital heart disease [45]. Umbilical and middle cerebral artery flow in fetuses with congenital heart disease was evaluated by Meise et al., who found little change in arterial blood flow velocities compared with normal fetuses [46]. Only in fetuses with severe outflow tract obstructions were there significant changes in arterial flow. They felt that abnormal arterial Doppler waveforms reflected uteroplacental dysfunction rather than alterations caused by the congenital heart disease.

A number of authors have reported hydrops fetalis and fetal heart failure associated with congenital heart disease. Sahn et al. reported a case of trisomy 13 with hypoplastic left heart syndrome that developed hydrops fetalis [44]. Interrogation of the tricuspid valve revealed high-velocity flow, 1.5 times great-

er than the normal values for their laboratory. Blake et al. reviewed a series of twenty fetuses with hypoplastic left heart syndrome [33]. Three of the 11 (27%) fetuses that were not terminated died in utero, most likely secondary to fetal cardiac failure. These authors also point out the importance of antenatal diagnosis of congenital heart disease. It allows (a) timely cytogenetic studies to be done, (b) early diagnosis and intervention in the neonatal period and planning for definitive therapy, and (c) additional time for parents to plan and discuss various treatment options for the fetus and obtain sufficiently informed consent.

Additional reports of fetal heart failure in infants with congenital heart disease have also been published in the literature. Respondek et al. reported a case of heart failure in a fetus with left atrial isomerism (common atrium) associated with complete heart block [47]. Color Doppler flow showed abnormal, turbulent flow in the regions of both the pulmonary artery and the aortic valve and increased flow velocity across the atrioventricular valves. Pericardial effusion and hepatomegaly were also noted. The infant died shortly after birth and an autopsy also disclosed unsuspected vegetation close to the thickened atrioventricular valves. The endocardium also showed evidence of endocarditis. Guntheroth et al. [48] and DeVore et al. [49] have reported abnormal flow studies in cases of pulmonary valve stenosis or atresia. Tricuspid regurgitation was felt to be a key sign of impending fetal heart failure. Rustico et al. reported a case of endocardial fibroelastosis associated with critical aortic stenosis and abnormal outflow tract flow diagnosed at 15 weeks' gestation.

An excellent review of the use of color Doppler flow studies for the diagnosis of congenital heart disease can be found in two articles by DeVore et al. [49] and DeVore [51]. They describe abnormal Doppler flow findings in some of the more common cardiac anomalies:

1. Aortic stenosis: retrograde flow into the left atrium during ventricular systole.
2. Ventricular septal defect (VSD): since the pressure in the left and right ventricle are almost identical in the fetus, there is frequently no flow disturbance across the septum. Flow disturbances may be seen, however, when there is an associated abnormality of the outflow tract with increased resistance to the flow of blood leaving the ventricle.
3. Atrioventricular canal defect (AV canal): the presence of AV valvular regurgitation has been found to be a sign of developing hydrops fetalis and heart failure.
4. Atrial septal defect (ASD): reverse flow (left-right shunt) across the ASD may lead to right ventricular dilatation and heart failure.

5. The presence of valvular regurgitation, especially tricuspid regurgitation, has been associated with fetal anemia, right ventricular volume overload, and ductal constriction.

One important consideration that must be emphasized in the evaluation of fetal congenital heart disease is the high association between structural heart disease in the fetus and chromosomal abnormalities. Abnormal karyotypes have been reported in 20%–45% of fetuses with cardiac defects, and Paladini et al. have reported that 48% of fetuses with congenital heart disease had abnormal karyotype: 29% with isolated cardiac anomalies and 71% with cardiac and extracardiac anomalies [52]. Amniocentesis or cordocentesis with cytogenetic evaluation is an integral part of the evaluation of suspected fetal cardiac anomalies.

One very rare but documented congenital condition that leads to fetal heart failure is intrauterine myocardial infarction. Birnbacher et al. reported a case of intrauterine myocardial infarction in a fetus that subsequently developed a large ventricular aneurysm [53]. Congenital heart disease, intrauterine asphyxia, infection, and maternal drug use have been associated with intrauterine myocardial infarction [54–56]. Findings include cardiomegaly, decreased contractility, and hypokinesia of the ventricular wall frequently associated with a ventricular aneurysm.

## Fetal Hydrops

Fetal hydrops is defined as a pathological increase in fluid accumulation in serous cavities and/or edema of soft tissues [57]. Prior to 1960, the most common recognizable cause of fetal hydrops leading to fetal or neonatal death was maternal Rh sensitization. Because of the widespread use of Rh prophylaxis, the incidence of fetal hydrops secondary to Rh sensitization has been drastically reduced. Many of the known causes of non-immune fetal hydrops are listed in Table 35.4.

Fetal heart failure is a central mechanism in the development of many cases of non-immune hydrops. In an excellent review of the topic Hutchinson listed six general causes of edema or ascites in the fetus [58]:

1. Heart failure or venous obstruction leading to alteration in hydrostatic pressure
2. Hypoproteinemia leading to alterations in colloid osmotic pressure
3. Changes in membrane permeability caused by inflammation or other causes
4. Change in interstitial gel and its affinity for water
5. Alterations in lymphatic drainage
6. Changes in water homeostasis of the fetal–maternal–placental unit.

**Table 35.4.** Causes of non-immune fetal hydrops

Hematological	
	Anemia due to maternal acquired pure red-cell aplasia

Although primary fetal heart failure can be a cause of non-immune fetal hydrops, heart failure secondary to other causes, such as anemia, hypoproteinemia, or hypoxia, may be a more common etiology of the problem. Many of these postulated causes of non-immune fetal hydrops are analogous to some of the causes of heart failure in the adult.

### ***Isoimmunization***

Isoimmunization in the fetus (usually as a result of Rh incompatibility) results in a progressive destruction of fetal red cells and fetal anemia [59]. Doppler studies have shown that both left and right cardiac outputs are significantly higher than normal in anemic fetuses, with a significant increase in volume flow, peak velocity in the outflow tracts, and an de-

**Fig. 35.10.** Regression of the peak velocity of the middle cerebral artery [converted to multiples of the mean (MOM) for gestational age] against the fetal/neonatal hematocrit (converted to MOM for gestational age) at cordocentesis or

delivery. The *right side* of the figure shows the peak velocity in the middle cerebral artery in anemic vs non-anemic fetuses or neonates

crease in the A/E ratio at both atrioventricular valves [60]. The increased cardiac output seen in these anemic fetuses may be due to a decrease in blood viscosity which, in turn, leads to increased venous return and cardiac preload; and/or to peripheral vasodilatation caused by a fall in blood oxygen content and therefore reduced cardiac afterload. There is no evidence for a redistribution of cardiac output similar to that described in hypoxic IUGR fetuses [60].

The traditional method of evaluating fetal anemia in sensitized patients is the serial determination of amniotic fluid changes in optical density at 450 nm [61, 62]. The use of Doppler ultrasound to measure peak velocity in the fetal middle cerebral artery has been shown to be an accurate, non-invasive method of evaluating fetal anemia [63–65]. Figure 35.10 shows the correlation between fetal/neonatal hematocrit and peak velocity in the fetal middle cerebral artery in 36 patients with suspected fetal anemia (primarily due to isoimmunization) followed at the author’s institution. Doppler ultrasound appears to be as accurate as serial amniocentesis in evaluating suspected fetal anemia, and has the important advantage of being a non-invasive test [66].

**Non-Immune Hydrops**

As has been mentioned previously non-immune fetal hydrops may be secondary to a multitude of different causes. The first step, therefore, in the evaluation and management of fetuses with suspected non-immune hydrops is to attempt to determine its etiology. Some of the more common causes of non-immune fetal hydrops include chromosomal abnormalities, mass lesions that affect fetal blood flow, lymphatic abnormalities, metabolic diseases of the fetus, and infection

**Table 35.5.** Evaluation of non-immune fetal hydrops. TORCH toxoplasmosis, other, rubella, cytomegalovirus, herpes. (From [57])

Evaluation	Test	Etiology?
Maternal	Antibody screen	Rule out isoimmunization
	Complete blood count and indices	Hematological disorders
	Electrophoresis	Thalassemia
	Kleihauer-Betke stain	Fetal–maternal hemorrhage
	VDRL and TORCH titers	Fetal infection
	Glucose tolerance test	Maternal diabetes
Fetus	Level II ultrasound and color Doppler	Anatomical or physiological abnormalities of the fetus
	Cordocentesis	Karyotype (chromosomal anomalies)
	Amniocentesis	Cultures/immunology (infection)
	Paracentesis Thoracenteses	

[67–72]. Table 35.5, modified from a review by Holzgreve et al., lists many of the tests necessary to appropriately evaluate cases of non-immune hydrops [57].

A study by Saltzman et al. reviewed the ultrasonic differences seen in anemic and non-anemic fetuses with hydrops [60]. The lack of a thickened placenta, and the presence of pleural effusions and/or marked edema, was more frequently associated with non-anemic causes of fetal hydrops. Doppler echocardiography may be useful in the additional differentiation between cardiac and non-cardiac causes of non-immune hydrops [45, 71]. Increased velocity in the middle cere-

bral artery correlates with fetal anemia. Low-peak velocity in the outflow tracts, exaggerated pulsations in the inferior vena cava, or an increase in the percentage of reverse flow in the inferior vena cava during atrial contractions, pulsations in the umbilical vein, and tricuspid regurgitation are all developing signs of fetal heart failure. Pulsations in the umbilical vein appear to be a sign of significant fetal compromise.

The outcome for fetal non-immune hydrops depends on the cause of the condition and the gestational age at diagnosis. Diagnosis before 20 weeks carries a worse prognosis, but even with aggressive therapy the mortality rate for non-immune hydrops is 40%–60% [73–75]. As has been mentioned previously, there are multiple causes of non-immune hydrops and a discussion of even some of its major causes is beyond the scope of this chapter; however, two specific causes of non-immune hydrops should be mentioned since they are directly related to fetal heart failure: fetal cardiac arrhythmia and fetal anemia.

### Fetal Cardiac Arrhythmia

Persistent alterations in the rate or rhythm of the fetal heart can lead to heart failure, non-immune hydrops, and significant neurological morbidity after delivery [76–84]. A number of excellent review articles on the diagnosis and treatment of fetal cardiac arrhythmia have been published [77]. Arrhythmia tachycardia is the most common pathological anomaly noted and the one that most frequently leads to hydrops.

Doppler echocardiographic evaluation of the fetal heart can be an important adjunct in the proper classification of fetal cardiac arrhythmia and in the evaluation of fetal therapy. Chan et al. reported the use of simultaneous recordings of the Doppler waveforms from the inferior vena cava and aorta for the precise diagnosis of the type of arrhythmia seen [82]. Intermittent or non-persistent tachycardia can be managed by careful observation [85–88]. In many situations, spontaneous resolution of fetal tachycardia has been noted, leading some investigators to recommend a conservative approach to fetal tachycardia if there is no evidence of fetal cardiac compromise (no evidence of chamber dilatation, valvular regurgitation, hydrops, or decreased ventricular systolic function) [89].

If there are any signs of fetal cardiac compromise or if the tachyarrhythmia is persistent, intrauterine therapy may be necessary. Table 35.6, modified from the work of a number of investigators, lists the dosage of maternally administered oral drugs frequently used in the treatment of in utero fetal arrhythmias [77–80]. Careful monitoring of both fetus and mother is necessary in the pharmacological treatment of fetal arrhythmia, and consultation with a cardiologist is essential.

**Table 35.6.** In utero therapy of fetal arrhythmia

Arrhythmia	Drug	Dosage (maternal)
Supraventricular tachycardia (may be added if no response)	Digoxin	0.25–0.75 mg q 8 h
	(Verapamil)	80–120 mg q 6–8 h
	(Flecainide)	100 mg three to four times a day

Persistent fetal bradycardia is a much less frequent problem. Congenital heart block, which may be associated with maternal systemic lupus or with some congenital heart defects (transposition of the great vessels or AV canal defects), can usually be managed conservatively [84]. The use of M-mode for diagnosis and evaluation of fetal arrhythmias has also been reported [86].

### Fetal Anemia

Fetal anemia can develop from a number of causes, with isoimmunization leading to fetal hemolysis being a classical case. Alpha-thalassemia-1 (Bart's disease), caused by an inherent deficiency in the alpha-globin hemoglobin chain, leads to severe fetal anemia, hydrops and fetal death [90]. Cardiomegaly, increasing velocities in the middle cerebral artery, and eventual fetal hydrops are ultrasonic hallmarks of the disease [90, 91].

Significant fetal–maternal hemorrhage can be a cause of stillbirth or neonatal anemia [92]. The diagnosis is usually made after delivery by finding significant fetal blood in the maternal circulation using the Kleihauer-Betke test. The use of Doppler ultrasound to measure the peak velocity in the middle cerebral artery has provided an accurate, non-invasive method of evaluating suspected fetal anemia. Figure 35.11 shows the graph of the peak velocity in the middle cerebral artery of a fetus that was evaluated for decreased movement at 32 weeks of gestation. The marked increase in peak velocity together with a non-reactive NST led to an emergency Cesarean delivery. The neonate was anemic with a hemoglobin/hematocrit of 10.2/29. A Kleihauer-Betke test on the mother's blood showed evidence of greater than 120 cc of fetal blood, confirming the diagnosis of fetal–maternal bleeding.

A number of other causes of fetal bleeding and subsequent anemia have been reported. Cases of intracranial hemorrhage secondary to trauma, thrombocytopenia, or preeclampsia has been published [93–95]. Fetal hemorrhage into cystic tumors or fetal bleeding secondary to abruption or ruptured vasa previa can also cause severe fetal anemia.

**Fig. 35.11.** The significantly elevated peak velocity (cm/s) in the middle cerebral artery of a 32-week fetus who was shown to have significant fetal-maternal hemorrhage

### Twin-Twin Transfusion Syndrome

A complication peculiar to monochorionic twin gestation is the “twin-twin transfusion syndrome” [96–101]. The clinical features of this syndrome are listed in Table 35.7.

The diagnostic criteria for the syndrome include the above clinical findings, and, in addition (a) a hemoglobin difference of greater than five grams of hemoglobin per decaliter, (b) weight discordance, and (c) pathological confirmation of monochorionic placentation with significant vascular communications between the placentas.

This last criterion is the suggested cause for the development of twin-twin transfusion, namely vascular anastomosis between the two twin placentae of the arterial-venous type, from the donor to the recipient, deep within the placenta that is uncompensated [101]. This in turn leads to anemia and IUGR in the donor twin, and polycythemia and high-output failure in the recipient twin [102–106]. The ultrasonic diagnosis of twin-twin transfusion requires the features listed in Table 35.8. Monochorionic twins have a 5%–20% risk developing some degree of twin-twin transfusion [107–109]. Twin-twin transfusion is exceedingly rare in monoamniotic twin gestation because of the large number of vascular anastomoses found in this type of twin gestation leading to an overall balanced flow between the two placentas. Reports of twin-twin transfusion syndrome cases list a mortality rate of 30%–60% for at least one of the twins and a high incidence of congenital abnormalities (10%) [107–109].

Doppler velocity studies of the umbilical artery and vascular communications between the twin pla-

centas have added additional information concerning the management of twin-twin transfusion [102, 103]. Although there is some disagreement between investigators, most authors feel that abnormal umbilical S/D ratios (or other abnormal ratios) are of prognostic value in determining the severity of the twin-twin transfusion [104–106]. Achiron et al. described a spontaneous remission of hydrops fetalis in a case of twin-twin transfusion syndrome that was followed using two-dimensional echocardiography, Doppler ultrasound, and color flow mapping [105]. The recipient twin, who developed hydrops, showed cardiome-

galy and venous distention. It also showed a significant increase in cardiac output and evidence of mitral and tricuspid regurgitation. Velocity flow studies remained stable throughout the pregnancy and a gradual improvement in the hydrops in the recipient twin was seen. After birth, a neonatal echocardiogram showed cardiomegaly, poor contractility, and mitral and tricuspid regurgitation in the recipient twin. The donor twin had normal cardiac output and velocity measurements. These authors recommended serial cardiac velocity flow studies in all cases of suspected twin-twin transfusions [104]. Cardiomegaly and tricuspid valve regurgitation are consistent findings seen in the recipient twin as it deteriorates [108].

Some investigators have attempted to identify pregnancies at risk for twin-twin transfusion by evaluating blood flow in the first trimester. Matias et al. evaluated 20 monochorionic twin pairs in the first trimester and felt that the presence of an increased nuchal fold and abnormal ductus venosus blood flow (reversed A wave) was highly predictive of the development of twin-twin transfusion syndrome later in pregnancy [109].

### **Intrauterine Growth Restriction**

True IUGR is a pathological process that affects normal fetal growth and results in an infant whose growth is less than its inherent potential [109–114]. A number of chronic maternal medical conditions, such as the hemoglobinopathies or significant heart disease, result in decreased oxygen delivery to the fetus and lead to IUGR. Other maternal diseases, especially those in which hypertension is a component, or abnormalities of the placenta can also cause IUGR. Problems such as congenital anomalies or intrauterine infection damage the developing fetus and decrease its growth. These pathological processes can diminish the normal inherent growth potential of the fetus. This, in turn, can result in chronic fetal hypoxia and eventual fetal heart failure and death. The combined use of ultrasonic fetal weight estimation, fetal anthropometric ratios, and Doppler ultrasound has been shown to be a reasonably accurate method of diagnosing and following fetuses with IUGR. This topic is discussed more fully in the chapter on IUGR and Doppler.

True IUGR caused by abnormalities in uteroplacental perfusion is characterized by selective changes in peripheral vascular resistance that can be evaluated using any of the angle-independent indices of Doppler velocity flow studies in the fetal peripheral vessels [112]. The author's experience has shown that umbilical artery Doppler velocity studies have been a significant help in the diagnosis and management of IUGR [13, 111].

The role of Doppler velocity flow studies in the heart and great vessels is not fully known. Increased placental resistance and increased systemic resistance due to hypoxia that may be seen in IUGR may lead to increased right heart work and decreased right ventricular flow. A redistribution of cardiac output in IUGR results in a decreased left ventricle afterload due to the cerebral vasodilatation, and an increased right ventricle afterload due to the systemic vasoconstriction [114–116]. Furthermore, hypoxemia may impair myocardial contractility, while the polycythemia that is usually present might alter blood viscosity and therefore preload. A number of investigators have shown alterations in velocity flow in the heart with impaired ventricular filling causing an increased A/E ratio at the level of the atrioventricular valves, lower peak velocity in the aorta and pulmonary arteries, increased aortic and decreased pulmonary time-to-peak velocities, and a relative increase of left cardiac output associated with decreased right cardiac output [110–114]. These changes are compatible with a preferential shift of cardiac output in favor of the left ventricle, leading to improved perfusion to the brain, the "brain-sparing" effect.

As the fetus deteriorates, peak velocity and cardiac output gradually decline and cardiac filling is impaired. An increase in reverse flow in the inferior vena cava during atrial contraction may occur and the fetus continues to deteriorate which, in turn, will lead to pulsations in the umbilical vein. Rizzo et al. have speculated that the fetal heart adapts to placental insufficiency in order to maximize brain substrates and oxygen supply [14]. With progressive deterioration of the fetal condition, this protective mechanism is overwhelmed by the fall in cardiac output and fetal distress occurs. These findings suggest that the study of cardiac and great vessel blood flow patterns will be a useful tool for longitudinal monitoring of the fetal condition in pregnancies complicated by uteroplacental insufficiency. Makikallio et al. have shown that the development of retrograde flow in the aortic isthmus of IUGR fetuses indicated high right ventricular afterload [116].

### **Diabetes Mellitus**

Infants of diabetic mothers have long been recognized as being at risk for cardiac enlargement, heart failure, and stillbirth. Cardiac hypertrophy and a transient type of hypertrophic subaortic stenosis have been described in these infants. Although many investigators feel that fetal cardiac hypertrophy in infants of diabetic mothers is due to poor maternal glucose control with resultant fetal hyperinsulinemia, Rizzo et al. have described a progressive thickening of the interventricular septum and right and left ventricular

walls in fetuses of diabetic mothers even in infants of mothers who were under good glucose control [117]. The hemodynamic effects of these morphological changes may lead to impairment of cardiac diastolic function and eventual heart failure. Infants of diabetic mothers, even in those situations where tight glucose control has been obtained, have a significantly higher incidence of sudden fetal death [117–122]. An increased thickness in the ventricular walls, particularly in the interventricular septum, has been noted in these infants. Hypertrophy and disorganization of the myofibrils of the fetal heart have also been found at time of autopsy.

Doppler studies have shown evidence that the disproportional thickening of the intraventricular septum results in functional left ventricular outflow tract obstruction which may lead to cardiac failure. Increased A/E ratios at the level of both atrioventricular valves and higher peak velocity values at the outflow tracts were found in such fetuses. Weiner et al. felt that this was due to an increasing A wave during the later part of gestation suggesting increased cardiac contractility and output in fetuses of diabetic women [121]. Polycythemia, which is frequently present at birth in infants of diabetic mothers, results in increased blood viscosity which may alter preload and affect ventricular filling. The high peak velocity values in the aorta and pulmonary artery may be due to increased contractility, or secondary to an increased intra-cardiac flow volume, due to the fetal macrosomia frequently seen in infants of diabetic mothers.

### Other Causes of Fetal Heart Failure

A wide variety of other known, and probably unknown, conditions can lead to fetal heart failure [122–129]. Primary myocarditis of viral etiology has been reported in the fetus. Blood-borne transplacental infection or ascending chorioamnionitis may cause significant systemic fetal infection which, in turn, may cause fetal cardiac failure. High output failure in the fetus has been reported in association with rare fetal tumors, such as fetal teratoma, goitrous hypothyroidism, hemangiomas, or rhabdomyosarcomas [122–129]. In most of these cases the high output failure is due to arterial-venous shunts within the tumor itself or secondary to vascular compression by an expanding mass.

Morine et al. described a case of high-output failure in a fetus (cardiomegaly, pleural effusion, and increased velocity in the carotid artery) diagnosed with goitrous hypothyroidism [127]. The symptoms reversed after intrauterine treatment with levothyroxine. Arterial-venous malformations in the fetus, such as an aneurysm of the vein of Galen, have also been reported to cause fetal hydrops [128]. Chorioangio-

mas of the placenta are benign hemangiomas that can be seen in 1% of all placentas. Usually they cause no problems, but when large (>5 cm), they can cause polyhydramnios and, occasionally, high-output failure in the fetus secondary to arterial-venous shunts [129]. Cardiomegaly and abnormal venous flow in the fetus are typical signs of developing heart failure [130].

Iatrogenic causes of fetal heart failure may be associated with maternal drug use, especially indomethacin, which has been reported to cause premature closure of the fetal ductus arteriosus resulting in fetal heart failure. Indomethacin has been shown to cause transient constriction of the ductus arteriosus, resulting in an increase in both systolic and diastolic velocity in the ductus. As a consequence, tricuspid regurgitation and heart failure may occur. Beta-agonists have an inotropic effect on the fetal heart which may lead to an increase of both peak velocity in the aorta and pulmonary artery and an increase of the stroke volume. Levy et al. have reported that the combined use of indomethacin and corticosteroids may have additive effects on ductal constriction [131]. The long-term effects of these drugs is still unknown.

Fisher has reviewed many of the causes of cardiomyopathies that may affect the fetus [132]. Hypoxia and acidemia, metabolic abnormalities, such as hypocalcemia, or congenital metabolic diseases, such as Pompe's disease or endocardial fibroelastosis, have all been reported to cause fetal cardiac failure.

### Summary and Conclusion

A large number of clinical conditions have been found that may lead to intrauterine cardiac failure. Pulsed and color Doppler techniques have improved our knowledge of fetal cardiovascular response to structural and functional heart diseases. Key features of developing fetal heart failure that may be seen include:

1. Valvular regurgitation
2. Altered velocities
3. Chamber dilatation
4. Fluid collections: ascites, edema, pericardial
5. Reverse flow: vena cava, umbilical pulsations.

Doppler blood flow studies have enabled investigators and clinicians to better understand the pathological processes involved in developing fetal heart failure and to plan appropriate treatments or interventions. We can expect that further study and experience with the use of Doppler blood flow studies will lead to increased improvement in perinatal morbidity and mortality.

# Doppler Echocardiographic Studies of Deteriorating Growth-Restricted Fetuses

Domenico Arduini, Giuseppe Rizzo

Intrauterine growth restriction (IUGR) is associated with significant perinatal mortality and morbidity [1, 2]. Adequate management of this condition requires early recognition of small-for-gestational-age (SGA) fetuses, a differential diagnosis of the factors that induce a delay in growth, monitoring the fetal condition, and determining the time of delivery.

The differential diagnosis between these etiologies is complex, but the introduction of noninvasive (i.e., high-resolution ultrasound imaging and Doppler ultrasonography) and invasive (i.e., cordocentesis) techniques allows a differential diagnosis in most of the cases [3]. Doppler ultrasonography, by providing a unique tool with which to examine fetal and maternal circulations noninvasively, has greatly enhanced our knowledge of the circulatory adaptive mechanisms that occur with various complications of pregnancy including IUGR [4, 5]. In particular, the study of fetal intracardiac hemodynamics has clarified the pathophysiologic steps in progressive fetal deterioration, allowing better definition of the severity of fetal compromise. Accurate assessment of the fetal condition may have favorable effects on perinatal mortality and morbidity, as fetuses can be delivered before irreversible damage occurs. In this chapter we outline the importance of Doppler echocardiography for antenatal monitoring of IUGR fetuses, with special emphasis on the hemodynamic changes at the level of the fetal heart in the presence of progressive deterioration.

## Pathophysiology

Although the pathophysiology underlying uteroplacental insufficiency is poorly understood, it is assumed that various maternal, uterine, placental, and perhaps fetal abnormalities cause a reduction in the supply of nutrients provided to the fetus through the placenta [5–7]. This situation induces Doppler-detectable modifications in various vascular districts. These changes may include increased impedance to flow at the level of the uterine arteries (believed secondary to failure or impairment of trophoblast invasion), which results

in poor uteroplacental blood perfusion [8, 9]. Similarly, impedance to flows is usually increased in the umbilical artery, which is considered an expression of high placental vascular resistance due to a reduction in the number of small muscular arteries in the tertiary stem villi or their obliteration [10–12]. Other explanations, such as increased fetal blood viscosity or reduced arterial blood pressure, have not been excluded [13, 14]. Irrespective of the underlying cause, the increased impedance in the uterine or umbilical arteries results in reduced delivery of oxygen and placental substrates to the fetus [5]. This condition causes differential changes of arterial vascular resistances in the fetal circulation with vasodilatation at the level of the brain and myocardium and constriction at the muscular and visceral level, resulting in the brain-sparing effect [15–17], a phenomenon long recognized in animal models [18]. Thus during the first stage of the disease, the supply of substrates and oxygen to vital organs is maintained at near-normal levels despite an absolute reduction of placental transfer.

The temporal sequence of Doppler-detectable modifications during a pregnancy with developing IUGR is still unknown. Sometimes abnormal uterine artery velocity waveforms are the first Doppler-detectable sign [19]. IUGR may occur even in the presence of normal uterine artery velocity waveforms, suggesting an etiology primarily related to abnormal placental function. Similarly, there is no evidence as to whether the abnormalities in the umbilical artery occur earlier, simultaneously, or later than those in fetal vessels [20]. As already stated, despite the common denominator of a reduced supply of nutrients, IUGR has multiple etiologies that may involve the uterine circulation, placenta, or fetal circulation.

Persistence of nutritional deprivation leads to progressive deterioration of the fetal condition with further hemodynamic changes mainly affecting cardiac function [21, 22] and causing abnormalities in the venous system [23]. Additional modifications include abnormalities in fetal motor behavior and heart rate patterns [6, 24]. Finally, if the fetus is not delivered in due course, fetal death ensues.

## General Principles of Doppler Echocardiography for Functional Study of Fetal Cardiac Function

### Fetal Circulation

Fetal cardiac hemodynamics differ from that seen postnatally. During fetal life blood is oxygenated in the placenta and returns to the fetal body via the umbilical vein. Studies on chronically instrumented fetal lambs have shown that under physiologic conditions about 55% of umbilical venous blood bypasses the hepatic circulation, entering the inferior vena cava (IVC) directly via the ductus venosus [5, 25]. From the IVC this highly oxygenated blood preferentially streams through the foramen ovalis into the left atrium, left ventricle, and descending aorta. In contrast, poorly oxygenated blood from the hepatic and superior vena cava circulations enters the right atrium and is almost completely directed through the tricuspid valve in the right ventricle and pulmonary artery [5, 25]. Because fetal blood is not oxygenated by the lungs an additional shunt (i.e., the ductus arteriosus) operates to bypass the pulmonary circulation, preferentially directing the right ventricular output to the descending aorta. As a consequence, both ventricles eject into the systemic circulation in parallel. The output of the left ventricle is directed through the ascending aorta to upper body organs, making the most highly oxygenated blood available to the heart and brain. The right ventricle ejects through the patent ductus arteriosus and the descending aorta to the lower body and placenta.

### Doppler Echocardiographic Technique

The parameters used to describe fetal cardiac velocity waveforms differ from those used for fetal peripheral vessels. In the latter situation indices such as the pulsatility index (PI), resistance index (RI), and systolic/diastolic (S/D) ratio are used. These indices are derived from relative ratios between the systolic, diastolic, and mean velocities and are therefore independent of the absolute velocity values and the angle of insonation between the Doppler beam and the direction of the blood flow [5, 26].

Unlike measurements at the cardiac level, other measurements yield absolute values. Measurements of absolute flow velocities require knowledge of the angle of insonation, which may be difficult to obtain with accuracy. Errors in the estimation of the absolute velocity resulting from the uncertainty of angle measurement are strongly dependent on the magnitude of the angle itself. For angles less than  $20^\circ$  the error is reduced to practical insignificance. For angles greater than  $20^\circ$

the cosine term in the Doppler equation changes the small uncertainty in the measurement of the angle into a large error in the velocity equations [5, 26]. As a consequence, recordings should be obtained with the Doppler beam as parallel as possible to the bloodstream. Moreover, all recordings with the estimated angle greater than  $20^\circ$  should be rejected.

Color Doppler sonography may solve many of these problems by showing in real time the flow direction, thereby allowing proper alignment of the Doppler beam with the direction of the blood flow. To record velocity waveforms, pulsed-wave Doppler sonography is generally preferred to the continuous-wave Doppler technique because of its range resolution. During recordings the sample volume is placed immediately distal to the location being investigated (e.g., distal to the aortic semilunar valves to record the left ventricular outflow).

### Parameters Measured

The parameters most commonly used to describe the cardiac velocity waveforms are the following: *peak velocity* (PV), expressed as the maximum velocity at a given moment (e.g., systole, diastole) on the Doppler spectrum; *time to peak velocity* (TPV), or acceleration time, expressed by the time interval between the onset of the waveform and its peak; and the *time velocity integral* (TVI), calculated by planimetry the area underneath the Doppler spectrum.

It is possible also to calculate *absolute cardiac flow* from the atrioventricular valve and outflow tracts by multiplying the TVI  $\times$  valve area  $\times$  fetal heart rate (HR). These measurements are particularly prone to errors mainly because of inaccuracies in the valve area. The area is derived from the valve diameter, which is near the limits of ultrasound resolution; this figure is then halved and squared during the calculation, thereby amplifying any potential error. The measurements can be used properly in longitudinal studies for a short time interval during which the valve dimensions are assumed to remain constant. Furthermore, it is also possible to calculate accurately the relative ratio between the right and left cardiac outputs (RCO/LCO), thereby avoiding measurement of the cardiac valve: The relative dimensions of the aorta and pulmonary valves remain constant throughout the gestation in the absence of cardiac structural disease [27].

### Recording Sites and Velocity Waveforms: Characteristics and Significance

In the human fetus blood flow velocity waveforms can be recorded at all cardiac levels, including venous return, foramen ovalis, atrioventricular valves, outflow tracts, and ductus arteriosus. Various factors af-

fect the morphology of the velocity waveforms from different areas, among them preload [28, 29], afterload [29, 30], myocardial contractility [31], ventricular compliance [32], and fetal heart rate [33]. It is not possible to obtain simultaneous recordings of pressure and volume, so we cannot fully differentiate between these factors in the human fetus. However, because each parameter and recording site can be specifically affected by any one of these factors it is possible to indirectly elucidate the underlying pathophysiology by performing measurements at various cardiac levels.

### **Venous Circulation**

Blood flow velocity waveforms may be recorded from the superior and inferior vena cava, ductus venosus, umbilical vein, and pulmonary veins. The vascular areas most intensively studied are the IVC, ductus venosus (DV), and umbilical vein.

The IVC velocity waveforms, recorded from the segment of the vessel just distal to the entrance of the ductus venosus [34], are characterized by a triphasic profile with a first forward wave concomitant with ventricular systole, a second forward wave of smaller dimensions seen during early diastole, and a third wave with reverse flow during atrial contraction [23]. Several indices have been suggested for analyzing IVC waveforms, but the most frequently used is the percent reverse flow, which is quantified as the percent of TVI during atrial contraction (reverse flow) with respect to total forward TVI (first and second wave) [23]. This index is considered to be related to the pressure gradient between the right atrium and the right ventricle during end-diastole, which is a function of both ventricular compliance and ventricular end-diastolic pressure [34].

Ductus venosus velocity may be recorded in a transverse section of the upper fetal abdomen, at the level of its origin from the umbilical vein [35, 36]. The ductus venosus velocity waveforms exhibit a biphasic pattern: a first peak concomitant with systole and a second peak during diastole, with a nadir during atrial contraction. The ratio between the maximum systolic (S) peak velocity and the atrial nadir (A) (S/A ratio) and the preload index (S-A)/S are the most commonly employed indices to assess DV hemodynamics [37–39].

Umbilical venous blood flow is usually continuous. However, in the presence of a relevant amount of reverse flow, during atrial contraction in the IVC pulsations occur with the heart rate in the umbilical venous flow. During normal pregnancies these pulsations occur only before the 12th week of gestation and are secondary to the stiffness of the ventricles at this gestational age, causing a high percentage of re-

verse flow in the IVC [40]. The presence of umbilical vein pulsations later in the gestation is considered a sign of impaired cardiac function. Only the qualitative venous Doppler waveform analysis seems to improve prediction of critical perinatal outcomes in preterm IUGR fetuses and therefore should be incorporated into the surveillance of these fetuses [40].

### **Atrioventricular Valves**

Flow velocity waveforms at the level of mitral and tricuspid valves are recorded from the apical four-chamber view of the fetal heart. They are characterized by two diastolic peaks that correspond to early ventricular filling (E wave) and active ventricular filling during atrial contraction (A wave). The ratio between the E and A waves (E/A) is a widely accepted index of ventricular diastolic function and is an expression of both cardiac compliance and preload conditions [28, 42].

### **Outflow Tracts**

Flow velocity waveforms from the aorta and pulmonary artery are recorded, respectively, from the five-chamber and short-axis views of the fetal heart. PV and TPV are the most commonly used indices. The former is influenced by several factors, including valve size, myocardial contractility, and afterload [29, 30], whereas the latter is believed secondary to the mean arterial pressure [43].

At the level of the outflow tracts the PV values linearly increase, and higher values are present in the aorta than in the pulmonary artery [33]. TPV values remain almost constant throughout gestation [44]. TPV values at the level of the pulmonary valve are lower than at the aortic level, suggesting slightly higher blood pressure in the pulmonary artery than in the ascending aorta [45]. Quantitative measurements have shown that the right cardiac output (RCO) is higher than the left cardiac output (LCO), and that from 20 weeks onward the RCO/LCO ratio remains constant at a mean of 1.3 [46, 47]. This value is lower than that reported in the fetal sheep (RCO/LCO=1.8), a difference that may be explained by the higher brain weight in humans, which increases left cardiac output [48].

## **Longitudinal Hemodynamic Modifications in IUGR Fetuses**

The timing of the delivery of IUGR fetuses is usually based on the results of biophysical tests (e.g., fetal heart rate monitoring or biophysical profile) or because there is an uncontrollable coexisting maternal disease (e.g., preeclampsia). The time interval be-

tween the first Doppler abnormalities in the umbilical or fetal circulation (i.e., brain-sparing effect) and delivery is usually wide. According to published data it may range from 1 to 9 weeks [49–52].

Knowledge of the temporal hemodynamic sequence in IUGR fetuses after establishment of the brain-sparing phenomenon has important clinical implications. In fact, there are reports that IUGR fetuses that are acidotic during intrauterine life or that have antepartum abnormal heart rate tracings exhibit poor neurologic development at 2 years [53, 54]. This finding has led some authors to suggest that IUGR fetuses should be delivered before the onset of abnormal fetal heart rate patterns (suggestive of fetal acidemia) in order to avoid the consequence of prolonged malnutrition and hypoxia on the brain [24]. Moreover, gestational age should be taken into account, as the anticipation of the time of delivery may increase the risk of prematurity-related neonatal complications [50, 51].

At present, irrespective of the criteria for timing the delivery of these fetuses, knowledge of the progressive hemodynamic changes in deteriorating IUGR fetuses may help to clarify their natural history and to predict the time left before the onset of abnormal heart rate patterns. Serial studies on IUGR fetuses followed from the diagnosis to the onset of heart rate late decelerations have allowed us to partly clarify the hemodynamic changes at various placental and fetal levels. A theoretic scheme of the temporal sequence of Doppler changes secondary to uteroplacental insufficiency is outlined in Table 36.1.

**Table 36.1.** Suggested hemodynamic steps during deterioration of IUGR fetuses and concomitant Doppler changes

Hemodynamic steps	Doppler findings
Brain-sparing phenomenon	Increased UA/MCA
Change of cardiac afterload	Increased pulmonary artery TPV Decreased aortic TPV
Redistribution of cardiac output	Decreased RCO/LCO
Decreased cardiac output	Decreased aortic PV Decreased pulmonary PV
Increased venous pressure	Increased percent reverse flow in IVC Increased S/A in DV UV pulsations
Decompensation	Abnormal FHR patterns

UA, umbilical artery; MCA, middle cerebral artery; TPV, time to peak velocity; RCO/LCO, right/left cardiac output; PV, peak velocity; IVC, inferior vena cava; S/A, systolic peak velocity/atrial madir ratio; DV, ductus venosus; UV, umbilical vein; FHR, fetal heart rate.

## Umbilical Artery

Experimental animal models in which obliteration of the placenta is achieved through embolization of the umbilical artery with microspheres have been used to show that only after 50% occlusion is there an increase in Doppler-measured vascular impedance [55]. This concept, validated in vitro [56, 57], suggests that wide damage of the placental vascular bed is already present at the time of diagnosis. However, further changes may occur, usually increasing progressively and dramatically around the onset of abnormal fetal heart rate patterns [16].

## Fetal Peripheral Vessels

Doppler studies on the fetal descending thoracic aorta and fetal renal artery have shown that after establishment of the brain-sparing phenomenon further modifications of the PI occur with a behavior similar to that described for the umbilical artery [16] (i.e., a slight increase during the first stage of the disease followed by a rapid increase at the last stage of the disease). Of particular interest are the relations between the fetal renal artery PI and fetal PO<sub>2</sub>, urine production, and amniotic fluid volume [58, 59].

## Cerebral Vessels

After establishment of the brain-sparing effect, additional changes occur in the cerebral circulation as assessed by the PI in the middle cerebral artery or internal carotid artery, but the trend of these changes differs from that described for the umbilical artery and fetal peripheral vessels [16, 17, 51]. Indeed, the PI decrease is progressive during the first stage of the disease, reaching a nadir at least 2 weeks before the onset of abnormal fetal heart rate patterns [16, 60]. Furthermore, it has been shown that a few hours before fetal death there is a loss of cerebral vasodilatation despite the persistence of high resistance in peripheral vessels [61, 62]. These terminal changes are consistent with those reported in animal models [63]. However, Hecher et al. [51] found that in fetuses delivered before 32 weeks' gestation, middle cerebral artery PI became progressively abnormal until delivery, which is in contrast to the findings of Arduini et al. [16], who found that PI of cerebral vessels did not change in the last week preceding fetal heart rate abnormalities, and Weiner et al. [63], who even found a normalization of middle cerebral artery PI before the occurrence of abnormal fetal heart rate. Johnson et al. [65] demonstrated that increased middle cerebral artery PI may also occur in absence of premorbid fetal state, particularly in very preterm IUGR fetuses.

The significance of the different trends between cerebral vessels and peripheral or umbilical vessels is ob-

scure, but two hypotheses can be suggested. The first is related to different vascular sensitivities to fetal hypoxemia. The cerebral vessels may experience massive vasodilatation in reaction to a mild to moderate level of hypoxemia, whereas profound changes in fetal peripheral vessels may occur only after severe hypoxemia or acidosis [18]. This concept is validated by cordocentesis data showing that the relation between vasodilatation in the middle cerebral artery and hypoxemia exists only if the hypoxemia is mild to moderate; with more severe hypoxemia and acidemia the reduction in PI reaches a nadir that has been suggested to represent maximal cerebral vessel dilatation [66]. Similarly, in fetal lamb models with progressively deteriorating fetal oxygenation, it has been shown that the modifications in cerebral blood flow occur at an early stage of hypoxemia, whereas only minimal changes are present in peripheral vascular areas [18]. With more severe hypoxemia vascular resistance and organ flow changes in peripheral vessels occur abruptly, associated with further small increases or even reductions in cerebral blood flow [63].

An alternative explanation is based on the impairment of fetal cardiac function at the last stage of the disease, leading to decreased cardiac output [51, 66, 67]. Because the PI is highly and inversely dependent on input pressure and therefore on cardiac output [68], a decrease in cardiac contractility may explain the increase in peripheral and umbilical vessels. Moreover, the autoregulatory mechanisms of the cerebral circulation may maintain the nadir of cerebral vasodilatation until impending fetal death when the PI values may increase [66, 69].

The implications of changes in middle cerebral artery blood flow on subsequent long-term neurodevel-

opment are unclear. Some follow-up studies have suggested that the brain-sparing effect is a benign adaptation in IUGR fetuses [70, 71]; however, further long-term studies are required to establish the natural history of such cases.

### Fetal Cardiac Flows

Uteroplacental insufficiency greatly affects fetal cardiac function. The brain-sparing effect induces selective changes in cardiac afterload that occur in IUGR fetuses (i.e., decreased left ventricle afterload due to cerebral vasodilatation and increased right ventricle afterload due to systemic vasoconstriction). Furthermore, hypoxemia may impair myocardial contractility and polycythemia, which is usually present [72], may alter blood viscosity and therefore the preload. As a consequence, IUGR fetuses exhibit impaired ventricular filling properties [67, 73], lower peak velocities in the aorta and pulmonary arteries [21, 74] (Figs. 36.1, 36.2), increased aortic and decreased pulmonary TPV [44], and a relative increase in left cardiac output associated with decreased right cardiac output [67]. These hemodynamic intracardiac modifications are compatible with a preferential shift of cardiac output in favor of the left ventricle, leading to improved perfusion to the brain; and they occur simultaneously with the changes in fetal peripheral vessels.

Serial recordings have allowed us to clarify the evolution of intracardiac modifications in IUGR fetuses [66]. TPV values and the ratio of right/left ventricular outputs remain stable during serial recordings in such fetuses, suggesting that there are no other significant changes in outflow resistance or cardiac output redistribution after establishment of the

**Fig. 36.1.** Doppler tracing from the aortic outflow tract in an IUGR fetus at 29 weeks' gestation. The peak velocity is 48 cm/s (normal value for gestation is 64 cm/s)

**Fig. 36.2.** Doppler tracing from the pulmonary artery in an IUGR fetus at 29 weeks' gestation. The peak velocity is 37 cm/s (normal value for gestation is 57 cm/s)

brain-sparing mechanism. However, peak velocities and cardiac output progressively decline, rather than rise with gestation as expected. The ventricular ejection force decreases in both ventricles and the different hemodynamic conditions in the vascular district (reduced cerebral resistance for the left ventricle and increased splanchnic and placental resistances for the right ventricle) can explain this decline in cardiac output. These changes may reflect decompensation of a normally protective mechanism responsible for the brain-sparing effect. According to this model, the fetal heart adapts to placental insufficiency in a manner that helps to maximize brain substrate and oxygen supply. With progressive deterioration of the fetal condition, this protective mechanism is overwhelmed by the decreased cardiac output, which may explain the reported changes in fetal peripheral vessels and the venous circulation.

### Fetal Venous Flows

Studies of inferior vena cava blood flow velocities have demonstrated a characteristic pattern during fetal heart failure [75, 76]. Changes in venous blood velocity have been described during congestive heart failure with decreased diastolic blood velocity and increased reversal of flow during atrial contraction [76].

In IUGR fetuses an increase of reverse flow during atrial contraction may be present in the most severely compromised fetuses [23, 77] (Fig. 36.3). As a consequence of these abnormal venous flow patterns, the return of blood from the placenta to the heart is impaired, further reducing the supply of oxygen and nutrients. These findings are compatible with the decrease in both cardiac output and aortic and pulmonary peak velocities in deteriorating IUGR fetuses [50, 66, 78]. These changes are an expression of the same phenomenon (i.e., cardiac decompensation) that impairs both the filling and the output of the heart. Concomitant changes are present in the ductus

**Fig. 36.3.** Doppler tracing from the inferior vena cava in an IUGR fetus at 29 weeks' gestation. The percent reverse flow in the inferior vena cava is 16.9% (normal value for gestation is 7.4%)

venosus of IUGR fetuses, where the velocity during atrial contraction is significantly reduced or reversed [50, 62, 79] (Fig. 36.4).

It seems that the blood velocity waveform in the hepatic vein is an earlier predictor of intrauterine death than that of the ductus venosus [78]. This might be due to the fact that the hepatic vein is nearer the heart and blood flow from the right liver lobe flows mainly to the right side of the heart, while that from the ductus venosus flows mainly to the left ventricle in the foramen ovale. The fetal left ventricle in IUGR fetuses usually has to work against a lower afterload than the right ventricle, due to brain spar-

**Fig. 36.4.** Doppler tracing from the ductus venosus in an IUGR fetus at 27 weeks' gestation. (The PI normal value for gestation is 0.55)

**Fig. 36.5.** Doppler tracing from the umbilical artery and vein in an IUGR fetus at 27 weeks' gestation. Note the absence of end-diastolic velocity in the umbilical artery and the end-diastolic pulsation in the umbilical vein

ing in chronic hypoxia. The differences in afterload might cause some differences in timing of signs of imminent heart failure in the two vessels. As flow from the right hepatic vein mainly enters the right ventricle, a compromised fetal state may therefore be expressed better in the hepatic vein than in the ductus venosus [79].

The presence of pulsations in the umbilical vein (Fig. 36.5) indicates severe cardiac compromise and imminent asphyxia. Double pulsation is known to be a more severe sign of fetal compromise and a direct reflection of pulsation in the central vein due to opening of the ductus venosus, either due to the hypoxia or increased central venous pressure [79, 80].

In IUGR fetuses the presence of pulsations in the umbilical vein is associated with a fivefold increase in perinatal mortality compared to IUGR fetuses with continuous umbilical flow [80, 81]. Actuarial analysis has demonstrated that of all the Doppler indices for IUGR fetuses, the pathological venous velocimetry in the vena cava, hepatic vein, and ductus venosus and the onset of umbilical vein pulsations are the events that best predict the onset of abnormal heart rate patterns [60, 79]. Hence, venous Doppler should be considered when timing delivery.

## Conclusions

Examination of the fetal circulation by Doppler techniques provides evidence of some of the mechanisms of adaptation and decompensation of the IUGR fetus in response to uteroplacental insufficiency. At present,

the condition of IUGR fetuses can be accurately assessed by sequential studies of Doppler waveforms from various vascular areas. Therefore the optimal timing of delivery to prevent intrauterine injury may be guided by combining multivessel Doppler ultrasounds. Combining Doppler, composite biophysical profile, and/or computerized fetal heart rate analysis will provide significant early indication for action in the management of severe IUGR fetuses.

# Evaluation of Pulmonary and Ductal Vasculature: Fetal Echocardiography for Evaluation of Therapy for Preterm Labor

James C. Huhta, Gerald Tulzer, Sharon R. Weil-Chalker

Studies about the effects of maternal drug administration on the fetus are limited. In early studies the useful effects of tocolytic drugs appeared to far outweigh their possible side effects as they relate to the fetus and any long-term effects. Data continue to accumulate about how the effects of a pharmacologic agent on fetal physiology may affect postnatal life. One tool used to assess fetal physiology is Doppler ultrasonography. The clinical investigator thus has immediate feedback about the effects of a currently used drug on the fetal circulation. This technique has opened up a new field of fetal circulatory investigation.

In this chapter we review current knowledge about how two tocolytic drugs, indomethacin and terbutaline, affect the fetal circulation acutely. The techniques are explained to illustrate how the fetal circulation can be evaluated globally to detect drug side effects. The effects of these drugs on the fetal ductus arteriosus are used as an example of the potential of this type of research to provide information about the “second patient” in the setting of maternal disease and preterm labor.

Doppler techniques provide an excellent noninvasive tool for assessing blood velocity and pressure gradients across the fetal ductus arteriosus [1]. The fetal ductus arteriosus may constrict during maternal indomethacin treatment for premature labor [2–4]. It was demonstrated in animal models that chronic fetal ductal constriction/occlusion affects the fetal right ventricle and leads to morphologic changes in the pulmonary vasculature, resulting in persistent pulmonary hypertension of the newborn [5–8]. Thus fetal echocardiography may play an important role in the management of drug use during pregnancy: It can be used to detect and monitor side effects of tocolytic medications such as indomethacin.

## Fetal Examination Technique

### Fetal Echocardiography

Complete fetal echocardiographic study generally involves three investigations: two-dimensional echocardiography, M-mode echocardiography, and Doppler

interrogation. With current technology, resolution is best after approximately 16 weeks' gestation. A complete initial study usually takes 30–45 min unless the fetus is active or poorly positioned for obtaining clear views. The most informative approach to integrating the Doppler technique into the fetal heart examination is to perform intracardiac Doppler sonography of the heart valves and a “peripheral” Doppler study of the cord and other vessels at the same time.

Ultrasonic imaging is commonplace for assessing the fetus during obstetric care. Imaging assesses the morphology, and the shape and movement of fetal/placental/uterine structures provides information about changes over the course of the pregnancy. Malformations can be detected prenatally, and growth can be calculated from images of the fetus. The placenta can be evaluated with regard to its position, size, and ultrasonic tissue characteristics; and the umbilical cord and its abnormalities can be detected. Improved ultrasonic imaging techniques have made imaging of fetal intracardiac and extracardiac anatomy feasible and reliable after 18 weeks' gestation. Fetal cardiac imaging requires high resolution at depth, and the development of real-time, gray-scale imaging allows imaging of the fetal cardiovascular system as never before possible. New techniques give current equipment the ability to image cardiac anatomy even at fast heart rates (>200 bpm). Experience is being gained with pre- and postprocessing of the images to optimize them for each application. Phased-array technology, computerization of imaging techniques, advanced digital scan converters, dynamic focusing, and annular array imaging now allow improved azimuthal resolution and better image quality.

A wealth of physiologic information is currently available to the clinician, and fetal physiology can be further evaluated noninvasively with Doppler techniques. In contrast to the strong imaging signals collected by an ultrasound instrument, the Doppler signals from blood flow are weak and technically more difficult to optimize. Artifacts still occur in Doppler recordings because of the limited quality of the Doppler signal or, more often, the inadequate exclusion of other signals, such as those from vessel walls or from structure movements.

The equipment for fetal Doppler examination is in a state of rapid evolution. At the present time, image-directed or color Doppler-directed pulsed-wave and continuous-wave Doppler ultrasonography is available to clinicians. Advances in several technologies have allowed progressive advances in this field. Better materials and an understanding of transducers and their design has led to improved acquisition of signals and an improved signal-to-noise ratio. The improvement in resolution for imaging also improves the spatial data collection for the Doppler setup and gives more confidence that the blood velocity came from the site where the sample volume was placed. Advances in broad-band amplifier design and phased-array and annular technologies affect modern obstetric Doppler equipment and allow the same transducer to be used efficiently for both Doppler sonography and imaging. Integration of imaging and Doppler sonography is now possible.

Color Doppler sonography is being applied to supplement other modes of ultrasonic scanning (see below). The color Doppler technique provides information about the flow of blood and specifically blood velocity in the structures being visualized.

The intensities of the various Doppler modalities are different. With a method of intensity assessment using the spatial peak temporal average (milliwatts per square centimeter, or  $\text{mW}/\text{cm}^2$ ) as a measure of the heating potential of the ultrasound, the exposure for pulsed-wave, continuous-wave, and color Doppler technology can be compared [7].

### Peripheral Doppler/Cardiac Doppler Sonography

The umbilical cord arterial Doppler pattern is characterized by a peak velocity during late systole, an end-diastolic velocity measured before the next upstroke, and the mean velocity, which is the average of the entire waveform over the cardiac cycle. The energy source for the umbilical waveform is the fetal heart. The left ventricle and (predominantly) the right ventricle pump blood to the placental circulation. The early part of the upstroke of the umbilical waveform gives information about the waveform passing from the heart to the peripheral circulation. It is determined by myocardial performance, large-vessel compliance and elastic properties, and arterial reflections along the fetal descending aorta. The rapidity of the upstroke should therefore relate to several factors that transmit a pressure waveform to the cord. Factors that would increase the rate of systolic velocity increase are increased myocardial inotropy, decreased compliance of the aortic wall, and high total impedance. The diastolic portion of the curve is not sharply demarcated but reflects the time when the semilunar valves are closed and the circulation propels blood based on its inertia and pressure

wave propagation during vascular relaxation. The principal determinant of the end-diastolic velocity is the distal resistance. The latter parameter is a consequence of both the systemic and parallel placental circulations. There is more pulsation (pulsatility) in an umbilical waveform when the distal impedance is increased. Therefore cord pulsatility can be used as an indirect indicator of placental impedance. Waveforms with a high diastolic velocity are associated with high flow during diastole, and those with low or absent diastolic velocity have low diastolic flow.

The best index to use for analysis and communication of umbilical cord Doppler information is controversial. Several authors have presented arguments for the options [8], which include the pulsatility index (PI), the resistance (Pourcelot) index (RI), and the systolic/diastolic (S/D) ratio.

$$\text{PI} = (S - D) / \text{mean velocity}$$

$$\text{RI} = (S - D) / S$$

$$\text{S/D ratio} = S / D$$

where S=peak systolic velocity and D=minimum diastolic velocity. Mean velocity equals the integrated mean over the cardiac cycle.

The PI is less susceptible to a variation in heart rate because the heart rate is an intrinsic factor in the mean velocity. This parameter requires digitalization of the entire waveform over one cycle and is the best parameter for longitudinal comparison. The RI and S/D ratio are popular because they require little computation. The PI of the peripheral circulation reflects the distal impedance and therefore is low with low impedance. In situations where there is kinetic energy release with discrete obstruction in the circulation, such as with carotid arterial obstruction or coarctation of the aorta, the PI may be used to describe the waveform changes. In this situation, a low PI is indicative of increased obstruction and pressure gradient and usually lower flow.

Cardiac Doppler examination is performed by placing the pulsed Doppler sample volume in the valve (arch) of interest during the examination as described below. The three major Doppler techniques (pulsed-wave, continuous-wave, and color) are complementary in the fetal examination. All three are used during a complete examination of the heart and the peripheral vessels. Continuous-wave and pulsed-wave Doppler techniques have been applied to the assessment of fetal hemodynamics by detecting flow in the umbilical cord and studying the pulsatility of that waveform. The typical examination includes sampling many sites in the circulation.

### ***Umbilical Cord***

Optimal recordings in the umbilical cord have both arterial and venous tracings. The umbilical venous tracing is a low-velocity (20–30 cm/s) signal with high intensity. If there are cardiac pulsations in the umbilical venous trace, one should suspect increased venous pressures and cardiac failure.

### ***Uterine Artery***

Sampling the maternal circulation at the uterine artery provides a waveform that appears to correlate with uterine impedance. Early studies in these vessels suggested that detection of growth restriction is possible during pregnancy.

### ***Descending Aorta***

The pulsed sample volume should completely insulate the lumen of the descending aorta. The descending aorta has a high systolic velocity (50–100 cm/s) and a low diastolic velocity in the same direction as the systolic velocity. This waveform has been shown to change in the presence of growth restriction, probably indicative of increased total systemic resistance. In the extreme example of a fetus with advanced growth disturbance, there is an absence of end-diastolic flow.

### ***Middle Cerebral Artery***

The middle cerebral artery (MCA) is used as an indicator of brain vascular impedance. The normal pattern is similar to that in the umbilical cord at a lower velocity. The diastolic velocity can be elevated with severe intrauterine growth restriction (IUGR), presumably indicative of compensatory cerebral vasodilation, the brain-sparing effect.

### ***Renal Artery***

The renal artery waveform is obtained in transverse sections of the abdomen during visualization of the kidneys. Color Doppler sonography greatly improves the percentage of patients from whom high-quality data can be obtained. The waveform has a high systolic velocity and a low diastolic velocity, similar to that in the descending aorta. The normally pulsatile renal vein is often noted while interrogating the proximal renal artery.

### ***Ductal and Aortic Arches***

The aortic arch and ductal arch may appear similar, but systolic velocity is always higher in the ductal arch. Ductal constriction is characterized by an increase in both systolic and diastolic velocities (see below).

### ***Pulmonary and Aortic Valves***

Pulsed-wave Doppler sonography in the semilunar valves shows a pattern of systolic ejection with a rapid upstroke in the pulmonary valve and a slower upstroke in the aortic valve. The peak velocities of ejection may be useful for assessing cardiac output indirectly. Integration of the waveform gives the time-velocity integral (TVI) and is proportional to the stroke volume. Correcting for heart rate, any change in valve flow can be studied by comparing the TVI-heart rate product before and after the intervention [9]. If valve stenosis is present, there will be evidence of turbulence and the peak velocity will be slightly increased. If valve regurgitation is present, there will be an abnormal turbulent jet back into the ventricle during diastole.

### ***Atrioventricular Valves***

The mitral and tricuspid valves are assessed using pulsed-wave Doppler sonography from an apical view. The 2-mm sample volume is placed at the valve annulus to obtain a biphasic pattern during diastole consisting of an E wave (corresponding to the rapid filling of the ventricle) and an A wave (corresponding to atrial contraction). Systolic velocity back into the atria suggests valvar regurgitation and is detected on the pulsed-wave evaluation; however, the use of continuous-wave Doppler sonography is helpful for interrogating the atrioventricular (A-V) valve area. Grading valvar regurgitation is qualitative, with a nonholosystolic jet being classed as trivial and a holosystolic jet as significant. Most fetal valve regurgitation is trivial or mild in the absence of other signs of fetal congestive heart failure, such as an abnormal venous Doppler result. Because the peak velocity of A-V valve regurgitation is so typical and is higher than any other velocity in the fetal circulation, the range ambiguity introduced by the use of continuous-wave Doppler sonography does not cause any confusion. On the contrary, continuous-wave Doppler sonography with high filter settings can detect a tiny jet of A-V valve regurgitation and characterize the timing of it and the nature of the early upstroke velocity. Such a jet is turbulent and creates an abnormal finding on color Doppler interrogation owing to the high peak velocity. The most common cause of tricuspid valve regurgitation in our practice is the effect of indomethacin on the fetal ductus arteriosus.

### ***Inferior Vena Cava***

The waveform in the inferior vena cava (IVC) is normally biphasic during flow to the heart with an additional brief period of reversal during atrial systole. This waveform is useful for detecting abnormal forward flow states in the fetal circulation. The abnormal

presence of an increase in reversal of blood velocity during atrial contraction suggests a state of fetal congestive heart failure [10, 11].

### Pulmonary Veins

Pulmonary venous waveforms are similar to systemic venous (IVC) waveforms. Reversal in this site could indicate A-V valvar regurgitation, myocardial failure, or an obstruction to emptying the atrium.

### Pulmonary Artery

Fetal pulmonary resistance is high, and a typical waveform in the left pulmonary artery reflects this state with biphasic forward flow: midsystolic reversal and brief reversal during early diastole. The end-diastolic velocity at this site is useful for evaluating the state of the fetal pulmonary vasculature. The normal finding is low velocity of forward flow into the pulmonary vascular bed. This flow is of markedly low velocity and may not be detectable using standard high-pass filter settings on the current equipment. Absence of this flow or the finding of reversal of flow during diastole suggests abnormal peripheral vascular impedance.

## Fetal Ductal Evaluation

An Acuson 128 scanner, in combination with 5.0- and 3.5-MHz probes, is used for the fetal cardiovascular examination. After evaluation of the cardiac anatomy, continuous-wave Doppler interrogation of the flow through the ductus arteriosus is performed using 5.0- or 3.5-MHz image-directed continuous-wave Doppler sonography in a sagittal plane showing the pulmonary artery, ductus arteriosus, and descending aorta simultaneously as previously described [1]. Power output is kept below  $100 \text{ mW/cm}^2$  spatial peak temporal average at all times. Each study is recorded on standard VHS 0.5-inch video tape for later analysis, although on-line analysis of the waveform of the blood velocity of the ductus is performed for immediate clinical reporting (pulsatility index). All Doppler recordings are obtained in the absence of fetal breathing movements at an angle of less than  $30^\circ$  to flow, and color flow mapping is used for alignment of the Doppler beam. Waveforms are analyzed for maximal, end-diastolic, and mean velocities, respectively. The PI is calculated using the formula: (maximal velocity - end-diastolic velocity)/mean velocity,

**Fig. 37.1.** Doppler waveforms in the fetal ductus arteriosus. *Top:* Normal waveform at 28 weeks shows a systolic velocity of approximately 1 m/s. *Middle:* During terbutaline administration to the mother, fetal Doppler sonography of the ductus shows increased peak velocity with little change in the end-diastolic velocity resulting in an increase in the pulsatility index (PI). *Bottom:* Fetal ductal constriction shows increased systolic and diastolic velocities and a decreased PI. (Reprinted from [13] with permission)

as described above. Therefore a decrease in the PI of the ductus arteriosus (below the normal values of 1.9–3.0) is suggestive of ductal constriction.

### Normal Doppler Waveforms

The normal Doppler waveform in the fetal ductus arteriosus is characterized by high systolic velocity and low diastolic velocity from the main pulmonary artery to the descending aorta (Fig. 37.1). This velocity is the highest systolic one in the normal fetus that can be obtained by Doppler interrogation of the fetal circulation and has a distinctive waveform. Color Doppler sonography is useful for obtaining continuous-wave Doppler images of the ductus in the ductal arch region where the velocity is highest. Aliasing in the ductal arch marks the site of peak velocity in a fetal sagittal imaging plane. It has been shown that maximal ductal blood velocity increases from 25 to 32 weeks' gestation [1], and data from our center based on a prospective longitudinal study from 121 examinations on 41 normal pregnant women showed a linear increase in systolic velocity from 14 to 40

weeks' gestation (Fig. 37.2). The ductal velocity was toward the descending aorta during systole (65–140 cm/s) and diastole (15–35 cm/s). The PI of the ductal velocity did not change with gestation (mean  $\pm$  2 standard deviations:  $2.46 \pm 0.52$ ).

### Ductal Constriction After Therapy for Preterm Labor

Second and third trimester fetuses have an increase in ductal blood velocities with increasing gestational age. The reasons for the increasing ductal blood velocity are complex: The ductal velocities are a function of multiple variables, including ductal wall caliber and compliance, systolic and diastolic ductal flow, and right ventricular function. Blood velocities of the fetal ductus arteriosus must be considered in relation to gestational age for correct interpretation.

Exposure to nonsteroidal antiinflammatory agents, with the prototype being indomethacin, can lead to constriction of the ductus and alterations in human cardiovascular physiology. This change is presumed due to inhibition of fetal prostaglandins. However, as-

**Fig. 37.2.** Ductus arteriosus flow and pulsatility index in fetuses exposed to terbutaline ( $n=10$ ), fetuses with ductal constriction ( $n=22$ ), and fetuses with hypoplastic left heart

syndrome ( $n=14$ ) compared with normal range (mean  $\pm$  2 SD) versus gestational age. (Reprinted from [13] with permission)

say of the indomethacin levels in the maternal circulation (and presumably the fetal circulation) did not correlate with the presence or severity of ductal constriction [2]. Fetal ductal constriction is characterized by elevation of maximal end-diastolic ductal velocity resulting in a Doppler waveform similar to that seen postnatally across coarctation of the aorta [1]. One may consider that fetal ductal constriction is really a hemodynamic coarctation of the ductus in utero. Typically, fetuses with structurally normal hearts presenting with preterm labor refractory to other agents with a gestational age of 23–32 weeks are treated with indomethacin in doses ranging from 25 to 50 mg every 4–6 h. After 24 h on indomethacin, increased ductal velocities consistent with constriction are found in 25%–40% of fetuses. Indications of constriction included increased systolic and diastolic velocities and a PI below 2.0 (Fig. 37.2). Evidence of constriction usually resolves within 1–5 days after discontinuation of indomethacin. Constriction also has been documented using ibuprofen or aspirin in this gestational age range.

**Fig. 37.3.** Top, middle: Doppler patterns of ductal constriction with tricuspid valve regurgitation. Note the peak systolic velocity of 4 m/s. Bottom: The pattern of ductal constriction and the method of obtaining the mean velocity is shown with a pulsatility index of 0.56 (normal range 1.9–3.0)

Ductal constriction with the highest elevations of ductal systolic and diastolic velocity are often associated with the new finding of tricuspid regurgitation on Doppler examination (Fig. 37.3). It appears to be due to the fact that ductal constriction increases the right ventricular afterload (pulmonary artery pressure), thereby altering normal fetal tricuspid valve function. Fetal tricuspid valve regurgitation without cause is rare [12]. Marked decreases in the shortening of the right ventricle are also observed during severe constriction. Typical decreases in right ventricular shortening are from approximately 30% to 15%–20%.

Prolonged or severe constriction of the ductus may also be associated with tricuspid regurgitation and eventually right ventricular dysfunction and abnormal fetal perfusion. We recommended baseline fetal echocardiography on all women at the start of indomethacin therapy (24–48 h after beginning therapy). Weekly echocardiograms should then be obtained for the duration of the therapy, specifically assessing the size and flow through the ductus, as well as the presence of tricuspid regurgitation. Venous Doppler examination is useful for detecting abnormal cardiac compensation [11]. Although tricuspid regurgitation in some settings is an ominous sign, in this setting it is of uncertain significance and in our experience has been transient [12]. Similar, ductal constriction has been observed but also resolves with discontinuation of indomethacin. Thus we do not alter indomethacin therapy solely on the basis of either ductal constriction (mild or moderate) or the finding of tricuspid regurgitation. Abnormal venous Doppler may indicate heart failure in this setting.

### Hemodynamic Effects of Ductal Constriction

Fetal ductal constriction causes a significant change in the distribution of the cardiac output between the ventricles. Measurements using pulsed-wave Doppler sonography attempting to quantitate the semilunar valve outputs before and after ductal constriction have shown that the left ventricular output increases significantly with constriction of the fetal ductus (average 21%) relative to the baseline value. The ratio of aortic/pulmonary valve flow (time-velocity integral/heart rate product) increases. This redistribution of fetal flow to the left heart is the result of increased flow through the foramen ovale due to a decrease in right ventricular stroke volume and an increase in fetal pulmonary flow, which increases fetal pulmonary venous return.

Two to three days of fetal ductal constriction during tocolysis with indomethacin is well tolerated because cardiac flow redistributes to the left heart during constriction and combined cardiac output is maintained, therapy maintaining normal peripheral organ perfusion.

### Clinical Implications of Ductal Constriction

Whether prolonged constriction of the ductus can lead to clinically significant hypertrophy of the smooth muscle in the pulmonary vascular bed is currently under investigation. The right ventricle develops hypertrophy rapidly during constriction, and little is known about its impact on gestation or the postnatal course. It seems prudent to evaluate a fetus exposed to chronic indomethacin at least weekly if there is no evidence of constriction and to increase the surveillance to daily examinations if ductal constriction is present with tricuspid regurgitation.

### Ductal Occlusion

Ductal occlusion of 1–5 days duration was diagnosed by fetal echocardiography in our practice over 2 years in 6 of 115 fetuses exposed to indomethacin (mean gestational age 27.4 weeks) at 31–35 weeks' gestation. None was hydropic, and all six had (1) right ventricular enlargement with decreased shortening and tricuspid valve regurgitation; (2) increased main and branch pulmonary artery sizes; and (3) increased left ventricular shortening and aortic arch velocity. Ductal occlusion was differentiated from ductal constriction by an absence of flow in the ductus, seen by color Doppler ex-

**Fig. 37.4.** Fetal echocardiography following fetal ductal occlusion of 1 week duration showing residual ductal constriction. *Top panel:* Ductal constriction is indicated by the persistently elevated velocities. *Second panel:* There is decreased forward flow in the pulmonary valve and slight pulmonary valve regurgitation, which is never seen in the normal fetus. *Third panel:* M-mode echocardiography shows residual thickening of the right ventricle. *Bottom panel:* Left branch of the pulmonary artery (LPA) Doppler velocity is abnormal, with diastolic reversal indicating elevated fetal pulmonary vascular resistance. The fetus resolved this pattern prior to birth and was delivered without complication

amination. Indomethacin was withdrawn when closure was diagnosed, and fetal echocardiography was repeated daily while terbutaline was used for tocolysis. The fetal ductus reopened 1–5 days after indomethacin withdrawal and was characterized by a period of ductal constriction varying from 1 to 10 days (median 2 days) (Fig. 37.4). All patients continued normal pregnancies, and none had postnatal pulmonary hypertension. The only residual finding after reopening was right ventricular hypertrophy in one pair of twins (both with closure that persisted 3 and 5 days, respectively, after two 50 mg doses at 32 weeks' gestation). One fetus with constriction was delivered without difficulty.

From this experience we concluded that the reopening of ductal occlusion occurred within 2 weeks of indomethacin withdrawal without residual abnormality. Withdrawal is the optimal treatment if the gestation is premature. Additional studies are focus-

ing on myocardial adaptation of the fetal right ventricle to this increase in workload and the fetal pulmonary vascular response to this complication of indomethacin use.

## Terbutaline

Fetuses whose mothers are treated with terbutaline for tocolysis have increased cardiac output [9], and we have noted markedly increased maximal ductal velocities in this setting. This drug, a sympathomimetic, increases the fetal heart rate and has a positive inotropic effect on the myocardium. Therefore all the peak systolic velocities in the fetal circulation are increased by maternal terbutaline administration (Fig. 37.5).

Clinically, mothers are often treated for preterm labor with terbutaline 5 mg PO every 4–6 h or by

**Fig. 37.5.** Fetal left heart pulsed Doppler findings in fetuses with active preterm labor and others exposed to terbutaline transplacentally. There were significant group differences. *Top:* Peak systolic velocity in the aortic and mitral valves (centimeters per second). *Middle:* Time-velocity integrals of aortic and mitral valve Doppler sonography for the three groups. *Bottom:* Product of the time-velocity integral and heart rate for the aortic and mitral valves (equivalent to mean velocity) for the three groups. (Reprinted from [9] with permission)

continuous infusion. Terbutaline, and premature labor itself, has a positive inotropic effect on the fetal heart [9]. Increased right ventricular output causes a higher blood volume to be pumped from the main pulmonary artery to the descending aorta, resulting in an elevated maximal ductal blood velocity.

### Terbutaline Effect Versus Ductal Constriction

An increase in ventricular stroke volume at times increases the ductal velocities such that the waveform may simulate ductal constriction. However, the PI increases in this situation, in contrast to a decreased PI with ductal constriction [13]. Terbutaline is not known to constrict the ductus, and we have not found such constriction. However, because it can increase fetal cardiac output and increase systolic velocities in the heart and arches, we have used the PI to distinguish these causes of increased systolic velocity (Fig. 37.1, 37.2). Ductal constriction lowers the PI to less than 2.0 owing to obstruction to flow and high velocities; increased fetal cardiac output elevates the PI to more than 3.0. This method of waveform analysis can therefore distinguish these two causes of increased ductal velocity.

When terbutaline fails to stop premature labor, indomethacin is frequently added as a second drug. Increased maximal velocity in these cases could be due to indomethacin-induced ductal constriction or the effect of terbutaline-induced increased right ventricular output. When using maximal ductal velocity alone, the latter case may be misinterpreted as fetal ductal constriction and could lead to discontinuation of an effective tocolysis regimen.

The flow pattern of a mildly constricted ductus and that of a wide open ductus with increased flow may have the same maximal systolic and end-diastolic velocities, but there is a significant difference in mean velocity and PI that clearly distinguishes the two etiologies.

The PI in peripheral vessels is thought to reflect peripheral impedance. In the ductus arteriosus, however, it is used only to help in the differential diagnosis of increased maximal velocity. Ductal constriction causes decreased pulsatility, with higher than normal velocities indicating obstruction; whereas decreased pulsatility in the umbilical circulation, for example, is at low velocity and indicates increased flow and lower impedance [13]. Mean ductal blood velocity alone may be able to distinguish ductal construction from other causes of increased maximal velocity, but it has to be interpreted in relation to gestational age. The PI, on the other hand, does not change with gestational age and may therefore be a more useful parameter in clinical practice.

### Fetal Pulmonary Assessment

Using Doppler, fetal pulmonary vascular status can be assessed. Pulsed Doppler has been shown to be obtainable in most pregnancies after 20 weeks' gestation. The typical blood velocity waveform with a systolic reversal pattern is obtained and can be quantitated with a PI. This approach was detailed by Rasanen [14] and showed that the pulmonary vascular resistance drops near 30 weeks' gestation and then rises near term. The fetal resistance is known to change with certain drugs such as indomethacin [15]. Reactivity of the human fetal pulmonary circulation to maternal hyperoxygenation was studied with advancing gestation and it was found that the fetal pulmonary circulation appeared to vasoconstrict after 31–36 weeks of gestation [16]. This technique has been applied in a cooperative study recently [17]. In this study, fetal pulmonary artery Doppler was used as a test during administration of 60% oxygen to the pregnant mother after 30 weeks' gestation to identify fetuses with pulmonary hypoplasia that would lead to perinatal death. A reactive test was defined as a decrease of at least 20% in the branch pulmonary PI with oxygen. Of the 14 fetuses who had a nonreactive hyperoxygenation test, 11 fetuses (79%) died of pulmonary hypoplasia. Of the 15 fetuses who had a reactive hyperoxygenation test, only one fetus (7%) died in the neonatal period (sensitivity, specificity, and positive and negative predictive values were 92%, 82%, 79%, and 93%, respectively).

We may speculate that application of this test could be of use in establishing the prognosis of fetuses at risk of pulmonary hypoplasia. Such a test has been performed in fetal lambs and the maternal hyperoxygenation test did predict those lungs with hypoplasia [18].

The test should be done by those with experience in normal and abnormal responses and may be technically difficult in some cases. Interventions designed to increase the pulmonary vascular bed cross-sectional area include occlusion of the trachea.

### Summary

Treatment of preterm labor with nonsteroidal antiinflammatory agents can lead to acute, transient changes in the caliber of the fetal ductus arteriosus. These changes can be detected and quantitated using fetal echocardiography. This complication can be successfully managed with serial study of the fetus using Doppler techniques and may be indicated serially. The  $\beta$ -agonist sympathomimetic medications used to treat preterm labor, such as terbutaline, have an immediate effect on the fetal circulation and increase the heart rate and the inotropic state of the fetal myo-

cardium. The future will see improved methods of fetal testing to assess the effects of both preterm labor and its treatment on the fetal circulation.

# Three-Dimensional Doppler Ultrasound in Gynecology

Ivica Zalud, Lawrence D. Platt

Three-dimensional (3D) reconstruction of ultrasound images was first demonstrated nearly 15 years ago but only now is becoming a clinical reality. In the meantime, methods for 3D reconstruction of computed tomography (CT) and magnetic resonance imaging (MRI) have achieved an advanced state of development, and 3D imaging with these modalities has been applied widely in clinical practice. Three-dimensional applications in ultrasound have lagged behind CT and MRI, because ultrasound data is much more difficult to render in 3D, for a variety of technical reasons, than either CT or MRI data. Only in the past few years has the computing power of ultrasound equipment reached a level adequate enough for the complex signal processing tasks needed to render ultrasound data in three dimensions. Within the past years several new ultrasound techniques have appeared. Three-dimensional ultrasound scanning, in which there has been great interest, is one of them [1]. Especially within obstetrics and gynecology several papers on that topic describe promising results. Gynecologic diagnostics relying on morphologic signs and accurate distance and volume measurements is one of the areas believed to benefit from 3D ultrasound; however, until now only few prospective works have been published, most of them counted as preliminary. One of the main reasons might be the huge technologic challenge. It is proposed that technologic progress over the next few years will allow feasible real-time 3D scanning. Gynecologic ultrasound scanning will thereby undoubtedly take another giant leap forward.

Why do we need 3D ultrasound in gynecology? Great strides have been made in gynecology secondary to the development of high-performance transvaginal ultrasound (TVS) instruments; however, even this advanced technology can provide only two-dimensional (2D) views of three-dimensional (3D) structures. Although an experienced examiner can easily piece together sequential 2D planes for creating a mental 3D image, individual sectional planes cannot be achieved in a 2D image because of various difficulties. Presently, 3D TVS can portray not only individual image planes, it can also store complex tissue volumes which can be digitally manipulated to dis-

play a multiplanar view, allowing a systematic tomographic survey of any particular field of interest. The same technology can also display surface rendering and transparency views to provide a more realistic 3D portrayal of various structures and anomalies.

## Technique

Since the end of the 1980s, 3D ultrasound has become a major field of research in gynecology. The technique of acquiring 3D data involves making a set of consecutive 2D ultrasound slices by moving the transducer and continuously storing the images. These ultrasound data must be converted into a regular cubic representation before presentation in different 3D visualization modes. The creation of new ultrasound sections from the 3D block, and also the surface shading of a structure of interest, promise improvement in the diagnosis of congenital uterine anomalies and pelvic masses. In addition, the possibility of volume calculation by 3D ultrasound has to be considered as a clear innovation. At present, almost all of the diagnoses illustrated by 3D ultrasound can be made by 2D ultrasound, and this will continue to be so in the foreseeable future. Recently, computer-assisted treatment of sonographic images has permitted 3D reconstruction in gynecology. This is achieved by scanning a given volume containing the organ of interest. Two practical options exist. Some ultrasound probes are equipped with an automatic scanning device while others use manual scanning, electronically normalized or not. Both approaches make use of an electronic matrix, i.e., a pile of 2D sonographic images. Secondary cuts are possible through the electronic matrix, including plans not normally accessible to ultrasound scanning because of anatomical limitations. One of the secondary cuts most clinically useful is the frontal plane of the uterus. This enables one to visualize the organ lying flat as it is commonly drawn on medical sketches. Studying the frontal plane of the uterus acquired electronically from a 3D matrix improves the visualization of possible interactions between structures such as uterine fibroids and the endometrium. The

**Fig. 38.1.** Three-dimensional ultrasound surface rendering of ectopic pregnancy

frontal plane of the uterus also offers marked improvements for studying uterine malformations.

Three-dimensional ultrasound offers several options extending conventional 2D scanning. Various imaging modes are available. Three perpendicular planes displayed simultaneously can be rotated and translated in order to obtain accurate sections and suitable views needed for diagnosis and geometric measurements. Three-dimensional ultrasound tomography combines the advantages of ultrasound, e.g., safety, simplicity of application and inexpensiveness, with the advantages of sequentially depictable sections in numerous rotatable and translatable sections. Surface rendering gives detailed plastic images if there are surrounding layers of different echogenicity allowing for the definition of a certain threshold. Transparent modes provide an imaging of structures with a higher echogenicity in the interior of the object. A combination of the two modes sequentially definable by the sonographer allows for the optimal viewing of structures. These imaging modes are innovative features that have to be evaluated for clinical applicability and usefulness (Fig. 38.1). Digital documentation of whole volumes enables full evaluation without loss of information at a later point. The 3D technology provides an enormous number of technical options that have to be evaluated for their diagnostic significance and limitations in obstetrics and gynecology.

### 3D Doppler Measurements

Doppler methods are routinely used to study the vascular system. Flow and tissue motion information can be obtained by frequency and time-domain processing. Instruments range in complexity from simple continuous-wave devices without imaging capability through advanced real-time 2D color-flow scanners and intra-vascular devices. A 3D display is now avail-

able. Contrast agents can be used to increase the detectability of blood flow signals. The properties of the tissue impose an envelope on achievable ultrasonic imaging. Doppler studies can provide information about flow velocity profile, vessel compliance, wall shear rate, pressure gradient, perfusion, tumor blood flow, and the presence of emboli. These capabilities can be integrated into a holistic picture of ultrasonic vascular studies [2, 3].

Three-dimensional Doppler ultrasound has the potential to study pelvic blood flow and process of neo-vascularization. The 3D Doppler superimposed to 3D gray scale can detect early vasculogenesis within the uterine or adnexal mass. Traditionally, we defined blood flow information as (a) quantitative, i.e., volume flow measurements (cc/min), and (b) semiquantitative, i.e., pulsed Doppler waveform analysis (RI, PI, S/D index).

Three-dimensional power Doppler introduces a new way to look at blood flow detection and analysis. Using the computer-generated VOCAL imaging program (virtual organ computer-aided analysis), different patterns of blood flow can be described:

1. Vascularization index (VI)
2. Flow index (FI)
3. Vascularization flow index (VFI)

Vascularization index gives information (in percentage) about the amount of color values (vessels) in the observed organ or area (e.g., uterus, ovary, or mass). Flow index is a dimensionless index (0–100) with information about intensity of blood flow. It is calculated as a ratio of weighted color values (amplitudes) to the number of color values. Vascularization flow index (VFI) is combined information of vascularization and mean blood flow intensity. It is also a dimensionless index (1–100) that is calculated by dividing weighted color values (amplitudes) by the total voxels minus background voxels. Three-dimensional Doppler was used to acquire volumes (Fig. 38.2). VOCAL was then used to delineate the 3D areas of interest (Fig. 38.3) and the “histogram facility” employed to generate three indices of vascularity: the VI; the FI; and the VFI (Fig. 38.4). The ultrasonographer should be aware that 3D Doppler is prone to the same artifacts and pitfalls as 2D Doppler. This information should be taken into account when any assessment of pelvic or tumor blood flow is made.

### 3D Doppler in Human Reproduction

Three-dimensional Doppler ultrasound is a new modality finding its way into clinical practice. We discuss recent publications related to 3D Doppler applications in human reproduction, gynecologic oncol-

**Fig. 38.2.** Three-dimensional Doppler was used to acquire volumes

ogy, and in the field of benign gynecology. Pan et al. aimed to test the hypothesis that the decreased ovarian sensitivity to gonadotropins observed in women embarking on an in vitro fertilization (IVF) treatment may be due to changes in ovarian stromal blood flow [4]. They used 3D power Doppler ultrasonographic indexes to quantify ovarian stromal blood flow and vascularization in poor responders. Forty patients undergoing an IVF cycle were collected and divided into two groups, a poor responder group ( $n=17$ ; estradiol  $<600$  pg/ml or  $\leq 3$  oocytes retrieved) and normal responder group ( $n=23$ ), based on their response to a standard down-regulation protocol for controlled ovarian stimulation. During ovarian stimulation, on the day of administration of human chorionic gonadotropin (HCG), patients underwent hormonal (serum E2), ultrasonographic (follicular number and diameter), and 3D power Doppler (ovarian stromal blood flow) evaluation. Compared with poor responders, the serum estradiol levels on the day of administration of HCG, the number of follicles  $>14$  mm, the number of oocytes retrieved, the number of embryos transferred, and the pregnancy rate were significantly higher in normal responders. The vascularization in-

dex, flow index, and vascularization flow index were significantly lower in the poor responders compared with the women with a normal response. They concluded that the 3D power Doppler indexes of ovarian stromal blood flow in poor responders was significantly lower than those of normal responders. This may help to explain the poor response during HCG administration in controlled ovarian stimulation.

The British group used 3D power Doppler to examine the periodic changes in endometrial and sub-endometrial vascularity during the normal menstrual cycle in 27 women without obvious menstrual dysfunction or subfertility [5]. Doppler exam was performed on alternate days from day 3 of the cycle until ovulation and then every 4 days until menses. Virtual organ computer-aided analysis and shell imaging were used to define and to quantify the power Doppler signal within the endometrial and sub-endometrial regions producing indices of their relative vascularity. Both the endometrial and sub-endometrial VI and VFI increased during the proliferative phase, peaking approximately 3 days prior to ovulation before decreasing to a nadir 5 days post-ovulation; thereafter, both vascular indices gradually increased

**Fig. 38.3.** Virtual organ computer-aided analysis was then used to delineate the 3D areas of interest

**Fig. 38.4.** The “histogram facility” was employed to generate three indices of vascularity: the vascular index; the flow index; and the vascularization flow index

during the transition from early to mid-secretory phase. The FI showed a similar pattern but with a longer nadir post-ovulation. Smoking was associated with a significantly lower VI and VFI. The FI was significantly lower in women aged  $\geq 31$  years and significantly higher in parous patients. The authors concluded that endometrial vascularity, as assessed by 3D Doppler, varies significantly during the menstrual cycle and is characterized by a pre-ovulatory peak and post-ovulatory nadir during the peri-implantation window.

Three-dimensional power Doppler has been largely used for the subjective assessment of vascular patterns, but semiquantification of the power Doppler signal is now possible. Raine-Fenning et al. addressed the intraobserver and interobserver error of the semiquantification of pelvic blood flow using 3D Doppler, VOCAL, and shell imaging [6]. The 3D Doppler was used to acquire 20 ovarian and 20 endometrial volumes from 40 different patients at various stages of in vitro fertilization treatment. The VOCAL was then used to delineate the 3D areas of interest and the "histogram facility" employed to generate three indices of vascularity: the VI; the FI; and the VFI. Intraobserver and interobserver reliability was assessed by two-way, mixed, intraclass correlation coefficients (ICCs) and general linear modeling was used to examine for differences in the mean values between each observer. The intraobserver reliability for both observers was extremely high and there were no differences in reliability between the observers for measurements of both volume and vascularity within the ovary or endometrium and its shells. With the exception of the outside sub-endometrial shell volumes, there were no significant differences between the two observers in the mean values obtained for either endometrial or ovarian volume and vascularity measurements. The interobserver reliability of measurements was equally high throughout with all measurements obtaining a mean ICC of above 0.985. They concluded that 3D Doppler and shell imaging offer a reliable, practical, and non-invasive method for the assessment of ovarian, endometrial, and sub-endometrial blood flow. Future work should concentrate upon confirming the reliability of data acquisition and the validity of the technique before its predictive value can be truly tested in prospective clinical studies.

Vlaisavljevic et al. wanted to study whether they might predict the outcome of unstimulated in vitro fertilization/intracytoplasmic sperm injection (IVF/ICSI) cycles with quantitative indices of perfollicular blood flow assessed with 3D reconstruction of power Doppler images [7]. This prospective study included an analysis of 52 unstimulated cycles. Color and power Doppler ultrasound examinations of a single dominant preovulatory follicle were performed on the day of oocyte pick-up. With 3D reconstruction and

processing, quantitative indices were obtained, i.e., the percentage of volume showing a flow signal (VFS) inside a 5-mm capsule of perfollicular tissue and the percentage of VFS of each of the three largest vessels in this capsule. These indices as well as pulsed Doppler indices were compared between the groups of cycles with different outcomes using a one-way analysis of variance test. In nine cycles no oocyte was retrieved (group A), in seven cycles no fertilization occurred (group B), and in 30 cycles no implantation occurred (group C). Six cycles resulted in pregnancy (group D). There were no statistically significant differences in pulsed and power Doppler indices between these groups; however, the percentage of VFS in the capsule was higher than average in cycles with implantation and the percentage of VFS in the main vessel exhibited lower than average values in cycles with implantation, but only reached borderline statistical significance. It can be hypothesized that the follicles containing oocytes able to produce a pregnancy have a distinctive and more uniform perfollicular vascular network.

Other authors also looked at 3D Doppler of the ovary and relationship with hormonal status in IVF patients. Wu et al. investigated, in a retrospective study, whether the quantification of ovarian stromal blood flow and/or leptin concentration are predictive of IVF outcomes in women after laparoscopic ovarian cystectomy for large endometriomas [8]. Twenty-two women undergoing IVF after laparoscopic surgery for ovarian endometriomas ( $> 6$  cm) comprised the study group. Twenty-six women with tubal factor infertility constituted the control group. Ovarian stromal blood flow was evaluated by 3D power Doppler ultrasound imaging using VOCAL. Serum and follicular fluid (FF) leptin concentrations were quantified using an enzyme-linked immunosorbent assay kit. There were significantly decreased ovarian stromal blood flow parameters (including VI, FI, and VFI) in the endometriosis group without an evident difference in total ovarian volume on the day of human chorionic gonadotropin. The value of FF leptin demonstrated a negative correlation with ovarian stromal FI in the control group, but there was a loss of this effect in the endometriosis group. It appeared that the quantification of ovarian stromal blood flow by 3D power Doppler ultrasound in women with endometriosis may provide an important prognostic indicator in those undergoing IVF.

Kupescic and Kurjak designed the study to evaluate whether ovarian antral follicle number, ovarian volume, stromal area, and ovarian stromal blood flow are predictive of ovarian response and IVF outcome [9]. A total of 56 women with normal basal serum FSH concentrations who had no history of ovarian surgery and no ovarian and/or uterine pathology

were non-smokers and undergoing their first IVF cycle using a standard long GnRH-agonist protocol were examined. Total ovarian antral follicle number, total ovarian volume, total stromal area, and mean FI of the ovarian stromal blood flow were determined by 3D and power Doppler ultrasound after pituitary suppression. Pretreatment 3D ultrasound ovarian measurements were compared with subsequent ovulation induction parameters [peak estradiol (E2) on HCG administration day and number of oocytes] and cycle outcome (fertilization and pregnancy rates). The total antral follicle number achieved the best predictive value for favorable IVF outcome, followed by ovarian stromal FI, peak E2 on HCG administration day, total ovarian volume, total ovarian stromal area, and age. Using these six parameters, they were able to predict a favorable IVF outcome in 50% (11 of 22) of patients and poor outcome in 85% (29 of 34) of patients. Three-dimensional ultrasound facilitates determination of the antral follicle number, ovarian volume calculation, evaluation of the ovarian stroma, and analysis of the intensity of ovarian stromal blood flow in a short time without increasing the patient's discomfort.

The study done by Schild et al. was designed to investigate the role of 3D power Doppler sonography of the sub-endometrial area on the first day of ovarian stimulation in predicting the outcome of an IVF program [10]. Among the 75 cycles analyzed, the overall pregnancy rate was 20% (15 of 75) per cycle and 23.8% (15 of 63) per embryo transfer. Intraobserver variability of the color histogram was checked in 14 patients with the results demonstrating a high level of agreement. Neither endometrial measurements nor uterine blood flow were correlated with the pregnancy rate. In contrast, all 3D indices were significantly lower in conception compared with non-conception cycles. Logistic regression analysis found the sub-endometrial flow index to be the strongest predictive factor of IVF success among the tested sonographic parameters. In conclusion, quantitative assessment of spiral artery blood flow may be of predictive value for implantation in IVF cycles even before ovarian stimulation therapy is started.

### **3D Doppler in Gynecologic Oncology**

The differentiation of benign from malignant pelvic mass is still a considerable clinical challenge using traditional 2D real-time and Doppler ultrasound. One could hope that 3D Doppler would add to more accurate diagnosis or at least shorten usually a long differential diagnosis list. Recent publications are certainly directed in this direction; however, when a new diag-

nosis modality is introduced into clinical practice, the pendulum usually swings from a very high optimism to the other side. Ultimately, it will get settled somewhere in the middle once many prospective studies are done and papers are published. One can still remember a similar story in early 1990s when transvaginal color Doppler was optimistically introduced into programs for early detection of ovarian cancer. We present most recent publications limited by a relatively small number of papers dealing with 3D Doppler and assessment of adnexal mass based on ultrasound criteria.

In their study, Kurjak et al. aimed to determine the diagnostic accuracy of 3D sonography and 3D power Doppler imaging, used together with standard 2D transvaginal gray scale and color/power Doppler modalities, for preoperative sonographic assessment of suspected ovarian lesions [11]. Five-year retrospective analysis was performed by their experts on ultrasonography and surgery on the reports from 43 referred patients with suspected stage-I ovarian cancer. All patients were evaluated during the week prior to surgery at our department. Preoperative sonographic assessment included careful examination of ovarian volume, morphology, and vascularity by four complementary sonographic methods. Scoring systems combining morphologic and Doppler parameters were adopted for 2D and 3D sonographic examinations. Final diagnosis was confirmed by a histopathologist. Of the 43 stage-I ovarian cancers, 42 cases were successfully detected preoperatively by four complementary sonographic methods. Only 30 (69.8%) and 37 (86.1%) cases of stage-I ovarian cancers were detected by 2D gray-scale and combined 2D gray-scale and color Doppler sonography, respectively. Morphologic analysis obtained by 3D sonography alone detected 32 of 43 ovarian malignancies, reaching a diagnostic rate of 74.4%. Qualitative analysis of tumor vascularity architecture by 3D power Doppler significantly improved the sonographic management process and successfully detected 41 cases of stage-I ovarian cancer (95.4%). When morphologic features obtained by 3D sonography were added to 3D power Doppler findings, we achieved an even higher diagnostic accuracy of 97.7%. The Zagreb group found a statistically significant difference in diagnostic rates of 3D power Doppler, and especially the combined use of 3D sonography and 3D power Doppler in comparison with those obtained with transvaginal 2D gray-scale or 3D sonography. They concluded that in comparison with transvaginal 2D gray-scale or 3D sonography, 3D power Doppler and especially the combined use of 3D sonography and power Doppler imaging significantly improve diagnostic accuracy in preoperative sonographic assessment of suspected ovarian lesions.

It appears that 3D sonography is a novel diagnostic method proposed to be an additional non-invasive tool in the assessment of ovarian tumors. Czekierdowski et al. also studied the diagnostic potential of 3D sonography and power Doppler in the preoperative differentiation of adnexal masses [12]. One hundred twenty-eight women with tumors thought to be of adnexal origin were examined preoperatively. Following morphologic (papillae, septa, tumor size, and volume) and color Doppler (PI, RI,  $V_{max}$ , and TAMX) assessment, 3D Doppler ultrasound of adnexal tumors was performed. Various scanners were used and included: ATL 5000 HDI (Phillips, Bothell, Mass.) and Combison 530 and Voluson 730 (Kretztechnik, Austria) machines. The following variables were studied: inner wall structure; presence of papillae; thickening >3 mm of septa as well as vascular branching pattern; number and localization of small blood vessels; and the presence of vascular anastomoses. Twenty-one tumors were malignant (3 FIGO stage I) and 101 masses were benign. Power Doppler combined with 3D sonography predicted malignancy with a sensitivity of 92.6% (25 of 27 patients). Commonly used morphologic and Doppler criteria produced lower sensitivity, the values being in range of 45%–87.5%. Negative predictive value of 97.2% was the highest for 3D sonography. The authors concluded that the selective use of 3D ultrasound and power Doppler could be used to better characterize adnexal tumors. Detailed 3D sonography can help in identifying women who can have less invasive surgical procedure, if needed, such as laparoscopy, or be referred to a gynecologic oncologist.

Cohen and co-authors wanted to determine if 3D power Doppler ultrasound improves the specificity for ovarian cancer detection as compared with 2D ultrasound [13]. Seventy-one women with a known complex pelvic mass were referred for a preoperative ultrasound evaluation with both 2D and 3D gray-scale ultrasonography. The 3D studies were performed with the Kretz Voluson 530D using a mechanized transvaginal probe. Surface rendering and power Doppler imaging were performed by the same gynecologic sonologist and reassigned to one of four echo patterns: cystic; multicystic; complex; or solid. Sonographic criteria used for diagnosing ovarian cancer were based on a system that included morphologic characteristics, histologic prediction, and power Doppler imaging. Seventy-one women underwent surgical exploration: 14 (19.7%) had ovarian cancer (2 FIGO stage I, 2 stage II, 7 stage III, and 3 metastatic colon) and 2 had uterine cancer. Two-dimensional gray-scale ultrasound identified 40 masses as suspicious for cancer, including all 14 malignancies, yielding a sensitivity, specificity, and positive predictive value of 100%, 54%, and 35%, respectively; however, evaluation with

3D power Doppler identified only 28 cases as suspicious (including all 14 cancers), resulting in a sensitivity, specificity, and positive predictive value of 100%, 75%, and 50%, respectively. It was an obvious conclusion from this study that 3D power Doppler imaging better defines the morphologic and vascular characteristics of ovarian lesions. Both 2D and 3D imaging correctly identified all malignancies; however, the specificity significantly improved with the addition of 3D power Doppler. This improved diagnostic accuracy may promote improved patient care by separating complex benign masses from ovarian cancer, thereby facilitating appropriate physician referral.

In another study, the Zagreb group tried to determine whether 3D and 3D power Doppler can improve the ability to differentiate benign from malignant ovarian lesions [14]. Transvaginal ultrasound, transvaginal color Doppler, 3D US, and 3D power Doppler were performed on 90 patients with ovarian lesions during the week prior to surgery. Four independent sonographers were blinded to the results of other ultrasound studies. Color Doppler studies added to transvaginal gray-scale characterization of ovarian lesions resulted in sensitivity of 88.89 and specificity of 97.53% in diagnosing ovarian malignancy. Qualitative analysis of tumor vascularity by 3D power Doppler added to morphologic features obtained by 3D ultrasound was clinically pertinent and reached sensitivity and specificity of 100% and 98.76%, respectively. They concluded that 3D ultrasound and power Doppler can enhance and facilitate the morphologic and functional evaluation of both benign and malignant ovarian lesions. Introduction of the 3D quantitative technique for measurements of blood flow and vascularization may increase clinical relevance of these studies.

The same authors investigated the potential usefulness of contrast-enhanced 3D power Doppler sonography in the differentiation of benign and malignant adnexal lesions [16]. Thirty-one patients with complex adnexal lesions of uncertain malignancy at transvaginal B-mode and/or color Doppler sonography were prospectively evaluated with 3D power Doppler sonography before and after injection of a contrast agent. Presence of a penetrating pattern and a mixed penetrating and/or peripheral pattern suggested adnexal malignancy. The results were compared with histopathologic findings. There were 10 cases of ovarian malignancy and 21 benign adnexal lesions. Of 10 ovarian cancers, 6 showed vascular distribution suggestive of malignancy at non-enhanced 3D power Doppler sonography. After injection of contrast agent, a penetrating vascular pattern and/or mixed penetrating and peripheral pattern were detected in all cases of ovarian malignancy as well as in

two benign lesions (fibroma and cystadenofibroma), which were misdiagnosed as malignant. The use of contrast agent with 3D power Doppler sonography showed diagnostic efficiency of 96.7%, superior to that of non-enhanced 3D power Doppler sonography (93.5%). The study conclusion was that contrast-enhanced 3D power Doppler sonography provides better visualization of tumor vascularity in complex adnexal masses. If used together with 3D morphologic ultrasound assessment, enhanced 3D power Doppler imaging may precisely discriminate benign from malignant adnexal lesions.

It is well known that angiogenesis is a fundamental event in the growth of tumors as well as in physiologic conditions. In an ongoing prospective study involving eight women, Suren et al. investigated the microvasculature within the cervix by the use of 3D Power Doppler [16]. The ultrasound equipment was used in conjunction with specialized software providing high-resolution "3D angiomode." The system provides the ability to visualize blood flow in small vessels that are undetectable by conventional color Doppler techniques and also to study the architecture and determine the number of blood vessels. Comparison of the vessels in the normal cervix with those in the cervix affected by carcinoma or bacterial or viral infection demonstrated that, in malignant tissue, there is a chaotic network of tortuous vessels traversing the tumor mass, whereas in benign tissue or tissue that is inflamed as a result of infection, the course of the vessels has a regular structure.

### 3D Doppler in Benign Gynecology

Recent developments in ultrasound have presented new opportunities for assessing tissue vascularity and blood flow with ultrasound. These new methods include 3D imaging, power Doppler sonography, and a variety of harmonic imaging techniques, ultrasound contrast agents, electronic compounding, and pulse-sequencing methods that improve the signal-to-noise relationship as well as structural conspicuity. By using these technologic advances, it is now possible to assess macroscopic blood flow in organs and tumors, and to assess changes in flow and vascularity that occur in response to therapeutic efforts.

It is obvious that technologic advances in ultrasonographic imaging have revolutionized the management of women's health care. Following the course, we also started to evaluate the clinical applications of 3D ultrasonography. Our study prospectively evaluated 161 obstetric and gynecologic patients [17]. Both 2D and 3D imaging data were acquired from real-time ultrasonography. Three orthogonal planes were displayed on a monitor and were used to create the

rendered 3D images. Two hundred one 3D ultrasonographic studies were performed, 165 transabdominally and 36 transvaginally. Transabdominally, an average of eight acquisitions per patient were obtained. Of the clinically suspected abnormalities, 29 of 32 (91%) were confirmed by 3D imaging. Three of 32 (9%) improved the diagnostic capabilities or changed the diagnosis. Of the 36 transvaginal studies, an average of four acquisitions per patient were done. Thirty (83%) of these patients had suspected abnormalities and all were confirmed. We concluded that 3D ultrasonographic imaging appears to be highly promising in the clinical setting.

Recent advances in ultrasound technology have enabled the diagnosis of overall tissue vascularization by 3D power Doppler (Fig. 38.5). The published case report describes 3D power Doppler characteristics of unilateral ovarian torsion 2 weeks after embryo transfer in a pregnant patient with bilateral hyperstimulated ovaries [18]. Before laparoscopic treatment, the twisted right ovary showed the following 3D power Doppler indices: mean grayness index, 15.66; vascularization index, 0.24; flow index, 21.99; and vascularization flow index, 0.05. One hour after laparoscopic treatment, 3D power Doppler indices of the untwisted ovary were as follows: mean grayness index, 25.61; vascularization index, 3.81; flow index, 42.80; and vascularization flow index, 1.63. The resistance index of the ovarian vessels before and after laparoscopy showed no significant difference (5.1 vs 5.2). The diagnosis of ovarian torsion can be better made with 3D power Doppler sonography than with 2D Doppler sonography.

Sladkevicius et al. performed the study to evaluate the feasibility of 3D Doppler in the assessment of the patency of the Fallopian tubes during hysterosalpingo-contrast sonography (HyCoSy) [19]. Women attending the fertility clinic were offered a Fallopian tu-

**Fig. 38.5.** Overall tissue vascularization of the enlarged ovary as assessed by 3D power Doppler

bal patency test as part of the initial investigation. Hysterosalpingo-contrast sonography using contrast medium Echovist was performed in 67 women. Findings on 2D gray-scale scanning and 3D power Doppler imaging were compared. The first technique visualizes positive contrast in the Fallopian tube; the second demonstrates flow of medium through the tube. Contrast medium Echovist produced prominent signals on the 3D Doppler image. Free spill from the fimbrial end of the Fallopian tubes was demonstrated in 114 (91%) tubes using the 3D Doppler technique and in 58 (46%) of tubes using conventional HyCoSy. The mean duration of the imaging procedure was less with 3D Doppler, but the operator time that included post-procedure analysis of the stored information was similar. A significantly lower volume of contrast medium ( $5.9 \pm 0.6$  ml) was used for 3D Doppler in comparison with that ( $11.2 \pm 1.9$  ml) used for conventional 2D HyCoSy. The authors concluded that 3D Doppler with surface rendering allowed visualization of the flow of contrast through the entire tubal length and free spill of contrast was clearly identified in the majority of cases. The 3D Doppler method appeared to have advantages over the conventional HyCoSy technique, especially in terms of visualization of spill from the distal end of the tube, which was achieved twice as often with the 3D technique. Although the design of the investigation did not allow the side effects of the two techniques to be compared, the shorter duration of the imaging and lower volume of the contrast medium used suggested that the 3D Doppler technique might have a better side-effect profile. This technique allowed better storage of the information for re-analysis and archiving than conventional HyCoSy.

Whether salpingectomy affects ovarian function is controversial. In Chan's et al. study, ovarian function was assessed by antral follicle count, ovarian volume, and ovarian stromal blood flow measured by 3D power Doppler ultrasonography [20]. The objectives of the study were to compare the ovarian function of the surgically treated side with the non-surgically treated side after unilateral salpingectomy performed through laparoscopy or laparotomy for ectopic pregnancy. Thirty-two patients with unilateral salpingectomy performed for ectopic pregnancy were recruited: 18 through laparoscopy and 14 through laparotomy. Ultrasound scans were performed in the early follicular phase. Ovarian volume, antral follicle count, and 3D power Doppler indices were comparable between the surgically treated and the non-surgically treated side in the whole group and in the laparotomy group. The antral follicle count and 3D power Doppler indices were significantly reduced on the surgically treated side in the laparoscopy group. Based on this study, ovarian function seems to be im-

paired after laparoscopic unilateral salpingectomy at short-term assessment.

Three-dimensional ultrasound, as any ultrasound image, is not immune from artifacts. Nelson and co-authors wanted to increase awareness of clinicians and sonographers with respect to common 3D ultrasound artifacts and to use this increased awareness to avoid or reduce the occurrence of misdiagnosis in clinical practice [21]. Patient 3D ultrasound data were acquired using several different scanners and reviewed interactively on the scanner and graphics workstations. Artifacts were catalogued according to artifact origin. Two-dimensional ultrasound (2D US) artifacts were classified whether they were of a B-mode or color/power Doppler origin and their presentation in the original scan planes and the resulting volume re-sliced planes and rendered images was identified. Artifacts unique to 3D US were observed, noted, and catalogued on the basis of whether they arose during acquisition, rendering, or volume-editing operations. Acoustic artifacts identified included drop-out, shadowing, etc., the presentation of which depended on the relationship between slice and imaging plane orientation. Color/power Doppler artifacts were related to gain, aliasing, and flash which could add apparent structure or confusion to the volume images. Rendered images also demonstrated artifacts due to shadowing and motion of adjacent structures, cardiac motion or pulsatility of the cardiac septum, or vessel walls. Editing artifacts potentially removed important structures. Three-dimensional ultrasound is prone to the same types of artifacts encountered in 2D US imaging plus others unique to volume acquisition and visualization. The consequences of these diagnostically significant artifacts include mimicking of abnormal development, masses, or missing structures thus requiring careful study before reaching a diagnosis.

The 3D reconstruction of ultrasound images has become a widespread option in ultrasound equipment. Specific softwares have become available and 3D reconstruction feasible since the early 1990s, particularly since 1994. Several clinical applications are feasible in some parenchymatous organs (such as uterus or ovaries), hollow pelvic masses (e.g., ovarian cysts), peripheral vessels (uterine artery and branches), and new-formed vessels (e.g., tumor neovascularization) or ectopic pregnancy. Moreover, tumoral vessels in pelvic organs can be reconstructed (Fig. 38.6). The introduction of echocontrast agents and second harmonic imaging has permitted study of normal and abnormal peripheral, central, and parenchymatous vessels, with patterns similar to those obtained with digital angiography. The spatial relationships between the vascular structures of the uterus, ovaries, and Fallopian tubes were studied with 3D Doppler ultrasound (Fig. 38.7). The applications

**Fig. 38.6.** Tumoral vessels network in ovarian mass reconstructed by 3D Doppler

of this new technique include the analysis of vascular anatomy and the potential assessment of organ perfusion. The latest application is intra-vascular study. Some catheters with an ultrasound transducer in the tip have been tested for intra-vascular studies. Just like conventional transducers, they provide 2D images which are then postprocessed into longitudinal 3D or volume reconstructions. The former resemble angio-

graphic images and can be viewed 3D rotating the image along its longitudinal axis. Volume images, which are more complex and slower to obtain, can be rotated on any spatial plane and provide rich detailing of the internal vascular lumen. The clinical importance of intravascular ultrasound with 3D volume reconstructions lies in the diagnosis of vascular conditions and the assessment and monitoring of intravascular interventional procedures, e.g., to detect inaccurate deployment of intravascular stents and endoluminal grafts during the maneuver. Three-dimensional reconstructions involve geometric data assembly and volumetric interpolation of a spatially related sequence of tomographic cross sections generated by an ultrasound catheter withdrawn at a constant rate through a vascular segment of interest, resulting in the display of a straight segment; therefore, particular care is needed and there are some useful hints to avoid mistakes.

Three-dimensional reconstructions of B-mode and Doppler images are no longer a work in progress and their clinical importance and possible applications are both established and ever-increasing. On the

**Fig. 38.7.** The spatial relationships between the vascular structures of ectopic pregnancy and Fallopian tubes as studied by 3D Doppler ultrasound

**Fig. 38.8.** Ovarian artery and vein and intraovarian vascular network as seen by 3D Doppler

other hand, independent of the different types of energy used, also computed tomography and magnetic resonance 3D reconstructions are very useful from a clinical viewpoint and they have become an established routine technique for both these methods. It is very likely that 3D volume reconstructions in ultrasound will find numerous applications in the near future (Fig. 38.8). They may help to increase the diagnostic confidence and to facilitate diagnosis, intraprocedure monitoring in interventional radiology, and follow-up and also to reduce the number of invasive examinations with iodinated contrast agents.

## Conclusion

At this point in time, the clinical application of 3D Doppler ultrasound is likely to advance rapidly, as improved 3D rendering technology becomes more widely available. In the past 10 years, gynecological ultrasonography has proliferated rapidly, and is by some gynecologists considered an integral part of the gynecological exam. Abnormalities are detected in asymptomatic women at a high rate, resulting in a number of surgical interventions due to suspected malignancy. Present evidence is insufficient to determine the medical and economical value, if any, of surgical removal. Such intervention may in fact be as detrimental as leaving an abnormality in place. Gynecologic ultrasonography should therefore be performed on strict medical indications. Proper training of operators is also vital. In the past decade, research investigators and commercial companies have further advanced ultrasound imaging with the development of 3D ultrasound. This new imaging approach is rapidly achieving widespread use with numerous applications in human reproduction, gynecologic oncology, and benign gynecology. The major reason for the increase in the use of 3D ultrasound is related to the limitations of 2D viewing of 3D anatomy, using conventional ultrasound. This occurs because:

1. Conventional ultrasound images are 2D, yet the anatomy is 3D; hence, the diagnostician must integrate multiple images in his mind. This practice is

inefficient, and may lead to variability and incorrect diagnoses.

2. The 2D ultrasound image represents a thin plane at some arbitrary angle in the body. It is difficult to localize the image plane and reproduce it at a later time for follow-up studies.

Three-dimensional Doppler ultrasound is a new modality finding its way into clinical practice. Most of the major ultrasound vendors are now developing 3D ultrasound capabilities. We expect that, although 3D ultrasound will not replace 2D ultrasound, many additional benefits will be identified and its use will continue to grow, especially when 3D Doppler is used. The ability to evaluate pelvic anatomy, pathology, and blood flow with multiplanar and surface-rendered images provides physicians additional valuable clinical information. Volume data allows for a specific point in space to be evaluated from many different orientations by rotating, slicing, and referencing the slice to other orthogonal slices. It also allows for new volume-rendering displays that show depth, curvature, and surface images not available with conventional methods. The current limitations of image resolution, intuitive interfaces for obtaining and displaying optimal images, and technologic limitations for data storage and manipulation (including real-time 3D ultrasound) will surely be overcome in the near future. As 3D Doppler ultrasound continues to develop, the presence of real time 3D (or 4D) imaging equipment in the clinical setting will expand and stimulate new areas of investigation and identify new frontiers where 3D ultrasound can further enhance clinical care.

# Doppler Ultrasonography for Benign Gynecologic Disorders, Ectopic Pregnancy, and Infertility

Ivica Zalud

Doppler ultrasound has the potential to study patterns of pelvic flow and hence identify functional changes. The availability of pulsed Doppler instruments has made it possible to sample the signals at a chosen depth and thus to direct flow in any selected deep pelvic vessel. Transvaginal color Doppler is a system that uses pulsed Doppler that performs flow analysis at multiple points along each scan line of echo data. Flow information is then color-coded and displayed on the entire corresponding anatomical image. The main advantage of this color Doppler system is rapid and definitive determination of the position of the small vessel, accuracy of the measurements, and precise indication of flow direction and velocity. After simultaneous visualization of morphological and blood flow information, a pulsed Doppler gate is placed over the area of interests to provide flow velocity waveforms which may be analyzed in a conventional fashion.

This chapter presents the application of the various modalities of Doppler ultrasound for investigating benign gynecological conditions, ectopic pregnancy and infertility.

## Examination Technique

A brief explanation is required to ensure acceptance of this scanning technique and full cooperation by the patients. By comparing insertion of the probe with insertion of a tampon, speculum examination, or pelvic bimanual examination, a patient's fears are usually dispelled. The entire procedure can be done in a relaxed atmosphere without the inconvenience of the patient having a full bladder. All patients in fact should have a completely empty urinary bladder. Thus the patient and examiner do not have to wait for the slowly filling bladder in order to obtain satisfactory pelvic images. This point is important in case of an emergency, such as an ectopic pregnancy, acute pelvic inflammatory disease, or other pathology where the patient is a potential surgical candidate and consequently may not be permitted to drink in order to fill the bladder.

A regular gynecologic examination table with heel support is adequate for vaginal scanning, but a flat examination table can also be used. The patient is scanned in the lithotomy position with a slight reverse Trendelenburg tilt to localize free fluid in the pouch of Douglas. If present, this fluid creates tissue-fluid interfaces, which improves the outline of pelvic structures. In some instances, a Trendelenburg position helps to displace the bowel from the pelvic structures.

Normal menstruating women are best scanned during days 3–10 of the cycle to exclude changes in intraovarian blood flow that are known to occur during formation of the mature follicle and corpus luteum. The 5- to 10-MHz transvaginal transducer procedures a sector angle of  $90^{\circ}$ – $320^{\circ}$  to allow a satisfactory view of the pelvic organs. Before it is used, the probe should be covered with a coupling ultrasound gel, inserted into a condom, and gently inserted into the vagina. Pelvic structures may be brought closer to the acoustic focal range by placing the second hand on the patient's abdomen as for a bimanual examination. The scanning is done systematically, starting with the uterus as a landmark. The ovaries are next, then the fallopian tubes (not always seen), and finally the cul-de-sac. Various planes and depths are reached by the operator by tilting and angling the tip of the probe, thereby introducing various structures into the acoustic focal range. The morphology and size of the pelvic structures should be assessed.

After visualization of pelvic anatomy by B-mode sonography, color Doppler sonography is used to locate blood flow in normal or newly formed pelvic vessels. Subsequently, structures of particular interest are examined for prominent areas of vascularization, probably reflecting neovascularization. These vessels usually appear as continuously fluctuating color rather than the pulsating color seen with normal arteries. The color flow pattern of interest can be explored with the Doppler sample volume until the typical spectral waveform is seen. The angle of the transducer should be moved to obtain the maximum waveform amplitude and clarity. Pulsed repetition frequency for color and pulsed-wave Doppler examination should be properly set separately. The color

and pulsed-wave Doppler gain, color gate, sample volume, and wall filter must also be adjusted. Automatic default settings can be used to speed up the examination. However, manual adjustments of all mentioned parameters are needed to detect and differentiate low-velocity and high-velocity vessels. If inadequate Doppler settings are used, low-velocity vessels might not be visualized at all and high-velocity vessels might exhibit an artifact known as aliasing. Unfortunately, there are no universal guidelines for Doppler studies in gynecology, one reason being the large variety of Doppler ultrasound instruments that use different technical setups for blood flow visualization and measurement. Another more unfortunate reason is the lack of standardization of Doppler measurements. The setups are often not mentioned in the literature, making comparisons of studies impossible. Reports of these studies with precise information about the Doppler settings are rare. Moreover, the results reported vary widely and are sometimes controversial, which may ultimately compromise and devalue this relatively new ultrasound technique. Standardization of Doppler measurements is urgently needed.

Color flow can be quantified by pulsed-wave Doppler waveform analysis. The peak systolic (A) and end-diastolic (B) Doppler shift frequency can be recorded; and the A/B ratio, Pourcelot resistance index (RI), the pulsatility index (PI), and other indices may be calculated. The RI is a useful way of expressing blood flow impedance distal to the point of sampling. Each parameter is angle-dependent, but once they are in proper relation the RI becomes independent of the angle between the investigated vessels and the emitted ultrasound beam. Although the volume flow measurement would be of more benefit than Doppler waveform analysis, this approach requires precise measurement of the angle of insonation and the diameter of the vessel. If achieved, the volume (milliliters) of blood passing through a certain vessel during a particular time unit can be calculated. To avoid these measurement difficulties, waveform analysis offers semiquantitative assessment of the quality of blood flow. Because the systolic and diastolic blood flows are expressed as a ratio, measuring one or the other of these blood flows is not sufficient to report it as high-velocity or low-velocity flow: The flows cannot be observed and interpreted separately. This point is particularly important for randomly dispersed small vessels, for which the angle of insonation and the diameter of the vessel are almost impossible to determine. The basic question is whether the color signal represents a single small vessel or it is a summary of flow from an unknown number of small vessels. It is believed that the increased RI value results from increased peripheral vascular resistance. For each measurement, at least three cardiac cycles must be re-

corded and the mean value of the RI calculated. The mean duration of examination is usually no longer than 15 min in experienced hands. The spatial peak temporal average intensity should not exceed  $100 \text{ mW/cm}^2$ , which is the highest limit of insonation energy permitted by the US Food and Drug Administration (FDA) for use in fetal medicine.

## Normal Pelvic Blood Flow

Transvaginal color Doppler (TVCD) sonography and pulsed-wave Doppler sonography provide a unique noninvasive method for the evaluation of normal and abnormal conditions in the female pelvis [1]. Transvaginal ultrasonography displays uterine, iliac, and ovarian blood flow in pregnant and nongravid women and identifies physiologic flow patterns. Blood flow in the main pelvic vessels can be easily visualized and recognized. The artery and vein are distinguished according to the pulsation and brightness of color flow (Fig. 39.1). The internal iliac vessels can be visualized in the entire population. The iliac vein is most commonly seen immediately below the ovary. The ability to view iliac veins is an excellent way to document patency or thrombosis. The iliac arteries at the bifurcation have characteristic waveforms. The common and external iliac arteries, which are part of the aortofemoral segment, show plug flow, a window under the waveform, and a reversed component during diastole. The internal iliac artery, in contrast, has parabolic flow with an even distribution of velocities within the waveform. Internal iliac vessels can usually be observed in the side wall of the pelvis, often lying deep and close to the ovary. The internal iliac artery produces prominent, pulsating color flow at high velocity, typically with reverse flow and high impedance of flow.

**Fig. 39.1.** The internal iliac artery (red) and vein (blue) are distinguished by color Doppler according to the brightness of the color and pulsation, not by the color itself

**Fig. 39.2.** Uterine artery spectral Doppler waveform has high systolic flow, high resistance, low diastolic flow, and a characteristic notch during diastole. The uterine vein Doppler pattern is shown *below the zero line*

The color Doppler signal from the main uterine vessels may be seen in all patients lateral to the cervix. The transvaginal transducer clearly displays all the vessels coursing from the sides of the cervix, up to the lateral wall of the uterus, along the fallopian tube, and terminating above the ovaries. Branches of the uterine artery can be followed as they enter the myometrium, and even endometrial perfusion can be studied. The uterine artery spectral Doppler waveform in both nongravid and first-trimester pregnant women has high impedance (low diastolic flow) with a characteristic notch during diastole. Uterine flow states can be determined by the Doppler spectrum (Fig. 39.2). The impedance to blood flow depends on age, phase of the menstrual cycle, and special conditions (e.g., pregnancy, tumor). It is usually a high-resistance system.

The ovarian artery is a tributary of the upper aorta and reaches the lateral aspect of the ovary through the infundibulopelvic ligament. In some patients, these vessels are not clearly visualized and the sample volume should be moved across the ligament and then through the substance of the ovary until the arterial signal is identified. Signals from the ovarian artery are characterized by the low Doppler shifts of a small vessel with low velocity [2]. The waveform shape varies with the state of activity of the ovary. Studies of ovarian artery blood flow show the difference in the vascular resistance between the two ovarian arteries depending on the presence of the dominant follicle or corpus luteum. A longitudinal study of the ovarian artery throughout the menstrual cycle will usually show decreased PIs and RIs, reflecting vascular impedance and implying increased flow to the ovary containing the dominant follicle or corpus

**Fig. 39.3.** Ovarian artery visualized in the lateral upper pole of the right ovary. Color flow is usually not prominent, velocity is low, and resistance varies greatly according to menstrual cycle

luteum. The ovarian artery of the “inactive” ovary in this cycle would show low end-diastolic flow or absence of diastolic flow. A rise in end-diastolic flow in the “active ovary” is most obvious around day 21 and suggests that the corpus luteum acts as a low-impedance shunt. The increased blood supply to the functioning corpus luteum is essential for delivery of precursors involved in steroidogenesis and for distribution of progesterone.

The ovarian artery is a high-pressure system with blood flow characteristics very different from intra-ovarian circulation (Fig. 39.3). Near the ovarian hilus the penetrating vessels are coiled and tortuous. This type of vascularity demonstrates high-resistance blood flow [3]. Every month during the woman’s reproductive life, one oocyte is released from the single

**Fig. 39.4.** Corpus luteum vascularization detected by color Doppler sonography. Such small randomly dispersed vessels are difficult to study without color as a guide

mature follicle that has completed development. Increased vascularity on the innermost rim of the follicle may represent the dilatation of new vessels that have developed between the relatively vascular theca cell layer and the normally hypoxic granulosa cell layer of the follicle. It is hoped that information on ovarian perfusion may be used both to predict ovulation and to investigate ovulatory dysfunction.

Color flow is more easily obtainable from ovarian tissue in the luteal phase. The qualitative postovulatory changes in intraovarian blood flow are characterized by increased turbulent flow accompanying morphological changes in the intraovarian vascular network and appearance of numerous arteriovenous shunts during the luteal phase (Fig. 39.4). In summary, changes in the intraovarian blood flow occur before ovulation, implying a complexity of these changes that may involve both angiogenesis and hormonal factors, while postovulatory vascular accommodation is potentially important in the luteal phase. Using transvaginal color Doppler, corpus luteum blood flow, characterized by low impedance and high flow requirements, can easily be detected in normal early pregnancy, ectopic pregnancy, and nonpregnant women.

## Benign Uterine Pathology

Transabdominal ultrasonography permits gross visualization of the uterine corpus through the distended urinary bladder. Estimates of size in terms of the sagittal, anteroposterior, and transverse diameters are easily obtained. In the clinical setting of an enlarged uterus (e.g., leiomyomata uteri) transabdominal scanning may be helpful.

Transvaginal scanning permits close examination of a structure of interest within the corpus or cervix of the normal or slightly enlarged uterus. Proximity and high-

er-frequency probes provide improved imaging and infrastructural detail not possible with the transabdominal approach. With the advent of color Doppler analysis, additional physiologic/functional and pathologic states may be identifiable. The blood supply to the uterus, the uterine arteries, are direct branches of the hypogastric artery and have a typically high-resistance/low-diastolic-flow velocity waveform. Pulsed-wave Doppler analysis of the uterine artery has been described previously. Color Doppler analysis allows identification of the small vessels within the myometrium (e.g., arcuate arteries and their branches). Again, the age of the patient, phase of the menstrual cycle, pregnancy state, and pathologic conditions influence the type of velocity waveform obtained.

## Fibroids/Leiomyomas

Leiomyomas are benign tumors of the uterine myometrium. They are derived from the mitotic division of a smooth muscle cell within the uterine wall. Among a screened population of women over 40 years of age, 25%–30% exhibit findings of intramural leiomyomas. They are often incidental findings, as they may occur in a uterus of overall normal size. Utilizing two-dimensional transvaginal scanning in the sagittal and transverse planes, leiomyomas can be described as intramural, submucous, subserosal, fundal, cervical, or intracavitary; anterior or posterior; lateral left or right. A variety of sonographic images are seen in leiomyomas. The internal echogenicity depends on the amount of smooth muscle and fibrous tissue, degeneration, and vascularity. Leiomyomas can undergo cystic degeneration (echo-lucent) or, conversely, calcific degeneration (echogenic) with shadowing, as well as the spectrum in between.

The addition of color Doppler analysis facilitates determination of the predominance of myometrial vessels feeding a leiomyoma and the type of flow present. The Zagreb group studied uterine flow and myometrial vessel flows in women with fibroids [4]. Diastolic flow is present in the myometrial vessels and is usually increased relative to that seen in the uterine arteries. Uterine artery flow velocity in the normal uterus has a mean RI of 0.84. In women with leiomyomas a slight decrease in the mean RI to 0.74 was observed. The mean RI of myometrial blood flow in these patients was 0.54.

In the clinical setting localization and flow determinations of leiomyomas may be helpful. Such information might influence one's surgical approach. In addition, the utility and effectiveness of new treatment modalities may become subjects of color Doppler analysis.

Investigations on the use of gonadotropin-releasing hormone (GnRH) analogs for treatment of leiomyoma

uteri and endometriosis are reported in increasing numbers. The effect of GnRH analogs, essentially a medically induced menopause, might be assessed in a semiquantitative manner using transvaginal sonography and color Doppler flow analysis. It has been our observation that women distant from menopause exhibit an increased resistance flow pattern and higher RI [5]. The utility of this modality for exploring benign conditions of the uterus continues to expand.

## Endometrium

Transvaginal sonography greatly enhances imaging of the uterine cavity and endocervix. It is now possible to identify small submucous myomas, endometrial polyps, distortions of the endometrial cavity, and the exact location of an intrauterine device (IUD). Measurement of the total thickness of the endometrium is facilitated by transvaginal scanning (Fig. 39.5). The measurement should be obtained in the sagittal plane and reported in millimeters. Literature accumulated to date suggests that endometrial thickness in the postmenopausal, non-hormone-replaced individual should be less than 6 mm (Table 39.1). A thickness of 6 mm or more is suspect [6, 7]. Pathologic conditions seen in the setting of increased endometrial thickness include endometrial hyperplasia, endometrial polyps, and adenocarcinomas of the endometrium (Fig. 39.6). Among a screened population at our institution, more than 2,000 women underwent transvaginal sonography and color Doppler analysis, with assessment of the endometrial cavity as well. There were 20 asymptomatic women who underwent endometrial sampling or biopsy based on a report of the endometrium being greater than 6 mm. None of the women had symptoms (i.e., postmenopausal bleeding or staining) (Table 39.2). There were three cases of adenocarcinoma

**Fig. 39.7.** Myometrial invasion in the case of an advanced stage of endometrial cancer seen by transvaginal ultrasonography

of the endometrium, five hyperplasias (one with atypia), and seven polyps (one with hyperplasia). There was no cutoff value, however, whereby benign versus malignant conditions could be discriminated. In one of the adenocarcinoma cases abnormal blood flow was observed in the uterine artery and the myometrial vessels by waveform analysis. Attention should be given to the endometrial-myometrial interface, as myometrial invasion can be visualized (Fig. 39.7). Others have also evaluated the use of color Doppler analysis for assessing endometrial cancer [8–11].

When hormone replacement therapy is used, a cutoff value of 6 mm cannot be used as an accurate criterion for suspicion. In the case of breakthrough bleeding on hormone therapy, these authors utilize transvaginal sonography and color Doppler analysis to assess the endometrium [12, 13]. If a thin echo is seen at 2–3 mm and color Doppler velocimetry is normal, the patient may be able to avoid repeated endometrial biopsies. In the case of an endometrial thickness of more than 6 mm, sampling for breakthrough bleeding (i.e., endometrial sampling) is suggested and supported.

**Fig. 39.8.** Transvaginal sonography from a case of septic abortion. The patient had undergone elective termination of pregnancy at 16 weeks' gestation. Ten days later she presented with pelvic pain, fever, and bleeding. Transvaginal sonography of the uterus showed "tissue" in the uterine cavity. Close examination of the ultrasound image shows intraabdominal contents entering the left fundus

### Retained Products of Conception

Transvaginal sonography can be valuable when evaluating a postabortal patient. After a spontaneous abortion the uterine cavity may be inspected for retained products of conception, determining if surgical completion is required. In the case of elective termination of pregnancy (TOP) or postsurgically completed abortion, postoperative bleeding can be assessed for retained tissue. The application of color Doppler analysis is new and uncertain in this setting.

Transvaginal sonography proved vital in a case of septic abortion presenting to the emergency room at our hospital. The patient had undergone an elective TOP at 16 weeks' gestation at another institution. Ten days later she presented with pelvic pain, fever, and bleeding. Transvaginal sonography of the uterus revealed "tissue" in the uterine cavity. Close examination of the ultrasound image showed intraabdominal contents entering at the left fundus (Fig. 39.8). A color flow analysis may have been interesting in this case, looking for bowel motility within the cavity. More than likely, however, any bowel would have "ileus", or diminished motility. Laparotomy confirmed a left fundal perforation, with omentum and transverse colon within the defect. Reinstrumentation of this patient would have been harmful and potentially fatal. Ultrasound findings in this case were paramount to the management.

The other uterine condition connected to pregnancy is gestational trophoblastic disease (GTD). This term describes a group of tumors that share several characteristics: (1) they arise in fetal chorion; (2) they produce human chorionic gonadotropin (hCG); and (3) they respond well to chemotherapy. The inci-

dence of hydatidiform mole appears to be about 1 per 1,000 pregnancies in most parts of the world, with that figure perhaps twice as high in Japan [14]. Choriocarcinoma is much less common, and estimates of the incidence are highly variable.

Ultrasonography is one of the most valuable non-invasive diagnostic methods for diagnosing GTD. Molar pregnancy can be easily diagnosed by ultrasonography by its typical snowstorm pattern. However, ultrasonography is thought to be unreliable for distinguishing a noninvasive mole from an invasive one or from choriocarcinoma, as the sonographic appearance is almost the same for all three lesions. The clinical management and prognosis depend on a correct diagnosis [15]. Other diagnostic modalities, such as the  $\beta$ -hCG level and its dynamics, computed tomography (CT), and magnetic resonance imaging (MRI), or even an invasive procedure such as pelvic arteriography or hysterectomy, are performed to confirm clinical suspicion.

Many patients with persistent GTD have been treated without ever demonstrating the site of the persistent trophoblastic focus. TVCD ultrasonography has been reported to be able to accurately map uterine blood flow during pregnancy. The arcuate, radial, and spiral arteries can be precisely localized by color flow analysis and studied by pulsed-wave Doppler waveform analysis [16–18].

GTD is a clinically complex, diagnostically challenging condition. It might be fatal if it turns malignant. Fortunately, the disease is considered a treatable malignant tumor, with a survival rate approaching 100% [15]. The prognosis is highly dependent on early, reliable diagnosis. Ultrasonography has played a major role in differential considerations when GTD is suspected [19–21].

The ultrasonographic appearance of molar pregnancy varies with the gestational age at which the examination is performed. During the first trimester a hydatidiform mole may mimic a missed abortion, an incomplete abortion, or a blighted ovum. In most cases an accurate diagnosis can be made. Myometrial invasion can also be estimated by ultrasonography, but the degree of invasion is usually arbitrary. The ultrasound features of choriocarcinoma are difficult to distinguish from those of an invasive mole. Other diagnostic techniques, usually more invasive and risky, are employed to solve the dilemma.

Color Doppler sonography was reported as an accurate way to distinguish the various segments of uterine vascularization during pregnancy [16]. Color flow analysis is used to locate the arcuate, radial, and spiral arteries. Pulsed-wave Doppler sonography is then used to study the various flow patterns of the visualized vessels. We described abnormal early pregnancies and the vascular changes in the uterus, and

we noted that some of the blighted ova were richly vascularized [22]. It was speculated that the intensity of color flow corresponds to trophoblast activity. Abundant color possibly indicates which blighted ovum would undergo molar changes. Different patterns of blood flow (intensity of color, number of vessels, degree of myometrial invasion, velocity, and waveform analysis) might reflect different aspects of gestational trophoblastic disease. We concluded that because there has been no typical ultrasound marker that can be used for differentiating between choriocarcinoma and invasive mole, color Doppler characterization might be of diagnostic value.

The level of myometrial invasion by trophoblastic tissue can be assessed by color flow sonography. It is obvious in patients with choriocarcinoma and invasive mole: The normal vascular network is changed, and as the process progresses the spiral and radial arteries are either incorporated in the tumor tissue or destroyed by invasive disease. The latter condition is probably more common. The basis for abundant color flow relies almost entirely on neovascularization. All six patients with choriocarcinoma in our study showed this disturbed, markedly changed intrauterine blood flow. One of two patients with proved invasive mole also presented with the same chaotic blood flow pattern.

Such a change suggests two prognostic possibilities when the invasive mole is considered: destructive invasion of the myometrium and metastasis or spontaneous regression. These possibilities are supported by clinical experience. Carter et al. used TVCD sonography to study GTD [23]. They evaluated blood flow characteristics of the uterine artery and intratumoral vessels. The uterine artery PI correlated significantly with age, uterine size, and  $\beta$ -hCG titer. The intratumoral PI correlated significantly only with uterine size. Regression analysis of  $\beta$ -hCG titers in the uterine artery and intratumoral PI revealed a linear association. They concluded that the PI is strongly associated with prognosis and correlates with the  $\beta$ -hCG titers.

It seems now that ultrasonography may be able to distinguish reliably between the forms of gestational trophoblastic disease. Because of its noninvasiveness and relatively simple, easily performed technique, TVCD sonography can be of considerable clinical value. The other important point is that the study results are available immediately for clinical judgment.

## Benign Adnexal Pathology

Functional cysts are the most common source of adnexal masses in women of reproductive age. The two main types of functional cyst, follicle and corpus luteum cysts, are benign and derived from either an unruptured follicle or the cystic degeneration of a

corpus luteum, respectively. Typically, these cysts are unilateral and are less than 6 cm in diameter, and during pelvic examination they feel smooth and cystic. On sonograms, the cysts appear unilocular and fluid-filled, without evidence of solid components or excrescences. It seems that transvaginal color Doppler is helpful in the differential diagnosis of different causes of acute abdomen and in the detection of torsion of the functional cyst [24]. Torsion affects blood supply to the ovary both from the ovarian artery and the ovarian branch of the uterine artery. Below a morphologically recognized point, no blood supply was detected. Hemorrhage from a ruptured corpus luteum cyst can be severe enough to be mistaken for a ruptured ectopic pregnancy. This new technique enhances our ability to distinguish between these two conditions and to select the patients for surgical intervention when necessary.

Mature teratomas (dermoid cysts) occur commonly in women of reproductive age. They contain elements of mature adult structures derived from all three embryonic layers: endoderm, mesoderm and, peripherally, ectoderm. These structures include hair, teeth, bone, skin, and calcified components that give focal, high-amplitude reflectors with acoustic shadowing. Unfortunately, these high-amplitude reflectors may simulate bowel gas; therefore, these lesions may be camouflaged and sometimes even large lesions can go undetected on sonograms.

Serous and mucinous cystadenomas are also common lesions. Serous cystadenomas may be unilocular but they are mostly multilocular, with or without papillary growth into the cavity. Mucinous cystadenomas may attain a huge size, and several have been reported to weigh 45–90 kg. Grossly, they present as rounded or ovoid masses with a smooth capsule that is usually translucent or bluish-whitish gray. Mucinous cystadenomas are thin-walled and mostly multilocular. Papillary formations may be present, but they are less common than in serous cystadenomas. Sonographic evaluation whether alone or in combination with tumor markers cannot determine the nature of the lesion before Doppler assessment. This is not surprising, because it can be difficult to distinguish a benign ovarian tumor from a malignant or borderline one by macroscopic inspection of the specimen or even by microscopic evaluation.

Fibromas, thecomas, and Brenner's tumors are solid, benign tumors found in premenopausal and postmenopausal patients. Small, solid tumors are difficult to detect on sonograms because they are similar in echo texture to the normal ovary. If a solid lesion is observed in the adnexa of a premenopausal woman, it is more likely to be a pedunculated or broad ligament leiomyoma than a solid ovarian neoplasm. Transvaginal color Doppler is useful in differentiating

fibroids from solid ovarian masses on the basis of their vascularity. Within or on the periphery of the uterine mass, even when it is out of the contour of the uterus, it is possible to detect waveform signals that are typical for the uterine vascular network. In such cases, blood flow is usually similar to normal myometrial perfusion, originating from terminal branches of the uterine artery. On the other hand, small vessels that feed a growing ovarian tumor are of ovarian vasculature origin.

## Endometriosis

Endometriosis is a condition in which abnormal growth of tissue, histologically resembling endometrial tissue, occurs outside the uterus, including the surfaces of the bowel, bladder, or abdominal wall. The ovary represents a relatively unique site of implantation, as the levels of steroids surpass those in the circulation, and hence this affords an ideal environment for implantation of endometrial growth. It seems that the surface epithelium and the proximity of the tubal ostia influence transplacental production. When endometrial cells enter the ovarian stroma, large endometrial cysts filled with viscous chocolate-colored liquid may be formed. There is usually a well-demarcated separation between the endometrial cyst wall and the normal adjacent ovarian stroma. The most prominent vascular area in these common benign cysts is at the level of the ovarian hilus. This type of neovascularization was often seen with endometriomas. It seems that low-impedance/high-diastolic flow is present when there is a hemorrhage during the menstrual phase of the cycle. Therefore, it is recommended to study the ovarian endometrioma vascularity during the late follicular phase. It is postulated that the effect of medical treatment is highly dependent on the metabolically active implants arriving via a blood-supplying network. Conservative treatment has encouraging potential and can be successfully used in patients with an optimal vascular pattern. Surrounding inflammation and fibrotic changes that may disturb this process can be detected by transvaginal color Doppler. Based on some experience, avascular ovarian lesions could be best removed surgically.

## Pelvic Inflammatory Disease

Ultrasonography is often used to exclude intrauterine and ectopic pregnancy or to document the presence of an adnexal mass. Sonography shows a predominantly cystic collection with internal echoes that may have multiple loculations. Occasionally, distinction from fluid-filled loops of bowel may be difficult. In this instance, a water enema may be helpful because the movement of water through the bowel will be observed on real-time ultrasound. Because the inflam-

matory process in the ovary involves both structural and vascular changes, color Doppler ultrasound can be a useful tool in its diagnosis and management. Edema of the fallopian tubes and dilatation of the blood vessels in their walls characterize the early phase of the disease. The inflamed ovaries are enlarged and filled with multiple cysts, which represent infected follicles, or corpus luteum cysts. Intraovarian vessels can easily be identified and show usually moderate resistance to blood flow.

It is well known that the sonographic appearance of a complex adnexal mass should be interpreted in the context of the clinical setting. For example, in the febrile patient, a thick-walled mass containing echogenic fluid is likely to be an abscess. In this advanced and most severe form of pelvic inflammatory disease, it is difficult to identify the pelvic anatomy. Ovaries are usually adherent to the pelvic sidewall or to the uterus, and the scarring process can alter their endocrine function and circulation. Based on our experience, dynamic use of color Doppler ultrasound in patients affected with pelvic inflammatory disease is important for accurate diagnosis, follow-up, and evaluation of the ovulatory function and ovarian perfusion.

Color Doppler ultrasound is a useful tool in the diagnosis of pelvic inflammatory disease. It helps distinguish between dilated vessels and a fluid-filled hydrosalpinx, and it can be useful in the differential diagnosis of tubo-ovarian abscess. Measurements of the intraovarian resistance in the acute phase of the disease reveal the ovarian involvement and function, as these relate to the rapidly changing pattern of the disease. An increased resistance to blood flow in the chronic phase is probably related to the extensive scarring. This condition of reduced perfusion may have long-term effects on the endocrine function of the ovary.

**Fig. 39.9.** Transvaginal color Doppler of an ovarian cyst with feeding vessels

**Fig. 39.10.** Pulsed-wave Doppler waveform of the same ovarian vessels as shown in Fig. 39.9, with typically high resistance blood flow. A benign ovarian cystadenoma was found on histopathology

**Fig. 39.11.** Color and pulsed-wave Doppler findings in the case of a benign ovarian mass

Previous studies have suggested that ovarian ultrasound morphology is not precise for diagnosing ovarian neoplasms; sensitivities vary from 70% upward [25, 26]. Standard ultrasound criteria that suggest a benign condition are well known: unilocular, cystic, unilateral, absence of internal echoes. Conversely, malignant tumors have been characterized as complex: multilocular, cystic-solid, bilateral, with positive free fluid in the peritoneal cavity. Using these criteria both false negatives and false positives are encountered. In a premenopausal population these morphologic criteria may be misleading. Certain pathologic conditions, though benign, appear sonographically with malignant morphology. Examples are dermoid cysts, endometriosis, corpus luteum, and hemorrhagic cysts. Color Doppler waveform analysis provides additional information (Figs. 39.9–39.11). If a

high-resistance velocity wave pattern is observed, one may be more confident that the lesion is benign (Fig. 39.12). In the case where a high-velocity/low-resistance pattern is seen the examination must be repeated during the next cycle. Recall that the corpus luteum or luteal flow may exhibit a low-resistance waveform pattern (Fig. 39.13).

Several investigators are now applying a scoring system to both morphologic criteria and color Doppler waveform analysis [27, 28]. Table 39.3 shows the scoring system used by the Zagreb group. This study is the largest series of adnexal tumors analyzed by color Doppler velocimetry [28]. The data yielded a Pourcelot RI cutoff of 0.40 as a discriminatory value for benign versus malignant lesions.

Application of color flow analysis may have important implications with respect to clinical management. Traditionally, the standard of care for an adnexal mass has been laparotomy with surgical excision. For a lesion where the morphology and Doppler analysis suggest a benign condition, conservative therapeutic options may be entertained. Advances in video-endoscopic laparoscopy offer a conservative surgical approach to removing an ovarian cyst.

**Fig. 39.12.** Tumor feeding vessel with typical high-resistance blood flow in the case of benign multilocular ovarian enlargement

## Doppler Ultrasound and Ectopic Pregnancy

Ectopic pregnancy is defined as implantation of the fertilized ovum anywhere outside the normal uterine cavity. It accounts for 2% of all pregnancies in the United States, with its incidence is reported to be increasing over the past two decades [29, 30]. Ectopic pregnancy is associated with a high maternal mortality and morbidity, accounting for 9%–13% of all pregnancy-related deaths [31]. The most common site

<b>Color Doppler score</b>		
≤2 Benign		
3–4 Questionable for malignancy		

for an ectopic pregnancy is the fallopian tube; rare types include interstitial, cervical, ovarian and abdominal pregnancy. The management of ectopic pregnancy has metamorphosed impressively from a period in the 1970s and early 1980s when laparotomy was the only choice, to the present period of advances in operative laparoscopy and ultimately high-resolution ultrasonography. This was in step with sensitive quantitative  $\beta$ -hCG determinations, when earlier diagnosis of ectopic pregnancy not only allowed greater use of conservative therapy, but also drastically reduced maternal mortality rates from 35.5 per 10,000 women with ectopic pregnancy in 1970 to 3.8 in 1989 [31]. Ruptured ectopic pregnancy cannot be managed conservatively, and acute cases require emergency laparotomy. Women who have one ectopic pregnancy are at increased risk for another such pregnancy and for future infertility. Early detection and subsequent surgical and medical intervention may account for this reduction in mortality. The exact cause of blastocyst implantation and development outside the endo-

metrial cavity is unknown. Abnormal tubal morphology, alterations in the hormonal environment affecting tubal motility, uterine abnormalities, foreign bodies, and defects of the fertilized ovum are associated with its occurrence. Early recognition of the symptoms and risk factors attributed to ectopic pregnancy and prompt application of advanced technology gives a quicker diagnosis and allows initiation of conservative therapy to reduce the morbidity.

The diagnosis of ectopic pregnancy remains a challenge to the clinician despite advances in ultrasound and biochemical technology. Contemporary practice requires an understanding of the normal sonographic features and hormonal profiles as well as the pathogenesis of an ectopic nidation. Frequently, the diagnosis remains uncertain until laparoscopy or dilatation and curettage has been performed.

The practicing gynecologist should consider all relevant factors, including the patient's clinical history and predictive risk factors, symptoms, and physical findings, serum  $\beta$ -hCG level, and the ultrasound scans, before deciding whether operative intervention is indicated and necessary. Nevertheless, further improvement in imaging techniques may aid in enhancing preoperative certainty and possibly eliminate or reduce the performance of unnecessary surgery. For this purpose, transvaginal Doppler ultrasonography was introduced to add more information by looking at the blood flow characteristics in the adnexa (Figs. 39.14–39.23).

Color and pulsed Doppler flow imaging capabilities have been added to transvaginal sonography (TVS) in an effort to improve sonographic diagnosis. The technique consists of identifying the site of vascular color in a characteristic placental shape called "ring of fire" pattern and a high-velocity, low-impedance flow pattern of placental perfusion. When this pattern is seen outside the uterus while the uterine

**Fig. 39.14.** Small gestational sac measuring 1 cm with prominent blood flow signals obtained from its periphery

cavity is “cold” with respect to blood flow, diagnosis of ectopic pregnancy is confirmed. It has been reported to increase the diagnostic sensitivity of sonography for ectopic pregnancy from 71% to 87% [32–34]. It also helps eliminate the problem of false positives, except in rare situations of ovarian pregnancy.

Kurjak et al. have reported on the difference between the RI of the corpus luteum blood flow and peritrophoblastic flow of the ectopic pregnancy. The cutoff value for the RI of corpus luteum blood flow has been described to be 0.4 and the RI of peritrophoblastic blood flow below 0.4 [34]. Kirchler has described the use of Doppler blood flow in measuring the RI in tubal branches of the bilateral uterine ar-

teries. The vessel with low-resistance flow indicates the side of the ectopic pregnancy [35].

Endometrial color flow/image-directed Doppler imaging has also been reported to reduce the false-positive TVS examinations which occur in 5%–10% of patients with high-risk findings. Ectopic pregnancy has no intrauterine trophoblastic activity, hence the presence of trophoblastic flow (arterial blood flow within the endometrium) lowers the risk of ectopic pregnancy whether an intrauterine gestational sac is present or not. However, care must be taken to ensure that arterial and not venous flow signals are obtained. The Doppler cursor should be completely within the endometrium to ensure that the signal is endometrial

**Fig. 39.15.** High-velocity/low-impedance (RI=0.42) blood flow signals are obtained from the color-coded area and represent active, invasive trophoblast

**Fig. 39.16.** Blood flow signals isolated from ipsilateral corpus luteum demonstrate a moderate to high resistance index (RI=0.54)

**Fig. 39.17.** Complex adnexal mass representing an ectopic pregnancy (prominent color signals on the left) and a corpus luteum cyst on the right

and not from the endometrium-myometrial junction. Further, correlation with serum  $\beta$ -hCG levels is essential [36].

Kemp et al. have reported on the use of Doppler sonographic criterion, i.e., the presence of a signal-intensive ring of vessels (correlated to neovascularization of the tube) for differentiating between a viable ectopic pregnancy with trophoblastic activity and a dissolving tubal abortion [37]. This may help decide about the optimal management, since surgical methods or injection of drugs must arrest chorionic activity, while tubal abortion may be managed expectantly in a clinically stable patient. However, further studies are needed to determine the efficacy of this approach in management of tubal ectopic pregnancy.

**Fig. 39.18.** Gestational sac 1 cm in diameter with peripheral vascularization indicating invasive trophoblast

**Fig. 39.19.** Same patient as shown in Fig. 39.5. The pulsed-wave Doppler waveform analysis demonstrates low impedance to blood flow (RI=0.35)

**Fig. 39.20.** Ipsilateral corpus luteum shows significantly higher impedance to blood flow (RI=0.52) and can be distinguished from signals obtained from the periphery of the gestational sac

**Fig. 39.21.** Ectopic gestational sac in the left adnexal region surrounded by a “ring of fire” (nearby vessels)

## Other Types of Ectopic Pregnancy

### Interstitial/Cornual Pregnancy

These two terms are used interchangeably, though strictly speaking the term cornual pregnancy should be reserved for pregnancy in a rudimentary uterine horn. Only 2%–4% of ectopic pregnancies develop in the interstitial portion of the fallopian tube [38]. The surrounding myometrium permits the pregnancy to progress to an advanced age (12–16 weeks) before it ruptures. Severe hemorrhage ensues leading to a significantly higher mortality and morbidity.

High-resolution ultrasound along with the color flow Doppler equipment enables an early and accurate diagnosis to be made. Sonographic findings include eccentric location of the gestational sac and myometrial thinning. Ackerman et al. have described the “interstitial line” sign in cases where the visible myometrium completely surrounds the gestational sac, making the diagnosis difficult. They proposed that since interstitial pregnancy grows within the lumen of the tube, the endometrial cavity or interstitial portion of the tube can be traced directly to the eccentric gestational sac. This sign was reported to be 80% sensitive and 99% specific for the interstitial pregnancy [39].

**Fig. 39.22.** Blood flow signals isolated from the periphery of an ectopic gestational sac demonstrate low impedance to blood flow (RI=0.43)

**Fig. 39.23.** Pulsed-wave Doppler waveform analysis obtained from an ectopic pregnancy in a regression phase demonstrates significantly higher impedance to blood flow (RI=0.73)

### Cervical Pregnancy

Cervical pregnancy is a rare condition accounting for approximately 0.15% of all ectopic pregnancy [40]. When undiagnosed, it leads to massive hemorrhage requiring an emergency hysterectomy. In 1978, Ras-kin presented the first report of a sonographic diagnosis of a cervical pregnancy [41]. Subsequently other workers have reported on use of TVS in early diagnosis of cervical pregnancy [42, 43]. Location of the gestational sac within the endocervical canal is the cardinal sonographic sign. This leads to cervical enlargement and the classically described “hourglass appearance” of the uterus [44]. With the advent of

TVS, cervical pregnancies can be diagnosed early in gestation at less than 7 weeks of menstrual age, enabling prompt treatment.

### Ovarian Pregnancy

Ovarian pregnancy is an uncommon type of ectopic pregnancy. Its incidence has been reported to be 1 per 7,000 pregnancies and it accounts for 1%–6% of all ectopic pregnancies [45]. Presenting symptoms are similar to those of tubal pregnancy. A causative relationship with an intrauterine device has been recognized [46]. It is difficult to preoperatively diagnose ovarian pregnancy clinically [47].

However, recent advances in hCG determination and ultrasound, especially TVS, have helped in its early diagnosis and correct localization [48, 49]. TVS has been reported to be of diagnostic value in differentiating ovarian pregnancy from tubal pregnancy [50]. The image of ovarian mass is characterized by a double hyperechoic ring surrounding a small hypoechogenic field. A case of twin ovarian pregnancy diagnosis on TVS has also been reported [51]. Bontis et al. have evaluated the criteria for diagnosis of ovarian pregnancy based on currently available diagnostic methods [52].

### Abdominal Pregnancy

It accounts for 0.03% of ectopic pregnancies [40]. Its diagnosis is often missed on TVS or delayed, as most of these are secondary implantations occurring after tubal rupture or abortion. In most of the cases abdominal scanning is preferable. TVS may have a role in suspected abdominal pregnancy by virtue of clear depiction of the gestation sac outside the uterus. The endocervical canal does not extend up to the placenta but is present either posterior or anterior to it. Walls of the lower uterine segment are seen opposed to each other and not separated by the gestational sac.

### Diagnostic Difficulties

The ultrasonologist should be aware of conditions causing false-positive or false-negative Doppler ultrasound diagnosis of ectopic pregnancy [32], which are listed in Table 39.4. A false-positive diagnosis predominantly comes from corpus luteum, but other adnexal tumors may also be a source of error. Malignant ovarian or tubal masses, endometriosis, or inflammation can be a diagnostic challenge. Corpus luteum can produce color and pulsed-wave Doppler patterns that are similar and sometimes almost identical to those seen with an ectopic pregnancy. Zalud and Kurjak studied luteal blood flow in pregnant and nonpregnant women [53]. Typical luteal low-impedance blood flow was detected in 82.8% cases of normal early pregnancy, 80.8% cases of ectopic pregnancy, and 69.3% cases of nonpregnant women during the luteal phase of the menstrual cycle. The lowest RI ( $0.42 \pm 0.12$ ) of luteal flow was found in nonpregnant women, and the highest RI ( $0.53 \pm 0.09$ ) was seen with an early intrauterine pregnancy. The RI in cases of ectopic pregnancy was  $0.48 \pm 0.07$ . In 86.4% of patients with proved ectopic pregnancy, luteal flow was detected on the same side as the ectopic pregnancy. This observation can be used as a guide when searching for an ectopic pregnancy.

A false-negative result may arise from technical inadequacy of the performed ultrasound scan, lack of

**Table 39.4.** Conditions affecting Doppler ultrasound findings for ectopic pregnancy

False-positive findings	
■	Corpus luteum <sup>a</sup>
■	Endometriosis
■	Pelvic inflammatory disease
■	Other adnexal masses or structures <sup>b</sup>
■	Ovarian cancer
False-negative findings	
■	Very early ectopic pregnancy
■	Avascular ectopic gestation
■	Lack of experience of the technician
■	Technical difficulties
■	Nonvascularized ectopic pregnancy
■	Patient noncompliance <sup>c</sup>

<sup>a</sup> The corpus luteum may create the impression of a sac-like structure because it is eccentrically located within the ovary and surrounded by ovarian tissue.

<sup>b</sup> A thin-walled ovarian follicle; the small intestine; and tubal pathologic conditions such as a fluid-containing hydrosalpinx.

<sup>c</sup> Patient is not lying very still.

experience, or the patient's noncompliance. Another possibility is a nonvascularized ectopic gestation. Noting that one-third of ectopic pregnancies showed no evidence of detectable vascularity, Meyers and associates investigated the hypothesis that this group represented nonviable ectopic pregnancies [54]. They studied them by comparing the serum  $\beta$ -hCG levels in women with vascular and nonvascular ectopic pregnancies. A statistically significant difference was seen between the serum hCG level of those women with ectopic pregnancies with vascularity compared with those women without vascularity. The avascular ectopic pregnancies showed low levels of serum  $\beta$ -hCG, suggesting a nonthriving or dying embryo. We diagnosed ectopic gestations routinely by color Doppler sonography when the  $\beta$ -hCG level was below 1,000 IU/L. The impact of these observations on possible conservative therapy has yet to be considered.

## Management

### Conservative Management

Initiation of conservative therapy for ectopic pregnancy requires fulfillment of strict selection norms [4]. The established criteria for patient selection are listed in Table 39.5.

Conservative management of ectopic pregnancy includes: (a) tubal-conserving surgery which is usually performed laparoscopically; (b) expectant management; and (c) medical management. The conservative laparoscopic procedures for treatment of ectopic preg-

**Table 39.5.** Criteria for conservative management of ectopic pregnancy

■ $\beta$ -hCG level is indicative of ectopic pregnancy <sup>a</sup>
■ Ectopic gestation has been identified on a sonogram
■ Ectopic gestation has not ruptured
■ Gestational sac size is less than 4 cm (preferably without embryonal cardiac activity)
■ Hemoglobin level and hematocrit are in the normal range
■ Patient is compliant <sup>b</sup>
■ Patient is hemodynamically stable

<sup>a</sup> An increase of less than 66% of an initial value over a 48-h period is indicative of either an ectopic pregnancy or a missed abortion.

<sup>b</sup> Patient is able to reliably and precisely follow postoperative instructions (usually at home) for very early signs of unsuccessful conservative management (e.g., ruptured ectopic pregnancy with pelvic pain and intraabdominal or vaginal bleeding).

nancy include salpingostomy, injection of antimetabolites (e.g., methotrexate) or lytic agents (e.g., potassium chloride). The operative manipulations can be achieved with use of endoscissors, endocoagulation, electrocautery, laser, endoloops, and endosutures.

Ultrasound imaging, used in conjunction with serum  $\beta$ -hCG estimation, is indispensable for conservative management of ectopic pregnancy. It helps in (a) early diagnosis of ectopic pregnancy and selection of cases, (b) execution of local treatment, and (c) monitoring the response to treatment and follow-up of the patients managed conservatively.

### Expectant Management

Here, asymptomatic women with declining or stable  $\beta$ -hCG levels and small adnexal masses at transvaginal sonography (TVS) are monitored without intervention. Monitoring involves clinical evaluation and repeated ultrasound and  $\beta$ -hCG estimations. The basis of expectant management is that a substantial number of ectopic pregnancies are diagnosed at a very early stage when some may be expected to resolve spontaneously – “involuting ectopic pregnancy.” In 1955, Lund first reported on a conservative nonsurgical approach to the treatment of tubal pregnancies [55]. Subsequently several other workers have reported on expectant management of ectopic pregnancy [56].

Strict ultrasound parameters have been used as inclusion criteria. Trio et al. expectantly managed 67 stable patients with (a) no adnexal embryonic cardiac activity, (b) no adnexal mass greater than 4 cm in diameter, and (c) cul de sac fluid estimated to be less than 100 ml. In total, 73% of their patients showed complete resolution of ectopic pregnancy; however,

success depended on a low initial HCG level [57]. Stovall and Ling restricted expectant management to tubal ectopic pregnancies with a diameter not greater than 3.5 cm and reported a 48% spontaneous resolution rate [58]. However, the safety and efficacy of this management are questionable and it remains a controversial mode of treatment. A longer time to resolution and need for intensive monitoring are inconvenient, but the subsequent repeat ectopic rate is not increased.

**The role of ultrasound in medical management of ectopic pregnancy** was first proposed in 1982 by Tanaka et al. using methotrexate (MTX) [59]. Since then a large number of studies have reported on intramuscular and local injection of MTX and other agents like potassium chloride (KCl), prostaglandin E2 and F2a, and hyperosmolar glucose [60–62]. Medical treatment with MTX is cost-effective and it is estimated that a cost saving of 265 million dollars/year can be achieved in the United States if 30% of all patients with ectopic pregnancy are eligible for this therapy [63].

Studies reporting on systemic MTX employ ultrasound imaging for selection of cases, the important criteria being an adnexal mass less than 3.5 cm in diameter in a hemodynamically stable patient [64]. The other important application of ultrasound is local MTX injection into the tubal gestational sac (salpingocentesis) by the transvaginal route under transvaginal sonographic guidance, first reported by Feichtinger et al. in 1987 [65]. Transabdominal puncture under transabdominal sonography has also been reported for both tubal and interstitial pregnancies [66]. However, the transvaginal route offers the advantage of accurate needle placement and is the route of choice for intrasac injection in most cases of ectopic pregnancy. Accurate placement of the needle into the gestational sac enables use of MTX locally and avoids side effects of systemic treatment. Success rates with this procedure vary from 60%–100%, and patients should be carefully instructed to report if signs and symptoms of worsening pain or rupture of the ectopic pregnancy occur [67].

Ultrasound-guided salpingocentesis can be performed using manual needle insertion or an automated puncture device. For manual needle insertion analgesia and sometimes local anesthesia is used and the procedure is performed with guidance of a 5–7.5-MHz vaginal transducer probe through a fixed needle guide attached to the probe shaft. This permits easier visualization of the entire length of the needle and better control for accurate needle placement. Amniotic fluid is aspirated from the ectopic gestational sac followed by injection of MTX or another chosen agent. Usually a single 50-mg injection of MTX is used but as little as 5 mg has been used successfully

[60]. If a 50-mg dose is used, it is usually followed by a single dose of folic acid to prevent systemic side effects. When using KCl, approximately 0.25–0.5 ml of the solution (2 mEq/l) is injected in the area of the beating fetal heart and observed for 10 min.

At completion of the procedure and after an observation period of 2–3 h, the pelvic structures and cul de sac are observed sonographically to detect possible internal bleed or any other complication.

An automated puncture device is more accurate and potentially less painful than manual needle introduction. This spring-loaded device, when mated to the shaft of the vaginal probe, provides extreme accuracy and precision and its high-velocity release makes the procedure virtually painless thus obviating the need for anesthesia.

### **Interstitial Pregnancy**

Systemic chemotherapy with MTX can be used for nonsurgical management of interstitial pregnancy. MTX or KCl solution can also be used for local injection into the gestational sac under sonographic guidance. Some additional sonographic parameters have been defined to refine patient selection and posttreatment monitoring [68]. These are: (a) Peritrophoblastic blood flow – a solid “ring of fire” sign suggests a highly vascularized implantation which may respond better to direct intrasac therapy than systemic MTX. Color flow Doppler may also indicate resolution if blood flow can be shown to decrease with treatment [69]. Persistent trophoblastic blood flow may be associated with increased risk of spontaneous rupture and deferral of subsequent pregnancy might be considered until the blood flow pattern returns to normal. (b) Myometrial thickness assessed akin to that described for lower uterine segment thickness in patients with previous cesarean section [70]. When it is less than 3.5 mm the patient may be at an increased risk for rupture and this may be a pertinent parameter for guiding the management. The precise predictive value of these parameters is, however, uncertain and requires further evaluation.

### **Cervical Pregnancy**

Local intrasac injection of MTX or KCl has been described. Paltzi et al. used a combination of MTX given intracervically followed by intramuscular injection [71]. Kaplan et al. used transabdominal sonography to guide injection of MTX into the amniotic sac of a cervical pregnancy [72]. Timor-Tritsch et al. used transvaginal sonography-guided MTX injection with an automated puncture device and 21G needle in five cases of viable cervical pregnancy [73]. Frates et al. used TVS-guided injection of KCl into the embryo or

gestational sac in six cases of cervical pregnancy of less than 7.9 weeks' gestation [74]. Success was reported in all the cases. Thus, when cervical pregnancy is diagnosed early, ultrasound-guided local therapy is safe and effective. It involves minimal patient discomfort and recovery time and preserves the patient's reproductive potential.

### **Ovarian Pregnancy**

Traditional treatment for ovarian pregnancy involves ipsilateral oophorectomy. Koike et al. reported the first successful case of an unruptured ovarian pregnancy treated medically by local injection of 0.5 mg prostaglandin F<sub>2</sub> with an additional dose of prostaglandin E<sub>2</sub> (dinoprostone) administered orally for 14 postoperative days [75]. Subsequently systemic MTX has been used for medical management of ovarian pregnancies [76]. The response to treatment can be assessed by ultrasound imaging, as described for tubal pregnancy.

### **Heterotopic Pregnancy**

Ultrasonography helps in conservative management of heterotrophic pregnancies. Unlike MTX, KCl is only embryotoxic and not antitrophoblastic therefore ultrasound-guided local injection of KCl into the ectopic sac is used to avoid harm to the coexistent intrauterine pregnancy.

### **Ultrasound Monitoring of Conservative Management**

Ultrasonography is crucial to follow up along with  $\beta$ -hCG estimations every 3–5 days. Real-time sonography is carried out to observe the decrease in size of the adnexal mass. Color Doppler is used to assess vascularity and normalization of the RI. Disappearance of adnexal/ectopic pregnancy mass usually occurs by day 30–40, with the RI normalizing by day 5–20.  $\beta$ -hCG levels gradually fall rapidly to normal levels by 2 weeks to a maximum of 8 weeks. Following systemic or intratubal MTX, a visible adnexal mass may persist on TVS for more than 3 months, even after a  $\beta$ -hCG test yields negative results. It is not uncommon for these to transiently enlarge and have increased Doppler flow signal [67].

Ultrasound imaging thus helps in monitoring the response to treatment and evaluation of potential complications both during and after the therapy. In the literature, a few patients treated by salpingocentesis underwent hysterosalpingography and were found to have patent fallopian tubes [60]. A rise in  $\beta$ -hCG levels and an increase in ectopic pregnancy mass associated with

persistent or acute upon subacute clinical symptoms apprise of possible failure of conservative treatment.

## Doppler Ultrasound and Infertility

### Uterine Blood Flow during Menstrual Cycle

Transvaginal color Doppler (TVCD) sonography provides an opportunity to visualize and quantify pelvic blood flow in relation to hormonal changes during the menstrual cycle. The follicle and corpus luteum of the ovary and endometrium are the only areas in the normal adult where angiogenesis occurs [77, 78]. Uterine artery waveform analysis shows high to moderate flow velocity (Figs. 39.24 and 39.25). The resistance index (RI) depends on the patient's age, the

phase of the menstrual cycle, and specific conditions such as pregnancy and uterine tumors.

Transvaginal color Doppler sonography can be used to obtain flow velocity waveforms at any time during the menstrual period. Apparently there are complex relations between the concentration of ovarian hormones in peripheral blood and uterine artery blood flow parameters [79, 80]. In most women there is a small amount of end-diastolic flow in the uterine artery during the proliferative phase. Collins and co-workers reported that diastolic flow in the uterine artery disappeared during the day of ovulation [81]. Goswamy et al. found an increasing RI and systolic/diastolic (S/D) ratio during the postovulatory drop in the serum estradiol concentration [79]. Steer et al. reported increased uterine artery impedance 3 days after the luteinizing hormone (LH) peak [82]. Scholtes and colleagues recorded the highest pulsatility index (PI) value in the uterine artery on cycle day 16 [83]. These findings may be explained by increased uterine contractility and compression of the vessels transverse the uterine wall, which decreases their diameter and causes a consequent higher resistance to flow.

During the normal menstrual cycle there is a sharp increase in end-diastolic velocity between the proliferative and secretory phases of the menstrual cycle. It is particularly interesting that the lowest blood flow impedance occurs at the time of peak luteal function, during which time implantation is most likely to occur. It is logical that the blood supply to the uterus should be high during the late luteal phase as reported by Kurjak, Goswamy, Steer, Battaglia, and their colleagues [78, 79, 82, 84]. During anovulatory cycles these changes are not present, and a continu-

**Fig. 39.24.** Uterine artery and vein visualized by transvaginal color Doppler sonography

**Fig. 39.25.** Typical pulsed-wave Doppler waveform of the uterine artery during the luteal phase of a normal menstrual cycle

ous increase in the RI is not seen. In some infertile patients the end-diastolic flow is not present [80]. There are no data yet on which to base speculation whether absent diastolic flow is associated with infertility or poor reproductive performance. It seems that transvaginal Doppler sonography may be used as a noninvasive assay of uterine receptivity; it would enable clinicians to cryopreserve the embryos if uterine conditions are adverse and reduce the number of transferred embryos when conditions are optimal. Uterine artery blood flow could be used to predict a hostile uterine environment before embryo transfer [82]. Those women with poor uterine perfusion could then be advised that pregnancy is unlikely during their treatment cycle and so have their embryos cryopreserved for transfer at a later date.

One of the major problems associated with current in vitro fertilization (IVF) is the need to use multiple-embryo transfer to increase the pregnancy rate, which results in an increase in multiple pregnancies. This increase may contribute to increased obstetric risk and diminished perinatal outcome compared to singleton pregnancies. It is well known that the probability of pregnancy is strongly related to embryo quality and uterine receptivity. Instead of performing an endometrial biopsy, which may cause trauma and bleeding at the implantation site, uterine receptivity could be assessed by color Doppler ultrasonography. This noninvasive technique is rapid, is easy to perform, and may predict the likelihood of implantation, thereby minimizing the risk of multiple pregnancy. Circulatory changes similar to those observed in the main uterine artery are seen in the minute arteries (radial and spiral) (Figs. 39.26–39.28). The endometrium has an exceptional capacity to undergo changes in structure and

function during the menstrual cycle. Histologic changes include the striking development of blood vessels, the spiral arteries becoming more developed during the menstrual cycle. The increased endometrial vascularity during the menstrual cycle depends on changes in the uterine, arcuate, and radial artery blood flow. Changes in blood flow velocity waveform of the spiral arterises during a normal ovulatory cycle have been demonstrated for the first time by TVCD sonography [85]. Endometrial perfusion may be used to predict implantation success and to reveal unexplained infertility problems.

**Fig. 39.26.** Color Doppler mapping of the radial and spiral arteries. The spiral arteries are closer to endometrium (endometrial thickness 1.02 cm is shown)

**Fig. 39.27.** Pulsed-wave Doppler waveform of the radial artery

**Fig. 39.28.** Doppler analysis of blood flow in the spiral artery in the same patient as shown in Fig. 39.27. Note the lower velocity but almost the same impedance to blood flow

### Ovarian Blood Flow during Menstrual Cycle

Using the same method it is possible to assess intra-ovarian blood flow during the menstrual cycle (Figs. 39.29–39.37). Color Doppler imaging facilitates detection of small vascular areas in the ovarian stroma and follicular rim [86]. Pulsed-wave Doppler sonography has become available on high-resolution vaginal ultrasound probes for studying ovarian blood flow. Doppler studies of ovarian blood flow are based on semiquantitative analysis of Doppler flow waves recorded over the ovarian artery at their entry into the ovary and color Doppler mapping of intraovarian vessels. Semiquantitative analysis of the ovarian artery Doppler flow waves is frequently insufficient for identifying the ovarian artery, particularly in multiparous women. Mapping intraovarian vessels, however, appears to be a promising feature of vaginal Doppler imaging for studying ovarian blood flow, provided the proper ultrasound equipment is used. Specifically, TVCD sonographic mapping of intraovarian vessels allows positive visual detection of the onset of the ovulatory process prior to follicular rupture. Thus color Doppler sonographic mapping of ovarian vessels provides an improved, simplified approach to timing intercourse and inseminations in infertile patients. With controlled ovarian hyperstimulation used for IVF, mapping of intraovarian vessels by color Doppler sonography offers a fascinating insight into normal and pathologic responses of ovarian follicles to human chorionic gonadotropin (hCG). Finally, color Doppler imaging seems to be a promising adjunct to transvaginal ultrasonography for distinguishing suspicious ovarian cysts from their benign counterparts.

Blood flow from the follicle can be seen when the follicle reaches 10–12 mm in diameter and may be a hemodynamic parameter of its growth, maturation, and ovulation. The RI is approximately  $0.54 \pm 0.04$  until ovulation approaches. A decline begins 2 days before ovulation and reaches a nadir ( $0.44 \pm 0.04$ ) at ovulation. At the time of presumed ovulation there is increased vascularity on the inner wall of the follicle and a coincident surge in blood velocity just before eruption. These changes may represent dilatation of new vessels that have developed between the relatively vascular theca cell layer and the normally hypoxic granulosa cell layer of the follicle [87]. These vascular changes compound the effect of the oxygen concentration across the follicular epithelium. Immediately after follicular rupture, there is another dramatic increase in the velocity of blood flow to the early corpus luteum. The RI remains at that level for 4–5 days and then gradually climbs to  $0.50 \pm 0.004$ , which is still lower than that seen during the proliferative phase. Collins et al. found that the changes of PI observed from the wall of the dominant follicle and corpus luteum were less marked than the changes in blood velocity [81]. Merce and coworkers obtained Doppler shift waveforms from the parenchyma adjacent to the dominant follicle or corpus luteum in the dominant ovary [87]. They noted that the blood flow velocity index in the dominant ovary was lower during the luteal phase than during the follicular phase. Increased resistance was observed during the late luteal phase.

These blood flow changes reflect changes in vascularization and function of the corpus luteum. Increased blood flow supply to the ovary that contains the dominant follicle and corpus luteum is necessary for delivery of steroid precursors to the ovary and

production of progesterone. Therefore changes in flow velocity occur in the uterine and ovarian vessels before ovulation, implying that these changes are complex and not purely secondary to progesterone action. Undoubtedly, many other vasoactive compounds, such as prostaglandins, are involved in regulation of the vasculature.

### Clinical Application

Transvaginal ultrasonography depicts anatomic and physiologic parameters that are important to the management of female infertility. Specifically, follicular development into functional corpus luteum, uter-

ine perfusion prior to implantation, studies of uterine integrity, and tubal potency are areas for clinical application of this relatively new diagnostic modality. Other applications involve detection of abnormally located or distended parauterine vessels. These vessels should be avoided during guided needle aspiration. Similarly, dilated uterine and ovarian veins are seen in some patients with pelvic congestion. Pelvic Doppler sonography has been useful for assessing blood flow to leiomyomas prior to initiation of hormonal suppression therapy. Perhaps those that have an intact blood supply are more likely to respond than those that are relatively avascular. Other possible applications for Doppler sonography in regard to infertility include diagnosis of endometriosis, ovarian hyperstimulation, ovarian torsion, pelvic inflammatory disease, and ectopic pregnancy.

A logical extension of this technology is its usefulness in the evaluation of infertile women [88–95]. In an earlier study, TVCD sonography was used to analyze uterine and ovarian blood flow during the menstrual cycle [78]. This study was carried out on 100 infertile women and the results compared to those from 150 women attending the clinic for annual checkups. Uterine flow velocity has an RI of 0.88 during the proliferative phase and starts to decrease the day before ovulation. A nadir of  $0.84 \pm 0.04$  is reached on day 18 and remains at that level for the rest of the cycle. These changes do not occur in anovulatory cycles. Some women with primary infertility showed a marked reduction in uterine flow velocity. Ovarian artery flow velocity is usually detected when the dominant follicle reaches 12–15 mm. The RI is 0.54 and declines on the day before ovulation. A nadir of

**Fig. 39.29.** Follicular blood flow visualized by color Doppler sonography in the left ovary. The internal iliac vessel is also shown (blue)

**Fig. 39.30.** Small vessels around the mature follicle can also be visualized by color Doppler sonography

**Fig. 39.31.** Intraovarian blood flow during the proliferative phase of the normal menstrual cycle

**Fig. 39.32.** Corpus luteum blood flow during the early secretory phase. The rich vascular supply shown here by color and Doppler sonography is typical

$0.44 \pm 0.04$  is reached 4–5 days later and then slowly rises to  $0.05-0.04$  before menstruation. Because the changes in the uterine and ovarian flow velocities begin prior to ovulation, it can be conjectured that these changes involve angiogenesis as well as hormonal factors. Our own study with color flow sonography confronted an important question. In most women there is a small amount of end-diastolic flow in the uterine arteries during the proliferative phase. In our study end-diastolic flow was not present in some infertile women. Currently, we are unable to determine whether absent end-diastolic flow is associated with infertility or poor reproductive perfor-

mance. A prospective study design is necessary to establish this point. These studies raised the interesting question of whether blood flow changes play a role in infertility. Could failure of adequate flow result in early pregnancy loss? Is it possible that endometrial defects could be hormonal or deficient on the basis of inadequate vascular support? Similarly, could inadequate vascularization play a role in the luteal phase defect? It is not clear at present whether the small but significant changes noted in this study can provide a sensitive enough differential to answer these questions.

**Fig. 39.35.** Hyperstimulated right ovary. Color Doppler velocimetry shows the intraovarian blood flow

**Fig. 39.36.** Corpus luteum blood flow visualized by color Doppler velocimetry is usually semilunar in appearance

ectopic pregnancy. It also reduces the morbidity associated with surgery and anesthesia and is more cost-effective than surgical management. Unlike laparoscopy, it is a procedure that is non-invasive, can be repeated, and is easily available. Further studies may help identify more accurate sonographic parameters for better patient selection and post-treatment follow-up.

Transvaginal ultrasonography has brought the pelvic organs into closer view than ever before. Color Doppler sonography has exposed small vessels that could not be seen with the B-mode technique alone, and pulsed-wave Doppler imaging is becoming an

important adjunct in the assessment of many physiologic and pathologic states. Vascular changes of the ovary and uterus during the menstrual cycle are now being followed during infertility protocols. They are also being investigated to determine the viability of an early pregnancy and may increase our confidence in the diagnosis of an ectopic pregnancy in selected cases. Color Doppler ultrasonography has been used to gain insight into the physiologic processes and pathologic conditions involving the female reproductive tract. The ability to assess uteroovarian blood flow with transvaginal color Doppler ultrasonography has several applications for the assessment of women

**Fig. 39.37.** Luteal blood flow waveform analysis

with fertility problems. It extends the scope of sonographic imaging from an anatomic to a physiologic modality. The changes in ovarian and uterine perfusion during spontaneous or induced menstrual cycles can be assessed and thereby optimized, allowing embryo transfer to take place when conditions are most favorable for implantation. Color Doppler processing also enhances detection of flow in nonvascular structures, such as contrast medium injected into the tubes to assess their potency. Although much of this work is preliminary, transvaginal Doppler ultrasonography has tremendous potential for assessment of infertility. In conclusion, we think that vaginal Doppler imaging should be considered a marvelous refinement of ultrasonography rather than a truly new diagnostic tool. Vaginal color Doppler imaging has the potential for markedly improving the sensitivity and specificity of vaginal ultrasonography in the assessment of infertility.

# Doppler Ultrasonography for Gynecologic Malignancies

Ivica Zalud

Ultrasonography has an important role in the evaluation of patients with a suspected or palpable pelvic mass. The origin, size, location, internal consistency, and definition of the walls of the mass, as well as the presence or absence of ascites or other metastatic lesions, are the main features determined by ultrasonography.

In clinical practice pelvic tumors are most commonly divided into three categories: cystic, solid, and complex. Each category has a relative specificity and should be viewed within the framework of other clinical findings as well. Prediction of whether a mass is benign or malignant according only to its sonographic appearance is moderately reliable, depending on the ultrasonographic findings of the septa, papillary projections, and inhomogeneous solid parts of the tumor.

The number of false-positive and false-negative sonograms of adnexal masses has been too high. Most errors of the sonographic evaluation of pelvic masses can be attributed to the misinterpretation of displayed tumor features on the ultrasound monitor.

Ovarian cancer is of particular interest to ultrasonographers and oncologists since it is the leading cause of gynecological malignancy mortality in the United States, affecting 1 in 56 women and causing about 14,500 deaths annually [1]. The natural history of this disease remains poorly understood; thus, there has been no reduction in mortality from this cause in the past 60 years [1]. Ovarian cancer usually presents late, greatly reducing the chances of curative therapy. The 5-year survival rate for stage I disease is approximately 75%, whereas the survival rate for stage IV is <5% [1]. Older women are more likely to present with advanced disease, and their relative 5-year survival rates are less than half that for women under 65 [1]. Thus the postmenopausal woman must be the target of any effective screening for ovarian cancer. In the quest to diagnose ovarian cancer early, various methods have been advocated for screening in the asymptomatic postmenopausal woman. In 1971 Barber and Graber [2] described the postmenopausal palpable ovary syndrome. At the time, before the widespread use of ultrasound, they stated that “a pelvic mass found during a pelvic examination is the

only practical and consistent method available to us to detect an ovarian tumor.”

The first report of an attempt to screen women for ovarian cancer by transabdominal ultrasonography was by Campbell et al. [3]. The overall specificity of such a screening procedure was high, but abdominal ultrasonography as a predictor of malignancy in postmenopausal women had low specificity [4]. High-frequency probes and the vicinity of the explored organs provided the possibility of exploring small details. Hence abdominal ultrasonography was abandoned and transvaginal ultrasonography has been used extensively. Color Doppler ultrasonography as a method for transvaginal imaging to assess pelvic pathology has now been described by many investigators [5–9]. The absence of intratumoral neovascularization and a high pulsatility index (PI) can be used to exclude the presence of invasive carcinoma [5]. On the other hand, a low resistance index (RI) value was reported in the case of adnexal malignancies [8, 9]. The authors agree that low impedance to blood flow with high blood speed within arteriovenous shunts is suggestive of malignancy, whereas moderate to high impedance to blood flow is correlated to benign tumors.

On the basis of our experience, morphology alone is of limited value for characterizing adnexal masses. All ovarian neoplasms should be precisely classified according to the ultrasound appearance determined by the shape, size, and inner cystic echoes (e.g., from the septa, papillary projections, irregularities of the wall) as well as the echogenicity and loculations. Transvaginal application of color Doppler (TVCD) sonography allows visualization of the small vessels that feed the growing tumor. Color Doppler parameters (vascular location as peripheral or central; vascular quality as regular, separated vessels or randomly dispersed vessels; and Doppler waveform type by means of low values for the RI or PI) should be combined with the morphologic tissue characterization to differentiate benign from malignant pelvic tumors.

The amount and vascularity of the stroma vary greatly among tumors. Slowly growing tumors are less vascularized than tumors with a high growth potential. In general, rapidly growing tumors, particu-

larly sarcomas, have a highly vascularized stroma with little connective tissue.

## Angiogenesis in Tumors of Low Malignant Potential

Ultrasonography has been widely used to detect, characterize, and evaluate ovarian tumors. The principle of the diagnostic imaging study is based on macropathology. Thick septae, irregular solid parts within a mass, indefinite margins, and presence of ascites are regarded as malignant patterns. Some authors have reported that ovarian tumors of low malignant potential presented the same patterns as malignant tumors. On the other hand, other authors mentioned that borderline tumors had an appearance similar to that of benign tumors and it was difficult to differentiate them from their benign counterparts. Therefore, assessment of vascular changes and the resistance to blood flow would be required in the ovarian tumor presenting either benign or malignant features by conventional ultrasound [10]. Blood flow velocity waveforms obtained from borderline tumors are of relatively high diastolic flow and low resistance. Doppler features are extracted from large arterioles or sinusoids with no muscles in their walls. This is a possible hemodynamic response to the tumor angiogenesis factor produced from low-malignant-potential cells. Therefore the preoperative assessment of the adnexal mass by ultrasonography would include the size, consistency, and blood flow to determine the likelihood of malignancy [8, 11–13].

## Angiogenesis in Malignant Ovarian Masses

The advent of vaginal ultrasound screening methods for ovarian cancer has made the ovaries more accessible [14]. Dramatic changes in ovarian tissue vascularity during oncogenesis are mediated by numerous angiogenic factors and can be detected by using flow data from color Doppler (Figs. 40.1–40.4). Malignant tumor vessels are usually dilated, saccular, and tortuous, and may contain tumor cells within the endothelial lining of the vessel wall. Other features include the presence of arteriovenous shunting (large and direct communications, or microscopic communications in the tumor microcirculation) and bizarre thin-walled tortuous vessels lined by tumor cells that end in amorphous spaces constituting “tumor lakes” with or without associated necrosis. Arteriovenous shunts are remarkable because of extreme velocities that occur at sites of high-pressure gradients. This type of vessel is usually situated on the periphery of the tu-

**Fig. 40.1.** Randomly dispersed small vessels detected by color Doppler in the central portion of a solid adnexal mass

**Fig. 40.2.** Small vessel visualized on the periphery of the solid-cystic adnexal tumor

mor. New vessels are continually produced on the periphery of the tumor, creating the potential for its proliferation and growth. The second type of signal, exhibiting little systolic-diastolic variation, is usually present in the central vessels within the malignant tumor. This is, most probably, their response to the angiogenic activity of tumor cells. These vessels have a relative paucity of smooth muscle in their walls in comparison with their caliber and “behave” more like capillaries than true arteries or arterioles. Vessels deficient in their muscular elements present diminished resistance to flow and thereby receive a larger volume of flow than vessels with high impedance. It seems that distribution of the vessels and impedance to blood flow are dependent on tumor type and size. Tumors gradually begin to compress their own blood vessels when they continue growing beyond a certain size. The absence of functional lymphatic vessels in the tumor stroma, and the increase in cell mass and tumor vessel permeability, result in an increase in the interstitial pressure in the tumor core and lead to the

**Fig. 40.3.** Pulsed-wave Doppler findings in a case of malignant ovarian tumor. Arrows indicate the peak systolic and diastolic velocity on the Doppler waveforms

**Fig. 40.4.** Example of Doppler findings for a dominantly solid ovarian mass. Doppler sonography was essential to visualize newly formed vessels. Pulsed-wave Doppler was used to quantify blood flow in these vessels. Low resistance blood flow is a typical finding

occlusion of centrally located tumor vessels. This causes prolonged cessation of flow in the center of the tumor, followed by central necrosis. It seems that low resistance in centrally located vessels is a consequence of a response to the angiogenic activity of the tumor cells and to the differences in necrotic processes. Another important parameter for the assessment of tumor vascularity is the vascular arrangement. Randomly dispersed vessels within the solid part of malignant tumors were seen four times more than regularly separated vessels.

Color and pulsed Doppler sonography demonstrates the vascularity of an adnexal mass. Blood flow data should be considered to indicate the angiogenic intensity of a tumor, rather than indicating malignancy itself [15–17]. It seems clear that initial attempts to classify ovarian tumors solely on the basis of their impedance to blood flow have been too simplistic. This problem

has been partly solved by the introduction of other “vascular parameters” such as blood vessel arrangement and location, shape of the pulsed Doppler waveform, and appearance of an early diastolic notch, as well as assessment of blood flow velocities. However, the difference in flow parameters in benign versus malignant lesions may not always be sufficient to form the basis of a firm diagnostic impression [18–21]. A common criticism of color Doppler is that the operator is never blind to the B-mode image: there is a tendency to search harder for low-impedance blood flow patterns in lesions with a malignant appearance rather than in simple adnexal cysts. However, when applied by expert operators and in a disciplined fashion, it may significantly add to diagnostic information about an adnexal mass and its morphological appearance. If blood flow data are treated as providing an insight into the pathology of a tumor, they give reassurance when

masses have a benign appearance, while giving confirmation of malignancy in adnexal masses with suspicious morphological features.

It is important to emphasize that the areas of overlap in benign versus malignant pelvic lesions tend to involve nonneoplastic masses that contain vasodilated vessels, owing to local or general hormonal imbalances. Whereas some malignant tumors elicit sparse angiogenesis and may appear avascular, and therefore benign, in terms of color Doppler sonography. Obese women and women with irregular cycles and hormonal disturbances may produce ovarian blood flow patterns with typical low vascular resistance to blood flow. Therefore, measurements of estradiol and progesterone serum levels on the day of the transvaginal color Doppler examination should be performed when low vascular impedance to blood flow is found. It is possible that – with further improvement of color and pulsed Doppler sensitivity, and in conjunction with clinical findings, gray-scale ultrasound imaging, and serum hormonal levels when necessary – a better distinction between malignant and benign pelvic tumors will be made. Contrast agents are another possibility for enhancing both color and power Doppler examinations by increasing the detection rate of small vessels [22].

## Ovarian Cancer

Among gynecologic cancer-related deaths, ovarian cancer heads the list. The mortality due to ovarian cancer exceeds that of all uterine cancers, endometrial and cervical, combined. More than 65% of women with cancer of the ovary present with advanced-stage disease (stage

III or greater). The 5-year survival rates for stage III and IV carcinoma of the ovary are 13% and less than 5%, respectively. Morbidity and mortality rates remain high despite improvements in surgical technologies, chemotherapy, and imaging techniques. There is presently no adequate screening tool for this disease.

The Zagreb group has studied the largest series of patients to date. Among approximately 14,000 women, more than 700 cases of adnexal pathology were detected [8], 624 were benign masses. Color flow was typically present in about one-third of the lesions. In all but one of the cases the RI was greater than 0.40. Color flow was present in more than 95% of ovarian malignancies, and the RI ranged from 0.28 to 0.40. Figures 40.5 and 40.6 show a malignant tumor with a high-velocity/low-resistance Doppler velocimetry pat-

**Fig. 40.5.** Complex, dominantly cystic adnexal mass with blood flow detected by color Doppler in the septal portion

**Fig. 40.6.** Same patient as in Fig. 40.5. Pulsed-wave Doppler sonography showed high-velocity/low-resistance blood flow. Arrows indicate the peak systolic and diastolic velocity on the Doppler waveforms

tern. This original study was followed by a prospective series in which 1,000 postmenopausal women were examined by TVCD ultrasonography [9]. In these women, 74% of the lesions were detected by screening studies; the other patients were referred with a history. A total of 83 of the women underwent surgery, and 29 malignant neoplasms were found. Color flow was found in 27 of the 29 malignant tumors and in 36% of the benign tumors. The same cutoff value for the RI (0.41) yielded the best discriminatory value: sensitivity 96% and specificity 95%. The same scoring system as described previously was applied to these data. Morphology alone has poor sensitivity, as might be expected. When morphology and color Doppler indices were combined, the sensitivity improved to 90% (only 48% for morphology).

Bourne et al. studied 50 women referred because of a significant history [5]. Thirty of these women had normal ovaries, ten of whom were premenopausal and examined during the follicular phase. All of these had normal color Doppler analyses. Of the 20 women with surgical pathology in whom a positive color Doppler screen was noted, 2 had hydrosalpinges, 10 had benign tumors, and 8 had primary ovarian cancer. The PI of the nonmalignant masses ranged from 3.2 to 7.0, with no areas of suspicious neovascularization. Seven of the eight patients with ovarian cancer had clear areas of neovascularization, and the PI values ranged from 0.3 to 1.0. There was one false negative with an intraepithelial serous cystadenocarcinoma in a small ovary (<5 ml volume); it had no sign of neovascularization and the PI for the feeding vessel was 5.5. It was the conclusion of this study that color Doppler flow analysis proved useful for identifying malignant conditions. Fleischer et al. reported color Doppler flow studies in women with malignant neoplasms and color flow Doppler indices suggestive of high-velocity/low-impedance indices [23]. Timor-Tritsch et al. reported on a series of adnexal masses with a similar scoring system whereby the diagnostic sensitivity was increased with the application of color Doppler analysis [24].

Transvaginal sonography has also been combined with measurements of serum CA-125, a tumor-associated antigen found in some women with ovarian cancer. Jacobs and colleagues obtained high sensitivity (99%) when the CA-125 assay and ultrasonography were used in combination [25]. The number of cases was small, and there was only one ovarian cancer detected. The CA-125 assay alone has routinely demonstrated inadequate sensitivity but may prove more helpful when added to color Doppler analysis.

## Malignant Uterine Conditions

Malignant conditions of the uterine corpus are often difficult to distinguish from benign conditions (i.e., leiomyoma uteri). Both may present as enlarged uterine masses with typical or atypical echogenicity when assessed by ultrasound imaging techniques. The Zagreb group did observe leiomyosarcomas with significant increased blood flow patterns [26]. It is a rare tumor, and so large numbers of patients are not available. At our institutions, uterine sarcoma was diagnosed preoperatively by ultrasonography and color Doppler velocimetry. The pattern seen was consistent with the presence of many aberrant vessels with high-velocity/low-resistance flow.

Endometrial cancer, the most common gynecologic cancer, often presents with abnormal bleeding, which leads to its diagnosis, versus primary detection by ultrasonography. In the postmenopausal, non-hormone-replacement individual the endometrium should measure less than 6 mm. Studies in the literature have proposed a discriminatory cutoff value for endometrial neoplasms. Many of these patients have symptoms. Color Doppler analysis was also performed in the screening population alluded to previously, wherein three asymptomatic endometrial cancers were diagnosed. In only one of the patients was an aberrant blood flow pattern seen. Low resistance vessels were observed in the myometrium and within the uterine arteries. The Zagreb group observed abnormal Doppler velocimetry in several cases as well [27]. Bourne and colleagues have studied the blood flow in women with endometrial cancer [28]. They used a PI cutoff value of 1.5 as a positive suspicious result. They studied the uterine vessels and concluded that in postmenopausal women who present with symptoms (i.e., bleeding) the predictive value of a positive test is 94%. It would be interesting to determine if sensitivity is better with color Doppler analysis of myometrial "feeding" vessels or intratumoral vessels. Again this modality may not significantly affect the diagnostic capability, as endometrial cancer is accompanied by symptoms in its early stage. The impact of such testing may not be as dramatic as with ovarian screening because of the many women who bleed early in the course of their disease. Early-stage endometrial cancer has a high cure rate, and most of the morbidity is related to the perioperative treatment. Data on carcinoma of the endometrium and color Doppler analysis are accumulating.

## Potential of Screening

The next obvious question is whether this modality might prove useful in a screening capacity (Table 40.1). Ovarian cancer is significant in terms of dis-

**Table 40.1.** Comparative analysis: organ sites and screening programs

Site	Prevalence (1991)	Deaths per year	Screening method	Significant disease per 1,000	Cancer (no. per 1,000)
Cervix	13,000	4,500	Cytology	19	5.0
Breast	175,000	44,500	Radiography	16	5.0
Ovary	20,700	12,500	TVS, color flow	10	0.4
Endometrium	33,000	5,500	TVS	20	3–6

TVS, transvaginal sonography.

Classification		
Mass	Fluid	Internal borders
Unilocular	Clear (0) Internal echoes (1)	Smooth (0) Irregular (2)
Multilocular	Clear (1) Internal echoes (1)	Smooth (1) Irregular (2)
Cystic, solid	Clear (1) Internal echoes (2)	Smooth (1) Irregular (2)
Papillary projections	Suspicious (1)	Definite (2)
Solid	Homogeneous (1)	Echogenic (2)
Peritoneal fluid	Absent (0)	Present (1)
Laterality	Unilateral (0)	Bilateral (1)

<b>Ultrasound score</b>	
≤2	Benign
3–4	Questionable
>4	Suspicious for malignancy
<b>Color Doppler</b>	
No vessels seen	(0)
Regular separate vessels	(1)
Randomly dispersed vessels	(2)
<b>Pulsed Doppler (RI index)</b>	
No Doppler signal	(0)
≥0.40	(1)
<0.40	(2)
<i>Note:</i> If corpus luteum blood flow is suspected, repeat the scan at the next menstrual cycle during the proliferative phase	
<b>Color Doppler score</b>	
2 or less	Benign
3–4	Questionable for malignancy

ease morbidity and mortality, but it remains a low-prevalence disease in terms of screening. The annual pelvic examinations contributes little to the detection of ovarian neoplasms.

Pinotti et al. examined 499 women prior to ultrasound evaluation [29]. Bimanual detection of 4- to 6-cm cysts was approximately 33%. Only 75% of cysts

measuring 6–8 cm were palpated. One of the first attempts to assess the utility of ultrasonography as a screening procedure for early detection of ovarian neoplasms was by Campbell et al. [3], who used transabdominal ultrasonography and ovarian volumes. Although the pathology correlated with the ultrasound findings in terms of the presence of a tumor and its size, it did not distinguish benign from malignant lesions. The addition of color Doppler analysis may provide this much needed utility – a discriminator of benign versus malignant disease (Table 40.2). There are several factors to consider when attempting to apply a new modality as a screening tool. As already stated, ovarian cancer is a low-prevalence condition. Large numbers of women have to be screened to report significant results. The eligibility of those who should undergo this type of screening must be considered. Ideally, in any screening program the screening test should not lead to an excess of interventions. The cost-effective issue must be raised as well.

### Three-Dimensional Ultrasound

The three-dimensional capability has been extended to various diagnostic ultrasound modalities. In the case of ovarian tumor vascularity, the three-dimensional display allows the physician to visualize multiple overlapping vessels and to establish their relationship to other vessels and tumors or other surrounding tissues. The implementation of the three-dimensional display permits the physician to view structures in three dimensions interactively, rather than assembling the sectional images mentally. The three-dimensional power Doppler system may enable physicians to study the region of interest in more detail (Figs. 40.7, 40.8). Although power Doppler has several advantages over conventional color Doppler ultrasound, it is still a kind of color Doppler imaging and therefore subject to some of the limitations of the conventional technique. For example, various parameters of color Doppler ultrasound, such as pulse repetition frequency, wall filter, priority, power gain, color persistence, and frame rate, must be optimized for

**Fig. 40.7.** Three-dimensional power Doppler in the case of malignant ovarian tumor

**Fig. 40.8.** The same patient as in Fig. 40.7 with detailed three-dimensional display of tumor vessels by power Doppler

three-dimensional display, as well as for qualitative and quantitative analysis of these power Doppler data. A change in color setting may lead to a totally different three-dimensional vascular image and dissimilar quantitative results. In addition, since now both color and power Doppler can be combined with more complex computing, the frame rate will be significantly reduced when the power/color Doppler mode is active. Therefore, if a mechanical three-dimensional probe is used, some very small vessels may escape from image capture. The effects of ultrasound attenuation can sometimes cause different “power intensity” and hence vessel detection between nearer and deeper parts of the tissue being explored.

Morphological analysis of the blood vessel system represents another approach to tumor diagnosis that, so far, has not been extensively evaluated. Neverthe-

less, there is a distinct impression from some reports that the distribution and branching pattern of blood vessels that supply fast-growing tumors differ from those of the normal blood supply to normal organs. This means that the blood vessel distribution seems to carry additional information that is missed by the present diagnostic approaches. However, describing branching structures such as the blood vessel tree is a mathematically complicated task. Microvessel density in ovarian cancers has been correlated with the likelihood of recurrence. The density (determined histologically) of microvessels, irrespective of their distribution, was found also to have significant implications for recurrence. In color Doppler studies the density can be determined by counting the number of color spots in a tumor area.

Different types of angiogenesis in different physiological and pathological conditions have been described. Physiological angiogenesis is seen in folliculogenesis, embryogenesis and implantation, chronic inflammation, and some benign neoplasms. According to some authors the luteal vessels are usually fewer and seldom have complicated branching or encircle the cyst, in contrast to the findings in a malignant neoplasm. In simple cysts the vessels are usually straight and regularly branching, whereas in “chocolate” cysts vessels usually branch from a hilar vessel then run along the surface of the tumor. Similar vascular anatomy is detected in dermoid cysts. In cases of malignant ovarian neoplasm the tumor vessels are usually randomly dispersed within the stroma and periphery, and some of them form several tangles or coils around the surface. The course of the main tumor vessel is usually irregular with more complicated branching. The diameter of these vessels is felt to be more uneven and “thorn-like.” These findings can be compared to previous studies with conventional color Doppler ultrasound. However, the appeal of the three-dimensional display is that it is more comprehensive and allows physicians to understand the three-dimensional architecture of the microcirculation interactively. In addition, the resolution of current power Doppler is sufficient to detect vessels of around 1 mm in diameter. In an attempt to systematize the extent of perfusion, four regions of different perfusion states can be recognized: a necrotic region (central portion); a seminecrotic (ischemic) region; a stabilized microcirculation; and the hyperemic region within the outermost area. Different pathological types, tumors with different growth rates, primary tumors, or metastases can all exhibit different perfusion patterns.

The results reported in the recent literature on three-dimensional color and/or power Doppler raise many new questions about the regulation of tumor angiogenesis, the density of tumor vessels, and the

differences between vessel architecture in benign and malignant ovarian growths [22, 30]. Improved detection and classification of tumor architecture after instillation of contrast agents might contribute to better diagnostic accuracy.

## Pitfalls and Artifacts

It is well known that artifacts can be observed during ultrasound examinations. The same is true for color and pulsed-wave Doppler images of blood flow [31, 32]. Recognizing these artifacts is important so as to avoid image misinterpretation and, when possible, to overcome them by modifying the technique, the unit settings, or both. Most manufacturers have introduced, and many diagnostic units have obtained, color Doppler scanners. However, as with any new technology, color scanning is being used by many without a complete understanding of how the instrument can be optimally adjusted to provide the best possible diagnostic information. The examiner must have good working knowledge of the instrument controls that affect the color display and how these controls interact with each other. In addition, knowledge of Doppler physics, the basics of image display formats, and the hemodynamics of blood flow is essential to optimize color and pulsed-wave Doppler examinations.

Two basic colors – red and blue by convention – are assigned to represent the direction of blood flow relative to the ultrasound transducer. This rule assumes an ideal situation, where the artery and vein lie parallel to the skin surface and are straight, long tubes with blood flow parallel to the vessel walls. In reality, vessels do not follow these rules. They do not lie parallel to the skin surface. They are branched and tortuous, and their diameters often change. The flow pattern can be complicated. The combination of these features makes interpretation of the direction of blood flow difficult under ideal circumstances. The most important tip for determining the direction of flow is always to know where the ultrasound beams are coming from and how they are intersecting the vessels.

The length of the color or pulsed-wave Doppler bar represents the range of frequencies obtainable at a designated pulsed repetition frequency (PRF). The PRF is adjustable but is limited by the depth of the image. The Doppler bar is divided into maximum positive frequency and minimum frequency, with each assigned relative color or pulsed-wave Doppler assignments. The color shading can be selected by the operator in most systems. Once a “color map” is chosen, it should remain constant for each type of examination. The range of the Doppler scale is displayed as either the frequency or the velocity. The velocity values are calculated using a standard angle, usually  $0^\circ$ . The numbers

displayed are not quantitative values because most vessels examined do not lie parallel to the probe. These values are used, rather, in a qualitative manner; that is, as the numbers increase, the PRF increases and the ability to detect higher frequencies without aliasing is increased. The color frequency does not represent a peak frequency but a mean or mode frequency. The frequency displayed by the color is a single representative frequency between the maximum and minimum frequencies, as would be seen on a spectral waveform. These values should not be used for peak frequency or velocity measurements as is traditionally done with spectral waveforms.

The PRF should be changed constantly throughout the examination to accommodate the changing velocity patterns that may be present in the observed pelvic vessels. As a general rule, one should be aware that if the PRF is set too high the lower frequencies may not be detected; and if the PRF is set too low the higher frequencies are aliased. Color flow is essentially a guide for pulsed-wave Doppler exploration of solid tissue perfusion (i.e., uterus and ovary and tumor vascularization). Basically, if there is no color flow, waveform analysis is not done. The presettings of the instrument may be the reason for false-negative Doppler findings.

Aliasing refers to generation of one of the most common Doppler artifacts. It is a low-frequency component in the signal spectrum when the PRF of the instrument is less than two times the Doppler signal frequency. Doppler spectral waveforms display the aliased frequencies beginning at the opposite end of the scale and moving toward the zero baseline. Color Doppler sonography shows aliasing in the same manner: The aliased frequencies are displayed as the opposite color within the flow. In the display, dark color next to dark color usually indicates a directional change, but this color pattern also may occur with severe aliasing. Here the aliased frequencies are so high they go through the opposite color and cross the zero baseline into the dark shade of the original color. It is displayed as an apparent directional change and may be falsely interpreted. Aliasing occurs in areas where the frequency is increased owing to vessel obstruction or the angle of the vessels approaching  $0^\circ$  relative to the transducer. Therefore aliasing is often mistaken for true flow phenomena (e.g., turbulence or eddying) rather than a display artifact. Increased PRF, adjusted zero baseline, and decreased image depth can help to avoid aliasing.

The colors displayed can be chosen by the operator in most instruments. Usually manufacturer-preset maps are available, as is a method for creating personally selected maps. Experimentation with different maps for different studies is recommended to allow the operator to choose the most demonstrative colors

and shadings for each area of study. These maps can be stored and used again. Some instruments offer a "green tag" function, which allows the operator to tag, in green, a specific velocity/frequency or to set a threshold level above which all the velocities are colored green. The green tag is often used to help identify areas of increased velocity more rapidly or to aid identification of aliasing by making more obvious the highest frequency before the alias point.

The wall filter is a high-pass filter that allows the higher frequencies to be detected and allows the operator to selectively remove low frequencies due to motion of the tissue. The filter is usually displayed in hertz units. Some wall filters are directly connected to the PRF and increase automatically as the PRF is increased; they may need to be manually decreased with decreasing PRF. It is generally suggested to keep the wall filter as low as possible during most pelvic studies, although the wall filter may need to be increased to reduce color "flash" from bowel noise or transmitted pulsation from large pelvic vessels.

The gain is a front panel control that adjusts the amplification of the displayed Doppler signal. Color and pulsed-wave Doppler gains should be constantly adjusted throughout the examination to accommodate the changing signal strengths. If the gain is set too low, some Doppler information may not be detected, or if it is set too high too much "noise" is observed. Increased color gain is suggested in situations of suspected low-velocity blood flow. An "overgain" adjustment may be useful in areas of questionably low flow or no flow, as this change can enhance any flow that may be present. Power settings also affect the gain; that is, increasing the power allows lower gain settings.

As mentioned earlier, aliasing, the mirrorimage artifact, consists of a similar time-velocity spectrum appearing above and below the zero line (Fig. 40.9). It occurs at large angles of interrogation, particularly at low signal-to-noise, when a large receiver gain is used to detect weak Doppler signals. It results in saturation of one quadrature phase detector due to strong clutter signals from stationary scatterers.

Flow direction artifacts occur in tortuous vessels, such as the uterine or umbilical artery. Hence the same vessel can produce diverse color signals, depending on the temporary position of the vaginal probe. As the angle of insonation decreases at each end of the scan the velocity appears to increase. Experience allows us to recognize such artifacts. In a color Doppler study, any movement is modulated into color, which may produce an artifactual impression of blood flow. Bowel loop movements, such as peristalsis, can produce such an artifact, called color modulation of biologic movement. Several studies have presented the most common Doppler pitfalls and artifacts [33–37]. Potential solutions to avoid artifacts are also suggested. There is an urgent need for more standardization of the Doppler technique.

Artifacts in color and spectral Doppler imaging can be confusing and lead to misinterpretation of blood flow information. Inappropriate equipment settings, anatomic factors, and physical and technical limitations of the modality are the major causes. Incorrect gain, wall filter, or velocity scale settings can cause loss of clinically important information or distortion of the tracing. Reflection of the Doppler signal from highly reflective surfaces can create a color Doppler mirror image. Vascular motion can introduce

**Fig. 40.9.** Aliasing is a common artifact in Doppler studies. The mirror-image artifact shown here is at least as common. Arrows indicate the peak systolic and diastolic velocity on the Doppler waveforms

artifactual variation in velocity as the sample volume passes through different velocities in a laminar flow state. Unintentional motion can cause a generalized Doppler shift. Increasing the angle of Doppler interrogation degrades the quality of the tracing and gives the impression of spectral broadening. As angulation approaches 90°, directional ambiguity can occur, suggesting bidirectional flow. Recognition of these artifacts is essential for proper interpretation of Doppler information and for rendering a correct diagnosis. It is obvious that the display of color and pulsed-wave Doppler information is a complicated, sometimes confusing technology because of the many controls and their interactions. Understanding what each of these controls does independently and how the image is affected by adjustment and change is essential. More importantly, a permanent awareness of which control to sacrifice and which to enhance for the particular pelvic vessel is critical for obtaining the most diagnostically useful Doppler information.

## Conclusions

The color Doppler modality provides a valuable approach to the pathology of female reproductive organs. The results reported in the recent literature on three-dimensional color and/or power Doppler are indeed provocative and, not surprisingly, raise many new questions about the regulation of tumor angiogenesis, the density of tumor vessels, and the differences between vessel architecture in benign and malignant growths. Three-dimensional power Doppler depiction of tumor angiogenesis has many clinical implications, including early detection of ovarian and endometrial cancers. Improved detection and classification of tumor architecture after instillation of contrast agents might contribute to better diagnostic accuracy. Early detection of ovarian carcinoma is still the most attractive argument for conducting additional studies.
