The use of aliphatic diisocyanates in biodegradable polyurethanes facilitates degradation and avoids the potentially carcinogenic aromatic diisocyanates, MDI and TDI. The use of LDI and BDI as hard segments is of interest because of their putative nontoxic degradation products, ethanol and L-lysine, and putrescine, respectively. A number of reports have characterized the biocompatibility of biodegradable polyurethanes by culturing cells on the polymers and performing in-vivo studies. An extensive biocompatibility study was performed on polymers prepared from PCL soft segments, PHB/PHV diol hard segments with either TMDI or LDI.^[38] Macrophages and fibroblasts were cultured on four different polyurethane compositions as well as on tissue polystyrene (TCPS). With macrophages, a mitochondrial activity assay indicated cell adhesion with polyurethanes from 65–100% of TCPS

Fig. 5 Degradable shape-memory suture for wound closure. The photo series from the animal experiment shows (left to right) the shrinkage of the fiber when temperature increases. Reproduced from Ref. [40].

and a doubling time of 124–143% of TCPS.^[38] Similar results were found with fibroblasts with adhesion to the polymers 50–85% of TCPS and doubling times 125–140% of TCPS.^[38] These cells preserved their phenotypes as shown by nitric oxide (NO) tumor necrosis factor α (TNF- α) production by macrophages as well as extracellular matrix production by the cells cultured on the polymers. Adherent macrophages also responded to lipopolysaccharide by increasing NO and TNF- α production in a manner similar to cells on control surfaces.^[38]

To encourage cell adhesion, the poly(ester-urethane urea) synthesized by Guan et al. were surface-modified with radio frequency glow discharge followed by coupling of the adhesion peptide RGDS using a BDI spacer. Adhesion after one day of culture on films of the unmodified polymer was 85% of TCPS and, to films of the RGDS-modified polymer, was greater than 160% of TCPS.^[23] This study also demonstrated the biocompatibility of poly(ester urethane urea) degradation products in a cell culture assay.^[23]

Processing and Applications

Physical cross-linking is reversible with heat treatment or solvation, which allows polyurethanes to be processed by such methods as extrusion, injection molding, and solvent casting. Polyurethanes or poly(urethane ureas) consisting of physical cross-links are referred to as linear or thermoplastic elastomers. Examples of some techniques to process polymers into porous scaffolds for cellular ingrowth in tissue engineering applications include freeze drying (lyophilization) and salt leaching. Salt leaching occurs when sieved particles of sodium chloride are added to a polymer solution. The solvent is allowed to evaporate, which leaves dry polymer. The salt present in the polymer can then be leached out with water.^[43] The BDO and BDI-b-BDO-b-BDI-b-BDO-b-BDI chain-extended polyurethanes by Spaans et al. were processed into porous scaffolds by a combination of salt leaching and freeze drying in 1,4-dioxane solvent.^[25] The scaffolds possessed interconnected pores ranging in size from 150–300 μm . This material showed a high compression modulus and was thought suitable for application as a meniscal prosthesis. Scaffolds for tissue engineering of the knee meniscus were created from

polyurethanes based on a 50/50 poly(L-lactide-co- ϵ -caprolactone) prepolymer with BDI.^[37] In a subsequently study, porous scaffolds of the above polymer were constructed by the same method described in the preceding discussion to create two types of scaffolds.^[44] One type of scaffold possessed interconnected micropores of 15–20 μm and a compression modulus of 460 kPa, whereas the other had interconnected micropores of 30 μm and a compression modulus of 74 kPa. Samples were implanted in rats and characterized at 1, 4, 8, and 24 weeks. The scaffold with the smaller pore size displayed incomplete tissue ingrowth as compared to the scaffold with larger pores. However, the scaffold with the larger pore size had a compression modulus that was too low. Both foams were concluded to be unsuitable for meniscal reconstruction.^[44]

Lendlein and Langer designed and characterized shape-memory thermoplastic polyurethanes to be used in minimally invasive surgical procedures.^[40] The elastic polymers were melted and extruded into monofilaments to be used as sutures. The filaments were loosely sutured in dead rats and heated to 41°C. With the increase in temperature came shrinkage of the polymer, which resulted in a tighter wound closure (Fig. 5).

Different compositions of polymers prepared from poly[glycolide-co-(ϵ -caprolactone)-diol and crystalline poly(*R*)-3-hydroxybutyric acid-co-(*R*)-3-hydroxyvaleric acid]-diol with TMDI were melt-extruded into thin hollow tubes for tissue engineering of nerve guidance channels.^[45] Nerve guidance channels are polymer tubes onto which severed nerve endings can be grafted. Borkenhagen et al. studied nerve regeneration in rats at 4, 12, and 24 weeks. Twenty-three out of 26 implants contained regenerated tissue cables composed of myelinated axons and Schwann cells within the lumen.

CONCLUSION

The number of research reports published in the area of biodegradable elastomers is rapidly rising as appreciation for the role of mechanical properties in tissue-biomaterial interactions grows. The negative effects of mechanical property mismatch between an implant, e.g., a stiff vascular graft, and the surrounding tissue have been documented and studied for some time. The importance of mechanical training in the

appropriate development of tissue-engineered constructs is more recently being recognized in several systems.^[46–48] To create new biodegradable elastomeric materials that meet the needs for a variety of clinical applications, researchers are working toward solutions from platforms of naturally occurring materials or elastomers based on synthetic polymers widely utilized for nonmedical applications. The synthetic approach advances as biomaterials engineers work from an increasingly diverse array of biocompatible starting materials and incorporate specific bioactivity. There is a trend towards convergence wherein materials ideally would be created that possess the processing and design flexibility of synthetic approaches and the inherent bioactivity and biocompatibility of natural materials.

Electric Cell-Substrate Impedance Sensing

Philippe Lam

Genentech, Inc., South San Francisco, California, U.S.A.

INTRODUCTION

Invented by I. Giaever and C. Keese in the early 1980s, electrical cell impedance sensing (ECIS) is a non-invasive technique that permits monitoring live cells in situ and in real time. A small amplitude AC signal is imposed across a pair of electrodes onto which cells are deposited and the impedance of the system measured by a dedicated instrument. ECIS is capable of detecting the behavior of cells at each phase of culture—from attachment, spreading, and growth to mitosis, and death. This versatile technique has been successfully used to study adhesion, cell locomotion, tight junction barrier functions, response to toxicants, membrane electroporation, and various other applications. Ease of implementation and broad applicability make ECIS an ideal tool for any type of adherent cell-based assays.

The following provides an overview of the ECIS method by reviewing some fundamental concepts, discussing the instrumentation used, and briefly presenting some applications.

IMPEDANCE CONCEPT

For electrical circuits involving direct currents (DC), the voltage (E) and current (I) are related by a simple proportionality constant termed the resistance (R), as described by the well-known equation:

$$E = R \times I$$

The voltage, current, and resistance have units of volts (V), amperes (A), and ohms (Ω), respectively.

In systems involving alternating currents (AC), the time-dependent nature of the signal introduces an additional dimension. In this instance, the proportionality factor must describe both magnitude and phase relationships between the voltage and the current as illustrated in Fig. 1. This factor, the impedance (Z), is typically represented in complex notation and can be viewed as the AC analogue of the resistance and has the same unit. The equation above can be rewritten more generally as:

$$E = Z \times I$$

Whereas there are many accepted notations for the impedance, the following are more commonly found in the ECIS literature:

$$Z = a + ib$$

in which i is the imaginary number and a and b are the real and imaginary parts representing pure resistive and pure reactive (capacitive and inductive) contributions, respectively.

With this notation, the total impedance is:

$$|Z| = (a^2 + b^2)^{0.5}$$

If we assume a simple circuit representation for the system comprising an ideal resistor and capacitor in series, the impedance can be written as:

$$Z = R + 1/(2i\pi fC)$$

in which f is the frequency of the excitation signal in hertz (Hz), and C is the capacitance in Farads (F). Representing the impedance in such manner gives some physical meaning to the measured quantities as it is a simple model for the electrode-electrolyte interface in which C represents the double-layer capacitance, and R accounts for the resistance to interfacial charge transfer and double-layer charging current.^[1] In general, the quantities (a , b , R , C) in the above expressions depend on the system under study as well as frequency. It should also be noted that all of the representations of the impedance are equivalent and can be converted to any other notation to facilitate interpretation of the data.^[2]

PRINCIPLE OF ECIS

For conducting electrolytes, the potential measured across an electrochemical cell is typically dominated by the potential drop at the electrode-solution interface. Using AC provides greater sensitivity and versatility and alleviates electrode polarization problems associated with DC methods. The exquisite sensitivity of the ECIS technique hinges upon the dimensions of the sensing and counter electrodes used. By making the area of the sensing electrode small, on the order of 10^{-3} to 10^{-4} cm² (10^5 to 10^4 μ m²), and the counter

Fig. 1 Current-potential relationship. a) For DC, the potential and current differ only in magnitude: b) for AC, the signals can be different in both magnitude and the relative position of the peaks and valleys (phase difference). As shown, the current is said to be leading the potential by 90° . Because the signal is periodic, we can also say that the current is lagging the potential by 270° .

electrode much larger, approximately 1 cm^2 , the impedance of the system comprising the two electrodes and typical cell culture media will be dominated by the impedance at the sensing electrode-solution interface.^[1,3] This arrangement creates an electrical bottleneck about the sensing electrode. The contributions of the counter electrode and the culture medium represent a very small percentage (typically $<1\%$) of the total system impedance. Because cell membrane is electrically insulating, the presence and activity of cells on the surface of the sensing electrode can easily be detected. Figure 2 illustrates this concept. Only adherent cells

Fig. 2 ECIS electrodes. A schematic of typical electrodes, shown not-to-scale. Cells cover the surface of the whole dish; however, the only bottleneck is at the sensing electrode (shown by the current path in the magnified views). AC current can flow out from the sensing electrode surface from around (solid lines) or through the cells because cell membrane is capacitive (dashed lines).

cause an appreciable increase in impedance. Dead cells or rounded cells that have not attached do not result in significant blockage of the current path and thus are not detected.

INSTRUMENTATION

In principle, common impedance measurement methods such as bridges, LRC (inductance-resistance-capacitance) meters, frequency response analyzers, etc. may be used to collect data from the cell-covered electrodes. However, due to the delicate nature of the test specimen, one must ensure that the instrument is capable of obtaining reliable readings using low excitation potentials and currents so as not to be disruptive to the culture. A suitable instrument must also be able to conduct measurements at various frequencies in order to provide maximum sensitivity depending on the type of cells under study.^[1] Generally, the current across the cell layer should be on the order of a microampere and the potential should be limited to a few millivolts.^[3] Giaever and Keese have shown that, under these conditions, the cells are not affected by the electrical probing and behave identically to cells cultivated in regular culture dishes. By continuously monitoring the impedance response of the culture as a function of excitation frequency over time, the optimum frequency can be selected based upon the time change of the observed impedance signal. Once the desired frequency has been obtained, a typical ECIS experiment would involve probing the culture over time at that particular frequency.

Frequency response analyzers (FRA) such as the Solartron 1260 (Farnborough, United Kingdom) are well suited for ECIS measurements. However, due to high costs, FRAs have not been adopted by the ECIS community. Most of the ECIS work reported in the literature has been conducted on a phase-sensitive lock-in amplifier as described by Giaever and Keese.^[1,3] In this setup, schematized in Fig. 3, the sensing and counter electrodes are connected to an AC signal generator through a current limiting $1\text{ M}\Omega$ resistor in series. The typical impedance of a populated ECIS electrode (sensing, counter) and culture medium is several orders of magnitude less than $1\text{ M}\Omega$ at the frequencies used in the experiments. Therefore, the current through the system (sensing electrode, culture media, counter electrode, and resistor) may be considered to be nearly constant. The impedance of the cell layer can then be computed from the in-phase and out-of-phase voltage readings from the lock-in amplifier.

Using a single instrument, only one electrode pair (sensing, counter) can be measured at a time. However, each measurement can typically be completed in well

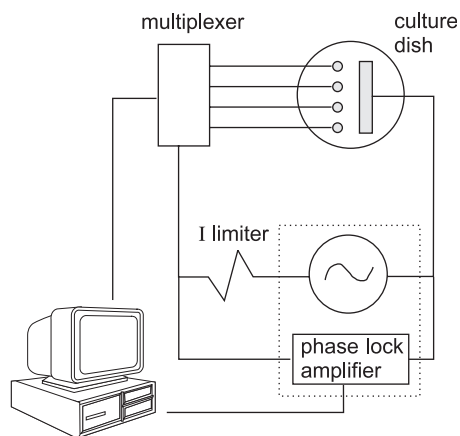

Fig. 3 ECIS system. This depicts a complete system, including multiplexing capability. The culture dish is located inside an incubator. The current-limiting resistor may be of different denomination depending on the application and instrument used. The AC signal source and phase-lock amplifier can be substituted by other impedance-measuring instruments such as a frequency response analyzer.

under one second. Because of the relatively slow nature of biological systems, measurement rates on the order of one per minute are sufficient to capture most of the dynamic behavior of a culture. For faster transients, such as monitoring membrane permeation, higher measurement rates can be used. An additional advantage of this technique is that the probing potential need only be present during the actual measurement. Therefore, cells are subjected to the externally applied potential only for a very brief instant, minimizing the risks of culture disruption.

Because the measurements involve low amplitude signals, care should be taken to reduce the influences of electrical noise. This means using high-quality, short cable runs, proper electrical connectors, and appropriate shielding. It is especially important to eliminate ground loops as well as any DC leakages, as these may cause artifacts in the data and have adverse effects on the culture. Furthermore, it is recommended to use a separate circuit for the power feed to the instrument from that of high-load devices such as water baths and laminar flow hoods.

Construction of the electrode assembly presents some challenges due to the diminutive size of the sensing electrode. Also, the electrode material must be nontoxic, conducive to cellular attachment, and present negligible electrical resistance. According to the guidelines recommended by the inventors, for a sensing electrode area of approximately 10^{-4} cm^2 , the physical dimensions would need to be approximately $120 \mu\text{m}$ in diameter if a disk or approximately $100 \mu\text{m}$ per side if a square. Larger electrodes that are several times the ideal area may be used successfully, but, if made too

large, sensitivity will be lost. These dimensions are easily obtained by common photolithography techniques. In their initial work, Giaever and Keese deposited a thin layer of gold by evaporation through a mask onto a polystyrene substrate. Red wax, which was found to be nontoxic was used to seal electrical connection and limit electrode areas.^[1,3] Gold is highly conductive, provides a good biocompatible surface, and, in a thin layer, is sufficiently transparent to allow observation of the cultured cells by optical microscopy.

A complete ECIS apparatus can now be purchased from Applied Biophysics (Troy, New York). The system comprises the measuring instrument, a multiplexer to allow quasisimultaneous monitoring of up to 16 different electrodes, and a computer with software for control and data acquisition/analysis. Also available are specially designed multiwell gold, disk-shaped microelectrode culture dishes. Photoresist material, in lieu of red wax, is used to limit electrode size to approximately $250 \mu\text{m}$ in diameter.

ECIS APPLICATIONS

The ECIS method was originally conceived to permit in situ and real-time monitoring of adherent cell cultures. The following gives a brief overview of some of the many applications that have been reported in the literature.

In the original account detailing an ECIS experiment, Giaever and Keese demonstrated that the behavior of fibroblast cells undergoing various stages could easily be monitored as a function of time.^[3] They also confirmed the noninvasive nature of the measurements by observing cell morphology and division time. In their experiments, the cells were seeded from a suspension onto a gold-sensing electrode. The attachment, spreading of the cells, growth, replication, and confluence stages of the culture were clearly reflected in the impedance data. Figure 4 depicts typical ECIS data showing the impedance response of a culture at various stages. As cells grow to confluence on the electrode surface, the impedance data typically exhibits a maximum. Thereafter, rapid noiselike fluctuations in the signal can be seen. These fluctuations, which are found to be fractal in nature, can be attributed to the micromotion of live cells.^[4] Such features are absent from either unpopulated electrodes or these occupied by dead cells.

Because of the large impedance change associated with the presence of live cells on the electrode, ECIS provides an excellent method for monitoring cell adhesion. For instance, it has been shown that cells were attaching and spreading quite differently depending on the specific proteins that were precoated onto the culture surface.^[1,5] Fibronectin, laminin,

Fig. 4 Typical ECIS data. Normalized resistance data generated from a culture of endothelial cells exposed to a toxicant (0.025% solution of diisobutylphenoxyethoxyethyl dimethyl benzyl ammonium chloride) at various levels. Trace (1) plain media, no cells; (2) control, no toxicant; (3) 1 μ l toxicant; and (4) 5 μ l toxicant added. Media volume is approximately 0.5 ml. A large increase in resistance, starting at about 1 hour, is a result of cell attachment onto the electrodes. The typical ECIS noiselike signal due to cellular micromotion can be seen in healthy cells (Trace 2). The signal from cells exposed to toxicant (Traces 3 and 4) eventually fell to levels of no-cell control, which indicated seriously impaired or dead cells. (Data courtesy of Prof. Gary Bowlin, Dept. of Biomedical Engineering, Virginia Commonwealth University, Richmond, Virginia, U.S.A.)

vitronectin, and bovine serum albumin were coated onto separate ECIS electrodes from 100 μ g/ml protein solutions in saline. A suspension of canine kidney-derived MDCK epithelial cells was then inoculated onto the precoated electrodes, and the impedance of each culture followed over time. A preliminary experiment determined 40 kHz to be the optimum frequency for monitoring attachment and spreading of these cells. For each case, $t_{1/2}$, the time required for the cells to achieve half-coverage of the electrode, was extracted from a plot of the series capacitance versus time. The data revealed that MDCK cells attached and spread most easily onto fibronectin-coated electrodes with $t_{1/2}$ of approximately 1 hour. Laminin and vitronectin coatings yielded $t_{1/2}$ of 3.8 and 4.6 hours, respectively, whereas bovine serum albumin surfaces were the least amenable to cell spreading ($t_{1/2}$ = 10 hours). Traditional cell-substrate interaction assays are more prone to experimental variation as they typically require seeding, attachment, rinsing off weakly or nonattached cells, and then quantification of the surface cells. Using ECIS, the researchers were able to obtain data without disrupting the culture.

The effects of various factors, such as genes, growth factors, signaling molecules, etc., that influence cell attachment/motion can also be observed by ECIS. Charboneau et al. reported that MCF-7 breast cancer cell transfected to express adenocarcinoma of the lung-1 (DAL-1) protein resulted in enhanced cell attachment.^[6] These researchers used ECIS to compare transfected cells to a control by measuring the rate of increase in resistance during attachment as well as total increase in resistance over longer times. Similarly, Schmidt et al. used an ECIS-based assay as evidence that the adaptor protein SETA/CIN85/Ruk and binding partner AIP1 were involved in regulating astrocyte adhesion.^[7] More recently, Sawhney et al. have shown that epidermal growth factor (EGF) receptor mediated cell adhesion and motion.^[8] In these experiments, ECIS was used to detect the micromotion of human colon carcinoma HCT116 cells in response to exogenous EGF. This was accomplished by analyzing the fluctuations in the impedance signal from established cultures over time. The amount of signal fluctuation, observed after the large initial impedance change due to attachment (e.g., Fig. 4, trace #2) is a quantitative measure of cellular movement. As each cell changed position about the surface, the inter-cellular distance as well as the gap between the cell membrane and the electrode also changed. This, in turn, resulted in changing current paths, which leads to measured impedance fluctuations.

Furthermore, it has been shown that alteration of environmental factors such as temperature, pH, and media composition can also be detected from the fluctuation in the signal caused by the micromotion of the cells.^[9] For instance, small pH fluctuations of the culture media can be observed in some on-off type CO₂ controlled incubators. Although these subtle changes are not easily detectable using conventional pH probes, they can affect cellular morphology as seen in ECIS data.^[10] Care must be taken when designing and conducting experiments to minimize effects from factors not under study.

Certain cultures, such as endothelial or epithelial cells, form tight junctions at confluence. Traditionally, the study of tight junctions have been conducted via electrical resistance measurements from cells grown on permeable filter substrates. These populated filters are placed between two media-filled chambers and an electrical signal imposed across the cell layers. An increase in the permeability of the cell layer results in a lower measured resistance. However, the type of filters used (material, pore size) may affect the morphology of the cultured layer; hence, the measurements can be influenced by factors other than tight junctions alone. ECIS provides a more convenient method for such investigations as the culture setup involves only one chamber and eliminates the risk of cells penetrating

into the permeable filter pores that can cause erroneously high tight junctions resistance values. Tiruppathi et al. first reported that endothelial barrier function could be followed in real time by ECIS.^[11] In these experiments, bovine pulmonary microvessel endothelial and bovine artery pulmonary endothelial cells were first grown to confluence on ECIS electrodes. The cells were then challenged with addition of α -thrombin, and the electrical response was measured. Molecules such as α -thrombin are implicated in inflammation and are known to increase the permeability of endothelial cell layers. The results, which were consistent with literature accounts, indicated that α -thrombin caused a reversible decrease in endothelial barrier resistance. These changes were due to cell shape alteration mediated by α -thrombin. A later communication by Lo et al. gave some insights on other factors that can affect measured transepithelial resistance and compared results from cell layers grown on filters and by ECIS.^[12] The researchers reported that certain types of cells, when grown on polycarbonate filters, yielded unusually high measured resistance values. They attributed this to an additional resistance from the restricted current path between the base of the cells and the substrate (see Fig. 2). The smaller the cell-substrate distance, the higher the measured resistance. In the analysis of ECIS data, Lo et al. utilized a mathematical model proposed by Giaever and Keese^[13–15] and obtained parameters such as average cell membrane capacitance, average cell-substrate distance, and inter-cellular junction resistance. The model abstracts cells as being disks of radius r_c located at a distance h from the electrode surface. The current originates from the sensing electrode surface uniformly and follow various paths to the counter electrode (see Fig. 2). Since the excitation is AC in nature, a fraction of the current goes through the cell as capacitive current. The remainder travels horizontally through the small gap between the cell bottom and the electrode surface, vertically through the space between neighboring cells, through the tight junction (if present), and out to the counter electrode via the cell culture medium. By conducting measurements at various excitation frequencies, adjustable model parameters can be fitted to the data. Using this approach, the average cell-substrate distances for MDCK epithelial cells, WI38-VA13 and WI38 fibroblasts cells were estimated to be 1, 13, and 113 nm, respectively. Such parameters would be difficult to obtain via traditional microscopy.

Neutrophil migration through endothelial cell layers occurs at sites of tissue infection or injury. This process is normally studied by microscopy (electron microscopy, immunofluorescence, etc.). However, these conventional techniques are complex, require a great deal of sample preparation, and most do not give real-time data. Burns et al. used ECIS to study human

peripheral blood neutrophil (PMN) migration through human umbilical vein endothelial cell (HUVEC) layers and found that the endothelial tight junctions were not disrupted.^[16] The HUVEC cells were cultured to confluence on ECIS electrodes. IL-8-activated PMNs were then added in a 20 to 1 ratio over the HUVEC layer. In separate electrode wells, addition of unactivated neutrophils was used as a negative control, and histamine addition, which disrupts tight junctions, was the positive control. No noticeable decrease in trans-endothelial electrical resistance was recorded for either of the neutrophil addition cases, whereas histamine caused a significant drop. The ECIS results were in agreement with electron microscopy data. Migration of the neutrophils at the discontinuities present at the junction of three neighboring HUVEC cells may explain why no significant disruption to the tight junctions was detected.

In contrast, Keese et al. showed that deposited metastatic cells were severely disruptive as they invaded an endothelial cell culture.^[17] The process by which cancerous cells migrate from one tumor site to another is important in understanding disease progression. Furthermore, quantifying the metastatic potential of each type of cancer cell can provide valuable information. Multiple lines of cancer cells with varying degrees of metastatic potential (non-metastatic to highly metastatic) were used to challenge HUVEC cell layers grown on ECIS electrodes. Several sublines of Dunning murine prostatic adenocarcinoma cells as well as several human prostatic cell lines were added to separate confluent layers of HUVEC in a 1 to 1 ratio. The impedance at 4 kHz was followed over time. Results indicated that the change in measured resistance was proportional to the degree of metastasis of the invading cells. Highly metastatic cells caused a large decrease in resistance, whereas weakly or non-metastatic cells caused a small or no decrease in resistance. This work shows that ECIS can be a valuable tool for oncology research.

Another ideally suited application for ECIS is that of cell-based, in-vitro toxicology. Giaever and Keese suggested that the impedance response of cultured cells could be used as an indicator of cell health.^[18] Presumably, the behavior of cells at various stages of culture (attachment, spreading, motility, replication, death) would be disrupted by an introduced toxicant, and the change in impedance compared to a control be used to gauge the level of toxicity. In this case, it would be advantageous to determine which culture phase should be monitored in order to obtain the most useful information. A carefully planned experiment may be able to tease out information on the mechanism of action as well as obtain level-of-toxicity data. For instance, one possible scenario would be to mix the toxicant with the cell suspension and monitor the

effects during attachment. Another possibility would be to add the toxicant after establishment of the culture. Keese et al. chose to expose confluent MDCK epithelial and WI-38/VA13 fibroblasts cell layers to various levels of several common detergents such as Tween 20 and sodium lauryl sulfate and measure the resulting cellular micromotion.^[19] The data were analyzed in terms of disruption to the micromotion signal as compared to a control. Using this approach, they were able to rank the detergents in order of effects. Their findings are in agreement with other published reports obtained using conventional animal testing or skin testing. Another study by Xiao et al. employed a different procedure, adding toxicants—either arsenate, cadmium or benzalkonium salts at various concentrations—to a suspension of V79 fibroblast and monitored cellular attachment and growth by ECIS.^[20] They analyzed the response of the challenged cells at 16 hours postinoculation as compared to a control. They showed comparability of ECIS to the traditional neutral red uptake assay. Although test conditions and analysis procedures must be optimized for each case, it is evident that ECIS can be applied to cell-based toxicity assays.

An elegant use of ECIS for monitoring chemotaxis of eukaryotic *Dictyostelium discoideum* cells exposed to a folic acid gradient was reported by Hadjout et al.^[21] Quantitative measurements of cell chemotaxis can be difficult to obtain as there are several issues involved. First, a stable gradient must be established. This can be accomplished by using a gel matrix or a porous filter to eliminate convective and reduce diffusive mixing of the agent under test. Second, one must be able to detect cellular motion. Most conventional methods are based on microscopy, and involve cell staining or tracking with elaborate video systems. Hadjout et al. proposed a novel method whereby they have adapted the commercial ECIS multiwell gold microelectrode dish to permit real-time monitoring of cell migration. In their setup, each well of the electrode array was partially filled with agarose gel, and small plugs—one on each side of the sensing electrode—were removed from the gel. Cells were deposited in one of the newly created openings and chemoattractant was deposited in the other. Impedance was monitored as the cells migrated across the sensing electrode and under the agarose gel. Initially, the electrode was uncovered by cells. The agarose did not contribute significantly to the measured impedance as the gel was ionically permeable. As the cells migrated onto the sensing electrode, an increase in impedance, which was proportional to the number of cells present, was detected. When the cells moved off the electrode, the impedance decreased. The time of arrival of the cells to the electrode, i.e., a measure of cell-moving speed, can be easily obtained as well. In this example, ECIS

was used as an on-off type sensor in a setup that was simple, sensitive, multiplexable, and capable of providing data in real time.

With minor modifications to the instrumentation, in situ electroporation of the cells growing on the sensing electrode can be performed. Furthermore, with computer-controlled setups, the instrument can be reverted back to the regular mode immediately after the electroporation step and begin monitoring cell behavior. In contrast to traditional electroporation chambers in which high voltages (hundreds to thousands of volts) are necessary for efficient permeation, the ECIS asymmetrical electrode configuration permits high current densities and large potential drops at the sensing electrode from low applied potentials. Furthermore, the process can be conducted in regular culture media without risks of heating. Ghosh et al. demonstrated feasibility by using AC pulses to introduce horseradish peroxidase into fibroblast cells.^[22] WI-38/VA-13 human lung fibroblast cells were first cultured to confluence onto ECIS electrodes. After addition of horseradish peroxidase to the culture media, 1–5 V pulses at the same frequency as the measurement signal and 200 ms in duration, were applied to each electrode. The data showed that there was a significant drop in impedance as a result of the high voltage exposure, which was an indication that cell membranes had been temporarily permeabilized. The impedance returned to prepulse value within several seconds. Uptake of the horseradish peroxidase was detected colorimetrically after fixing the cells. Later, Wegener et al. conducted extensive investigations aimed at optimizing electroporation conditions on several types of cells.^[23] They studied the effects of pulse amplitude, pulse duration, and pulse frequency and found optimum conditions to be cell-type dependent. Because only the cells present on the sensing electrode are affected, it is also possible to conduct wound healing experiments by applying a lethal voltage to the targeted cells and observing the surrounding cells repopulate the electrode area.

CONCLUSION

As evidenced by the multitude of applications that have been reported, ECIS is an elegant, versatile, and easily implementable technique that is well suited for a variety of adherent cell-based assays. It offers many advantages over traditional optical microscopy, such as low cost, high sensitivity, reproducibility, noninvasiveness, real-time, in situ monitoring, and multiplexing capabilities. Furthermore, the technique is based on simple, fundamental principles and can be adapted to new applications. For instance, it may be possible to use nonplanar sensing electrodes to probe whether cells

can recognize three-dimensional features or even use ECIS for noncell-based applications to detect molecular interaction between solution species and an immobilized ligand.

Already well-established as a powerful research tool with computer-controlled operation and scalability, this technique can potentially be an attractive solution for automated high-throughput, cell-based assay screening systems.

Electrical Impedance Imaging

Keith D. Paulsen
Alex Hartov

INTRODUCTION

Electrical impedance imaging, which is usually referred to as electrical impedance tomography (EIT) but sometimes called electrical impedance spectroscopic imaging (EIS or EITS) when multiple frequencies are involved, is the process of forming spatially resolved electrical property images of tissue using actively driven source and sensing electrodes located on the body surface. The bulk electrical properties of conductivity (Siemens/meter) and permittivity (Farads/meter) are the intrinsic tissue characteristics that the technique directly recovers, although these parameters are often exploited as surrogates for other physiological or biological processes of medical interest (e.g., temperature,^[1] radiation injury,^[2] etc.). EIT is usually distinguished from other electromagnetic (EM) imaging approaches (e.g., magnetic resonance, microwave tomography, etc.) by the frequency range of the applied EM fields—typically 10 KHz to 1 MHz but sometimes as high as 10 MHz or as low as 100 Hz. It is also recognized by its use of exciting currents/voltages exogenous to the body in contrast to other electrical sensing techniques, which detect the body's intrinsic electrical activity (electrocardiogram, electroencephalogram, etc.).

OVERVIEW

There are three basic requirements for electrical impedance imaging: 1) an externally applied electrical stimulus or set of stimuli that can be controlled by the operator and falls within the relevant frequency range (less than 10 MHz); 2) a recording device to measure the magnitude and phase that is relative to the driving signal of the electrical potential and/or current that develops at multiple locations on the tissue surface as a result of the applied stimulus; and 3) an algorithm for converting the data acquired in concert with the known stimulating signals into an image of the electrical property distribution (conductivity and permittivity) in the tissue region of interest. The first two requirements are embodied in the hardware of the imaging instrument itself; whereas, the third requirement involves subsequent software processing of the basic

measurements provided by the hardware data acquisition system. This article explores the tenets that underpin EIT from the perspective of the hardware and software components necessary to generate impedance, i.e., electrical property, images in tissue. Figure 1 illustrates the conceptual framework for EIT in terms of these requisite system modules.

Bioimpedance measurements have a rich history dating back to the early 1930s and before with seminal contributions from Cole^[3] and Schwan^[4] among others. There is extensive literature on the electrical properties of tissue that has been periodically reviewed and catalogued.^[5] One of the most comprehensive compilations of the knowledge base on bioimpedance techniques, including EIT, can be found in^[6] and is recommended reading for any newcomer to this exciting field. A very recent special issue illustrating the state-of-the-art in EIT can be found in.^[7] For the purposes of this synopsis on EIT, it is sufficient to recognize that the induced current density, \mathbf{J} , (in amps/m²) in tissue is related to an applied time-harmonic electric field, \mathbf{E} , (in volts/m) through the distributed analogue of Ohm's Law:

$$\mathbf{J} = \sigma^* \mathbf{E} \quad (1)$$

in which $\sigma^* = \sigma - i\omega\epsilon$ is the complex-valued conductivity that conveniently—in mathematical terms—incorporates the conduction current component due to ion transfer in tissue with the displacement current contribution resulting from capacitive energy storage due to bound (dipolar) charge at cellular membranes. Here, σ is the electrical conductivity, ϵ is the electrical permittivity, ω is the radian frequency of the applied electrical stimulus. Further, the electric field and electric potential, Φ , are related through the equation:

$$\mathbf{E} = -\nabla\Phi \quad (2)$$

under the assumption that the electromagnetic wavelength is sufficiently large relative to the scale of the imaging geometry that the spatial variation in the induced magnetic field (from the time-harmonic current) is small from the perspective of determining the electric field and/or electric potential via Eq. 2. However, note that, whereas the size of $\omega\epsilon$ is generally small (relative to σ) at EIT frequencies, it is possible to detect a phase

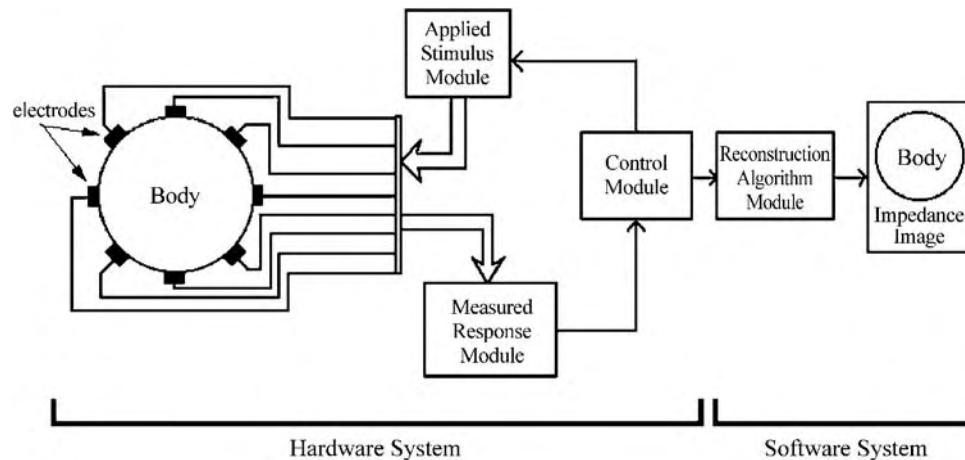

Fig. 1 Conceptual diagram of an EIT system illustrating the primary functional modules needed to generate an image of the body.

difference between an applied current or voltage and a measured voltage or current with well-designed instrumentation, which provides sufficient information for the creation of permittivity images with EIT—even though this does complicate both the hardware and software requirements for electrical impedance imaging.

HARDWARE CONSIDERATIONS

Electrical Impedance Tomography has been developed to image a cross section of the anatomy using signals applied at electrodes on the body surface that define a plane of intersection. As the technology has advanced, it has been extended to three-dimensional configurations in some cases. From the hardware point of view, the implications for developing a three-dimensional system versus a two-dimensional instrument are few—primarily that a three-dimensional system implies a larger number of channels. Typical two-dimensional systems that have been presented in the literature utilize 16 electrodes for breast imaging,^[8] for example, or 32 electrodes for chest imaging.^[9] In this section, some of the basic design decisions for EIT data acquisition, which are the same for either a two-dimensional or a three-dimensional system, will be reviewed.

An additional distinction should be made between tomographic devices and mapping instruments. The latter consist of arrays of electrodes arranged in a planar rectangular or circular configuration that are applied to the area to be examined, which is typically the breast, and measure the load impedance sensed by each electrode. As few as 64 and as many as 256 electrodes have been arranged in handheld probes. The measured impedances are usually represented as shades of gray on a map representing the array configuration. These devices are significantly different in that they do not reconstruct tissue properties in a tomographic

fashion. Two groups have been pursuing these types of devices for breast cancer screening—one in Russia^[10] and one in Israel.^[11] The Israeli group developed the device known as the T-Scan, which is currently marketed in the United States for clinical testing.

It is important to recognize that when an electrode carries a current, a potential will be developed at the electrode-skin interface due to the contact impedance between the two surfaces. This contact impedance can result in erroneous voltage readings. The contact impedance can be reduced by using appropriate electrodes, e.g., Ag–AgCl, and proper skin surface preparation with a conductive gel. However, the artifact is essentially unavoidable. One method to minimize the problem consists of measuring potentials only at electrodes that do not drive currents, which is equivalent to the tetrapolar resistance measurement technique used when lead losses are significant. The measurement approach has been adopted by the pioneering EIT group in Sheffield.^[12] Unfortunately, contact impedance is not the only consideration. From a sensitivity perspective, this approach is less than optimal. For a circular geometry, maximum distinguishability is obtained when trigonometric current patterns are applied on all electrodes simultaneously while voltages are measured at these same sites.^[13] For three-dimensional systems or arbitrary geometries, the optimum current pattern can be computed adaptively.^[14] The effect of the contact impedance is then taken into account during image reconstruction by using a full electrode model.^[15]

Various excitation patterns have been used in EIT. The simplest consists of applying a current between two electrodes and measuring the voltages at all of the remaining channels. Although not optimal, the simplicity of this approach has its appeal. In such a design, a single source can be switched between electrode pairs. With this type of excitation pattern, there is freedom in selecting the electrode pairing. Most designs use

adjacent electrodes as paired partners, which results in the greatest sensitivity occurring at the periphery of the imaged cross section that is nearest the electrodes. The significant lack of sensitivity at the center of the imaged area can be improved by also using patterns in which opposing electrodes are paired. Note that, with a given number of electrodes (N), it is possible to pair them in $N^*(N-1)/2$ ways.

The electronics behind each electrode constitutes a channel and can be designed to apply a desired potential (voltage mode), drive a specific current (current mode), or simply sense the potential at a given location (passive mode). In general, it is much simpler to design a voltage source; however, over extended frequency and load ranges, neither voltage nor current sources behave ideally. As a result, it is preferable to measure both the applied and induced signals. A practical method to achieve measurement duality is to use a sense resistor in the feedback loop of an op-amp buffer. By measuring voltages on both sides of the resistor, the electrode potential is known directly, and the current can be computed. Alternatively, one can use a sense resistor in series with the electrode. This design will result in a potential at the electrode that will vary with the load experienced, which can be corrected by adjusting the driving voltage. The approach is readily implemented in a DSP (digital signal processing)-based design, for example.

Early EIT devices operated at a single frequency, usually in the tens of kilohertz, which made their design relatively simple. Most tissues exhibit significant frequency dependence in their electrical properties, and, in some applications, this dispersion is the basis for discriminating between normal and pathological conditions. The ability to image at multiple frequencies or perform spectroscopy in a spatially resolved manner has therefore become an important goal for EIT. This requirement complicates the level of circuitry involved significantly. It is important to be aware of two critical issues that stem from the desire to realize a multi-frequency system, source design and signal coherence. If current sources are to be used, their output shunt impedance must be very high (on the order of $64\text{ M}\Omega$ to maintain 16 bits of accuracy).^[16] In single frequency circuits, this is achieved by tuning a matching circuit.^[16] The matched circuit approach is not realizable for multiple frequency devices—other than through replication of the current source—and with each tuned to a different frequency. A second difficulty which stems from using high frequencies is signal integrity and coherence. At frequencies above 1MHz, the wire leads delivering the signals to the electrodes couple to ground or to other neighboring leads; hence, signals measured at the sensing point in the electronic circuit cards will be significantly different from signals present at the electrodes.^[17] Below 100 kHz, one can make effective use of

signal guards and shields. A guard consists of a coaxial shield, which is maintained at the same potential as the signal lead it surrounds. This effectively eliminates the capacitive loading between the signal and the shield. Usually, a second grounded shield surrounds the guard to prevent the guard from broadcasting. Unfortunately, at higher frequencies, these shields become ineffective due to small phase and gain errors in the guard-driving circuit. One remedy is to keep the driving and sensing circuits physically located as close as possible to the electrodes. If multiple channels are to be operated simultaneously to produce a spatial pattern with the driving signals, consideration must be given to the relative delay errors between channels in the signal paths. Interchannel propagation differences on the order of ± 5 to ± 10 ns can be expected. At low frequencies, these represent negligible phase or instantaneous amplitude errors; however, at higher frequencies, these can result in significant errors as shown in Table 1.

A compromise must be reached between the speed of measurements, the flexibility of the instrumentation, and its complexity. In the simplest implementation, an EIT system could consist of a single source and a single measurement module that are operated in conjunction with a switching or multiplexing matrix. The source or measurement module would be switched in succession between electrode pairs. Measurements would have to be performed sequentially, which thus increases the acquisition time for recording the data necessary for imaging. Such a system also precludes spatial current distributions that are desirable for maximum sensitivity. Data acquisition speed can be increased by having multiple measurements modules operating in parallel while still using a single source. For a system with maximum flexibility and speed, multiple sources can be used to create arbitrary patterns in combination with parallelized measurements.

For the purpose of image reconstruction, a set of voltages and corresponding currents for each applied pattern is required. In principle, it is of no consequence which quantity (voltage or current) is driven and which is measured. It is generally easier to design a high-fidelity voltage source relative to a current source. It is also simpler to measure a voltage than a current. One additional consideration in deciding whether to use current or voltage sources is the sensitivity of the

Table 1 Effect of differential propagation delays on phase and instantaneous amplitude coherence

Phase and amplitude error based on 10 nS difference				
Frequency (Hz)	50 kHz	100 kHz	1 MHz	10 MHz
Phase (°)	0.180	0.360	3.600	36.000
Amplitude (%)	0.000	0.002	0.197	19.098

measured variable to inaccuracies in electrode placement. For a cylindrical geometry, with electrodes completely covering the end surfaces of a cylinder of length (L) and cross-sectional area (A), the cylinder's resistance (R) can be expressed as: $R = (L \cdot \rho) / A$ in which ρ is the cylinder's resistivity. Using this as an approximation to the relationship between two neighboring electrodes, if a current is applied, the effect on the measured voltage of an error in the distance separating the electrodes will be directly proportional to the size of the error introduced: $V = I \cdot R = I \cdot L \cdot \rho / A$. Conversely, if a voltage is applied, the error in the measured current will go as $1/L$: $I = V / R = V \cdot A / (L \cdot \rho)$.

Differential voltage recordings between neighboring electrodes are potentially more precise than absolute measurements related to a common reference. The reason for this is that differential voltages between neighboring electrodes are usually much smaller, which results in a greater sensitivity for the system given a specific measurement resolution, assuming an identical set of applied currents or voltages. A more important aspect of differential measurements is that they bypass the problem of a common reference for all electrodes that can be noisy, which takes advantage of common mode rejection. Differential measurements are readily achievable at frequencies up to approximately 200 kHz, beyond which they become increasingly inaccurate due to the difficulty in designing differential amplifiers operating at these frequencies. At higher frequencies, absolute measurements are more readily realizable.

When designing a research tool, it is desirable to preserve as much operational flexibility as possible. One approach is to design a modular system that can be operated in any mode.^[18] Each channel consists of a selectable voltage or current source. A relay can also disconnect the driving circuitry, which makes the channel a passive sensing electrode. In order to simplify the hardware design, it is possible to use a voltage source to drive a current by continuously monitoring its current output and adjusting its amplitude.^[19] This is particularly effective with DSP-based designs in which the sensing and adjustment can be performed very rapidly.

Amplitude measurements alone allow one to reconstruct the conductivity map of the tissue cross section of interest. In order to obtain both permittivity and conductivity, it is necessary to obtain the complex voltages and currents at every electrode. Analog methods for recovering in-phase and quadrature (I & Q) components of a signal exist and can be used if a single measurement module is required. Their economical implementation on a per channel basis is difficult to achieve. Alternatives exist that can convert amplitude and phase to DC voltages.^[17] This approach, based on RMS to DC converters and phase detectors and filters, is practical; however, the integration times required for

a precise measurement result in an inherently slower system. As an alternative to these methods, direct sampling of the AC waveforms is possible using fast analog to digital components. The sampled waveforms can be numerically processed to extract magnitude and phase using software-based mixing or quadrature sampling. In order to adequately sample the waveforms, it is not essential to adhere to the Nyquist rate. Under-sampling techniques can be used to obtain effective rates that are very high.^[18] However, the input bandwidth of the sampling subsystem must be higher than the signal frequency. In addition, the sampling needs to be synchronized with the applied signal and across all channels for a coherent data set.

Digital signal processing (DSP) technology makes available some very attractive features for designing an EIT system. With components found commercially, it is possible to create a system that will generate and sample waveforms in lockstep. Furthermore, given the very high clocking frequency of existing devices, it is possible to have timing precision in generating the waveforms of better than 2 ns between channels. Very high-bandwidth, 16-bit analog to digital (A/D) converters are available with actual sampling rates that are on the order of 1 MHz. By combining programmable logic devices and DSP chips, extremely high performance systems can be fabricated. In such a system, the applied signal can be generated using direct digital synthesis. A 256×16 -bit memory buffer is loaded with a numeric sine wave scaled to the desired amplitude. The pattern uses 14 bits that are fed to a fast D/A. An address counter is clocked to scroll through this buffer continuously to generate the output signal. The frequency of the clock cycling through the buffer as well as the number of points used in creating the waveform control the signal frequency ($F_{sig} = F_{cl} / N_{samp-per-cycle}$). The 15th bit is used to clock the sampling A/Ds on each side of the sense resistor, which thus allows synchronous sampling of the voltage and current waveforms.

SAFETY CONSIDERATIONS

Prior to clinical deployment, one must examine issues that pertain to the safety of the patient or imaging subject. Standards have been established regarding the electrical safety of medical devices.^[20,21] The salient feature of these standards is the maximum current that can be allowed to flow through the body. This maximum current is a function of frequency and can be summarized as follows. Below 1 kHz, 1 mA (RMS) or less, from 1 kHz to 100 kHz, the allowable current increases from 1 mA to 10 mA linearly. Beyond that, it remains at 10 mA. When operating at 10 kHz or above, it is relatively simple to couple the signal to the body using a fairly large capacitor in order to suppress DC

and low frequency currents. It should be noted that these safety standards were developed for equipment and were not meant to deliberately apply currents to a subject. A conservative interpretation is that none of the electrodes should be applying a current of magnitude greater than the amount indicated in the guideline. The potential danger of applied currents is of particular concern in chest imaging in which it is possible to induce ventricular fibrillation. The relatively high frequencies (10 kHz and above) of operation of most EIT systems and their comparatively low current densities have proved to be safe. For subjects with pacemakers or other implanted active devices, e.g., neural stimulators, EIT examinations should be avoided due to the risks of direct interference with the electronic operation of these devices.

SOFTWARE CONSIDERATIONS

Perhaps the most critical and difficult aspect of EIT is image reconstruction because the electrical property features of tissue, while attractive candidates for imaging because they offer large intrinsic contrast, are subtly encoded into small changes in surface currents/potentials that are difficult to extract. Further, the sensitivity of surface recordings to electrical property change decreases with distance from the measurement sites, i.e., electrodes, making the depth resolution of EIT relatively poor. It is also important to realize that the measured electrical response is not a linear function of the tissue electrical properties and this nonlinearity, when coupled to the spatial dependence of the sensitivity map to property change, makes for a very challenging and difficult parameter estimation problem.

In general, two classes of image reconstruction approaches have emerged over the years: 1) those that linearize the relationship between electrical property change and change in measured response;^[22] and 2) those that preserve this functional nonlinearity.^[23] In the former case, algorithms are generally fast and analytically motivated but highly approximate and best suited for nonquantitative difference imaging. Typically, the inversion problem has been linearized using variations on the ideas well developed for X-ray CT in which linear inversion is an excellent model. In the case of EIT, the back-propagation of the measured response to the generating source occurs along computed equipotential lines—rather than straight lines as in CT—defined by the governing Laplace equation under assumptions of a homogeneous medium. To develop this further, note that in the absence of any independent sources of time-varying charge within the tissue of interest, \mathbf{J} in Eq. 1 has no divergence, which, when coupled with Eq. 2, produces

$$\nabla \cdot \mathbf{J} = \nabla \cdot \sigma^* \mathbf{E} = \nabla \cdot \sigma^* \nabla \Phi = 0 \quad (3)$$

Equation 3 is readily recognized as the complex-valued Laplace equation in a source-free medium that defines the electric potential everywhere within the tissue. Because the electric potentials spread apart with distance from their source, pixel contributions to the measured response must be weighted appropriately, depending on their location within the equipotential map constituting a source-receive pair. The process leads to images that are typically rather blurred. Various strategies for improving image quality through filtering schemes have been devised.^[24] However, the approach is ultimately limited because the linear approximation of the relationship between measurement change and property change is essentially invalid.

The nonlinear image reconstruction approach is more promising, but it can only be realized at the expense of considerable computational costs that are also accompanied by instabilities due to measurement errors introduced in the data by the hardware acquisition. The functional nonlinearity forces stepwise linearization that is iteratively incremented as part of the solution. Further, because of the complexities associated with solving Eq. 3 when σ^* is arbitrarily defined, image reconstruction algorithms that seek to enforce nonlinearity are numerical in nature.

Perhaps the most popular approach in this regard is the finite element (FE) method,^[25,26] which is the technique that will be summarized here. It is important to recognize that, while finite element reconstruction for EIT has evolved to the point where codes are available for use,^[27,28] new image reconstruction methods continue to emerge from within the research community that hold exciting new prospects for improving EIT.^[29] Nonetheless, the current state-of-the-art in EIT image reconstruction is well represented by the finite element method. The most straightforward approach to nonlinear EIT image reconstruction minimizes the squared difference between measured and computed potentials (or currents) at a discrete set of electrodes:

$$\min \sum_{i=1}^0 (\Phi_i^m - \Phi_i^c)^2 \quad (4)$$

positioned on the body surface around the region of interest. In Eq. 4, the superscripts on Φ refer to measured (M) and computed (C) quantities, and the sum extends over the total number of measurement observations. For simplicity, Φ in Eq. 4 is assumed to be real-valued, and yields recovery of only the real-valued electrical conductivity in Eq. 1. Generalization of Eq. 4 to include permittivity estimation requires the introduction of complex-plane analysis, which is straightforward but serves to unnecessarily complicate the notation needed for the summary presented here. Analogous development for complex-valued image reconstruction can be found in.^[26,30]

Minimization of Eq. 4 requires determination of first-derivative stationarity:

$$\sum_{i=\phi}^0 (\Phi_i^m - \Phi_i^c) \frac{\partial \Phi_i^c}{\partial \sigma} = 0 \quad (5)$$

At this point, a number of mathematical strategies can be invoked. For example, the nonlinear set of equations in Eq. 5 can be solved iteratively for the σ -distribution via Newton's method in standard matrix form in which the second derivative of Φ_i^c with respect to σ is assumed to be small. Alternatively, the nonlinearity in the relationship between the potential and the property distribution can be linearized by Taylor series expansion of Φ^c around the current σ estimate:

$$\Phi^c(\sigma) \cong \Phi^c(\bar{\sigma}) + \partial_\sigma \Phi^c(\bar{\sigma}) \Delta\sigma + HOT \quad (6)$$

in which $\bar{\sigma}$ represents the current estimate, $\Delta\sigma = \sigma - \bar{\sigma}$; ∂_σ denotes partial differentiation with respect to σ ; and *HOT* indicates the higher-order-terms in the Taylor series. Substitution of Eq. 6 into Eq. 5 leads to the classical form for updating an initial conductivity distribution estimate:

$$\Delta\sigma = (J^T J)^{-1} J^T (\Phi^M - \Phi^c) \quad (7)$$

in which J is a matrix of derivatives, $\partial_\sigma \Phi_i^c$, of each observable for $i=1,2,\dots,0$ (e.g., potentials at a set of electrodes) with respect to each parameter for $k=1,2,\dots,M$ defining the conductivity distribution. Equation 7 is numerically unstable due to measurement errors and must be smoothed or regularized. Conceptually, this can be achieved by representing the *HOT* in Eq. 6 in various ways, for example, as:

$$HOT = \lambda (\partial_\sigma \Phi^c)^{-1} \Delta\sigma \quad (8)$$

in which λ is a scaling factor for improving stability, in which case Eq. 7 becomes:

$$\Delta\sigma = (J^T J + \lambda I)^{-1} J^T (\Phi^M - \Phi^c) \quad (9)$$

Reconstruction of finite elements (i.e., iteratively solving Eq. 9) is centered around FE solution of two partial differential equations:

$$\nabla \cdot \sigma \nabla \Phi = 0 \quad (10)$$

that is, Eq. 3, under assumption of the current estimate of the σ distribution and:

$$\nabla \cdot \sigma \nabla \Phi' = -\nabla \cdot \sigma' \nabla \Phi \quad (11)$$

in which the prime indicates differentiation with respect to a localized variation in the conductivity distribution.

Discretization of Eq. 10 by finite elements proceeds through the method of weighted residuals combined with basis function expansion of Φ and σ to yield the algebraic system of equations:

$$\sum_{j=1}^N \Phi_j \left\langle \sum_{k=1}^M \sigma_k \phi_k \nabla \phi_j \cdot \nabla \phi_i \right\rangle = \oint J \phi_i ds \quad (12)$$

for $i=1,2,\dots,N$ in which ϕ_i is a locally defined Lagrange polynomial (typically linear) centered at node i , $J = \sigma \nabla \Phi \cdot \hat{n}$ is the current density integrated as \oint around the boundary, and $\langle \cdot \rangle$ represents domain integration over the imaging body. N is the total number of nodes in the FE mesh on which Φ is computed, i.e., Φ_j is the potential solution at node j , whereas M is the number of parameters that defines the σ distribution (often discretized on a separate mesh such that σ_k is the conductivity at node k). In matrix form, it is convenient to partition Eq. 12 into quantities on the boundary (subscript b) and interior (subscript I) to the imaging field-of-view:

$$\begin{bmatrix} A_{bb} & A_{bI} \\ A_{Ib} & A_{II} \end{bmatrix} \begin{Bmatrix} \Phi_b \\ \Phi_I \end{Bmatrix} = \begin{bmatrix} B_{bb} & 0 \\ 0 & 0 \end{bmatrix} \begin{Bmatrix} J_b \\ 0 \end{Bmatrix} \quad (13)$$

in which the submatrices symbolize integration of the known basis functions and property assumptions depending on their location, i.e., boundary or interior.

Equation 11 is solved analogously for Φ' through FE discretization and yields the algebraic equations:

$$\begin{aligned} & \sum_{j=1}^N \Phi'_j \left\langle \sum_{k=1}^M \sigma_k \phi_k \nabla \phi_j \cdot \nabla \phi_i \right\rangle \\ &= - \sum_{j=1}^N \Phi_j \langle \phi_\ell \nabla \phi_j \cdot \nabla \phi_i \rangle \\ & \quad + \oint \sigma \nabla \Phi' \cdot \hat{n} \phi_i ds + \oint \sigma' \nabla \Phi \cdot \hat{n} \phi_i ds \\ &= - \sum_{j=1}^N \Phi_j \langle \phi_\ell \nabla \phi_j \cdot \nabla \phi_i \rangle + \oint J' \phi_i ds \end{aligned} \quad (14)$$

for $i=1,2,\dots,N$ in which the prime denotes differentiation with respect to the ℓ th parameter, σ_ℓ , in the sum $\sum_{k=1}^M \sigma_k \phi_k$. The matrix system in Eq. 14 is computed for each of the M terms in the sum to fill in the elements composing J in Eq. 9. It is likewise conveniently partitioned into boundary and interior contributions:

$$\begin{bmatrix} A_{bb} & A_{bI} \\ A_{Ib} & A_{II} \end{bmatrix} \begin{Bmatrix} \Phi'_b \\ \Phi'_I \end{Bmatrix} = - \begin{bmatrix} A'_{bb} & A'_{bI} \\ A'_{Ib} & A'_{II} \end{bmatrix} \begin{Bmatrix} \Phi_b \\ \Phi_I \end{Bmatrix} + \begin{bmatrix} B_{bb} & 0 \\ 0 & 0 \end{bmatrix} \begin{Bmatrix} J'_b \\ 0 \end{Bmatrix} \quad (15)$$

Fig. 2 Representative images obtained from an agar study involving systematic variations in inclusion contrast, size, and depth. From left to right across each row: photograph of the experimental phantom agar setups; absolute conductivity image at 125 kHz using trigonometric patterns; difference conductivity image using trigonometric patterns; absolute conductivity image using RST patterns; and difference conductivity image using RST patterns. The inclusion in the second row is 2 cm from the edge of the agar, whereas the inclusions in the third and fourth rows are 1 cm from the edge.

An important part of EIT image reconstruction is electrode modeling^[25] because the discrete finite size of the electrodes utilized in practical imaging influences the measured potentials and currents. The framework for electrode modeling is readily developed on finite elements starting from the weighted residual weak form given in Eq. 12. As a two-dimensional example, a finite-length electrode might consist of three connected nodes along a small portion of the boundary. In voltage mode, the potential is specified at the electrode; hence, Eq. 12 for i corresponding to the three boundary nodes composing the electrode are removed from the algebraic system in Eq. 13 in favor of the known potential that is uniform across the electrode. These three Galerkin equations contain the relationships for computing the corresponding current, which is compared to the

measured value during the image reconstruction process. To obtain the current, these Galerkin equations are summed over the electrode nodes after the solution for Φ is computed, subject to the potential boundary conditions on the electrode:

$$\begin{aligned} \sum_{i=1}^3 \sum_{j=1}^N \Phi_j \left\langle \sum_{k=1}^M \sigma_k \phi_k \nabla \phi_j \cdot \nabla \phi_i \right\rangle &= \sum_{i=1}^3 \oint J \phi_i ds \\ &= \oint J \sum_{i=1}^3 \phi_i ds = \oint J ds = I \end{aligned} \quad (16)$$

to provide exactly the integrated current density along the electrode length (because $\sum \phi_i = 1$) which produces the value of interest. In Eq. 16, i runs from 1 to 3, which

Fig. 3 Graph of minimum discernable width (MDW) as a function of depth for various contrast inclusions embedded in (1X) agar. The graph is based on conductivity difference images at 50 kHz.

represent local node numbers spanning the three nodes that compose the electrode in this illustrative example.

In current mode, the summation in Eq. 16 is performed; however, this single Galerkin equation is retained in the matrix system for the unknown potential within the imaging region and is located on the row associated with a preselected nodal position for the electrode, i.e., the center node, locally numbered 2 in this example. The right-hand side of Eq. 16 is the driving current supplied by the hardware system to the electrode that becomes the known boundary condition for this position on the mesh surface. At this point, the matrix system in Eq. 13 is under-determined because two degrees-of-freedom (potential at local nodes 1 and 3) lack corresponding governing equations. Here, the

boundary constraints:

$$\Phi_1 - \Phi_2 = 0 \tag{17a}$$

$$\Phi_3 - \Phi_2 = 0 \tag{17b}$$

are applied that enforce a uniform potential across the electrode and supply the missing relationships needed to close the algebraic system.

Modeling the contact impedance follows similarly through use of a mixed boundary condition:

$$\sigma \nabla \Phi \cdot \hat{n} = J = \alpha(\Phi - V) \tag{18}$$

in which α is an electrode contact-coupling coefficient relating the current density to the voltage drop across

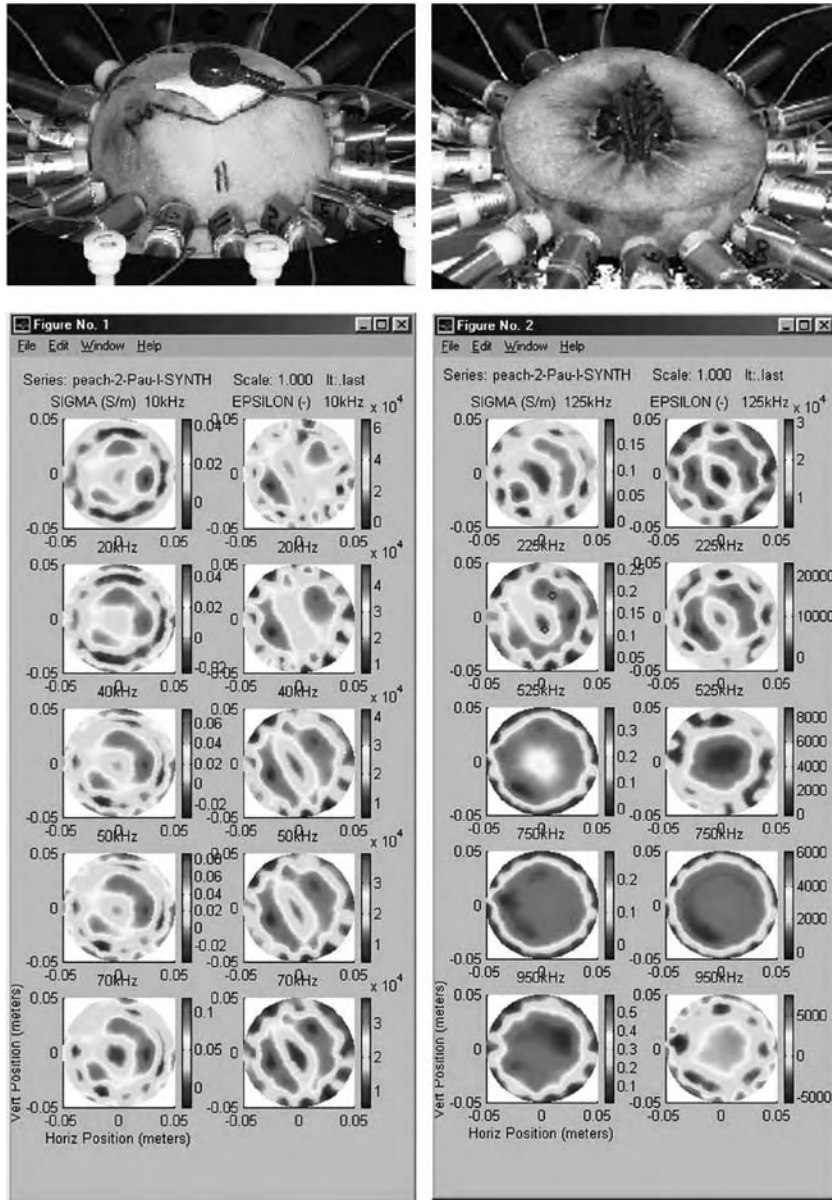

Fig. 4 Photographs of a peach situated in the electrode array during imaging (top, left) and at the end of the experiment after being cut in half (top, right) prior to removal from the array to reveal the orientation of the pit. Corresponding conductivity and permittivity images of the peach from 10–950 kHz using the RST excitation patterns.

the electrode, given V is the voltage recorded at the electrode itself. This condition is substituted into the boundary integral in Eq. 16:

$$\begin{aligned} \sum_{i=1}^3 \oint \alpha(\Phi - v)\phi_i ds &= \oint \alpha\Phi ds - \oint \alpha v ds \\ &= \alpha\Phi L - \alpha VL \end{aligned} \quad (19)$$

in which L is the electrode length. The first term in Eq. 19 is added to the system matrix of unknowns (locally Φ_2 —the potential at the center of the electrode) while the second term becomes the known driving data for the electrode. As in current mode, the missing constraints required to close the algebraic system are Eqs. 17a and 17b, which enforce a uniform potential along the electrode length. Once the potential distribution is calculated, the electrode current is readily computed from Eq. 19.

Note that, if a passive electrode (i.e. no driving current) is utilized in the hardware system configuration, the electrode model still applies. In this case, the right-hand side of Eq. 16 is set to zero, and the constraints in Eqs. 17a and 17b are invoked. The model leads to the situation in which the potential is uniform along the electrode but no current flows out of the system through this portion of the boundary, which are precisely the conditions that occur in practice and are to be emulated in the reconstruction process.

EXAMPLE IMAGES

Typically, prototype EIT instrumentation and concomitant image reconstruction software is evaluated in phantom studies to characterize its performance. A standard benchmark is to image high contrast conductors and insulators of various sizes at a series of depth locations

within a uniform background of either physiological saline or conductive solid agar intended to mimic the electrical properties of typical tissue. Figure 2 shows a series of typical images from a collection of experiments involving various inclusion sizes, locations, and contrasts. Both absolute and difference images are shown with two types of excitation patterns, Trigonometric (trig) and reversed synthesis trigonometric (RST). Standard practice is a complete contrast-detail analysis in which image recovery as a function of the contrast and size of a heterogeneity is investigated. For linear systems, this can be completed without regard to the location of the object. However, in the case of EIT, the response function is nonlinear and spatially dependent. Hence, the quality of the image will depend not only on the size and contrast of a heterogeneity but also on its location.

Figure 3 presents a typical contrast-detail analysis for EIT-based on agar phantoms. It shows the size of an object required for detection that is defined in terms of minimum discernable width (MDW) at a given depth for specific contrast levels. The degradation in depth resolution with EIT is evident. Objects less than 1 cm in diameter were not detectable in absolute EIT images when positioned at the center of a 10-cm diameter agar phantom, even with high contrast. It is also clear from Fig. 3 that the depth resolution of difference images is superior to absolute images.

It is important to recognize that, because agar lacks the cellular membrane structures present in tissue, the permittivity component of impedance is extremely small and not reliably imaged. To generate sufficient capacitance, it is necessary to image organic materials, and a suitable set of candidates for phantoms include fruits and vegetables available from the local market. Figure 4 shows results from a sample experiment using a peach as the object to be interrogated. The images were generated with a 16-electrode array attached to the surface

Fig. 5 In-vivo permittivity image of the upper arm accompanied by anatomical sketch indicating that the expected locations of the humerus bone and triceps and biceps muscle masses appear in the correct positions in the EIT image.

of the peach using EIT instrumentation capable of recording both the signal amplitude and phase. The recovered permittivity images are now meaningful and nicely illustrate the details of the peach anatomy. In this particular experiment, multifrequency data acquisition was employed. Both the conductivity and permittivity images indicate the orientation and location of the pit of the peach over the frequency range of 70 kHz to 225 kHz in which this EIT instrument operation is optimal. Independent measurements of the electrical properties show that the reconstructed images are quantitatively accurate to 20% of the true values across the frequency band illustrated here.

As a final in-vivo example, Fig. 5 shows the permittivity image of the upper arm of a human volunteer. The humerus bone and biceps and triceps muscle masses are evident in the image. These results were generated using a multifrequency EIT device with 16 electrodes operating in voltage mode. The anatomical detail and tissue-type discrimination within this image is encouraging.

CONCLUSION

Electrical impedance tomography uses single or multiple low-frequency signals (below 10 MHz) to probe the body from which electrical property distributions are estimated. The system is based on contact electrode arrays that serve as source and sensing elements during the process. Hardware considerations indicate that voltage sources are easier to produce than current sources and simultaneous measurement of both applied and induced signals is recommended, especially in the multifrequency setting. Costs per channel are relatively modest, which allows high-density two-dimensional and three-dimensional arrays to be developed. DSP-based designs are particularly attractive because of their superior speed and flexibility.

Image reconstruction for EIT is particularly challenging because of the nonlinear relationship between sensed signal change and change in the underlying tissue electrical properties. Iterative methods become essential in this regard and, to date, have yielded the highest image quality. Nonlinear image reconstruction centered around finite element technology is particularly popular, and several codes are available on the Internet. Sample images show that the depth resolution with EIT degrades significantly. However, recovery of distributions of both electrical conductivity and permittivity is clearly possible, provided adequate phase shift can be recorded. In-vivo images of the upper arm demonstrate clear permittivity variation between the humerus bone and the triceps and biceps muscle masses. State-of-the-art in EIT can be understood by consulting a recent special issue journal on the topic.^[7]

Electroactive Polymeric Materials

V. Prasad Shastri

Vanderbilt University, Nashville, Tennessee, U.S.A.

INTRODUCTION

Electroactive materials may be broadly defined as those materials whose bulk or surface properties may be altered reversibly or irreversibly upon exposure to an electrical stimulus. In keeping with the scope of this encyclopedia, only materials that have potential application in drug delivery, biosensing, tissue engineering, and high throughput screening will be discussed. The article is divided into four sections. The first two sections cover conductive and piezoelectric polymers in detail. Electroresponsive gels are discussed briefly in the third section and the last section covers more general topics that are material specific. Electrets are not covered in this article, as examples of these are few and their biomedical applications very limited.

OVERVIEW

Since the early 1980s the application of polymers in biomedical sciences has seen an exponential growth. This growth has been fueled in great part by the demand placed by emerging disciplines, such as drug delivery, tissue engineering, and genetic screening, for novel materials that may be fine-tuned with respect to their bulk and surface characteristics on demand as a function of time. Electroactive materials, by virtue of their ability to predictably respond to electrical stimulus, are therefore ideal candidates.

The role of electrical signals in modulating cellular response is well-recognized.^[1] Among various tissues where bioelectricity plays a role, the nervous system and osseous tissue are the most obvious examples. The neural synapse in essence is a biosensor. An action potential (electrical signal) arriving at the synaptic junction is transmitted across the synapse by depolarization of the adjacent synaptic membrane. This depolarization is triggered by acetylcholine, a biomolecule that is secreted in response to the action potential at the synapse.^[2] Bone is yet another tissue where electrical activity plays an important role in fulfilling its function. In the late 1890s, Wolff demonstrated that the bone responds to mechanical stress by growing.^[3,4] This relationship between applied mechanical stress and bone remodeling (growth) is known as Wolff's Law. It turns out that bone is piezoelectric in

nature. Iwao Yasuda was the first to demonstrate piezoelectricity in bone in the 1950s when he observed that compressive loading along a bone's major axis resulted in the accumulation of electrical charges on the surface along its axis.^[5,6] In a seminal study, Becker and Bassett demonstrated that when bone was mechanically loaded, the concave (bone formation) and convex (bone resorption) faces of bone yielded charges of opposing polarity due to compression and tension at the two respective faces.^[7] Therefore, cellular architecture in bone is able to sense the mechanical stress due to the localized electrical currents generated upon loading of the inorganic hydroxyapatite phase in bone.

Electroactive materials encompass ceramics and plastics that are capable of electro-mechanical and electrochemical transduction. However, two major considerations for biomedical applications are cellular and tissue compatibility and ease of processing. The library of organic chemical bonds and building blocks available for the synthesis of polymers make it a very versatile system capable of satisfying both of the aforementioned requirements. In emerging applications such as tissue engineering (TE), wherein a scaffold is used to guide the generation of neotissue from dissociated mammalian cells, it is plausible that the use of electroactive scaffolds will offer the possibility of manipulating cellular functions and tissue growth in a localized manner via minimally invasive methodologies.

CONDUCTIVE POLYMERS

Ease of processibility and their insulative properties are two important characteristics that distinguish plastics from metals. In the 1970s, Heeger, MacDiarmid, and Shirakawa, demonstrated that polyacetylene, an organic polymer characterized by alternating double bonds (Fig. 1a), can exhibit conductivity approaching that of conductors. Conductivities as high as that of copper (10^6 S/cm) have been reported in polyacetylenes doped with a cation or an anion.^[8,9] Their seminal work, for which they were awarded the 2000 Nobel Prize in Chemistry, led to the birth of an entirely new class of materials and an exciting field called conductive polymers. The origin of conductivity in this interesting class of polymers lies in the high degree of π - π overlap in a conjugated structure, which reduces the band gap

Fig. 1 (a) Chemical structure of oxidized polyacetylene; (b) Chemical structure of oxidized poly(heterocycles).

and facilitates carrier mobility.^[10] Since then several polymers that exhibit a high degree of extended polyconjugation have been shown to possess electrical conductivity in their doped state. They include poly(aniline), poly(heterocycles), poly(*p*-phenylene vinylene) and poly(*p*-phenylene ethynylene).

In 1979, Diaz and coworkers reported the electrochemical synthesis of polypyrrole (Ppy) (Fig. 1b).^[11] With the electrochemical approach, freestanding films of Ppy of varying thickness and crystallinity can be obtained by controlling the passage of current during electrochemical deposition and chemistry of the dopant anion. Three years later, Tourillon and Garnier reported the electrochemical polymerization of poly(thiophene) (Pth) from thiophene.^[12] Electrochemical polymerization offers several advantages over conventional chemical synthesis: 1) Thin films (membranes) of the polymer can be directly deposited on an electrode of interest or surface of a metal implant; and 2) freestanding thin films can be obtained that can then be fabricated into devices. Both Ppy and Pth exhibit reversible electrochemistry, which enables switching of the polymer from the conductive form (oxidized) to the insulator form (neutral) by the application of a small voltage.^[13] Electrical conduction in poly(heterocycles) occur via the interchain hopping and delocalization of radical cations called polarons.^[14] The conductivity in Ppy and Pth is significantly influenced by the crystallinity and long-range order in the polymer, which aids in reducing the conduction band gaps, the latter being more important. Among the various conductive polymers, Ppy and Pth (Fig. 1b) are the most promising for biomedical applications due to ease of their synthesis. However, Ppy is by far the most suited for biosensing and tissue-contacting applications as it can be electrochemically synthesized from aqueous solutions at a relatively low potential of 700 mV versus SEC. Furthermore, its oxidized form is far more stable in both air and water (physiological conditions of pH 7.2 phosphate buffer, 37°C) in comparison to Pth.

Since the mid-1980s Ppy has been extensively studied as an electrochemical transducer for sensing biomolecules in solution.^[15–17] In a Ppy-based biosensor, an oxidative enzyme such as glucose oxidase is entrapped in the film during electrochemical deposition on a platinum or palladium electrode (Fig. 2). When this film is brought into contact with an analyte such as glucose in presence of oxygen, hydrogen peroxide is liberated which is then detected electrochemically at the electrode.^[18–22] The advantage of this system is that it allows for the one-step fabrication of a sensor. However, the slow response time, due to the slow diffusion of hydrogen peroxide through the film to the electrode, and low current densities are limitations. These limitations have been overcome by introducing redox couple mediators, such as ferrocene (Fc) (II) ↔ ferrocinium (Fc⁺) (III), either by coentrapment or by covalent immobilization to the enzyme or polymer, that can act as an electron shunt.^[23–26] In this system, the electron transfer occurs directly from enzyme to the oxidized form of the mediator Fc⁺, yielding Fc which is then followed by cyclic voltammetry. In addition to the Fc ↔ Fc⁺ couple, other charge transfer systems such as tetrathiafulvalene-tetracyanoquinodimethane (TTF-TCNQ)^[27] and 4,4'-bipyridyl mediators have been explored as well.^[28] Polymers bearing such electron mediators are said to be wired and they typically yield sensors with faster response times and higher current densities. Besides enzyme-mediated oxidative reactions, changes in local pH have been leveraged in the development of Ppy-based biosensors. Ppy membrane microarrays containing immobilized penicillinase have been used to detect penicillin by monitoring the increase in Ppy membrane conductivity upon the release of acid at the membrane surface due to enzymatic hydrolysis of the penicillin.^[29] Ppy membranes/films with immobilized oligonucleotides have

Fig. 2 Enzyme-based conductive polymer biosensor: schematic of a Ppy-based glucose sensor containing glucose oxidase and ferrocene as an electron mediator.

been prepared by electrochemical polymerization of pyrroles covalently bound to oligonucleotides.^[30,31] By individually addressing microelectrodes in an array, surfaces bearing a spatially well-defined array of oligonucleotides have been fabricated. Such arrays might be useful in the development of high throughput devices for genomics and proteomics that are amperometric rather than colorimetric, thus increasing reliability and response time. In addition to Ppy, Pth and polyanilines have been explored in glucose-sensing applications.^[32,33]

In the late 1980s, Miller and coworkers demonstrated that a Ppy film doped with a polyanionic dopant poly(styrenesulfonate) sodium (PSS-Na) can behave as a cation exchanger.^[34,35] The immobilization of PSS-Na results in a film that has a net negative charge in its oxidized state. Because these charges are fixed, reduction of the film results in the binding of cations, which can be released upon oxidation of the film. Based on this principle, Miller and co-workers showed that dopamine, a neurotransmitter whose deficiency leads to lesions in the brain such as those found in Parkinson's disease, may be cathodically bound and anodically released from these Ppy films.^[34] Prezyna and co-workers later showed that these films can irreversibly bind polycations such as poly(lysine-HCl) and histones, which are responsible for compacting DNA in the nucleus of a cell.^[36] However, extensive exploration of Ppy films as drug-delivery vehicles has been limited by unpredictability associated with binding and release kinetics and low drug loading levels. These systems, however, are well suited for highly potent drugs and should not be overlooked especially in the delivery of drugs to the central nervous system. Diseases such as epilepsy and Parkinson's could significantly benefit from self-regulating delivery systems wherein the Ppy electrode serves as a biosensor for disease-predictive markers, thereby reducing the drug delivery response time.

Ppy has been explored in TE applications as well. Wong^[37] and Shastri^[38,39] have shown that by varying the dopant ion chemistry and oxidation state of Ppy, protein adsorption and conformation can be altered resulting in control over cell cycle progression. This has sparked an interest in using Ppy in cell and tissue contacting applications as interactive interfaces for dictating cell behavior and enhancing cell functions. In a seminal study demonstrating the potential of Ppy as an electroactive interface in manipulating cellular functions, the effect of applying of an electrical stimulus through a Ppy substrate on PC-12 cell differentiation was studied.^[40] PC-12 cells respond reversibly to soluble nerve growth factor by differentiation into a neuronal phenotype, a process accompanied by extension of neurites (neuronal processes). In this study, PC-12 cells grown on Ppy-PSS-Na

substrates were subjected to an electrical stimulus applied through the polymer film. It was observed that application of a constant potential or current dramatically improved PC-12 differentiation as assessed by an increase in both neurite numbers and lengths. These studies have also shown that tubular scaffolds fabricated from Ppy-PSS-Na can support the guided regeneration of transected sciatic nerve in rats.^[41] Furthermore, it has been shown that the soft-tissue biocompatibility of Ppy film doped with PSS-Na is far superior to that of most commonly used biodegradable polymers such poly(lactic-co-glycolic acid).^[40] The response to Ppy films is characterized by the total absence of a fibrous capsule even after 14 weeks (Fig. 3). Schmidt and co-workers have shown that vascularization around Ppy films can be enhanced by doping the film with polysaccharides.^[42] Ppy-PSS films have been shown to support the proliferation and osteogenic differentiation of mesenchymal progenitor cells (bone marrow stromal cells).^[43] It was observed that the production of alkaline phosphatase, a marker of osteogenic activity in these cells, was enhanced in cells cultured on Ppy-PSS substrates in comparison to those cultured on tissue culture plastic. These observations suggest that Ppy substrates have good cytocompatibility and should be useful as interactive coatings in tissue regeneration paradigms such as TE. One can also envisage the use of Ppy coatings to enhance cellular interactions towards metal implant surfaces.

However, Ppy synthesized from pyrrole or PNpy synthesized from N-methyl pyrrole-yields a highly cross-linked polymer that has low to no solubility in

Fig. 3 Hematoxylin-Eosin-stained histological cross-section of Ppy-PSS (PP)-laminated with a biocompatible poly(L-lactic acid-co-glycolic acid) (PLGA) polymer implanted in a intramuscular site in rat for two weeks. Note the absence of fibrous tissue adjacent to the Ppy film. The gap between the Ppy and PLGA phase is an artifact created during processing of the tissue explant. Reproduced from Ref. [40].

Fig. 4 Degradation characteristics of bioerodible Ppy pellets synthesized from pyrroles substituted in the β -position with ionizable or hydrolyzable side groups (polymer) as followed by dissolution (filled symbols) and mass loss (open symbols). From Ref. [44].

common organic solvents and hence not processible. The cross-linked structure also renders it nondegradable in a biological environment. Imparting degradability in a biological environment should significantly expand the use of Ppy in biomedical uses such as TE and drug delivery. Recently, Shastri and Langer reported the synthesis of conductive bioerodible Ppy from pyrroles substituted in the β -position with ionizable or hydrolyzable side groups.^[44] In this system, by controlling the ratio of the ionizable:hydrolyzable group, polymers with erosion times ranging from a few weeks to potentially over a year may be synthesized (Fig. 4). In addition to being bioerosible, Ppy possessing hydrolyzable groups show excellent solubility in common organic solvents such as tetrahydrofuran and methylene chloride, thus allowing for solution-based processing of these polymers into coatings and scaffolds for cell and tissue contacting applications.

These polymers possess excellent cytocompatibility and have been shown to support the proliferation and differentiation of human marrow-derived mesenchymal progenitor cells into osteoblast lineage.^[44] Another approach that has been explored to synthesize degradable Ppy is the coupling of 2,5-bis-(5-(3-hydroxypropoxycarbonyl)-2-pyrrolyl)thiophene with adipoyl chloride to yield a polymer with degradable ester linkages.^[45] Although this polymer has good tissue compatibility, it has extremely low conductivity which limits its potential use.

PIEZOELECTRIC POLYMERS

The piezoelectric effect was discovered by Jacques and Pierre Curie in the 1880s, when they observed that certain crystalline materials when subjected to tension

or compression became electrically polarized resulting in induced voltages of opposing polarity (compression tension).^[46] They also observed that the magnitude of this polarization was directly proportional to the applied stress. Conversely, minute changes in physical dimensions can be introduced in a piezoelectric material by subjecting it to an electric field. This phenomenon is called converse piezoelectricity. Piezoelectricity therefore may be defined as an electrical polarization induced in a solid in response to a mechanical stress (Figs. 5A and B). In order for a material to exhibit piezoelectric behavior, the crystalline domains (or crystal lattice) should be anisotropic (noncentrosymmetric) and polarizable. A piezoelectric material when heated above its Curie temperature loses its piezoelectric properties permanently. Most common examples of piezoelectric materials include naturally occurring substances such as quartz, polycrystalline ceramics such as barium titanate, lead zirconate titanate, and some inorganic salts (e.g., Rochelle's salt). Examples of synthetic and biological polymers that exhibit some form of piezoelectric behavior include poly(vinylidene difluoride) (PVDF), aromatic polyamides, polysulfones, polyparaxylene, poly(lactic acid), and some biopolymers such as collagen and poly(γ -methyl and γ -benzyl-L-glutamate).

In order to induce piezoelectric behavior in a ceramic or polymer, it first has to be poled in an external electric field. During the poling process, the dipoles in the crystalline regions align to form highly ordered domains resulting in a net dipole moment or polarization. The residual polarization after the electric field

is removed, termed remnant polarization, is responsible for the piezoelectric behavior in the material. The relationship between the induced polarization and applied stress and between the induced strain and applied electrical stimulus is described in terms of coupling constants that relate the two, namely:

d (C/N) = piezoelectric charge constant, the polarization generated by unit mechanical stress or the induced strain per unit electric field;

g (Vm/N) = piezoelectric voltage constant, the electric field generated per unit mechanical stress or the induced strain per applied unit displacement of charge;

C = current in coulombs; N = force in newtons; V = voltage in volts; and m = displacement in meters.

The d and g constants of a piezoelectric material are described using two subscripts, e.g., d_{33} and g_{31} , wherein the first subscript denotes the direction of the induced polarization and the second subscript denotes the direction of the applied stress. The coupling between the induced polarization and the direction of applied stress is described using an X,Y,Z system of notation (Fig. 5C), wherein the Z axis is the direction of the applied external poling field and represents a positive polarization; 1, 2, and 3 represent the stress along X, Y, and Z axes, respectively; and 4, 5, and 6 represent the shear stress about these axes. Therefore, in this system of notation, d_{33} means that the induced polarization is in the direction of the poling (Z axis)

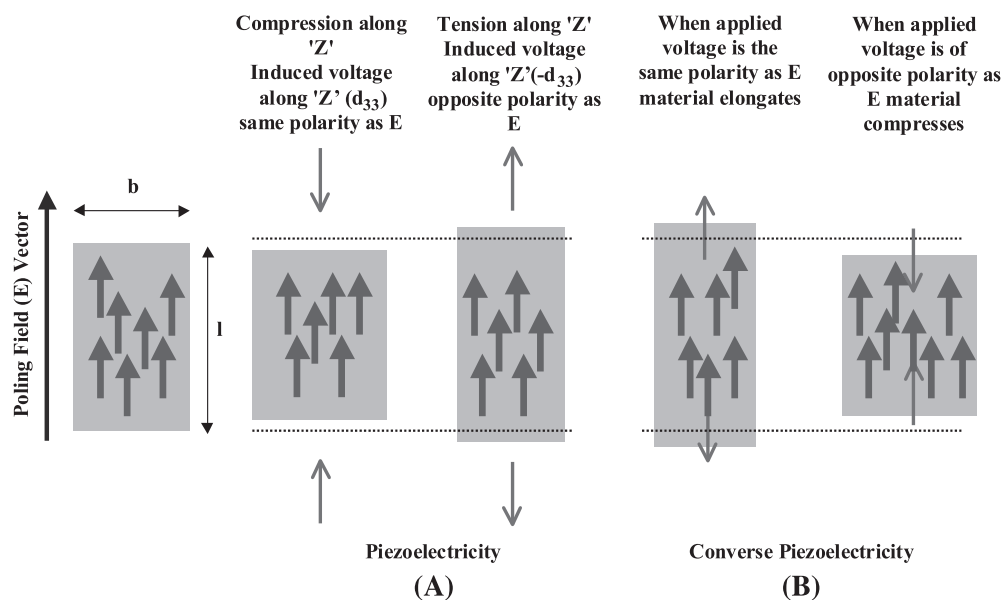

Fig. 5 (A) Schematic representation of the piezoelectric phenomenon in a material when subjected to compressive and tensile stress; (B) Schematic representation of reverse piezoelectric phenomenon in a material when subjected to an external field of the same and opposing polarity as the poling field; (C; see next page) Piezoelectric coupling tensors.

Fig. 5 (Continued)

(positive polarization) when the stress is applied in that same direction. Similarly, d_{25} means the induced polarization is along the Y axis when shear stress is applied along the X-Z plane.

Piezoelectricity in PVDF was discovered by Kawai in 1969.^[47] This discovery was followed by several reports showing that polypeptides and collagen exhibit piezoelectricity when subjected to shear stress.^[48–50] PVDF is a semicrystalline polymer composed of $-\text{CH}_2-\text{CF}_2-$ repeat units that are linked to each other predominantly in the *head-tail* fashion. The presence of the electronegative fluorine atom makes it responsible for the dipole moment of the CF_2 unit.^[51] The crystalline domains, which are responsible for long-range order in the polymer, are structurally anisotropic. The symmetry of the backbone dictates the overall dipole of the unit cell (crystalline domain). The crystalline domains in PVDF exist in four principal forms, called α , β , γ , and δ .^[52] Among these phases, only the β phase exhibits an all-*trans* conformation. This imparts a polar characteristic to this phase due to the alignment of the dipoles, something that is absent in the other phases due to a mixture of *trans*, *gauche*, and anti-*gauche* conformations. However, in the unpoled state, the dipoles cancel each other out due to random orientation of the crystalline domains resulting in a net dipole moment of zero. It has been observed that head-head $-\text{CH}_2-\text{CH}_2-$ and tail-tail $-\text{CF}_2-\text{CF}_2-$ linking of repeat units results in the formation of defects in the crystalline phase of PVDF, a process that favors the formation of the polar β phase.^[52] In fact, copolymers of PVDF with

tri-fluoroethylene (PVDF-TrFE) and tetrafluoroethylene (PVDF-TeFE) yield polymers with predominantly a β -phase backbone. The formation of β phase can also be induced by orienting the polymer chains through mechanical means such as drawing and stretching of fibers and films during extrusion. To impart persistent polarization in PVDF, the polymer is heated below its Curie temperature which is approximately 110°C and then subjected to an external electric field to align the dipoles in the crystalline domains. The polymer is then cooled in the presence of the field to freeze the orientation of the dipoles. The most likely mechanism for the alignment of dipoles based on the kinetic model proposed by Dvey-Aharon involves a 60° rotation of the polymer chain at the grain boundary resulting in the formation of a kink, which then propagates along the polymer chain and into the phase leading to long-range alignment within the phase.^[53] The piezoelectric charge constant, d , for PVDF depends on its configuration (fiber versus film). Films poled across its thickness (Z-axis) show a very strong d_{33} constant of about -30 pC/N and g_{33} constant of around -300 mV-m/N .

Collagen fibrils and other biopolymers exhibit piezoelectric properties when subjected to shear stress. The piezoelectricity in these polymers is thought to originate in the crystalline regions, which are formed when proteins and peptides form ordered structures such as α -helices and β -sheets. Piezoelectricity in these systems is thought to originate in the rotation of the amide bond. The straining of these ordered regions leads to rotation of the polar amide bonds in the backbone, which has a dipole moment of 3.4 debye, resulting in the generation of electrical currents. Biopolymers typically show d_{25} values of a few pC/N . Likewise, in the highly crystalline poly(L-lactic acid) a similar mechanism is presumed to be at play. The d_{25} values in highly oriented films of PLLA can be as large as -10 pC/N .

Among polymers, PVDF, poly(lactic acid), and poly(γ -methyl and γ -benzyl L-glutamate) are the most promising with respect to cell and tissue contacting applications. As discussed earlier, it has been shown that mechanical loading of bone leads to stimulation of bone remodeling and growth.^[5,6] The interplay between mechanical stress and osteoclastic (bone resorption) and osteoblastic (bone formation) activity occurs via the generation of localized electrical charges that in turn trigger cellular activity.^[7] The localized electrical activity is generated by the mechanical deformation of the piezoelectric microcrystalline inorganic hydroxyapatite phase. In addition, collagen fibrils, which are known to exhibit shear piezoelectricity, may play a role as well. The electrical charges generated upon compression and tension-loading in bone are of opposing polarity, which

suggests an intricate coupling between the bone resorption and formation processes through the microcrystalline hydroxyapatite-collagen composite matrix. Orthopaedic metal implants coated with various forms of hydroxyapatite have been shown to enhance new bone formation and integration of the implant.^[54] Whether the observed effect is due to the piezoelectric nature of the coating or due to the calcium-rich surface is still unclear. Similarly, in wound healing, electrical activity at the injury site due to the depolarization of cell membranes is thought to play a role in the migration of cells to the site. Several studies have shown that electromagnetic stimulation can aid in bone and wound healing.^[55–57] Aebischer and coworkers have shown that tubular scaffolds derived from poled PVDF are capable of supporting the regeneration of transected sciatic nerve in rat.^[58,59] They observed that the quality of the regenerated sciatic nerve using poled-PVDF guidance channels was superior to that of controls. They have attributed this outcome to localized electrical stimulation of the regenerating neuronal tissue mass by electrical currents generated as a consequence of minute mechanical deformations of the PVDF conduits. So it is entirely conceivable that, in the near future, scaffolds either composed entirely of or coated with piezoelectric polymers will find uses in wound healing and tissue regenerative applications. One can also envision using these polymers as barrier membranes or microvalves in smart drug delivery systems or artificial pores wherein permeability of the drug across the membrane or through a valve is triggered by an external electric field.

ELECTRO-RESPONSIVE GELS

A hydrogel is a cross-linked network of polymer and imbibed water. When the polymer phase is composed of a polyelectrolyte, the gel is called an ionic gel. If the polyelectrolyte is composed of a weakly ionizable group such as a carboxylic acid, the gel will undergo contraction at pHs below the isoelectric point (pI) of the acid moiety and expansion at pH's above the pI. This phenomenon is due to the ionization of the acid groups at higher pHs that leads to electrostatic repulsion within the gel resulting in an expansion in gel volume.^[60,61]

Pioneering work carried out by Toyochi Tanaka and later by Osada and coworkers have shown that when an ionic gel, irrespective of the nature of the ionizable group, is placed between two electrodes and subjected to a DC field, it undergoes anisotropic contraction with the concomitant expulsion of water. Upon removal of the electric field, the contracted gel expands by taking up water and returning to its resting volume. This results in the conversion of electrical

energy into mechanical strain.^[62,63] The basis for this deformation lies in the electrophoretic redistribution of ions within the cross-linked network. For example, in a cross-linked poly(acrylic acid) gel, because the carboxylic acid groups (negative charges) are fixed to the polymer backbone, upon the application of an electric field the positively charged counterions being mobile migrate toward the cathode. This migration of counterions is accompanied by expulsion of water resulting in shrinkage of the gel at the anode.^[64,65] The converse is true for a positively charged cross-linked network. Interestingly, when a weak polyelectrolyte gel such as poly(acrylic acid) gel is subjected to a mechanical stress, the pH in the local environment changes in response to this stress.^[66] This is thought to occur due to the elongation of polymer chains in response to the stress, resulting in an increase in free energy, which is compensated by ionization of the acid groups to yield protons. It has also been shown that, by a process akin to piezoelectric behavior, mechanical deformation of a weak polyelectrolyte gel can induce an electrical potential. Osada and co-workers have explored this phenomenon to develop tactile sensors that may find uses in robotic devices in remote surgery applications.^[66]

When a swollen cross-linked polyelectrolyte gel is exposed to a surfactant bearing opposite charge, the charges in the network are quenched leading to deswelling of the network. In the presence of an electric field, the de-swelling behavior can yield anisotropic stress within a gel film or fiber, resulting in bending of the gel toward one of the electrodes with concomitant mechanical motion. The gel-bending phenomenon has been leveraged to make a hydrogel-based device called the gel looper that is capable of moving in an electric field.^[67] Such smart polymer gels are bound to find applications in drug delivery and tissue engineering as these systems get more integrated with microelectromechanical system (MEMS)-based devices.

OTHER SYSTEMS

Matrices composed of a complex (salt) of polyelectrolytes of opposing charges have been explored as electroerodible systems for the release of proteins.^[68] The drug delivery matrix which in essence is a polymer complex can be made to dissociate upon exposure to an electrical potential in aqueous media. The dissociation originates at the face, opposing the counter electrode, and proceeds inward towards the working electrode. Although this system has its limitations with respect to ease of use and thickness of the delivery matrix, truly responsive drug delivery can nevertheless be achieved. Magnetite is an oxide of iron with a chemical composition of Fe_3O_4 wherein iron exists in

both +2 and +3 oxidation states ($\text{Fe}_3\text{O}_4 = \text{FeO} + \text{Fe}_2\text{O}_3$). Due to the mixed valence state of iron, magnetite has unpaired electrons, hence a net dipole moment, making it ferromagnetic. Ferrofluid is a dispersion of magnetite colloids (nanoparticles) in a hydrophobic medium such as silicone oil. When a ferrofluid is exposed to an external magnetic field, the magnetite nanoparticles become magnetized and align along the magnetic lines of force. This results in a physical transformation of the suspension from a liquid to a solid. Upon removal of the field the solidification is reversed. Ferrofluids can also be made from cobalt, zinc, and manganese oxides. However, magnetite is the most promising with respect to biological applications. One can envisage many applications for ferrofluids in medicine. Some obvious ones are localization media for drug delivery, plugs for coronary embolism, electroresponsive valves in implantable drug delivery systems, and implantable muscle actuators. However, as currently available, ferrofluids are not biocompatible; hence methodologies to improve biocompatibility of magnetite need to be worked out and alternative media for dispersion and delivery of the nanoparticles need to be developed. Iron oxide nanoparticles are already used in cell sorting and are being explored in cell and tissue imaging. Nevertheless, efforts are already underway to explore this system in localization of chemotherapy.^[69] Other *ex vivo* applications may include carriers for cell sorting, valves in bio-MEMS devices for high throughput applications, cuffs to prevent vascular embolism, and a battlefield tourniquet. As we gain a better understanding of biomolecular processes, the newly acquired knowledge has enabled us manipulate materials using the very tools of nature.^[70] The advent of biomolecular materials engineering as a science and discipline holds immense promise for the future, wherein medical devices are fully integrated with the human body via smart materials and interfaces that can respond to external stimuli such as an electrical signal to deliver drugs on demand^[71] or to change a fate of a cell^[37,40] or an implant surface^[72] to improve clinical outcomes.

Electrocardiography

Soumyadipta Acharya
Bruce Taylor

Department of Biomedical Engineering, The University of Akron, Akron, Ohio, U.S.A.

INTRODUCTION

The electrocardiogram (ECG or EKG) is a recording of the electrical activity of the heart, as manifested at the surface of the body. This simple noninvasive biomedical signal is a tool of tremendous clinical power, and when used in the proper clinical context, can provide deep insights into the health status of an individual. The material included in this article is intended as a review of some clinical and engineering aspects of the ECG and should not be used as a clinical text.

HISTORICAL PERSPECTIVE OF MODERN ELECTROCARDIOGRAPHY

The discovery that the mechanical activity of the heart was accompanied by an electrical signal was first reported by Kolliker and Mueller in 1856 and Donders in 1872.^[1] These researchers discovered that a frog gastrocnemius muscle and its attached sciatic nerve, when laid over a beating frog heart, would twitch in synchrony with the beating heart. This indicated that some sort of galvanic current was initiated in the frog heart and was sufficient to stimulate the sciatic nerve preparation. The first measurements of the time course of the electrical activity were performed by Burdon-Sanderson in 1879^[2] using a current-sampling “rheotome” and a slowly responding galvanometer. The first recordings of the electrical activity were performed by physiologists Marey and Lippmann in 1876^[1] using a device called a capillary electrometer.

Although he most certainly borrowed some of the ideas from his predecessors, Willem Einthoven is generally accepted as the father of electrocardiography, a distinction for which he received the Nobel Prize in 1924. In his physiology laboratory at the University of Leiden, Einthoven developed the string galvanometer, which permitted the first accurate representations of the ECG. Figure 1 is a reconstruction of Einthoven’s laboratory showing the means by which he was able to obtain sufficiently low electrode resistances to permit an accurate presentation of the electrical activity of the heart.

The string galvanometer consisted of a fine quartz fiber, coated with silver and placed in a strong electromagnetic field. A very small current traversing the silvered quartz filament would cause the filament to deflect slightly. The shadow of the deflecting filament was then projected onto a moving photographic surface, thereby producing the familiar ECG.

One problem of early galvanometers, for displaying the ECG, was the requirement that an electric current drive the measuring device. The source for this current was the parameter being measured, which for the beating heart is in the range of 100 mV. Figure 2 shows a simple electric circuit model of how cardiac electrical activity is measured. The voltage at the indicator, V_i , modified from Ohm’s law, is shown in Fig. 2.

The measured voltage as a function of the internal body resistance and the input resistance of the indicator $R_{indicator}$ is given by the following equation.

$$V_i = \frac{V_s R_{indicator}}{R_{body} + R_{indicator}}$$

From this equation, it can be seen that the indicator voltage V_i decreases as the indicator resistance $R_{indicator}$ decreases. In other words, the lower the input resistance of the indicator, the lower the measured voltage. Conversely, the higher the input resistance, the greater the percentage of V_s that can be detected by the indicator. This is an excellent example of insertion error, where the event we are trying to measure is disturbed by our method of measurement. The best way around this problem is to increase the input resistance $R_{indicator}$ of the indicator to the point where $R_{indicator}$ approaches infinity. In that case, V_i will equal V_s .

The development of the vacuum tube triode by Lee De Forest in 1906 and the efforts by General Electric to incorporate the vacuum tube into the electrocardiograph in 1921 provided the means by which the input resistance of the indicator could be increased to very high levels. This then initiated the modern era of practical electrocardiography that continues to this day. The main difference is that the vacuum tube amplifier has been replaced by integrated circuit amplifiers that are smaller, require less power to operate,

Fig. 1 Early measurements of the electrocardiogram required a large electrode surface area that could be achieved with the use of saline-filled buckets into which the appropriate limbs were immersed.

and have higher input resistance. A basic circuit model of a modern indicator method is shown in Fig. 3.

Once high-input-resistance amplifiers came into use in electrocardiography, the large-surface-area electrode requirement of Einthoven's string galvanometer was eliminated and smaller electrodes could be used. Today's electrodes are approximately 1 cm in diameter and are generally disposable.

AN OVERVIEW OF CARDIAC CELLULAR ELECTROPHYSIOLOGY

The cardiac cells, like all other cells in the body, maintain a negative resting membrane potential with respect to their exterior. This electrical polarization is maintained by a number of ionic pumps on the cellular

membrane, which pump the appropriate ions (Na^+ , K^+ , Ca^{++} , Cl^-) in and out in order to maintain the electronegativity of the interior.^[3] Slight perturbations in the resting state can cause a complete reversal of this negativity, due to the opening of many ionic channels that allow the charged ions to move along their gradient. Depolarization of one cell acts as a perturbation for its immediate neighbors, causing them to depolarize also. This process spreads from cell to cell, resulting in a depolarization wave at the macroscopic level. The open ionic channels close down in a few milliseconds, resulting in a cessation of the transient ionic flow along their gradient and causing the membrane potential to return to its resting state. This process is known as repolarization. Depolarization followed by repolarization is the fundamental electrical activity of the heart recorded in the electrocardiogram. However, the question remains: What initiates this depolarization?

The heart consists of localized areas of a special type of cells known as pacemaker cells. Unlike most other cells in the body, these have the property of autorhythmicity; in other words, they spontaneously depolarize at fixed intervals of time. This unique process occurs due to the presence of special types of "leaky" ionic channels on the membranes of these cells. These channels cause the membrane to gradually lose its electronegativity until the membrane potential reaches the threshold necessary for initiation of an action potential. Each spontaneous depolarization of these pacemaker cells acts as a source for initiating one complete cardiac cycle.

A recording of this wave of depolarization and repolarization using electrodes placed on the exterior of the cell looks quite different from the action potential as recorded by intracellular electrodes. Figure 4 shows a step by step recording of a wave of depolarization followed by repolarization. Note that there is no voltage difference between the two electrodes when the membrane is either fully depolarized or fully repolarized. The ECG is actually a similar recording of the depolarization and repolarization waves of the heart as measured at the surface of the body.

Fig. 2 A simple electrical circuit model of the heart (cardiac source), internal body resistance, and indicator.

Fig. 3 A basic circuit diagram of a voltage indicator, coupled with an integrated circuit (IC) amplifier that has a very high input resistance and a corresponding input current requirement approaching zero.

THE COMPONENTS OF THE NORMAL ECG

The heart is composed primarily of two types of tissues: the contractile myocardial muscles, which allow a wave of depolarization to pass slowly through them, and the specialized conducting and pacemaker tissues, which allow a rapid conduction of the depolarization wave.^[4,5] Figure 5 shows a cross-section of the heart, illustrating the specialized conducting pathways. The depolarization activity is rapidly propagated along these specialized pathways to the adjoining myocardium.

The ECG is a measurement of the mean, instantaneous, electrical vector of the heart resulting from electrical activity traversing the myocardium. Figure 6 depicts a typical ECG showing the P, Q, R, S, and T waves and some standard durations and segments.

Fig. 4 The appearance of the action potential depends on how it is measured. Part (a) shows the result of placing a microelectrode inside (intracellular) the active cell. In this instance, the depolarization wave—a section of intracellular positive charge (shaded area)—passes the recording electrode, causing a monophasic action potential. A biphasic action potential (b) is produced if the recording electrodes are placed on or near the surface of the active cells.

Atrial Depolarization and the P Wave

The sino-atrial (SA) node, located on the right atrium, acts as the normal pacemaker of the heart.^[4] Though the normal heart rate is 72 beats per minute, the rate at which the SA node fires can vary greatly depending upon modulation by the autonomic nervous system. Each spontaneous firing of the SA node results in a wave of depolarization spreading out across the atria. This depolarization is preferentially conducted via the three specialized atrial tracts. This event is reflected in the ECG as the P wave. Normally, the P wave can have varied shapes, from rounded to sharply peaked. Normal amplitude of the P wave varies from 0 to 0.3 mV and the normal duration is up to 0.1 seconds.^[6]

Atrio-Ventricular Delay

The wave of depolarization can normally move from the atrium to the ventricle only through the atrio-ventricular (AV) node, located at the base of the interventricular septum between the atria and ventricles.^[4] The speed of conduction through the AV node is very slow, resulting in an AV delay. This allows the atria to fully contract and empty the contents into the ventricles before the onset of ventricular contraction. Like the SA node, the AV node is modulated by the autonomic nervous system, resulting in variations in the delay. The P-R interval in the ECG is the total time between the onset of atrial depolarization to the onset of ventricular depolarization. The normal P R interval can vary between 0.12 and 0.2 seconds.^[6]

Ventricular Depolarization and the QRS Complex

After the delay at the AV node, the depolarization wave passes to the AV bundle (also known as the Bundle of His) and from there along the septum to the left and right bundle branches. The left bundle branch has two main divisions, the anterior and the posterior fascicles. Eventually, after successive branching, they terminate on the network of Purkinje fibers, which connect to the ventricular myocardium.^[4,5] Due to the

Fig. 5 Depiction of the conduction pathways of the heart. (Reprinted with permission, Biophysical Measurement Series: Electrocardiography by Charles A. Rawlings. SpaceLabs, Inc. 1991.)

presence of this elaborate conducting pathway, the depolarization wave passes very rapidly through the ventricles and is reflected in the ECG as the QRS complex. The Q wave is defined as the first downward deflection and is normally absent in most leads of the ECG. The R wave is the first positive deflection (with or without the Q wave) and the S wave is the negative deflection immediately following the R wave. Both the R and the S wave can vary greatly in amplitude, normally between 0 and 2.8 mV (R wave) and 0 to 0.8 mV (S wave).^[6] The normal QRS duration is between 0.05 and 0.1 seconds.^[6] Occasionally, in some conditions, there is a second upward deflection known as the R' (R prime) wave and a second downward deflection after the R' wave, known as the S' (S prime) wave.

Ventricular Repolarization and the T Wave

The T wave is a manifestation of ventricular repolarization. In most leads, the T wave is an upward deflection in the range of 0 to 0.8 mV with a duration of 0.1 to 0.25 seconds.^[6]

Atrial Repolarization

The atrial repolarization wave is normally not seen in the ECG because it coincides with and is obscured by the electrically dominant QRS complex.

The S-T Segment

This is a flat segment from the end of the QRS complex to the beginning of the T wave. Normally this segment is isoelectric with the P-R segment. Baseline elevation or depression of this segment with respect to the P-R segment can be manifestations of cardiac disease (discussed later).

Fig. 6 One cycle of a typical ECG showing P, Q, R, S, and T waves with segments and intervals.

The U Wave

The U wave is a rare occurrence in some ECGs immediately after the T wave, with a similar shape and size but an amplitude that is 5 to 20% of the T wave. It is believed to be caused by the repolarization of the papillary muscles.^[4]

RELATIONSHIP BETWEEN THE ECG AND THE MECHANICAL ACTIVITY OF THE HEART

Depolarization of the myocardial muscle membrane is immediately followed by release of calcium ions into the cells. This is responsible for a complex process known as excitation contraction coupling, resulting in contraction of the myocardial muscle fibers. Figure 7 shows the output from a representation by a simulation based on a circulatory system model modified from a representation by Rideout.^[7] The figure shows the temporal relationships among ECG, left atrial pressure (LAP), left ventricular pressure (LVP), and aortic pressure (AoP) through three beats of the cardiac cycle.

1. The P wave reflects the electrical activity that precedes contraction of the atria. Following this event, the atria contract, increasing LAP and giving the ventricles a final filling “kick” just before contraction of the ventricles. The pressure in the ventricle rises only slightly as a result of the atrial activity because the ventricles, which are still in diastole, are still very compliant.
2. The QRS complex reflects the electrical activity that precedes contraction of the ventricles. Following this event, the ventricles begin to contract (the beginning of ventricular systole), causing a rapid rise in intraventricular pressure. When the intraventricular pressure exceeds the aortic pressure (this is the diastolic pressure of approximately 80 mm Hg in the normal human), the aortic valve opens permitting ejection of the ventricular blood into the aorta. The AoP then follows the LVP through its peak (this is the systolic pressure of approximately 120 mm Hg in the normal human). The systolic pressure of 120 mm Hg and diastolic pressure of 80 mm Hg are the basis for normal human blood pressure to be given as 120/80.
3. The T wave reflects repolarization of the ventricles. Following this event, the ventricles begin to relax (initiation of ventricular diastole) and the AoP also falls, following the ventricular pressure. When the ventricular pressure decreases to a point below the AoP, the aortic valve closes and LVP decreases rapidly toward zero. Aortic Pressure then decreases gradually as a result of arterial runoff as the arterial blood perfuses the rest of the body.

Fig. 7 The output of a circulatory system model showing the relationships among the ECG, left atrial (LAP), left ventricular (LVP), and aortic (AoP) pressures. In this model, the systolic pressure is approximately 120 mm Hg and the diastolic pressure is approximately 75 mm Hg.

4. The time interval between successive R waves, the R-R interval, can be used to estimate the heart rate (HR) where $HR \text{ (beats/min)} = 60 \text{ (seconds per min)} / R\text{-R interval (seconds)}$.

It is important to note here that the electrical activity always precedes the associated mechanical activity. Also note that the repolarization of the atria is associated with an atrial T wave or “T of P”; however, this signal is obscured by the ventricular QRS and is rarely discussed in the literature.

THE 12 LEADS OF THE ECG: DIFFERENT VIEWS OF THE SAME EVENT

Figure 8 shows a three-dimensional object whose shadows look different when light is projected on it from different angles. Similarly, the ECG is a recording of the mean three-dimensional electrical vector of the heart. However, the same event can have different representations, depending on the angle from which this activity is viewed. The standard 12 leads of the ECG “see” the heart from different angles and therefore carry unique information about some particular region of the heart not viewed by the others.

Placement of Electrodes

Electrodes are placed on both the wrists and the ankles and form the basis for the six limb leads that represent

Fig. 8 Flashlights illuminating a three-dimensional-object create different-appearing shadows.

the vertical (frontal) plane. The standard bipolar limb leads (I, II, and III) measure the difference in potential between two limbs.^[4] The augmented unipolar leads (aVL, aVR, and aVF) are measurements between one limb and two of the others.^[4] This configuration increases the size of the potentials by 50% and therefore they are called “augmented” leads. Six more electrodes are placed across the chest wall (Table 1) to form the basis for the precordial leads, V1–V6. These view the heart in the horizontal plane. The different leads are created by a unique combination of the measuring electrodes as shown in Table 2. The particular angles of orientation of the different leads are depicted in Fig. 9.

MEASUREMENT OF THE ECG

With today’s modern instrumentation, the ECG is one of the easier physiological parameters to detect. At the surface of the body, the ECG is an electrical signal in the range of ± 1 mV with a maximum frequency content of approximately 125 Hz in the human. To detect this signal, it is necessary to amplify it by

Table 1 Placement of chest electrodes

Precordial electrodes	Placement on the chest wall
V1	Right 4th intercostal space, right of sternum
V2	Left 4th intercostal space, left of sternum
V3	Midway between V2 and V4
V4	Left 5th intercostal space, midclavicular line
V5	Midway between V4 and V6
V6	Left 5th intercostal space, midaxillary line

approximately $1000 \times$ with a frequency bandwidth requirement of 0 (sometimes referred to as DC for direct current, i.e., nonoscillatory) to 125 Hz. Surface electrodes provide the necessary coupling of the instrumentation with the body. The electrodes are generally made from chlorided silver with NaCl paste to provide electrical conductivity.

This electrode/electrolyte interface carries with it a half-cell potential of approximately 700 mV. Because this value is some 700 times greater than the magnitude of the event we are attempting to measure, some special precautions must be taken. To eliminate this electrode offset potential, a difference amplifier

Fig. 9 Twelve leads of the ECG. (Different views of the same electrical vector.)

(also called a differential amplifier) must be used. Because the difference amplifier amplifies the difference between two input quantities, the electrode potentials, if equal in magnitude and phase, will cancel each other out. In reality, however, small differences in the surface characteristics—such as motion artifact—will cause wild swings of the amplified signal.

One means to reduce this effect is to limit the low-frequency cutoff to 0.05 Hz rather than DC. This will eliminate the very-low-frequency changes that accompany electrode artifacts. The useful frequency range of the difference amplifier should therefore be 0.05 to 125 Hz to obtain a high-fidelity recording of the ECG. Without a DC component, the average value of the ECG will be centered at 0/V.

Another important advantage of the difference amplifier is the rejection of common mode inputs such as 60 and 120 Hz noise from the surrounding environment. With battery-powered equipment this periodic noise is not a problem, but if the equipment is powered by the 120-V AC line voltage, as is generally the case, 60 and 120 Hz noise can be a formidable adversary to the equipment designer. Commercial instrumentation amplifiers with common mode rejection ratios (CMRR) of > 100 db are readily available and provide a good rejection of 60 and 120 Hz noise.

ECG Paper

The conventional recording devices plot the ECG onto a special paper strip that has major gridlines (5 mm) and minor gridlines (1 mm). In the horizontal axis (time), each 1 mm represents 0.04 sec and each 5 mm (major grid) represents 0.2 sec. On the vertical axis (volts), each major gridline represents 0.5 mV.

A PRACTICAL ECG AMPLIFIER

A simple practical ECG amplifier is described in the following section. This amplifier can be built by the nominally capable engineer or experimentalist and can be used to investigate the characteristics of the ECG described elsewhere in this article. Most components—such as resistors, capacitors, controls, and operational amplifiers—can be obtained from your local retail outlet. The special components listed can be purchased over the Internet (URLs given).

Partial Parts List

Special components

- INA114 Instrumentation amplifier (Burr-Brown Corp., www.ti.com).
- ISO122 Isolation amplifier (Burr-Brown Corp., www.ti.com).
- AEE00-12Vin DC/DC converter (Astec, Inc., www.astec.com).

Resistors are all quarter-watt $\pm 5\%$ carbon composition resistors. The two 10 k Ω potentiometers (pots) should have a linear taper and, preferably, be wire-wound multiturn pots, for fine-tuning the amplifier. The circuit can be built using a hobby-type breadboard that is also available at your local retail outlet. It should have a dual 15 V supply used to power the nonisolated side of the amplifier.

The circuit shown in Fig. 10 can be used to demonstrate the principles of ECG monitoring. It will permit a reasonably high-fidelity reproduction of the ECG; however, it should not be used for diagnostic purposes.

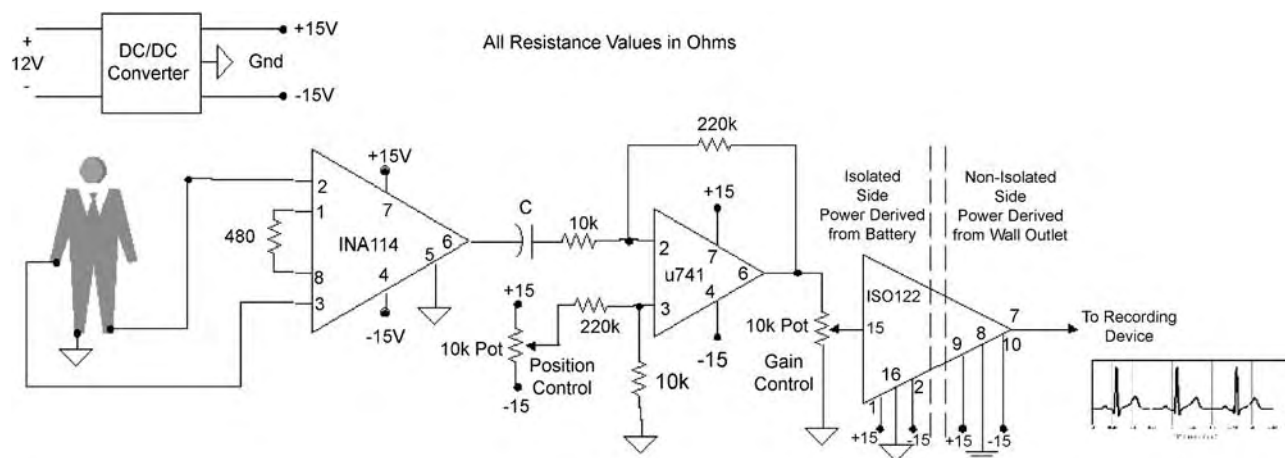

Fig. 10 Circuit diagram for a practical ECG amplifier.

Electrical Safety

The circuit is an electrically isolated circuit that provides a high degree of electrical safety if built properly. The first 2½ stages are powered from a 12 V battery. The DC/DC converter provides the ± 15 V needed to power the components. The INA114 instrumentation amplifier, the $\mu 741$ general purpose operational amplifier (op amp), and the isolated part of the ISO122 isolation amplifier are all powered from this source. The circuit grounds are also all connected to the circuit ground of the DC/DC converter. The output, nonisolated side of the ISO122 isolation amplifier is powered by a separate ± 15 V source whose power is derived from the wall outlet. This isolation method allows the user to connect the ECG amplifier to a subject and connect the output to a display device such as an oscilloscope or computer without fear of compromising the electrical safety of the subject. Under no circumstances should the isolated and nonisolated circuits be wired together. When the device is connected to a subject, there should be no direct connection between the isolated and nonisolated circuitry. *Without this isolation, the subject's electrical safety could be compromised if something were to go wrong or be miswired.*

Circuit Description

The subject is connected to the ECG amplifier using standard ECG disposable electrodes (available from a medical supply outlet, hospital, or urgent care center). The electrodes can be connected to the ECG amplifier using alligator clip leads or snap connectors.

The first stage makes use of the INA114 instrumentation amplifier, which has a differential input, a high CMRR, and a voltage gain of $105 \times$ (using the 480Ω gain resistor). The second stage has a voltage gain of $20 \times$, bringing the total voltage gain to $2310 \times$. The first two stages are coupled through a series capacitance C , whose value should be approximately $318 \mu\text{F}$. This value may be difficult to find, so a smaller capacitor can be used (something in the range of $50 \mu\text{F}$); however, the low-frequency cutoff will be 0.3 Hz, which may eliminate some low-frequency components of the ECG but, for the purposes of this discussion, will not substantially distort the waveform.

To reduce common-mode noise such as 60 Hz interference, the input leads can be twisted together. This will ensure that both inputs of the differential amplifier receive the same noise signal, which will reduce or eliminate this common-mode noise. If needed, a $0.02 \mu\text{F}$ capacitor can be added across the $220 \text{ k}\Omega$ feedback resistor to limit the high-frequency cutoff to 36 Hz, which will reduce 60 Hz noise but may also distort the QRS complex of the ECG.

The last stage uses the ISO122 isolation amplifier to electrically isolate the subject from wall-powered devices such as an oscilloscope or computer. The isolated side is powered from the DC/DC converter, which is connected to the 12 V battery. The nonisolated side is powered from a ± 15 V source whose power is derived from the 120 V AC wall outlet. The rated isolation of the device is 1500 V rms^a and should protect the subject from electrical shock.

To use the device, simply connect three disposable electrodes to the subject. Standard lead II can be obtained using the right arm/left leg leads with the right leg providing circuit ground. Other leads can be selected by moving the location of the electrodes. Standard leads I, II, and III can be used without additional components. The augmented unipolar and precordial leads require a resistor network connected to the input, so it is probably not practical to duplicate those conditions here.

SOME ABNORMALITIES OF THE ECG

The ECG is an invaluable diagnostic, monitoring, and prognostic tool that provides crucial information about numerous pathological states. Presented later is a brief discussion of some. For more detailed information, the reader may refer to any standard textbook on electrocardiography.^[8–10]

Axis Deviation and Hypertrophy

The average direction of the electrical vector of the heart during ventricular depolarization is known as the mean electrical axis. It is defined only in the vertical plane; therefore an estimate of the axis can be made from the shape of the QRS complex in leads I, II, III, aVL, aVF, and aVR. For example, a predominantly positive deflection (R wave) in one of these leads indicates that the mean electrical axis is directed toward that lead. Similarly, a biphasic QRS complex (equal positive and negative deflections) in one of the leads denotes a mean electrical axis that is perpendicular to the direction of that particular lead. Normally, the electrical axis of the heart lies between 0 and 90° . A left-axis deviation commonly occurs in hypertrophy of the left ventricle, which is associated with conditions such as long standing hypertension or aortic valvular diseases. Similarly, a right-axis

^aRMS (or rms) stands for root-mean-square. It is a measure of a sinusoidal voltage (and current) available for power calculations. The line voltage in the home is 120 V_{rms}. The actual peak voltage is 170 V. For a sinusoidal voltage (or current), the rms value is the (peak value)/1.414.

deviation (Fig. 11) may occur in long-standing pulmonary hypertension or severe pulmonary valvular disease. Axis deviation can also occur in conduction defects involving the AV bundle branches. However, in the case of hypertrophy, the amplitude and duration of the QRS complex is increased due to the increased muscle mass, generating more current over a longer period of time.

Heart Blocks

The failure of the AV node to allow normal passage of the depolarization wave from the atria to the ventricles results in varying degrees of "AV block" and can easily be diagnosed from the ECG by looking at the relationship between the P waves and the QRS complexes. In the absence of impulses from the SA node, the AV node itself can act as the pacemaker for the ventricles (but at a rate that is much slower than that at the SA node). In first-degree AV block (Fig. 12a), there is a prolongation of the P-R interval (greater than 0.2 sec). In second-degree AV block (Fig. 12b), some of the atrial depolarization waves fail to cross the AV node resulting in dropped beats. In third-degree or Complete AV block, no depolarization wave is conducted to the ventricles. The atria and the ventricles beat at their own separate rates, resulting in complete dissociation of the P wave and the QRS complexes

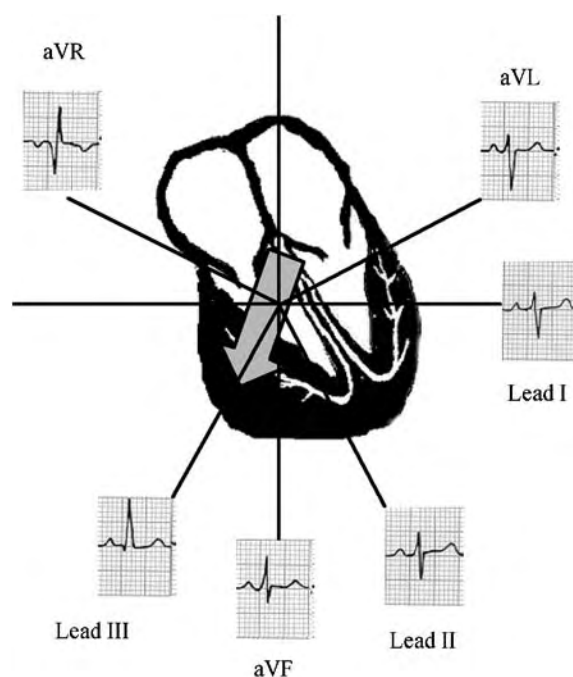

Fig. 11 Right axis deviation caused by right ventricular hypertrophy. Note the predominant R wave in lead III and the biphasic QRS complex in lead II.

Fig. 12 (a) First-degree heart block. Note the prolonged P-R interval. (b) A type of second-degree heart block with a dropped beat. (c) Third-degree heart block, showing complete dissociation of the atrial and ventricular rhythms.

(Fig. 12c). Conduction blocks can also occur in the left or right bundle branches, which are manifested as axis deviations in the ECG. Some of these heart blocks are potentially life threatening and require implantation of a pacemaker.

Arrhythmias

The heart normally beats with a regular rhythm of 60–100 beats per minute, originating at the SA node. Any deviations from the normal rate, rhythm, or site of origin are known as arrhythmias, and are reflected in the ECG. Depolarization waves arising from locations other than the normal pacemaker sites are known as ectopics. Of these, ventricular ectopic beats (resulting in premature ventricular contraction or PVC) are quite common and produce bizarre QRS patterns in the ECG (Fig. 13b). Another common arrhythmia is paroxysmal supraventricular tachycardia (PSVT), characterized by sudden onset premature ventricular beats originating from the atria or AV node and shown in Fig. 13a. These events can be triggered by alcohol or coffee, quite often spontaneously revert back to a regular rhythm, and do not necessarily indicate a cardiac abnormality.

Fibrillation is another type of arrhythmia caused by the coordinated electrical activity being replaced by random and chaotic impulses generated by the myocardium. This results in a loss of contractile activity. Atrial fibrillation (Fig. 14a) is generally not fatal, because the AV node allows the ventricles to continue with their normal coordinated contractile activity. However, ventricular fibrillation (Fig. 14b) is almost always fatal unless a cardio-pulmonary resuscitation or defibrillation is attempted immediately. Fibrillation is usually the end stage of a variety of

Fig. 13 (a) PSVT. The P waves are buried in the QRS complexes and cannot be seen. (b) PVC. Note the bizarre shape of the ventricular ectopic.

cardiac pathologies. In a healthy heart, a strong electric shock can cause ventricular fibrillation.

Myocardial Infarction

A myocardial infarction (commonly known as the heart attack) occurs due to the injury or death of a localized area of the heart resulting from complete occlusion of one or more coronary arteries. Some of the common ECG findings during an infarction are T wave inversion, S-T segment elevation, and appearance of a new Q wave (Fig. 15).

The S-T segment changes occur because the injured or dead myocardial tissue can no longer repolarize, and therefore events before and after the depolarization process are no longer isoelectric. The Q wave occurs because the dead tissue is electrically silent. This results in the electrical vector being directed away from

Fig. 14 (a) Atrial fibrillation. Note the absence of the P waves and an irregular and variable ventricular rate due to sporadic passage of impulses through the AV node. (b) Ventricular fibrillation. Absence of any organized electrical activity of the ventricles and a chaotic and random electrical pattern.

Fig. 15 Some typical ECG changes seen in a myocardial infarction. Note the S-T segment elevation (a, b, c), T wave inversion (c, d), and Q wave (c, d).

the electrodes overlying the dead tissue, causing the strong negative deflection. By examination of the ECG leads in which these changes occur, an estimate of the area of the injury can be made. For example, in an inferior wall infarction these characteristic changes are most pronounced in leads II, III, and aVF (because they “look” at the incident from below), whereas in an anterior wall infarct the changes are more pronounced in the chest leads V1 to V6, depending on the region of the anterior wall involved.

Note that the ECG is always interpreted in the context of the clinical symptoms and other findings, and is seldom used as a stand-alone diagnostic tool.

INTRODUCTION

Clinical use of the electrogastrogram (EGG) by gastroenterologists is increasing rapidly because of the ease, quality, and reliability of the recording methods for detecting normal gastric myoelectrical rhythms and gastric dysrhythmias. Increased knowledge about the relationship between gastric dysrhythmias and nausea is evolving. Novel pharmaceutical agents and electrical pacing of the stomach are exciting new therapeutic areas requiring EGG recordings to detect dysrhythmias, develop rational approaches to therapy, and assess results of treatment. The recent increase in the use of the EGG by gastroenterologists has brought with it refinements in both hardware and software.

BRIEF HISTORY

Electrogastrography refers to the cutaneous recording of the gastric pacesetter potentials or slow waves of the stomach. These waves in a healthy human are three cycles per minute (cpm), but do vary between 1 and 15 cpm, which will be described below. On October 14, 1921, after considerable experimentation with rabbits at the University of California in San Francisco, Walter Alvarez^[1] recorded the first human EGG from an elderly woman with an abdominal wall hernia. The woman was so thin that Alvarez could observe three per minute gastric contractions in the upper abdomen with the naked eye that corresponded to the 3cpm electrical waves that he recorded with cutaneous electrodes. Davis,^[2,3] a psychophysicologist, began a series of exploratory studies with the EGG in the mid-1950s. Davis was primarily interested in the interactive effects of psychological and physiological factors on gastric functioning. During the 1970s, Smout, van der Schee, and their colleagues at the University of Rotterdam and Utrecht conducted several validation studies of the EGG and made major contributions in the area of signal analysis. In their landmark 1980 paper, "What is Measured in Electrogastrography?"^[4] they showed that the amplitude of the EGG increases when

contractions occur. They also initiated the use of running spectral analysis (RSA), a technique for displaying EGG data in the frequency and time domain. Today, RSA is used in many laboratories. In 1985, Koch, Stewart, and Stern^[5] recorded simultaneously the EGG and fluoroscopy of the barium-filled stomach. The correspondence between individual EGG waves and antral peristaltic contractions was observed repeatedly during simultaneous EGG–fluoroscopy recordings (Fig. 1). And an ambulatory unit has flown on Space Shuttle flights in an effort to learn more about the relationship of gastric electrical activity and space motion sickness.^[7]

PHYSIOLOGICAL BASIS OF ELECTROGASTROGRAPHY

The anatomical regions of the stomach are the fundus, the body (corpus), the antrum, and the pyloroduodenal area (Fig. 2). Extrinsic innervation of the stomach is provided by the vagus nerve and splanchnic nerves. The pacemaker region is on the greater curvature of the stomach between the fundus and the corpus. From the pacemaker region, spontaneous electrical depolarization and repolarization occur and generate the myoelectrical waves that are termed the gastric pacesetter potentials or slow waves.

Gastric Pacesetter Potentials and Action Potentials

Important anatomical and functional relationships exist among the circular smooth muscle layer, the myenteric neurons, and the interstitial cells of Cajal (ICCs) (Fig. 2, bottom). The ICCs are the pacemaker cells, the cells that spontaneously depolarize and repolarize and set the myoelectrical rhythmicity of the stomach and other areas of the gastrointestinal tract. The interstitial cells are electrically coupled with the circular muscle cells. Low-amplitude rhythmic circular contractions occur at the pacemaker rhythm.

Fig. 1 Simultaneous EGG recording and fluoroscopic imaging of the barium-filled stomach in a healthy subject. Each EGG wave (A and B) correlated with a gastric peristaltic contraction (see radiographic frames 1–4 and 5–7). The small black arrow indicates the migrating peristaltic contraction. Each of the peristaltic waves emptied an aliquot of barium into the duodenum (see frames 3 and 7). These electrocontractile waves are examples of “antral systole.” *One EGG electrode. (From Ref. [6].)

Rhythmicity and contractility of the circular muscle layer are modulated by ongoing excitatory and inhibitory activity of myenteric neurons that synapse with the interstitial cells. The interstitial cells have a variety of other receptors. Electrocontractile activities of the gastric smooth muscle are modified by neuronal and hormonal inputs appropriate for fasting and specific postprandial conditions. Control of rhythmicity may be modulated by a variety of stimuli that affect the interstitial cells and is a focus of intense investigation. For more information about the ICC and the electrical rhythmicity of the stomach, see chapter 2 in Ref. [6].

A human gastric slow wave or pacesetter potential activity generated by the ICCs occurs at a rate of 3 cpm. Electrodes sewn onto the serosa of the stomach record the depolarization and repolarization waves of the pacesetter potentials. The electrical wavefront travels around the circumference of the stomach at a fast rate of speed and migrates slowly toward the antrum at an increasing velocity. As a slow wave disappears in the distal antrum, another slow wave originates in the pacemaker area and begins to migrate toward the antrum approximately every 20 sec. When there is little smooth muscle contractility, these electrical events reflect depolarization and repolarization of the ICCs and some small degree of contractility of the circular muscle cells.

From an *in vivo* electrical viewpoint, the fasting pacesetter potential activity is relatively weak compared with the gastric myoelectrical activity during the postprandial period, when luminal contents and other stimuli augment gastric neuromuscular activity. Human gastric pacesetter potentials migrate around the stomach very quickly and move distally through the antrum in approximately 20 sec resulting in the normal gastric electrical frequency of 3 cpm. It is this moving electrical wavefront that is recorded in the EGG, the gastric myoelectrical activity recorded from electrodes placed onto the surface of the epigastrium. Additional gastric myoelectrical activity occurs when stronger circular muscle contraction occurs (e.g., when vagal efferent activity and release of acetylcholine from the postganglionic cholinergic neurons are elicited in response to ingestion of a meal). Because of the increased gastric myoelectrical activity, the EGG signal during the postprandial peristaltic contractions is generally higher in amplitude in healthy subjects compared with the fasting EGG. Amplitude of the EGG signal may also be affected by the distance of the electrodes from the stomach. These basic gastric myoelectrical activities form the physiological basis for understanding fasting and postprandial EGG patterns recorded in healthy individuals. See chapters 2 and 3 in Ref. [6] for more information about the physiological basis of the EGG.

Fig. 2 Anatomical regions of the stomach. The upper figure shows the fundus, the body, and the antrum of the stomach. The pacemaker region is the origin of gastric pacesetter potential activity. The cutout of the gastric wall shown in the middle portion of the figure depicts the lumen of the stomach, the mucosa, and the muscularis of the stomach wall. The main muscle layers of the stomach are the longitudinal and circular muscle layers, with some contribution by the oblique muscle layer. In the lower portion of the figure, the relationship among the circular muscle layer, the ICCs, and the myenteric neurons of Auerbach's plexus are shown. The ICCs synapse with the circular muscle layer as well as the myenteric neurons. The ICCs are the origin of the electrical rhythmicity that is recorded as the gastric pacesetter potentials. The gastric pacesetter potentials coordinate the frequency and the propagation of the circular smooth muscle contractions. (From Ref. [6].)

RECORDING EGG

Electrogastrograms are recorded by placing electrocardiogram (EKG)-type electrodes on the surface of the epigastrium. The EGG is one of several biological signals that can be recorded from the electrodes on the epigastrium. Some of these signals, such as the EKG,

are much stronger than the EGG. The EGG signal is relatively of low amplitude, ranging from approximately 100 to 500 μV . Thus, the EGG signal must be properly amplified and filtered. To reduce baseline drift and to remove unwanted cardiac and respiratory signals, a 0.016 Hz high-pass filter and a 0.25 Hz low pass filter are used. These filters created a bandpass from

approximately 1 to 15 cpm through which the desired gastric myoelectrical signals pass during the EGG recording.

Equipment

Electrodes

High-quality, fresh, disposable electrodes such as those used for EKG recording are recommended. To minimize artifacts in the EGG recording caused by electrode movement on the skin, it is best to use electrodes that adhere very well to the skin, either disposable or reusable. The size of the electrode surface is not important, but the electrical stability of the electrode is important. The electrodes should show little bias or offset potential because the EGG signal is relatively of low amplitude and low frequency.

Recording equipment

A high-quality recording system is needed to amplify and process the 100–500- μ V EGG signal that ranges from 1.0 to 15.0 cpm. Several medical device companies produce complete EGG recording and analysis systems that include appropriate amplifiers and filters with analog-to-digital boards that digitize the EGG signal for analysis with software. Ambulatory EGG equipment is also available, and data are stored on a RAM card for later analysis. A visual display of the raw EGG signal is very important to select artifact-free EGG signal for visual or computer analysis and interpretation.

Recording Procedure

Electrode placement

EGGs are obtained with electrodes arranged for bipolar recordings. Electrodes are placed on the skin surface of the epigastrium over the general area of the corpus and antrum of the stomach. A reference electrode is positioned on the right side of the patient's abdomen. One active electrode should be placed approximately 10 cm cephalad from the umbilicus and 6 cm to the patient's left. It is important to place this electrode below and not on the lowest rib to avoid respiratory signals. The second active electrode should be placed approximately 4 cm above the umbilicus (midway between the umbilicus and xiphoid) on the midline of the abdomen. The reference electrode is placed 10–15 cm to the right of the midline electrode, usually along the midclavicular line and 2–3 cm below the lowest anterior rib on the right side. The recording

sites selected will depend on the nature of the EGG signal desired. From our experience, the electrode locations described above will provide the largest possible amplitude and least artifact in EGGs from most patients. The exact placement of the electrodes is not important if the frequency of the EGG signal is what is of interest.

We have sometimes recorded from two abdominal sites simultaneously and have chosen the more artifact-free channel for analysis and interpretation. Chen et al. have recorded multichannel EGGs, using four active electrodes and a common reference electrode, and reported detecting gastric slow wave propagation^[8] and quantifying the degree of slow wave coupling in normals and patient groups such as individuals with systemic sclerosis.^[9] Single channel EGG recording is usually sufficient for diagnosing gastric dysrhythmias in patients.

The EGG can be recorded from the patient's wrists, but the amplitude will be low compared to recordings from the abdomen because the wrist electrodes are far from the source of the signal, i.e., the gastric pacemaker in the corpus-antrum.^[10] On the other hand, wrist electrodes are recommended when recording from obese patients to minimize the fat layer under the electrodes, which acts as an insulator and decreases the amplitude of the EGG signal. The patient's girth may also affect the amplitude of the EGG signal.

Procedure

Patients should be instructed what and when to eat prior to an EGG recording session because the contents of the stomach will affect gastric neuromuscular activity and hence EGG activity. For our research studies, subjects are instructed to fast for at least four hours prior to the experimental session. For our clinical studies, patients fast after midnight, and then ingest a 200 kcal breakfast of two pieces of toast and 4 oz. of apple juice two hours prior to the EGG test. By controlling the pretest meal, a more standardized baseline EGG is obtained prior to provocative testing.

Prior to the attachment of electrodes, the patient's skin must be prepared by shaving excess hair, gently abrading the skin, and cleaning the area with alcohol to lower electrical resistance and achieve optimal electrode–skin interface. This is a very important part of the EGG recording procedure. If the electrical resistance between the electrode and skin is high, then the EGG signal amplitude will be decreased and artifacts may increase in the signal.

The best EGG recordings will be obtained if the patient reclines about 30° in a comfortable chair. The patient should be instructed to minimize talking and movement during EGG recording to prevent

movement artifacts. If possible, the patient should be in a quiet room separated by some distance from the person doing the testing. Loud noises, crying children, and other stimuli that might disturb the patient and the EGG recording should be avoided. If ambulatory EGG records are desired, then Fetrodes (UFI, Morro Bay, California, U.S.A.) should be used. Fetrodes are miniature preamplifiers that are attached to the electrodes, and they reduce movement artifacts. For more details about the procedure used to record EGG, see chapter 4 in Ref. [6].

ANALYSIS OF THE EGG

The analysis of EGG recordings involves an initial visual inspection of the signal to assess the quality of the signal, identification of artifacts, and selection of the minutes of EGG signal for the computer to analyze. The sections below describe the procedures used to analyze the EGG for clinical and research studies.

Visual Analysis of EGG Signal

All raw EGG recordings should be visually inspected to identify 3-cpm signals, gastric dysrhythmias, and any artifacts in the signal. Certain characteristics of the EGG and qualitative judgments can be made from visual inspection of an EGG record. Artifact-free minutes of the EGG signal must be selected for analysis.

Computer Analysis of the EGG Signal

There are three steps involved in the computer-aided quantitative analysis of the EGG:

1. The EGG recording is filtered digitally to remove unwanted frequencies such as 0.5-cpm ultra-slow drift, respiratory, and cardiac rhythms.
2. A spectral analysis is performed on the selected artifact-free minutes of EGG signal to quantify the different frequencies of interest in the signal.
3. Specific EGG parameters such as percentage distribution of EGG power are calculated.

Filters and the EGG signal

To record a high-quality EGG, myoelectrical activity that occurs at lower or higher frequencies must be filtered out. These filters reduce baseline drift and eliminate most respiratory and cardiac rhythms. Using a 0.016-Hz (~ 1 cpm) high-pass filter and a 0.25-Hz

(15 cpm) low pass filter, a bandpass from 1 to 15 cpm is achieved. The bandpass filter described above allows only frequencies between 1 and 15 cpm to reach the amplifier. The frequencies of interest from the stomach and duodenum are within the 1–15 cpm range: bradygastria (1–2.4 cpm), normal range (2.5–3.7 cpm), tachygastria (3.75–10.0 cpm), and duodenal/respiration (11–15 cpm).

Adaptive filtering

In adaptive filtering, a separate reference signal is used as an error signal or noise, which is subtracted from the primary signal of interest. For further discussion of adaptive filtering, see Ref. [11].

Spectral analysis of the EGG signal

Fourier analysis and RSA are used to determine the frequencies present in the EGG signal.^[12]

Fourier analysis

In the fast-Fourier transform (FFT) analysis of EGG recordings, the power in the bradygastria, normal, tachygastria, and duodenal/respiration ranges is determined. The percentage of the EGG power from 1 to 15 cpm in each of the four relevant frequency ranges is also expressed as the percentage distribution of EGG power. Ratios of the power can be calculated to indicate the changes within a frequency band of interest before and after a test meal or stimulus. The power value itself can also be used as a quantitative measure.

Running spectral analysis

Van der Schee, Smout, and Grashuis^[13] described modifications of the spectral analysis method—the RSA—to quantify frequencies in the EGG signal. The RSA is of interest because it provides EGG frequency and power information over time, whereas, the FFT provides only power as a function of frequency. Figs. 3A and 3B show FFTs of two minutes of EGG signal before and after a meal. Fig. 4 shows an RSA of a 15-min baseline EGG followed by 30 min of EGG signal recorded after the subject ingested 550 ml of water. In the RSA, the power of each of the four relevant frequency ranges in the EGG can be seen in the pseudo-three-dimensional (3-D) plot. The clear peaks at 3 cpm in the RSA (B) correspond with the clear 3-cpm waves seen in the rhythm strip.

The mathematical procedures used to convert the raw EGG signal to an RSA and pseudo-3-D are carried out by the proprietary EGG hardware and

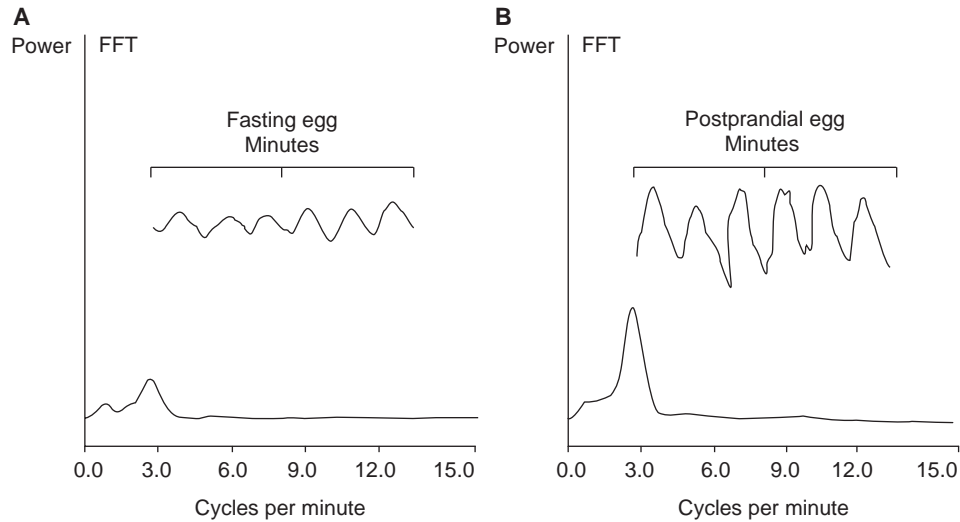

Fig. 3 Two-minute EGG rhythm strips and corresponding FFT recorded from a healthy subject. (A) The EGG recorded during fasting shows a low-amplitude 3-cpm EGG signal. The FFT plot of this signal shows a low-power peak at 3 cpm and (B) the postprandial EGG signal from the same subject after ingesting two pieces of toast and 8 oz. of apple juice shows an increase in amplitude in the 3-cpm EGG waves. The FFT shows a corresponding increase in power at 3 cpm. (From Ref. [6].)

software sold by medical equipment companies, but the first step in any quantification procedure is to insure that quality data are being analyzed. Hence, time must be taken to insure the quality of EGG recordings

before computer analyses are undertaken. The amplifying and recording system should filter out signals below 1.0 cpm and above 15 cpm. With these filter settings the slow rhythms (1.0–2.5 cpm) are recorded

Fig. 4 The RSA is shown with frequency in cpm on the X-axis, time in minutes going from bottom to top on the Y-axis, and power is depicted as the peaks in the Z-axis. During baseline, the subject had low-amplitude 3-cpm EGG waves (see A in EGG rhythm strip). Note the corresponding peaks at 3 cpm in the RSA (A). After 550 ml of water was ingested during the water load test, frequency decreased briefly to approximately 2 cpm, followed by clear 3-cpm peaks of increased power in the RSA (B). The EGG rhythm strip from after water ingestion (B) shows increased amplitude and regularity of 3-cpm activity. Thus, increases in the amplitude of EGG waves are reflected as increases in power in the RSA at that frequency. The frequency ranges of relevance (bradygastria, normal, tachygastria, and duodenal respiration) are shown above the RSA. (From Ref. [6].)

accurately, and the shifts in baseline because of DC potentials that are <0.5 cpm are eliminated. Frequencies higher than 15 cpm are filtered out to avoid contamination of the gastric signal by EKG signals. Respiration signals can obscure the EGG when breathing rates falls near that of tachygastria (3.7–10 cpm) or duodenal slow wave frequencies (12–14 cpm). Removal of respiration signals by setting the low pass filter at 10 cpm or less would also remove duodenal signals. Therefore, a separate respiration tracing is used to select visually and exclude minutes that contain the obvious artifacts related to respiratory rates or movement artifacts.

A/D conversion units typically allow a wide range of sampling rates. For over 20 years we have used 4.267 Hz for our sampling rate because it yields 256 data points per minute, and 256 is a power of 2, a requirement for the spectral analysis we use. Regardless of the analysis method used, we recommend a sampling rate of at least 4 Hz to eliminate the potential for aliasing.^[12] If aliasing is not eliminated prior to computer analysis, some EKG power will be erroneously added to the EGG power. This is referred to as leakage. A high sampling rate for EGG recording such as 4.267 Hz allows complete resolution of all potential frequencies in the EGG signal and thus prevents aliasing.

Once the entire EGG recording has been digitized, the data must be preprocessed to meet the assumptions of FFT analysis. Because the normal 3-cpm frequency in the EGG is a relatively slow frequency, we recommend the analysis of at least four minutes of EGG data. The data are “centered” for spectral analysis around a mean of zero. This is accomplished by subtracting the mean of the data segment from each individual data point. Additionally, the EGG is likely to contain some ultra-slow components (<0.5 cpm) that may reflect a drifting baseline. These ultra-slow components may not be completely filtered out by the bandpass filter. Such extremely low frequency shifts and simple linear trends should be removed. A high-pass digital filter that attenuates frequencies below 0.01 Hz (0.6 cpm) accomplishes the removal of ultra-slow frequency components in the digitized EGG data. One can also remove simple linear trends by fitting a least squares regression line and subtracting it from the data segment. Thus, the analog EGG signal is converted to a digital series of values and placed in a file that is subjected to various quantitative analyses.

After the preprocessing steps for the EGG signal are completed, the data undergo the FFT. Consecutive four-minute EGG data “segments” are overlapped to produce an RSA which displays frequency and power over time. We use a 75% overlap in both clinical and research recordings.^[12] In other words, segment 1

contains minutes 1–4 of EGG data, segment 2 includes minutes 2–5, segment three includes minutes 3–6, etc. Thus, one minute of new EGG signal (e.g., minute 6) is added to the previous three minutes of EGG signal (minutes 3, 4, and 5), thus accomplishing the 75% overlap. An FFT is then performed on each of the overlapped four-minute EGG data segments. These overlapping power spectra are plotted in a pseudo 3-D fashion to determine changes in power at various frequencies over time.

RSAs provide an informative picture of EGG frequency and power changes over time. Electro-gastrogram frequency changes of 60 sec or longer will usually appear as a concordant change at that frequency in the RSA. It should be noted that frequency changes lasting less than 60 sec may not be detected. For such cases adaptive spectral analysis methods are recommended.^[11] Dysrhythmias with a duration more than 60 sec are considered clinically significant and are easily seen in the raw EGG recording and in the RSA.^[13]

Specific EGG Parameters

1. *Percentage distribution of EGG power in the four frequency bands of interest:* The percentage distribution of EGG power in the four relevant frequency bands is the measure that the authors have found most useful in over 20 years of experience in recording and analyzing EGGs in studies involving patients and healthy research participants.^[2–4] The percentage distribution of total EGG power is calculated for each of the frequency bands of interest: bradygastria, normal 3 cpm, tachygastria, and duodenal/respiration. The power estimates for a given frequency range (e.g., the 1–2.5-bradygastria range) are obtained from the spectral analysis. The sum of the bradygastria power for a given time period is divided by the power for the entire frequency range (1–15 cpm) for the same time period, and multiplied by 100%. Thus, the percentage distribution of all the power from 1 to 15 cpm is determined for each of the four relevant frequency ranges: bradygastria, normal, tachygastria, and duodenal/respiration.^[12] The percentage of EGG power in the different frequency bands is altered by provocative stimuli such as the Water Load Test, or a caloric meal, or drug therapy. This measure should not be confused with Percentage of Time with The Dominant Frequency in the Normal (or other) Frequency Bands, which is described below.
2. *Percentage of time with the dominant frequency in the normal (or other) frequency band:* This measure

calculates the percentage of time (within a defined period) that the dominant EGG frequency (the specific frequency with the greatest power as determined by computer analysis) lies within a certain range of frequencies, e.g., 2–4 cpm.^[11] An adaptive filter analysis of the EGG is first computed using one or two minutes of EGG data to construct each power spectrum. A spectrum is considered normal if the dominant (highest) peak lies in the 2–4-cpm range. The percentage of time that the highest peak is in the 2–4-cpm range is determined visually. Thus, if eight one-minute spectra had the highest peak in the 2–4-cpm range in a 10-min period, then the percentage of time the dominant frequency was in the normal range would be 80.

3. *Power ratio:* The EGG activity in the frequency band of interest after a test or therapy is compared with the EGG activity in that same frequency band during the baseline period.^[12] For example, a clinician might calculate the ratio of power in the normal range before and after treatment with a particular drug used to reduce nausea and use the ratio as a measure of improvement. However, an increase in EGG activity in all frequency bands may occur and would make interpretation of the specific ratio difficult.
4. *Dominant frequency and its stability:* The dominant frequency is determined visually by identifying the frequency with the greatest power in the FTT or RSA during a specific time period. Frequencies can change even in healthy subjects. Note that a frequency dip to 1–2 cpm occurs briefly after a meal. Smout, Jebbink, and Samsom^[14] calculated various measures of stability of the dominant frequency and concluded that there was little evidence that either dominant frequency or the stability of the dominant frequency was physiologically related to gastric function.

NORMAL ELECTROGASTROGRAPHIC PATTERNS IN HEALTHY SUBJECTS

Fasting Electrogastrographic Patterns

During prolonged fasting, the stomach and the small intestine proceed through several stereotyped contraction patterns. The clearest 3-cpm EGG signals generally occur during phase I, when there is contractile quiescence, at least as measured by intraluminal pressure catheters. At this time, the 3-cpm EGG activity is the most stable and likely reflects the underlying activity of the ICCs. During phase II, when contractions are irregular, the 3-cpm EGG signal is

unstable. During phase III contractions, 3-cpm EGG waves may show increased amplitude. Thus, increased amplitude of the EGG signal during fasting does not reliably reflect the presence of phase III contractions.

In general, the EGG signal recorded when the stomach was empty is usually a low-amplitude 3-cpm rhythm or unstable signal that may vary from the 3 cpm normal range (2.5–3.7 cpm) to tachygastria (3.7–10.0 cpm) and bradygastria (1.0–2.5 cpm) ranges. For these reasons, investigators have used a variety of meals and drugs to stimulate the fasted or baseline gastric myoelectrical activity. The next section reviews postprandial EGG patterns in healthy individuals.

Postprandial Electrogastrographic Patterns

The stomach must respond appropriately to a vast variety of intraluminal stimuli. In addition, the stomach reacts to visual, olfactory, and gustatory stimuli during the cephalic phase of digestion. The stomach neuromuscular apparatus initially responds to the ingestion of solid foods and liquids with relaxation of the gastric muscular wall of the fundus. The fundus relaxes to receive the volume of food ingested. This important phenomenon is called receptive relaxation.

The relationships between the emptying of barium from the stomach and gastric electrical events recorded from a healthy subject are shown in Fig. 1. The fluoroscopic images of the stomach show that barium suspension is emptied from the corpus antrum into the duodenum by a peristaltic contraction. Sequential radiographs of the stomach during a gastric peristaltic wave are shown in frames 1, 2, 3, and 4. The asterisk indicates EGG recording electrodes positioned on the epigastrium. The small, black arrows indicate a circular muscle contraction that is migrating through the antrum (frames 1 and 2) and begins to empty barium into the duodenal bulb (frames 3 and 4). Electrogastrogram wave A with frames 1–4 was recorded during the progression of the gastric peristaltic wave shown by the radiographs in frames 1 to 4. During the gastric peristaltic wave, the EGG wave peaked (see 2 on EGG wave A) and then the amplitude decreased (see 4 on EGG wave A). Electrogastrogram wave B was recorded during the next gastric peristaltic wave, which is shown in the radiographs in frames 5–7. This peristaltic wave also emptied barium into the duodenal bulb as shown in frame 7. Thus, each gastric peristaltic wave emptied a small aliquot of the barium from the antrum into the duodenal bulb. One EGG wave reflected the myoelectrical activity of a peristaltic wave that migrated from proximal to distal stomach. This sequence repeated itself until the noncaloric barium meal was emptied from the stomach.

The important point is that each EGG wave is a summary of the electrical events that occur during a barium-induced peristaltic wave. The peristaltic wave is the “electrical halo” that is formed as the pacesetter potential linked to plateau or spike potential moves from the corpus to the pylorus beneath the recording electrodes. Thus, the EGG signal as recorded by surface electrodes after a barium meal, a provocative water load test, or a caloric meal reflects the gastric pacesetter potential activity (ICC activity) and the myoelectrical activity associated with circular muscle contraction (action and plateau potentials). These are the electrical events that produce gastric peristalsis, the peristaltic contractions that produce emptying of the barium meal.

CONCLUSIONS

The 3-cpm gastric pacesetter potential is a fundamental electrical phenomenon of the stomach. This low-frequency biorhythm is the basis for normal neuromuscular function of the stomach. In regard to the origins and the various neural and hormonal influences that affect the 3-cpm rhythm, many mysteries remain. Ongoing and future inquiries into the very nature of rhythmicity will provide deeper understanding of gastric myoelectrical activity and the electrical activity detected in the EGG. A delicate balance maintains normal 3-cpm activity. Stomach electrical rhythmicity is rather unstable during fasting, for example, compared with the rhythmic 3-cpm electrical events and contractile events that occur in the postprandial period. What mechanisms produce these fasting and postprandial electrical changes? Are neural or hormonal circuits most critical? Are extrinsic or intrinsic nerves the most important?

Different EGG patterns induced by different meals reflect the different gastric neuromuscular work required to receive, mix, and empty the specific meal. Characteristics of the EGG signal from frequency to amplitude may also correlate with perceptions of stomach activity. Future studies of the EGG may better define these relationships and provide important clues regarding the contribution of the stomach to perceptions of hunger and satiety, perceptions that are important in regard to our understanding of obesity and other eating-related disorders.

Electromyography

Didier Gamet

Odette Fokapu

Laboratory of Biomechanics and Bioengineering, UMR CNRS 6600, Research Center Royallieu, University of Technology of Compiègne, Compiègne, France

INTRODUCTION

Electromyography is the evaluation of muscles based on detection of the muscle's electrical activity (electromyogram or EMG) and its study (EMG signal processing and interpretation of the results). The electrical activity that precedes the muscle contraction is detectable using simple sensors and is painless for the majority of sensors used. In the case of voluntary muscle contractions, study of the EMG signal assesses the correct operation of the motor ways from the motor cortex to the muscle fiber itself. Thus, electromyography is a powerful method used in several investigative domains, including medical research (as functional neurology, gait and posture analysis), rehabilitation (as neurological rehabilitation, physical therapy), ergonomics (as risk prevention), and sports science (as biomechanics, movement analysis, training control).

Understanding of EMG signal composition is based on the anatomic and functional knowledge of the neuromuscular system. Skeletal muscle is made up of a large number of mostly parallel muscle cells called muscle fibers. Each fiber, as with all excitable cells, has electrical activity. However, to understand how an EMG signal is generated from the electrical activity of the muscle fiber, it is important to consider not only the muscle but also the nerve that transmits the motor command. Thus, the neuromuscular system must be considered an association of several functional units, called motor units.

The review is organized as follows: The motor unit is described in the first section. In the second section, genesis of an EMG signal from motor unit activity is presented. Electromyographic signal processing is described in the third section, including EMG detection, signal conditioning and recording, and data processing. At the output of processing chain, the EMG signal may be represented by several graphic models and characterized by several quantifiers in the time and frequency domain. The study of EMG signals and their changes, presented in the fourth section, is valuable to the understanding of physiological phenomena such as muscle fatigue, as well as to the discovery and

diagnosis of abnormalities in nerve and muscle. However, EMG signal study must take into account the test conditions resulting from measurements of other signals (for example, mechanical signals) in order to obtain reliable and repeatable results, as described in the fifth section. Lastly, in the sixth section, some examples of EMG signal changes are described, notably during muscle contraction and after electrical stimulations as used in clinical EMG.

MOTOR UNIT (MU)

The MU is the functional unit of the muscle (Fig. 1A). The MU is defined as the association of a motoneuron α (nervous cell) and the muscle fibers it innervates.^[1] The MU has the ability to contract itself (motor action or contraction) following a driving order (neuronal excitation) because of excitation–contraction coupling.^[2]

Nervous and muscular cells (muscle fibers) are excitable cells. These cells react to all external events (named excitation) that are mechanical, chemical or electrical in nature. As is the case for all live cells, these cells have electrical polarity on both sides of their cytoplasmic membrane (membrane potential or resting potential). Using microelectrodes (typical sensors in the cell electrophysiological domain) with a very thin tip, it is possible to measure the difference in potential between the outside (taken as an electric reference) and the inside of the cell (this detection type is qualified as intracellular detection). The measured membrane potential is stable with time and ranges between -70 and -90 mV according to cell type. After excitation, cells react with a transitory variation of the electrical polarity of the membrane, called the action potential (AP). The AP (Fig. 2) is identical in amplitude and in duration and is characteristic of the cell type (nervous or muscle). Moreover, AP is propagated along the membrane of these cells (axonal membrane for nervous cells, fiber membrane for muscle fibers). The cell parts considered are long extensions: the axon of the nervous cell whose cell body is located in the ventral horn of the spinal cord or a long cylindrical cell (muscle cell).

Fig. 1 (A) Schematic anatomical drawing of motor unit (MU) and (B) typical waveforms according to detection modalities. MUAP, motor unit action potential; SEMG, surface electromyogram.

The AP is transmitted from an axon (nervous AP) to a cell muscle (muscle AP fiber) through the neuromuscular junction (NMJ), also called the motor end plate, a chemical synapse whose neurotransmitter is acetylcholine. The single axon is subdivided at its end into several branches or collaterals. Thus, axonal AP is reproduced on each collateral ending with an NMJ and innervates several muscle fibers.

A muscle associated with its motor nerve is described as a set of MUs, from ten MUs for small muscles to several thousands of MUs for large muscles. The muscle fibers of one MU are distributed in the muscle. This distribution determines the concept of MU territory defined by Buchthal et al.^[3] In the first approximation, the MU territory corresponds to the muscle surface (in the muscle cross-section view)

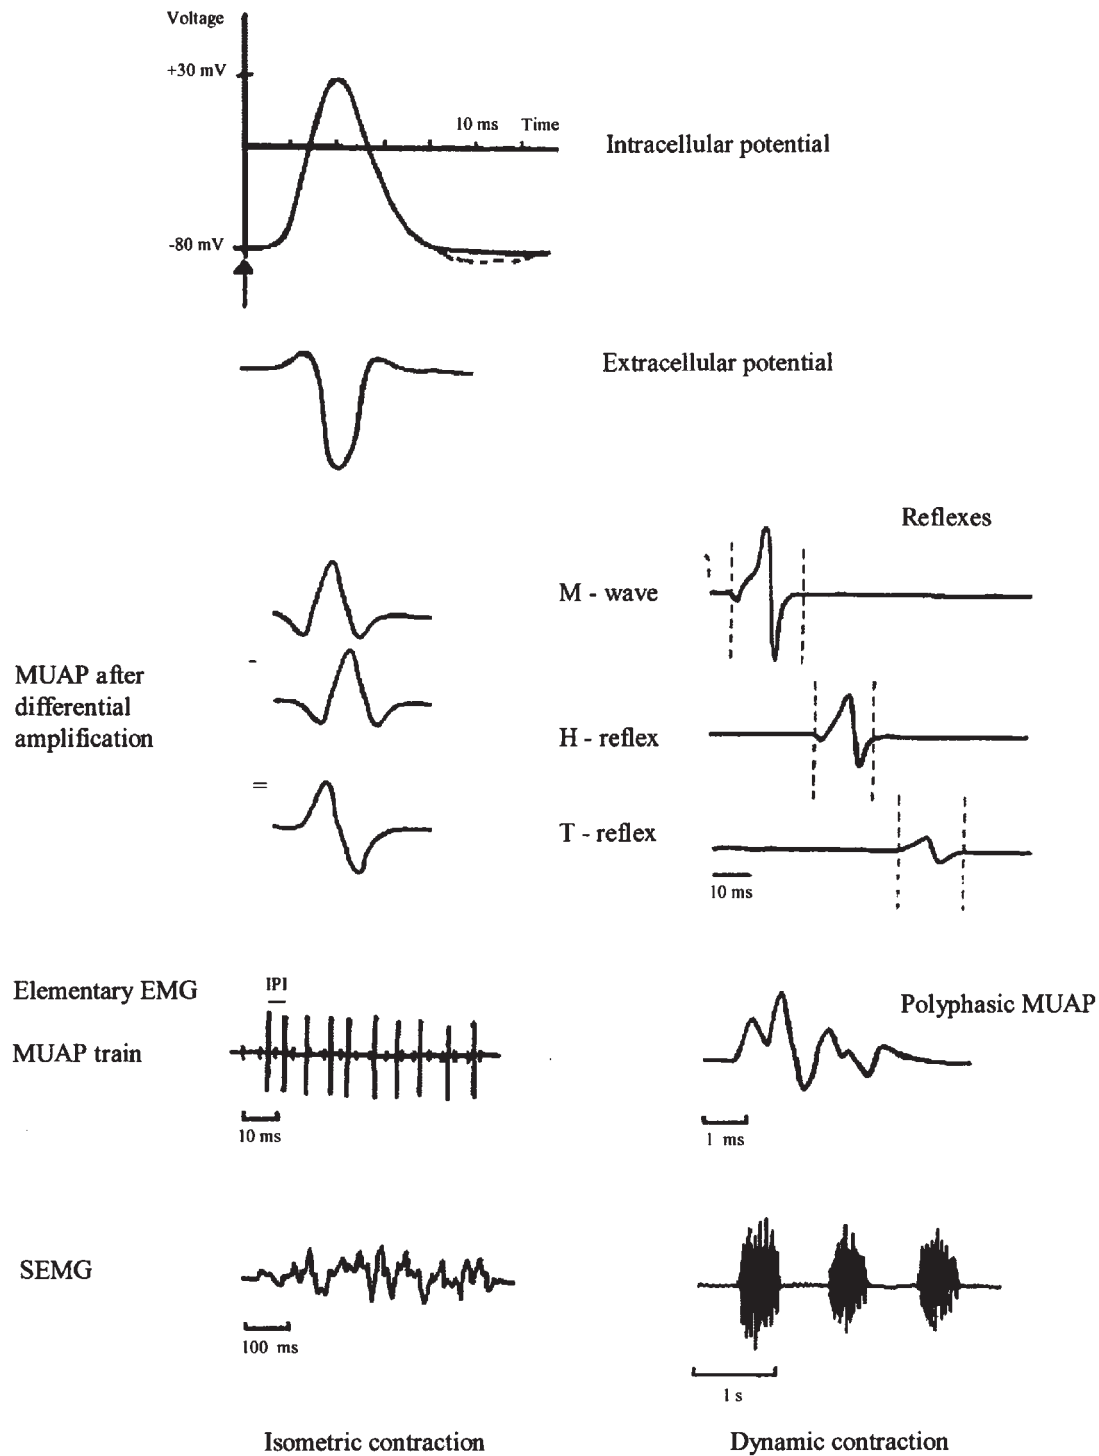

Fig. 2 Typical EMG signals (redrawn from personal results). MUAP, motor unit action potential; SEMG, surface electromyogram; IPI, interpotential interval.

delimited by the most distant fibers. The spatial scattering of fibers is regarded as a uniform or a Gaussian^[4] distribution. In the muscle cross-section, MU territories overlap each other. The rate of innervation of a MU is defined as the number of muscle fibers belonging to it. Muscles that must provide a coarse

effort (for example, in limb muscles) are constituted by MU with a large rate of innervation, whereas muscles that need to ensure a precious and discriminative activity (for example, face muscles) have MUs with a larger number of fibers, but each has a low rate of innervation.

The entire set of MU axons corresponds to the motor component of the mixed nerve that innervates the muscle. The other nervous component is sensitive and drives sensitive information from muscle spindles. The nervous endings on the muscle are a privileged area (identifiable by cutaneous electric stimulation) called the innervation zone, or motor point (MP). The MPs are located at different places on the muscle. Tables of MP localization were constructed previously.^[5]

Type of MU

The type of MU is related to the type of fiber that composes it.^[2] Several types of muscle fibers exist and are classified into two main categories: slow fibers (type I) and rapid fibers (type II). The fast fibers are divided into three groups, IIa, IIb, and IIc. The various fiber classes are determined from criteria or characteristics dependent on their structural, contractile, metabolic, and functional properties. For example, fiber diameter, AP amplitude, and generated force are larger in type II fibers, whereas the excitability threshold, fatigue resistance, and time of twitch contraction are larger for type I fibers. In one MU, the type of muscle fibers that composes it is the same. Categories of MU type are determined based on fiber type, such as slow or fast MU.

In a given muscle, the proportion of different types of MU assigns the properties of the muscle: slow muscle (98% slow MU; for example, soleus muscle), fast muscle (90% fast MU; for example, extraocular muscle), and mixed muscles (slow and fast MU; for example, biceps brachii muscle). During a progressive increase in the intensity of muscle contraction, Henneman^[6] determined that the larger the cell body of the motoneuron, the higher the threshold of excitability will be and consequently the motoneuron will be activated late; this result is called the size principle. Then, consequently, slow MUs are recruited before the fast MUs.

GENESIS OF THE EMG SIGNAL

Muscle Fiber Potential

In electromyography, independent of the method used, electrical activity detection is realized extracellularly. The changes in detected potential are collected outside the cell. The relation between intracellular and extracellular AP is a second derivative with respect to time.^[7] The activity of just one cell can be picked up (Fig. 1B) and represents the muscle fiber action potential (MFAP). The propagation velocity of the

MFAP along the muscle fiber is about 2 to 5 m/sec. The propagation velocity is smaller than that of axons, which is about 45 to 65 m/sec. The propagation velocity in the axons is increased because of saltatory conduction, which is conduction resulting from the presence of a sheath of myelin (Fig. 1A) that surrounds and electrically insulates the axon in small sections. Each myelin section corresponds to a Schwann cell in the case of peripheral nerves.

Motor Unit Action Potential

When a motoneuron is activated, an AP is generated and propagated along the axon and its collaterals. These AP are transmitted by NMJ to muscle fibers and then each muscle fiber generates MFAP. The motor unit action potential (MUAP) is the algebraic sum of MFAP (Fig. 1B). These potentials, detected using intramuscular electrodes, have amplitudes and shapes that depend on the following parameters: electrode–fiber distance, fiber conduction velocity, density of fibers at the site of detection, and length of collateral.

Elementary EMG

Elementary EMG is an intramuscular EMG constituted from algebraic summation of a restricted number of MUAP (from 1 to 4–5 MUs; Fig. 2). If a needle electrode with one wire is used, MFAP may be detected.^[8]

Surface EMG

Surface EMG (SEMG) is a global EMG because a large number of MUAP are detected (Fig. 2). Surface EMG is picked up on the surface of the skin (Fig. 1B) and thus the electromyographic evaluation is reduced to the most external muscles. The potentials then cross various media such as the fat layer (via adipocytes) and the skin layers (via keratocytes). The detected EMG signals are altered in amplitude and frequency by the cell layers. Signals with the greatest amplitudes come from the muscle fibers closest to the electrodes.

EMG Characteristics

Electromyographic signals have different characteristics according to the modalities used to generate them. The two kinds of modalities are stimulation and voluntary contraction performed by the subject. Using electric stimulation (applied to the motor nerve or the muscle itself) or mechanical stimulation (impact on one of the muscle tendons by a hammer), EMG signal is deterministic. At the occurrence of stimulation or

excitation, activation of each MU is synchronous, i.e., all are active at the same time. Using electric stimulation (adjustable in intensity and duration), the size principle is reversed: type II MU are initially excited. During voluntary activity, the EMG signal presents characteristics of a random signal; the activities of MUs are asynchronous. The EMG signal in bipolar detection and collected on the skin is called interferential EMG and is centered on electrical zero (baseline). In some cases of muscle contraction, such as fast or explosive contractions, MUs tend to have synchronous activity.

EMG SIGNAL PROCESSING CHAIN

A typical EMG signal measurement chain^[9-11] consists of three basic units: detection, signal conditioning, and signal acquisition and processing. Because an EMG signal is extremely weak, ranging from microvolts to millivolts, it is easily contaminated by undesirable noise. Thus, the higher the performance of each unit, the better the quality of EMG in terms of signal-to-noise ratio. The Surface Electromyography Not Invasive for the Assessment of Muscles (SENIAM) research group,^[5] supported by the European Union in the biomedical research program (BIOMEDII) proposed in 1999, made recommendations based on practical methods for the use of SEMG in clinical diagnostics. These recommendations help users standardize measurement methods, analysis, and modeling of SEMG.

Detection

The detection of EMG is performed by specific sensor electrodes. These electrodes, which come in direct contact with the muscle or skin, are made of different metals that must be non-toxic for the subject and do not polarize with an electrical current across the electrode (unpolarizable electrode). The interface, or the contact surface, between a metal and the biological environment produces long-lasting polarization effects. In order to minimize polarization, the metal must be covered with a layer of salt of the same metal. Generally, silver chloride (Ag/AgCl) is used for sensor electrodes. The most important characteristics of the interface of the electrode–biological medium are their electric impedance (in ohms) and their filtering effect (in particular the low-pass filter) on the detected signal. The EMG signal depends on these electrical characteristics but also on the electrode position. The detected electrical activity is a signal under high impedance.

This high electric impedance is lowered using an impedance transformer (preamplification circuit).

Three electrodes must be used: two electrodes (active electrodes) are connected to the high impedance inputs (one input for each electrode). The third electrode (the reference electrode) is connected to the low-input impedance (placed in a region without electrophysiological activity that is linked to the ground).

Special care must be taken to realize EMG detection; the amplifier requires electric insulation in order to protect the subject electrically (subject safety) because devices in the acquisition system are linked to the AC power line.

Two modes of detection (monopolar and bipolar) are usually used. The monopolar mode involves only one active electrode and gives information regarding changes in potential under the detection place. The second electrode must be placed on an electrically inactive zone (wrist, ankle, or ear lobe). In the bipolar mode, which is most generally used, two electrodes are placed with a gap between them. Because of the difference in potential, the undesirable remote potentials (parasitic or noise) are eliminated, thus improving the signal-to-noise ratio. A bipolar EMG signal obtained is very different in shape from the monopolar EMG signal; this must be taken into account in the conditioning and treatment of the signal. The bipolar EMG is dependent on the interelectrode distance. A pair of electrodes will detect more or less remote electric activity with a large or small interelectrode distance, respectively. Then active muscle volume (or conductor volume) will be larger or smaller depending on the interelectrode distance. When the interelectrode distance is small, the conducting volume is low and the electrodes have high selectivity. The distance between electrodes must be chosen in such a way that the conductor volume receives no activity from neighboring muscles (concept of “cross-talk”).

KINDS OF ELECTRODES

Two kinds of electrodes are used (Fig. 3): invasive electrodes cross the skin (intramuscular electrodes) and noninvasive electrodes are attached to the skin surface (surface electrodes). Invasive electrodes have electrode needles with one or more Ag wire of detection (coaxial, multiple) and wire electrodes (with or without hooks) allowing detection of the electrical activity during motion with low amplitude and low speed. The first electrodes are mostly for neurophysiological evaluation, whereas the second electrodes are generally dedicated to biomedical research. Non-invasive electrodes, or cutaneous surface electrodes, are widespread in the fields of kinesiology and sport. They consist of a round metal plate a few millimeters in diameter or a rectangular plate of Ag/AgCl (about 2×10 mm). Moreover, special kinds of electrodes can be constructed in relation to the

Fig. 3 Different kinds of electrodes (intramuscular, surface).

geometry and position of the muscle (for example, for vaginal and anal probes). In order to ensure the best contact between the skin and the electrode, it is necessary to use a layer of conductive paste. Wet gel electrodes are used when the shape of the electrode makes it possible to maintain the conducting layer. If the detection surface is directly on the skin with only a very thin layer of conductive paste to ensure contact, the

electrodes are called dry electrodes. The advantage of wet gel electrodes compared with dry electrodes is their insensitivity to the movements of wire-linked electrodes to amplifiers during the evaluation.

Electrode Placement in Surface EMG

Skin preparation

When surface electrodes are used, contact impedance with the skin is higher because the skin may be fatty and dirty, have a large cutaneous keratinization, or be senile skin. In such cases, before electrode placement it is necessary to eliminate fatty impregnation of the skin, scaled cells, and abnormally high pilosity as much as possible. The reduction techniques for cutaneous impedance consist of shaving and then abrading the zone on which the electrodes will be fixed using an abrasive paste or an equivalent mixture of alcohol and acetone. Once the electrodes are correctly positioned, interelectrode resistance is measured. Interelectrode resistance must be lower than $5 \text{ k}\Omega$.

Electrode placement

The electrodes are placed in parallel to the orientation of muscle fibers and one of the two sides of the MP. The best placement is in the position the muscle will have during its contraction phase, which does not necessarily coincide with the resting position. The electrodes are fixed using double-face adhesive tape. For most muscles, surface electrodes of 10 mm in diameter and a distance of 20 mm intercenter is recommended by the SENIAM^[5], but for small muscles the size of the electrodes and their distance must be adapted.

Electrode Placement in Elementary Electromyography

The use of intramuscular electrodes is a medical act and requires initial asepsis of the electrode. After the skin is cleaned with alcohol, the skin is locally anesthetized (by spray cooling or local analgesic) before needle puncture.

Electromyographic Multidetector (Fig. 3)

In some elementary EMG uses, the needle contains several detection wires constituting a multielectrode bundle, which makes it possible to detect several channels of signals simultaneously. For SEMG, several electrodes can be arranged, either online with equivalent interelectrode distances or matrix built for mapping EMG investigations.

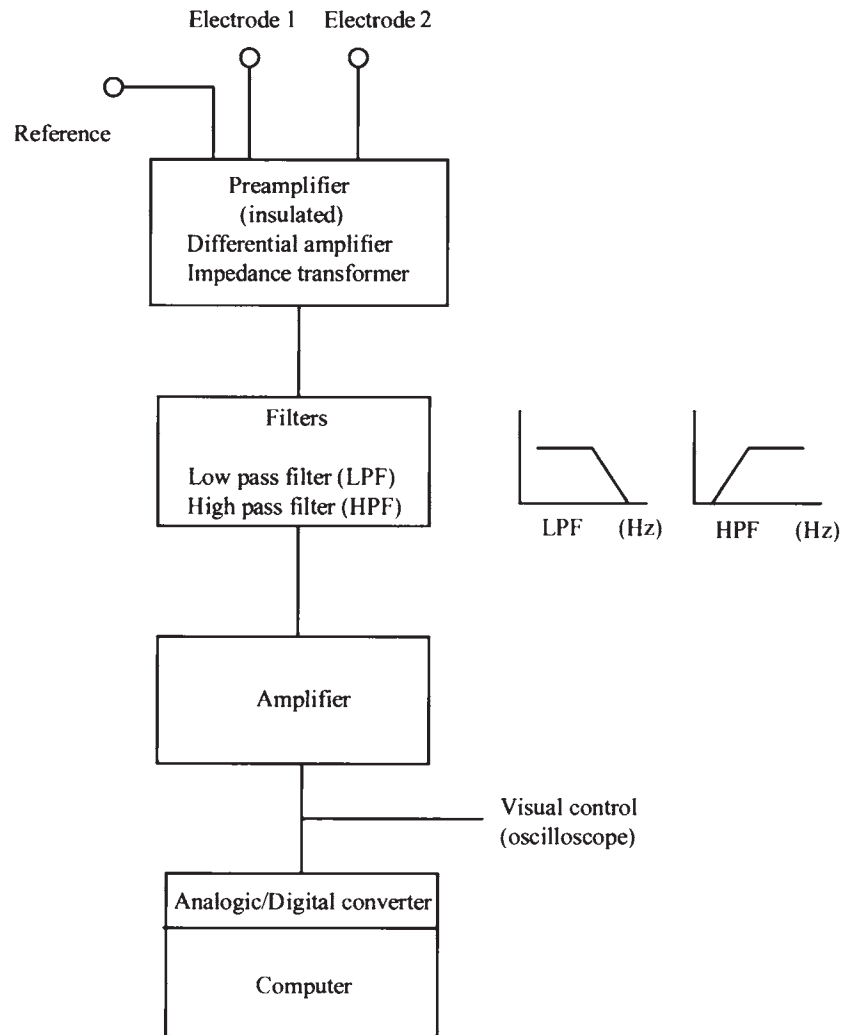

Fig. 4 A typical signal processing chain.

In these cases, the associated signal processing is specifically developed. As an example, an electrode device called a laplacian electrode made with five electrodes is used to perform space filtering. Laplacian detection enhances the depth of detection with high selectivity. A second example is n -electrodes in line with constant interelectrode distances in order to compute the velocity of propagation of muscle potential.

At the present time, the needle and cutaneous electrodes are manufactured industrially and ready for use. The disposable electrodes available for SEMG are wet gel or adhesive gel electrodes.

SIGNAL CONDITIONING AND DATA RECORDING (FIG. 4)

The primary purpose for analog signal conditioning circuitry is to modify sensor output into a form that can be optimally converted to a discrete time digital data stream by data acquisition. The conditioning circuit consists of three consecutive stages:

preamplification, filtering, and amplification. The accuracy of the data recording relies on the precision of these three units.^[9,10]

Preamplification

The preamplification stage boosts the scaled electrical signal received from the electrodes. The most important circuit configuration for amplifying sensor output is the instrumentation amplifier. The EMG preamplifiers are typically built around an instrumentation amplifier with the following requirements: accurate and stable weak gain (usually between 2 and 10), extremely high input impedance (about $101\text{M}\Omega$), extremely low output impedance (about 100 ohms), and an extremely high common mode rejection ration (more than 110 dB). Because signals received from the electrodes have high impedance and low amplitude, the preamplification stage operates as an impedance transformer. Usually, it is located as close as possible to the detection site.

Filtering

The filter section will comb out irrelevant frequencies, electrical noise, and other unwanted interference from the signal, leaving only the part of the converted bio-potential signal one wishes to measure and record. To reduce the undesirable signals (noises) as best as possible, the filtering unit uses both low- and high-pass filters. Noise has an extrinsic origin (electromagnetic disturbances of 50 or 60 Hz, engine in action, wire movements) or an intrinsic origin (other biopotential signals, such as ECG, the amplitude of which is larger than that of an EMG). The high-pass filter removes unbalanced components of half-cell potentials and movement artifacts of the cables, i.e., spurious changes in the signal resulting from movements of the leads and slipping during gesticulation or motion. Low-pass filtering limits the spectral characteristic of the EMG signal to the known bandwidth so the signal can be sampled at the required rate. The filters are analogic devices and are tunable according to frequency bandwidth. A notch filter (which ideally attenuates the frequency for which the filter was built) is currently added to enhance the suppression of electromagnetic disturbance. The bandwidth of each filter is set according to the frequency band of the EMG signal, the value of which depends on the type of EMG (elementary or surface), on electrodes placement, and also on muscle size and type. Typical amplitudes and frequency bands are 1–10 mV and 5–500 Hz for surface EMG and 200–250 μ V and 30–3000 Hz for intramuscular EMG, respectively.

Amplification

Before the signal is sent to the last unit (visualization or processing devices), the EMG signal passes through a final amplification with a very high gain. By placing high-gain amplification at the filter output unit, selective increase in the desired signal is ensured without noise amplification because the majority of the electrical interference has already been filtered. The high gain significantly increases the amplitude of the EMG signal, making it easily detectable and manageable by visualization or numerical acquisition devices. To avoid distortion or saturation, the output signal must not exceed the specific range of the device (example of voltage range: ± 1.4 V, ± 5 V, ± 10 V).

The active sensor is a specific system use for SEMG detection, and includes a preamplification circuit and a filtering circuit placed nearest the two active electrodes. Thus it generates a low self-impedance signal that is ready to be amplified. In some cases, the signal must be brought far from the detection site and be transmitted by radiotelemetry.

Signal Insulation

For human safety, it is necessary to isolate the sensor from the power supply of the conditioning units. The EMG preamplification unit includes electric insulation in order to protect the subject. This occurs in one of two ways: magnetic isolation or optical isolation. Magnetic isolation is primarily used for coupling power from the computer or the wall outlet to the sensor. This is performed through the use of a transformer. Optical isolation is used for coupling the sensor signal to the data acquisition input. This is usually performed through the use of a light-emitting diode and a photodetector.

Recording

Some devices are used for visualization or acquisition of the conditioned EMG. Using an oscilloscope (analog or digital), the amplitude in time variation of the EMG signal can be investigated.

In order to permanently record the signal, tape or graphic recorders are used to produce a trace paper. Tape recorders, which are less used nowadays, make it possible to reread the recorded signal. Graphic recorders using ink jet or thermic paper are commonly used, as for ECG or EEG. In choosing a recorder, particular care must be given to the value of the recorder's bandwidth because it is dependent on technical considerations. During an examination or a test using elementary EMG, it is common to listen to EMG signals via a loudspeaker. The EMG is transformed into a signal compatible with that of loudspeakers. Hearing the activity allows the investigator to have a "third hand": it enables him to position the needle without having to see the signal.

All contemporary analyses and applications of EMG signals are accomplished using algorithms implemented on computers, and necessitates that the signals be expressed as numerical sequences. The process by which the detected signals are converted into these numerical sequences is called analog-to-digital conversion. Analog signals are voltage signals that are analogous to the physical signal they represent. The amplitude of these signals typically varies continuously throughout their range. The analog-to-digital conversion process generates a sequence of numbers. Each number represents the amplitude of the analog signal at a specific point in time. The resulting number sequence is called a digital signal, and the analog signal is said to be sampled. Numerical recording for upcoming EMG signal processing requires devices with an analog-to-digital converter (ADC). Their use is highly varied and widespread. Each application must be

assessed with consideration of the advantages and limitations of the specified ADC.

Knowledge of the signal ranges is strongly recommended—both amplitude and frequency—in order to match the dynamic of the signal as well as the sampling rate as much as possible. It is advisable to sufficiently but not excessively (to avoid an overload) amplify the signal with regard with the voltage range of the AD boards (typical ranges for ADCs are ± 1.25 , ± 2.5 , ± 5 , and ± 10 V) and to choose a sampling rate at least twice the maximum frequency of the signal (according to Shannon's theorem).

DATA PROCESSING—EMG QUANTIFICATION

Data processing and computation of EMG depend on the type of electrode, the type of detection, and the type of study that justifies the use of electromyography.^[9,11–14] Data processing is applied to numerical signals, which are then sampled. Pretreatment may be carried out to enhance the signal-to-noise ratio. For example, a numerical filtering may be applied to the signal in the temporal domain (e.g., filter of Butterworth or Tchebychev) or in the spectral domain to eliminate one frequency, where after the frequency component is reset (zero value) the signal is rebuilt. Another technique is signal averaging, and requires three conditions. The first is the existence of a trigger event, which will correlate with the signal; the second is that the time between the trigger event and the signal is invariable; and the third condition is that it is possible to repeat several times the generation of the signal without changes in the two first conditions. By summation of sampling epochs, only the signal generated at the same time will appear and thus its amplitude will increase, whereas the existing signals not generated by the starting signal will decrease in amplitude. This method, often used in EEG to extract evoked potentials, makes it possible to extract a signal from a composite signal. For example, it is possible to extract the force generated by one MU from the force signal during contraction; the trigger event is the MU potential itself.^[15] Finally, the use of adaptive filtering eliminates undesirable signal but the signal must be recorded independently. For example, if the SEMG of back muscle is contaminated by an ECG signal, to delete the ECG in the SEMG it is necessary to record the subject's ECG on an additional channel in order to apply adaptive filtering.

After pretreatment, the signals can be quantified using numerical parameters. In the case of elementary EMG, MUAP are analyzed individually or in the entire activity during a defined duration. Individually, the shape of the MUAP is characterized by this duration and number of phases, amplitude, and area. In a defined time interval, the firing rate of the potentials, the

mean interpotential interval (IPI), the instantaneous frequencies (inverse of IPI), and the jitter (mean variation in IPI between single-fiber action potential of the same MU) will be studied.

In the case of SEMG, the signal may be studied in the temporal domain (according to time) and in the spectral domain (according to the frequencies which it contains). In the temporal domain, common processing involves wave rectification (absolute value of the signal, knowing the signal is centered on a level mean, generally zero), counting the number of passages to zero, integration (calculation of the signal area with respect to the baseline), and calculation of the signal envelope (the total shape of the signal). Moreover, the envelope may be estimated using a moving average of rectified EMG (average of the amplitude in the moving time window).

In the spectral domain, characterization is carried out on the power density spectrum of the signal. Using a fast calculation algorithm (fast Fourier transform or FFT), the temporal signal is transformed into the spectral domain. Using a calculation associated with FFT, the signal is then represented as a power density spectrum. The signal is graphically represented by a continuous curve (power density) according to frequencies the signal contains. The power density spectrum is characterized by quantifiers such as the root mean square (RMS), corresponding to total power of the signal computed as the spectrum surface, the mean power frequency (frequency corresponding to the barycenter of all the frequencies according to their power), and the median frequency (the frequency that divides the power spectrum into two equal RMS parts). Using the most common parameters, other parameters such as the symmetry of the power density spectrum or flatness with respect to a normal Gaussian curve can be calculated.

If, by calculation of these parameters, it is possible to quantify the EMG signal, interpretation of the results and their changes during the time course must take into account the test set-up in which the signal is generated. For example, according to the level of contraction (maximal or submaximal) or during muscle fatigue the parameters may be different, thus leading to different interpretations.

Specific Computation of EMG Signal

Data computation^[12–14,16] can be used to improve the detected EMG signal or to seek particular information regarding the signal using specific algorithms. For example, new algorithms in filtering methods are elaborated upon to improve the preprocessing step, such as the removal of artifacts in the electrical signal. The methods most used to extract information from the

EMG signal are decomposition of the EMG signal into MUAP trains and classification of MUAP parameters using wavelet transform or neural network methods. Following the application of extraction methods, data are analyzed using statistical analysis (such as mean, variance, or correlation analysis to evaluate the relevance of a given parameter) or multivariate methods (such as principal component analysis or discriminant analysis to classify data and to take a decision from many parameters).

Graphical Representation of EMG Signals

Other characterizations of the EMG signal, such as graphic modes of representation, provide information on the shape, duration, and intensity of the electric activity of the muscle during contraction.

In the monodimensional mode (1-D), observation of the signal (one channel) as a function of time provides information regarding the signal amplitude. However, another representation called graphical superposition of signal epochs provides information regarding shape changes. Graphical superposition is made from a characteristic in each signal (such as trigger event or maximal amplitude). For example, by triggering the visualization of multiphasic MUAP (Fig. 2) in the first phase, it is possible to identify changes in the other phases. The jitter is defined as the delay in propagation on the branches of collateral of the motor nerve. In the same way, the superposition of power density spectra may identify spectral changes in EMG, such as in the case of muscle fatigue processes.

In the two-dimensional mode (2-D), according to the axes (abscissa and ordinate) the parameters used may be homogeneous or heterogeneous. For example, the time (abscissa)–frequency (ordinate) representation called a periodogram demonstrates power spectra for each segment of the raw signal. The possible spectrum change appears upon visual examination of the graph. When several channels of EMG are recorded, one image can be built pixel by pixel using an interpolation between the signals and by transforming the amplitude to color according to a color chart. This corresponds to a 2-D representation or a pseudo 3-D representation. The most current application concerns the EMG mapping (position of electrode in abscissa and in ordinate), or a pixel has a determined color (amplitude), which illustrates the distribution of EMG activity on the surface of the skin. More recently, by using an n-electrode line array (electrode positioned in the abscissa and time in the ordinate with color as amplitude), it is possible to estimate the propagation velocity of electric activity by computing the slope of the colored lines, which appear on the image.

PRINCIPAL FACTORS LEADING TO EMG SIGNAL CHANGE

The principal factors implied in EMG signal changes for a healthy subject^[13,14,16] are as follows:

1. Methodological factors such as those linked to the sensors (chemical properties of the detection surface, size and shape of the electrodes) and sensor placement (orientation of the electrodes compared with the direction of muscle fibers, sensor placement with respect to the motor point, distance and impedance between electrodes);
2. Structural physiological factors such as the space distribution of MUs, the diameter of fibers constituting the MU, and the filter properties of muscle tissue and skin; and
3. Functional physiological factors such as the kind and the level of contraction, the degree of synchronization in MU behavior, muscle metabolism (ionic disorder: pH, balance in release–production of lactate), intramuscular pressure, blood flow, and muscle temperature.

In addition to these factors, it is necessary to consider the age of the subject and the various neuromuscular pathologies^[17,18]

1. Structural factors such as diseases of the central nervous pathways (e.g., brain motor area) or peripheral diseases (neuropathies), structural changes in the neuromuscular junction (such as myasthenia gravis) and in muscle fibers (myopathies); and
2. Functional factors such as those associated with diabetes and obesity or muscle fiber function such as McArdle's syndrome (abnormal glycogen accumulation in muscle tissue).

Finally, electromyography characterizes specific changes in the neuromuscular system that have led to a specialization of this system as this is identified after endurance or pliometric training, after reduced muscle activity (limb immobilization), and during exposition in extreme environments such as space flights of long duration. These neuromuscular changes, which are generally reversible, illustrate the neuromuscular plasticity.

ASSOCIATION OF EMG SIGNALS TO OTHER ELECTROPHYSIOLOGICAL SIGNALS

The study of EMG signal and its changes is dependent on the conditions of signal generation. The EMG signal is evoked from a muscle activity (muscle contraction), which requires voluntary motor control or involuntary solicitation (external stimulation, e.g., the

electromyographical component in the study of reflexes).

Using experimental devices called ergometers, it is possible to normalize or standardize muscle contractions according to a fixed protocol. The detected EMG signal is associated with other signals (such as force, power, position, and speed for mechanical signals) or related to the stimulation parameters (e.g., intensity and duration for electric stimulations).

Two kinds of contractions exist: isometric contractions (the muscle does not modify its length and thus a force torque is measured) and dynamic or anisometric contractions (the muscle works with variable length). The interest in using mechanical devices or ergometers that are more or less complex lies in seeking the most reliable, reproducible, and even standard experimental conditions. Moreover, specific protocols such as the research of maximum (e.g. maximal voluntary force, maximal RMS) are generally proposed and leads to standardization of the instructions given to the subject or to normalization of the calculated parameters values to this reference value. Under test conditions, it is possible to identify changes in the EMG signal in comparison to standard signals or characteristic signals obtained from healthy subjects.

According to the properties of the SEMG signal, the signal is not reproducible but the quantifier values and evolution are (e.g., total energy, mean frequency during muscle fatigue) if test conditions are repeatable. Changes in EMG signal are then perceived by its parameters rather than the signal waveform variations.

EXAMPLES OF PHYSIOLOGICAL CHANGES IN EMG SIGNAL

Level of Contraction

Under isometric conditions of contraction, when a subject increases the intensity of a voluntary contraction in arm flexion, the SEMG of the biceps brachii muscle increases gradually in amplitude, as characterized by an increase in the EMG RMS. The muscle activity is dependent on the number of recruited MU (by spatial recruitment according to the size principle) and on the activity of each MU by their firing rate (temporal recruitment). For various levels of contraction, the MU firing rates differ with respect to MU type; the firing rate of MU ranges from 4–5 to 25–30 Hz for slow MU and up to 60 Hz for fast MU. For small muscles, all the MU are recruited before the intensity of contraction reaches 50% of the maximal voluntary force, whereas for large muscles the entire MU recruitment is obtained when contraction levels range between 70 and 80%.

Muscle Fatigue

Muscle fatigue is a reversible physiological phenomenon that is studied during isometric contractions (with maximal or submaximal level). During the submaximal level, which is maintained until exhaustion, the SEMG is altered and RMS and mean power frequency changes are observed. The increase in RMS is associated with a decrease in the mean power frequency of the signal. The interpretation is that increased MU activity is required to maintain the force and mean power frequency changes are associated with biochemical disorders such as muscle acidification.

In maximal contraction, the number of active MU cannot be increased and the muscle activity is close to the maximal activity. Fatigue is identified by a fall in mean power frequency and force produced.

Body Motion in Cycling, Walking, and Jumping

Using of an ergometer (for cycling), EMG signals (Fig. 2) can be detected with multiple channels and demonstrate patterns of activity that are quantified during body motion. For example, the beginning and end of activities may be quantified in duration and in magnitude with signal RMS. Each motion, such as walking, jumping, or exercising on a bicycle, is associated with mechanical variables (such as position, speed, and acceleration). Interrelations between the EMG quantifiers and the mechanical parameters are studied and may describe anomalies in motor coordination.

CLINICAL ELECTROMYOGRAPHY

Elementary EMG with needles is currently used in clinical electromyography.

Neuromuscular evaluation^[17,18] using electromyography corresponds to the evaluation of the most distal organ (muscle) and, consequently, leads to the identification of signs of suspicious pathologies at various places from the cerebral motor area to the muscle (localization of the excitation–contraction coupling). Electromyography is used to assess the effect of medicinal therapy or to follow up with rehabilitation (e.g., in the case of muscle reinnervation: the MU territories decrease, whereas the rate of innervation increases).

In practice, an EMG signal is generated following a verbal instruction to the subject and signal anomalies with respect to reference signals may be identified. Another manner of generating EMG signal consists of evoking EMG responses following stimulations that are electric (electrodiagnostic) or mechanical (tendinous stimulation or disruption of posture). The

method, which is most often used in the study of reflexes, is called reflexology.

For example, electrostimulation of the sciatic nerve applied to the hollow poplity (area located behind the knee) generates various muscle responses (Fig. 2) according to the intensity of stimulation. With low intensities, the sensitive nervous fibers (Ia fibers from muscle spindles) are the only ones to be excited and by the monosynaptic loop reflex of the homonymous muscle will produce the slow type of MU contraction. The EMG response is called Hoffman's reflex (H reflex). With stronger stimulation intensities, the H reflex gradually decreases and the direct response of the muscle, called the M wave, appears. The evoked EMG response to abrupt percussion on the Achilles' tendon is called tendinous reflex (T reflex). The T reflex occurs later than the H reflex because of the coupling between tendinous mechanical stimulation and the response of the spindles.

CONCLUSION

Electromyography, or the study of EMG signal, provides information on nerve and muscle functionality. First, after drawing up a protocol and deciding whether an ergometer should be used, special care must be given to the choice of muscle investigated, kinds of electrodes, and their placement. Second, when the EMG signal processing chain is constructed, each unit of the chain must be adjusted according to the modality of the EMG signal generation (voluntary contraction or stimulation) and the signal kind (intramuscular or surface). In the third step, the kind of data analysis must be chosen to extract the researched information. In comparison with "normal" waveforms or changes, the EMG signal may reveal abnormalities in nerve or muscle function.

At the present time, new methods for EMG signal processing are in progress. The study of EMG is also associated with other means (for example, Nuclear Magnetic Resonance or NMR) used to investigate nerve and muscle function.

INTRODUCTION

As technology has improved and we have moved toward the ability to engineer biomaterials, cells, and tissues, the necessity to image submicron details in a variety of sample types has also increased. Although light microscopy, confocal scanning laser microscopy, and other imaging modes—such as microcomputed tomography and X-ray imaging—can provide significant morphological information regarding samples, it is only through scanning (SEM) and transmission (TEM) electron microscopy that we can image the ultrastructural information required to adequately analyze information at the nanoscale level. As detailed in this article, biomaterials and bioengineering studies involving electron microscopy cover a wide range of applications, including the imaging of cell:cell and cell:extracellular matrix interactions, intracellular events, and nanoscale changes in biomaterials used as tissue substrates and in microspheres used in the delivery of targeted drugs.

INSTRUMENTATION

Although a detailed description of the design and operation of SEM and TEM instruments goes beyond the scope of this article, a basic description of the differences between the two types of microscopes and the types of studies they are used for is appropriate. The primary advantage of electron microscopes over other types of imaging sources is their improved resolution, which allows detail to be resolved routinely at the submicron to nanometer level. In some cases,

resolution at the angstrom level is also possible when the proper instrumentation and samples are used. This high resolution is based on the use of electrons as the imaging source. When compared to other types of imaging sources, such as photons that are used in regular light microscopes and laser-based imaging systems, electrons have very short wavelengths. When the formula that determines resolution is examined, the importance of the wavelength of the imaging source is evident.

$$\text{Resolution} = 0.612\lambda/n(\sin \alpha)$$

In this equation, 0.612 is a constant used in calculating the resolution of various systems; λ represents the wavelength of the illumination source; n represents the refractive index of the medium that the illumination source passes through; and $\sin \alpha$ represents the numerical aperture, or angle, of the lens. Typically, the wavelength of light used in optical systems is longer than 380 nm (blue light), whereas the wavelength of electrons is shorter than 0.005 nm. Although other factors, including aberrations in the lenses, may affect the overall resolution of a system, this fundamental difference in the wavelengths of the illuminating sources is responsible for the improved resolution of electron microscopes. This basic difference in the ability to resolve structures is illustrated in Fig. 1, which shows the structure of cardiac myocytes imaged by confocal scanning laser microscopy and transmission and scanning electron microscopy. For a more detailed discussion of the factors involved in the calculation of resolution, there are several good references available, including Bozzola and Russell.^[1]

Fig. 1 Comparison of micrographs of cardiac myocytes collected by confocal scanning laser microscopy, TEM, and SEM, illustrating the differences in resolution and types of images collected by the three imaging systems. Part A shows an image of cardiac myocytes stained with phalloidin conjugated to rhodamine. Rhodamine phalloidin is a specific stain for f-actin, which is a primary component of the contractile apparatus of cardiac myocytes. Staining by this method allows imaging of intercalated disks (I) and the characteristic striations of individual sarcomeres in the myocytes. In this image, the bright white striations represent areas with actin and the dark bands represent the Z-disks where no actin is present. Part B illustrates the higher resolution obtainable by TEM, where individual Z-disks and the actin filaments between the Z-disks are easily resolved. It is also possible to determine the interaction of individual sarcomeres with components of the extracellular matrix, such as collagen (C). Part C is an SEM micrograph illustrating the surface imaging of myocytes (M) and the collagen fibrils (C) that interact with them. Scale bars: Part A, 200 μm ; Part B, 1 μm ; Part C, 20 μm .

BRIEF COMPARISON OF SCANNING AND TRANSMISSION ELECTRON MICROSCOPES

A basic diagram comparing the structure of typical SEM and TEM instruments is shown in Fig. 2. In both systems the illuminating source, or gun area, and the column of the microscope are maintained under high vacuum. This provides an unimpeded path for the electrons to pass through without striking molecules of air. The gun region consists of three components: an electron source, a bias shield, and an anode. The electron source is usually a tungsten or lanthanum hexaboride (LaB_6) filament. To generate electrons, a low-current, high-voltage power source is applied to heat the filament until the metal reaches its work function, or the point at which electron emission occurs. High-voltage (accelerating voltage) sources typically operate in the range of 50 to 100 kV, although instruments are available that operate at one million volts. As the accelerating voltage increases, the wavelength of the electrons decreases, providing a higher-resolution system. In addition, electrons have more energy as the accelerating voltage increases, allowing the imaging of thicker specimens.

Surrounding the filament is a bias shield (Wehnelt cylinder) that has a 2- to 3-mm aperture directly in front of the filament tip. The bias shield is maintained at a slightly negative potential with respect to the filament and the electrons emitted from it. This repels the electrons and directs them toward the aperture in the bias shield. Electrons exit through this aperture

Comparison of Transmission and Scanning Electron Microscopes

Fig. 2 Comparison of the structure and specimen placement in SEM and TEM instruments. A major difference in the two types of instruments is the placement of the specimen between the condenser (CL) and objective (OL) lenses of the TEM, and at the base of the column in the SEM. Abbreviations: CL, condenser lenses; OL, objective lenses; PL, projector lenses.

E

and are strongly drawn toward the gun anode, which has a positive charge with respect to the electrons. From the anode region the high-energy electrons enter the microscope column, which consists of a series of electromagnetic lenses that are used to control the path of the electrons. Controlling the path of the electrons makes it possible to control the magnification as well as the focus of the system, in order to create an image. Images can be recorded when electrons strike a sheet of film, or as digital media when electrons strike a phosphor-coated surface and are converted to a digital image.

The two types of instruments differ in placement of the specimen, which in the SEM is slightly below the final lens and in the TEM is in a plane between the final condenser and the objective lenses. This leads to the basic difference in the types of images that can be collected in the two types of instruments. In the SEM, the electron beam is condensed to a point of adjustable diameter that is rastered, or scanned, across the specimen. As the electrons interact with the molecular structure of the specimen, a series of interactions occur that result in primary, or backscattered, electrons that have lost little energy; secondary electrons that have interacted with the molecular structure of the specimen and have lower energy than those that were in the original electron beam; and a number of other types of signals, such as X rays. Most SEM studies involving biomaterials and biomedical engineering utilize secondary electrons as the imaging signal. Images collected from SEM instruments are primarily used to determine surface structure and the three-dimensional topography of a specimen that can be several centimeters in size.

For imaging in the TEM, most specimens must be sectioned or otherwise prepared so that electrons can

pass through the specimen to give an image of its internal ultrastructure. Because the goal of TEM is to image the interior of a specimen, instruments are operated at much higher accelerating voltages (50,000 to 1 million volts) than in the SEM (10,000 to 40,000 volts), and the resolution of images is much higher than that typically collected in an SEM. As detailed below, specimen preparation for the two types of microscopes also differs.

Recent advances in the design of electron microscopes include the development of field emission guns that provide a very small, bright source of electrons, which allows much brighter and higher-resolution imaging capabilities for both SEM and TEM instruments. Differential vacuum systems that allow for the examination of wet specimens in the specimen chambers of environmental SEMs have been developed, and the addition of cryostages in both types of instruments allow the elimination of much of the preparation procedure that may damage or change the molecular structure of a specimen. Although these modifications provide specific advantages in the imaging of biomaterials and biological specimens, the added cost of these enhanced instruments may be prohibitive for many applications.

ROUTINE PREPARATION OF BIOLOGICAL SPECIMENS

Specimen preparation varies a great deal depending on the type of specimen to be examined, the imaging mode that will be used, and the laboratory making the preparation. A generalized step-by-step protocol for the preparation of biological samples for SEM and TEM is presented in Fig. 3, but it must be remembered

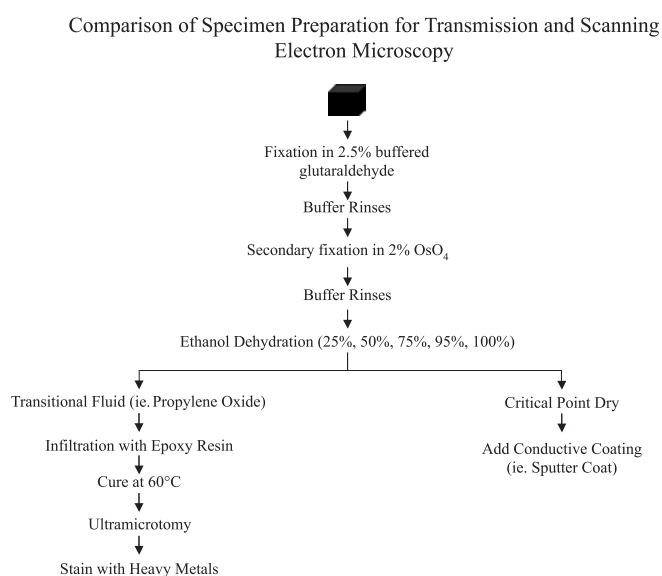

Fig. 3 Diagrammatic representation of the basic steps in specimen preparation for SEM and TEM.

that this protocol will not work equally well for all sample types. However, the routine processing of cells and soft tissues for both SEM and TEM follows a few general principles, or common variations of these principles, that are presented in the following text as a guideline for routine specimen preparation. A good rule of thumb is to search the literature to determine how others have successfully prepared specimens similar to those being examined.

The goal of fixation and subsequent specimen preparation is to rapidly stop and preserve ongoing cellular function and to maintain the three-dimensional structure of the specimen. Rapid fixation in 2 to 3% buffered glutaraldehyde is required for good ultrastructural preservation. Autolytic changes in cells and tissues begin to occur within seconds following death. For deep tissues such as the brain, it may be necessary to perform a cardiovascular perfusion technique to adequately deliver the fixative to the tissue prior to the onset of membrane disruption and the swelling of mitochondria. Following fixation, samples should undergo a series of buffer rinses to remove free aldehyde groups and a secondary fixation in 1 to 2% osmium tetroxide (OsO_4), which is also followed by a buffer rinse. Specimens are then dehydrated through a graded ethanol series. Care should be taken not to extend dehydration in concentrations above 70%, as this may result in extensive shrinkage and disruption of the three-dimensional architecture of the sample. As shown in Fig. 3 and in the following discussion, preparation methods for biological tissues for the two imaging modes diverge following the dehydration steps.

ROUTINE PREPARATION OF BIOLOGICAL SPECIMENS FOR SEM

Imaging of biological SEM samples in a standard microscope column requires that the specimen be completely dried and coated with a conductive substance, typically carbon or gold, prior to examination. Following dehydration in the graded ethanol series, the most common specimen drying method is critical-point drying, during which the ethanol is exchanged with liquid CO_2 at low temperatures. The CO_2 is then heated in a sealed chamber until it reaches its critical temperature and pressure, at which point it rapidly changes from a liquid to a gas, resulting in minimal shrinkage and damage to the specimen. Instruments for automated critical-point drying are available from several companies.

Dried specimens need to be coated with a conductive substance that will dissipate the charge accumulated in the specimen during interaction with the electron beam in the SEM. If the charge is not

Fig. 4 Prepared SEM specimen (section of heart) that has been critical-point dried, sputter-coated with a thin layer of gold, and mounted on a 24-mm aluminum stub for imaging.

dissipated it will cause very bright areas in the image, which are usually found along the edges of a specimen or associated with thin cellular processes such as cilia and filopodia. Prevention of charging is usually accomplished by the process of sputter-coating a 20- to 30-nm layer of gold or palladium onto the surface of the specimen. Alternatively, for high-resolution studies a layer of these metals or carbon can be evaporated onto the surface of the specimen. Instrumentation for these processes is also available from several companies that manufacture equipment for electron microscopy. Figure 4 shows a prepared specimen ready to be examined by SEM.

VARIATIONS IN THE PREPARATION OF BIOLOGICAL SPECIMENS FOR SEM

As might be expected, the drying and coating of samples often introduces shrinkage artifacts in the three-dimensional structure of samples, which may result in the fracture of membranes and fine cellular processes (Fig. 5). Several modifications of protocols and instrumentation have been introduced to help minimize these effects. A common protocol involves the further stabilization of the cytoskeleton by the addition of repetitive treatments of glutaraldehyde, tannic acid, and OsO_4 , which maintains the structure of samples during drying and renders them conductive without further coating with heavy metals or carbon.^[2] Although this method renders specimens relatively stable and minimizes apparent damage, the repetitive addition of tannic acid and OsO_4 to small cytoskeletal structures may increase the apparent size of cell

components such as microfilaments and extended cell processes. An alternative method, although limited to relatively low magnification and low-resolution work is to examine specimens that have not been coated. Since these samples are not conductive, imaging is often difficult because of charging effects, but the fracture of membranes and cellular processes is minimal and the examination of cellular interaction with the surrounding extracellular environment is often enhanced.

Specialized equipment, including the addition of cryostages and low-vacuum environmental chambers to microscopes, has also been designed to minimize the introduction of drying artifacts in specimens. In experiments that utilize cryo-SEM, specimens may be fixed in glutaraldehyde prior to freezing, but in many cases this is not essential. Freezing is typically

accomplished by high-pressure freezing in liquid nitrogen or by plunge freezing in liquid ethane at -183°C .^[3,4] Specimens are then coated under cryo-conditions and examined in microscopes equipped with a cryostage. This procedure eliminates artifacts induced by the dehydration of samples, but it requires relatively expensive modifications of the microscope.

Alternatively, wet, uncoated samples can be examined in instruments equipped with an environmental stage, by controlling the pressure in the immediate area surrounding the specimen. With biological specimens it is often difficult to reach an equilibrium between a hydrated state and the hydrated condition that results from the low vacuum maintained in the instrument. In addition, the potential charging that results from examining an uncoated specimen often requires an experienced operator to acquire good images. However, these instruments do provide the opportunity to examine specimens that do not have artifacts introduced by the drying and coating processes, and they also allow imaging of dynamic processes such as crystal formation and the microstructure of biomaterials.^[5,6]

PREPARATION OF HARD BIOMATERIALS AND POLYMERS FOR SEM

Stable polymers and hard substances, such as apatite crystals, used as substrates or scaffolds for tissue growth generally require little specimen preparation for SEM, other than a light coating of gold or carbon if

Fig. 5. Comparison of specimen damage and images collected by SEM following three methods of preparation. Part A represents cardiac myocytes that have been prepared as diagrammed in Fig. 3, except they have not been coated with gold. This prevents much of the specimen damage created by sputter-coating, but it requires that the samples be imaged by low-accelerating voltages, which limits resolution. Charging (C) is often a problem when small fibrils and contiguous cells are present. Part B is from an adjacent area of the culture dish seen in Part A, but it has been processed as diagrammed in Fig. 3, including sputter-coating. Although coating with gold allows operation at higher accelerating voltages and the collection of higher resolution images, specimen damage, including the fracture (F) of fine cellular processes and membranes (M), is often present. In addition, the process often results in the artifactual separation of cells and the peeling away of edges (E) from the culture substrate. The sample in Part C was prepared by the OTAOTAO procedure, which involves repeated treatment with OSO_4 and tannic acid to stabilize the cell cytoskeleton. In this procedure, fine cell processes (arrows) remain intact and cell shrinkage is minimal.

they are not inherently conductive samples. Examples of these types of samples include a variety of polymers^[7,8] and crystals.^[9]

ROUTINE PREPARATION OF BIOLOGICAL SPECIMENS FOR TEM

Following ethanol dehydration, biological samples that will be examined by TEM must be infiltrated and embedded in a resinous material that will allow them to be cut into thin sections (typically in the range of 70–200 nm) that are mounted onto a grid substrate and placed in the TEM (Fig. 6). Several resins are available, but the most common are epoxy-based resins for routine ultrastructural work and acrylic resins that may be used when immunocytochemistry is to be performed on the samples. After specimens are embedded, the resins are polymerized with heat or UV irradiation and the specimens are sectioned on an ultramicrotome using a diamond knife. To enhance the contrast of sections and highlight structures of interest, they are frequently stained with lead and uranyl compounds. Although the exact mechanism of staining with these components is not fully understood, it is believed that the uranyl salts react with phosphate and amino groups of nucleic acids and some proteins, and lead stains bind to negatively charged components such as hydroxyl ions and areas that have reacted with OsO₄.^[1]

VARIATIONS IN THE PREPARATION OF BIOLOGICAL SPECIMENS FOR TEM

A variation in the preparation of biological specimens for TEM involves those studies that require immunocytochemical labeling with electron-dense substances

Fig. 6 TEM grid with three thin sections across the center of the grid.

Fig. 7 High-resolution TEM immunocytochemistry showing 5 nm gold particles (arrows) labeling the extracellular matrix component laminin surrounding collagen fibrils in the region that they insert into a cardiac myocyte. Scale bar: 0.25 μm.

such as colloidal gold. These experiments are often used to localize the presence of specific proteins at high resolution (Fig. 7). In these types of studies, the extensive cross-linking of proteins that results from glutaraldehyde fixation and the effects of OsO₄ usually reduces the antigenicity of a specimen to the point that antibodies no longer recognize the antigens of interest. Various modifications of the fixation and dehydration protocol are often required in order to maintain the antigenicity of a sample. Ultrastructural immunocytochemical protocols have been developed for both pre-embedding experiments, in which the antigen:antibody reactions are performed prior to normal processing for TEM, and post-embedding experiments, in which the reaction is performed after resin embedding and sectioning. In both types of experiments, the ultrastructural integrity of the specimen is usually sacrificed to some extent to maintain the antigenicity of the sample by fixing it in a freshly prepared 2–4% solution of phosphate-buffered paraformaldehyde that contains a small concentration (0.1–0.2%) of glutaraldehyde. In general, pre-embedding protocols result in more efficient labeling of surface antigens, and post-embedding protocols should be used for intracellular labeling of antigens or in experiments that involve a large piece of tissue that would prevent penetration of the sample by antibodies and the labeling agent.

PREPARATION OF HARD BIOMATERIALS AND POLYMERS FOR TEM

The aforementioned techniques work well for biological samples and for soft nonbiological samples that

can be embedded in a resin and sectioned with a diamond knife on an ultramicrotome. However, many composite materials and alloys used as biomaterials and in biomedical engineering applications may be too hard to section on a routine basis. Examples of these types of samples are nanocrystals, which may be used for targeted drug delivery as discussed in the following text, or larger materials that may be used as scaffolds for tissue growth. Because of the small size of nanocrystals, it is often possible to spray a concentrated solution of particles directly onto a TEM grid that is coated with a thin plastic formvar or nitrocellulose film. When the solution dries on the grid, the material can be directly imaged by a TEM.^[10]

To image larger pieces of hard biomaterials, it may be necessary to thin the material to a point where the TEM electron beam can pass through the material to form an image. In this case, it may be necessary to use specialized equipment and techniques such as jet polishing, ion milling, or a focused ion beam to remove specific layers of material prior to imaging, or to create particles small enough to prepare as described earlier.^[11,12]

OVERVIEW OF SOME SEM AND TEM APPLICATIONS

Cell and tissue engineering often rely on biomaterials that act as scaffolds to physically support tissue growth and stimulate specific cell functions.^[13] Over the past several years, electron microscopy studies have certainly been important in developing a number of tissue engineering protocols for materials such as the hydroxyapatite composites used for bone and dental implants,^[14-16] the plastics used as a bridge to grow neuronal tissue,^[17] and other naturally occurring biomaterials, such as collagen, that have been used to grow a variety of cells and tissues.^[18-20]

Characterization of the ultrastructural morphology of these biomaterials by electron microscopy often includes imaging and defining features such as porosity,^[16,21-23] the arrangement of fibrous material such as carbon or collagen within a substrate,^[18,20,24,25] and topographical characteristics, such as minute ridges, that may guide cell growth and/or attachment.^[22,26] An extension of these basic studies that characterize biomaterials is the examination of cell and tissue phenotype and growth following exposure to a scaffold material. These studies frequently utilize SEM to characterize cell-spreading patterns, in order to illustrate that cells respond more in an *in vivo* like preparation on one substrate than another. Studies of this nature have shown that structures as small as a few nanometers can significantly alter the morphology and behavior of cells in culture.^[26-28] Other examples

of these types of studies include the application of chondrocytes to a variety of alginate and fibrin matrices to determine if they would promote sufficient chondrocyte proliferation and differentiation to produce a cartilage matrix. In these studies, Perka et al. found that specific mixtures of these biomaterials created stable cartilage transplants for reconstructive surgery.^[29]

In addition to the characterization of nanoparticles,^[11,15] TEM is frequently used to examine the interaction of extracellular matrix components, such as collagen, with implanted biomaterials;^[30] the differentiation and structure of cells in response to culture in the presence of a variety of biomaterials;^[18,25] and inflammatory responses to materials used in the construction of long-term bioengineering scaffolds or implants. For example, when metallic alloys used to repair bones are in contact with physiological fluids they frequently corrode and release small metal particles into the surrounding tissues and blood.^[31] This is often a problem in the use of long-term implants such as those used in hip replacements and in metals used for the internal repair of long bones. Germaine et al. found that nanoparticles of cobalt-chromium and alumina ceramics commonly associated with the wear of hip replacements resulted in the increased death of cells in culture.^[32] Vöggenreiter et al. also demonstrated by TEM that microparticles associated with the wear of stainless-steel and titanium implants in long bones were phagocytosed by cells in the vicinity of the implants, and that ingestion of the particles by the cells resulted in a significant inflammatory response.^[33]

Electron microscopy has also been used recently to examine a number of biomaterials designed to provide the controlled delivery of reagents to a specific tissue site for targeted drug delivery to tumors.^[34-36] As in the examples previously cited, it is important when designing these targeted carriers to be able to characterize the structure of these materials in order to determine factors such as size, shape, and porosity,^[10] as well as biodegradability and the immunological responses of the host.^[37,38] As nano-biomaterials get smaller and are used more frequently, electron microscopy will become even more important in their manufacture and characterization. Indeed, techniques and instrumentation associated with electron microscopy will need to be improved to keep pace with the technology.

SPECIFIC APPLICATIONS IN CARDIOVASCULAR TISSUE ENGINEERING

In our laboratories both SEM and TEM techniques have been used extensively to characterize a cardiovascular tissue-engineering model that involves the

Fig. 8 SEM micrograph of cardiac fibroblasts (Part A) and TEM micrograph of cardiac myocytes (Part B) that have been cultured on collagen tubes used in a tissue engineering model for cardiac tissue. Thin collagen fibrils (C) from the tube are evident in both images. In Part A it is possible to determine fibroblast interaction with the collagen (arrows). In Part B, undifferentiated cardiac myocytes were placed in the tube and cultured for up to six weeks. During the culture period myocytes differentiate and develop mature sarcomeres, as illustrated by the well-developed Z-disks (Z), sarcomeres, and nuclei (N). Scale bars: Part A, 10 mm, ; Part B, 1 μ m.

seeding of cardiac myocytes and/or fibroblasts on an aligned collagen tube (Fig. 8). Descriptions of the collagen tubes, the equipment needed to produce them, and how these tubes are being used to examine the maturation of embryonic cardiac myocytes have recently been published.^[20,25] In this model system it is possible to seed the collagen tubes with undifferentiated embryonic cardiac myocytes, to observe their differentiation over time, and to treat the myocytes with a variety of growth factors and/or mechanical stimulants to induce increased rates of differentiation. This provides a model to study embryonic cardiac development during the period of time that myocytes convert from a hyperplastic to a differentiated hypertrophic phenotype, and also to study the potential to produce a viable cardiac patch with mature functional

cardiac myocytes, which can be implanted in an area of a cardiac infarct. Further development of this cardiac tissue-engineering model may provide a unique mechanism for repair of damaged heart tissue.

CONCLUSION

The Microscopy Society of America has adopted the slogan “We are the eyes of science,” and this statement certainly applies to the use of SEM and TEM in the fields of biomaterials and tissue engineering. As detailed earlier, both types of microscopy can be used to answer a number of questions concerning materials used in engineering, as well as the response of cells and tissues to variations in the materials. As these fields continue to develop, electron microscopy will play a central role in biomedical engineering and applications of the nanosciences in targeted drug and gene delivery for the modeling of cells and tissues.

Electrospinning

Darrell H. Reneker

Haoqing Hou

Department of Polymer Science, The University of Akron, Akron, Ohio, U.S.A.

INTRODUCTION

Electrospinning is a unique process that produces polymer fibers with diameters ranging from a few nanometers to a few microns. The electrospinning process is being used or finding uses in protective clothing,^[1] air filtration,^[2] template nanofibers for preparing metal or polymer nanotubes,^[3,4] biomedical applications including biomedicine,^[5–7] scaffoldings for tissue growth,^[8,9] and drug-delivery systems.^[10] Other possible uses include solar sails, light sails, mirrors for use in space,^[11] and nanoelectronics.^[12]

It is the purpose of this article to describe what polymer nanofibers are, how they are made by an electrohydrodynamical process called electrospinning, and show their potential relevance to the broad range of biomaterial needs outlined above. Hundreds of kinds of nanofibers have been made from polymers, including elastomers, and polymers that can be heated to form carbon, glass, or ceramics. Solvents ranging from paraffin oil to sulfuric acid have been used. Fibers have been electrospun from a shorter list of molten polymers. Nanofibers were used for more than two decades in the air filtration industry,^[2] e.g., to remove particles from the inlet air stream of large turbine and engines. Interest in the applications of nanofibers in filtration is widespread. The interest in the biomaterial applications of polymer nanofibers is not far behind. The technology of making and using nanofibers is not yet fully developed. Many technical and scientific problems need to be solved. It is fortunate that the electrospinning apparatus is inexpensive, simple to operate, fits nicely on a laboratory bench, and can be scaled up to produce large quantities of nanofibers.

ELECTROSPINNING PROCESS AND NANOFIBERS

History of the Electrospinning Process

Although the first patent on electrospinning of polymer fibers was issued to Formhals^[13] in 1934, Lord Rayleigh^[14] in the late 1800s studied the fundamental principles of electrospinning and calculated the maximum amount of charge that a drop of liquid can hold before the electrostatic driving forces overcome the

surface tension of the drop and eject a jet. Zeleny^[15] described and photographed electrospinning phenomena in the early 1910s. In the 1960s, Taylor^[16] studied the deformation and disintegration of water droplets in an electrical field and analyzed the conditions at the point that formed. He showed that a conical interface between two fluids in an electric field is stable if the cone has a semiangle of 49.3 degrees. During the past decade, Reneker and others studied the electrospinning process—both experimentally and theoretically—and also developed its applications.^[17–25] The average fiber diameter can be adjusted throughout a broad range down to a few nanometers^[26,27] by proper selection of the processing parameters.^[11,19] The electrospun fibers can be oriented and ordered as they are collected.^[28,29]

Apparatus and Description of the Electrically Charged Fluid Jet

The apparatus for the electrospinning process is simple, as shown schematically in Fig. 1. The high voltage power supply produces a voltage in the range of 0–30 kV or higher. For safety, the current is often limited to a few hundred microamperes. The schematic shows a jet moving in a horizontal direction from the tip of a syringe needle to the grounded collector. In fact, the direction of the jet can be vertical and directed up or down since the electrical forces on the jet are usually much larger than gravitational forces. For melt electrospinning, the apparatus is similar in principle. An electrical heater maintains the temperature of a reservoir of molten polymer, which is pumped to the tip.

When a strong electrostatic field is applied to the syringe needle or a capillary, a droplet of the polymer solution held at the tip by surface tension is deformed into a conical shape, which is called the Taylor cone. When electrostatic force overcomes the surface tension of the solution, a liquid jet is ejected from the tip of Taylor cone. The high frame rate images in Fig. 2 reveal the change of the shape of the drop to a sharp cone, the ejection of the jet, and the readjustment of the shape of the drop after the flow of the jet is established. The as-formed jet has a relatively large

Fig. 1 Schematic of electrospinning setup using polymer solution.

diameter at the beginning and becomes thinner as the electrical forces elongate the jet.

The jet travels in a straight line for some distance in the direction of the applied electric field. Beyond that distance, the path is curved and more complicated. The path of the jet can be observed^[19] stereographically at a high frame rate using an exposure time for each frame that stopped the motion so that the incremental evolution of the path of the jet is observed in successive frames. A mathematical and computer model^[19] developed by Alexander L. Yarin shows that the curved path is a consequence of an electrically driven bending instability of the charged jet. The Yarin model reproduced the path of the jet, its motion, the large elongation that was observed, and other data. In a subsequent paper,^[30] it was shown that including the increase in viscosity, which occurs as the solvent evaporates from the jet, improved the agreement between the observed path and the calculated path.

A typical segment of the jet does not flow along the path shown in a particular stopped-motion image except in the straight part of the path. The trajectory of the

center of mass of a typical segment in the curved part of a jet path moves both outwardly and in the direction of the applied electric field between the tip and collector. There is also an influence from the charge carried on the more distant parts of the jet. All the while, the curved segment is elongated, mostly by the self-repulsion of the electrical charges carried with the segment.

This bending and elongating behavior of segments in the curved part of a jet is not self-evident. Neither splaying nor whipping provide adequate descriptions of the actual path of the jet. These words were used^[18,22,23,25] to attempt to describe the paths^[25,31] deduced from visual observations, ordinary video photography, and single stop-motion images. Splaying and whipping have been used uncritically in the introductions of contemporary papers on electrospinning.

Nanofibers and Nonwoven Nanofiber Sheets

A polymer nanofiber can be formed after solvent evaporates or the melt solidifies while the jet moves

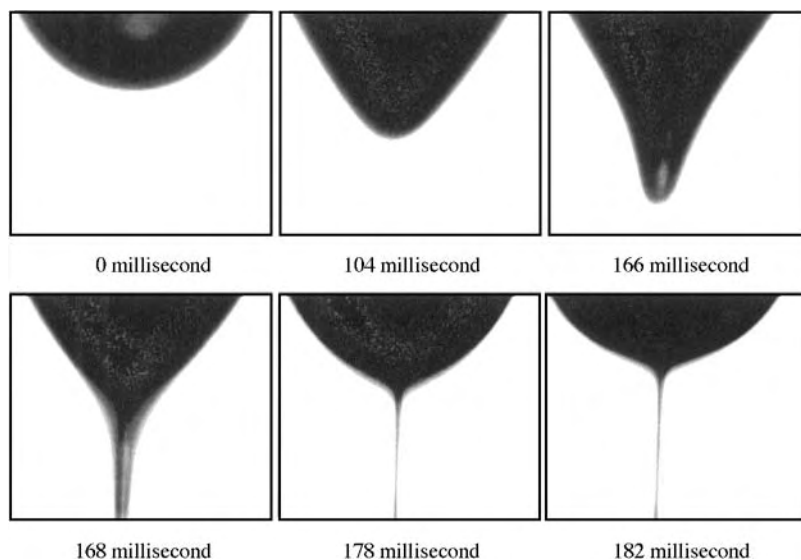

Fig. 2 High-speed images from CCD camera taken as the droplet became a Taylor cone from which a charged jet was ejected. A 7.0% solution of polyethylene oxide (Mw 400,000) in water was used for the experiment.

from the tip to the grounded collector. The diameter of the as-formed polymer nanofiber can be made as small as a few nanometers, as shown in Fig. 3A, by empirical choices of solvents and process parameters. The nanofibers are gathered on the collector in the form of a nonwoven sheet. Residual charges on the collected nonconductive nanofibers repel the oncoming nanofibers and tend to spread the nanofibers uniformly on the collector. Figure 3B shows a scanning electron microscope image of an electrospun nonwoven nanofiber sheet of biodegradable and bioresorbable polylactide. If a collector in the form of a cylinder rotating around its axis with a surface velocity greater than a few meters per second is used, a partially aligned nanofiber sheet is obtained, as shown in Fig. 3C and D.

Parameter Measurements and Nanofiber Characterization

The measurement concepts and methods for characterization of electrospun nanofibers described previously are helpful for control of the electrospinning process. Useful process parameters include: 1) electrical potential difference and electric field; 2) electrical current; 3) solution flow rate; 4) the diameter of the straight segment of the jet; 5) typical three-dimensional paths of the jet; and 6) the distribution of diameters of the nanofibers produced. The following provide practical comments on each of these measurements. Other parameters may also be useful.

Potential difference—in volts—between the tip and the collector

For a flat collector plate with a diameter that is not much smaller than the distance between the tip and the collector, the electric field along a line that passes through the tip and is perpendicular to the collector plate is equal to the potential difference divided by the distance between the tip and the plate. There are important differences from this rule at locations that are typically less than one micron from a conical tip with a half angle of 35 to 50 degrees. This rule only

applies before the jet is created. The jet is charged and has a complicated, changing path, which affects the electric field near other parts of the jet. The electric field at a particular segment can be approximated by calculations based on models of the experimentally observed paths.^[20]

Electrical current carried by a jet

Typical currents carried away from the tip by the electrically charged jet of polymer solution range from less than 100 nanoamperes to around 100 microamperes. The jet can be affected by currents caused by the movement of airborne ions that are sometimes generated inadvertently by corona discharge from parts of the apparatus that are surrounded by high electric fields. The presence of airborne ion currents can be detected by measuring the current between a metal ball placed near the apparatus and the grounded terminal of the power supply. It is usually possible to reduce the corona current by avoiding fine wires and sharp points in the parts of the apparatus to which the high voltage is applied or covering the conductors with insulating tubes.

Flow rate of the polymer solution

Pumps of various sorts can be used to establish controlled rates of flow into the tip although the part of the pump that contains the fluid will need to be at a high electrical potential if the collector plate is connected to ground. Alternatively, the pump and reservoir may be connected to ground, and the electrical potential difference between the tip and the collector established by applying a high voltage to the collector. The flow rate can be determined by the pumping rate, observing the change in the amount of fluid in the reservoir, or measuring the mass of dry fibers collected. Even with a constant flow rate pump, the flow rate of the jet may oscillate with time if the shape of the droplet varies with time. The flow rate of solution to the jet can be adjusted in an experimentally simple way by changing the height of a liquid column of solution

Fig. 3 (A) Transmission electron microscope image of nylon-4,6 electrospun nanofibers; (B) SEM image of PLA electrospun nonwoven nanofiber sheet. (C) and (D) are aligned PLA and collagen fibers. (Reproduced with permission from Ref. [9]. Copyright (2002) American Chemical Society.)

that feeds the droplet, e.g., by using a tilted pipette in place of the syringe pump shown in Fig. 1.

The electrical conductivity

Electrical conductivity of the solution can be measured with any of a wide variety of electrode geometries that are calibrated in a solution of known conductivity using an ohmmeter. Wires in contact with the ends of a column of liquid in a tube of known diameter is convenient since the length of the electrical path is determined by the distance between the ends of the wires. Bubbles of gas produced at the electrodes by electrolysis should be avoided by using low current and short measurement time.

Diameter of the jet

The diameter of a flowing jet in the straight segment before the electrically driven bending instability develops can be measured as a function of position by diffraction of laser light. This method, used by Doshi,^[17] measures the jet diameters in the range from around one micron to a few hundred microns. Video photography of the diffraction patterns follows temporal changes in the diameter of the segment of the jet that is illuminated by the laser beam.

Interference colors generated when white light is scattered in certain directions by a tapered cylindrical polymer fiber that is larger than the wavelength of visible light, which is around 0.5 microns, provide an elegant way to compare the diameters of adjacent segments of a jet when the diameter is in the range of 0.5 to 10 microns.^[32] Photography of the interference colors captures the time dependence of the diameters. The interference colors can be seen even where the jet path becomes complicated after the development of the electrically driven bending instability. The region within the envelope cone (Fig. 1), where the jet diameter is larger than the wavelength of light, is easily distinguished by its color from the faint white region where the jet diameter is smaller.

Three-dimensional path of the jet

Stereo images of the jet can be obtained by photographing the jet through a pair of wedge-shaped prisms with an apex angle of around 10 degrees. The prisms are placed near the jet, which is just far enough away to avoid attracting the charged jet to the prisms. The light that passes through one prism is captured on one side of a frame in a digital video camera, and the light that passes through the other prism is recorded on the other side of the frame. The size of the field that can be

photographed in this way is commensurate with the area of each of the wedge prisms. Stereo pairs captured synchronously with two or more digital video cameras allow the observation of larger or smaller fields and provide an adjustable choice of angles between the stereo views. The stereographic apparatus collects data that can be compared with the computer model described by Reneker et al.^[19,30]

Flash illumination with argon or other gas discharge lamps is very useful since the jet path does not change much during the 50 to 100 microsecond duration of the flash. An easy way to obtain representative images of jet paths is to set up a digital video camera to observe the interference colors described previously, and then illuminate the jet with periodic, unsynchronized sequences of flashes. The flashes from inexpensive strobe lights can be made to occur at a frequency slightly different from the 30 frames per second that is typical of video cameras. Occasional frames, in which the flash occurs while the camera is capturing an image, record images of the jet path at the instant of the flash. This illumination scheme was also used with the prisms described previously to obtain stereographic images of many typical paths in only a few minutes. The evolution of the shape of the jet path cannot be followed in detail by this method. A flash repetition rate of a kilohertz or more may be required to record the incremental changes satisfactorily.

Diameter distribution of nanofibers

Scanning electron microscope images provide data useful for determining the distribution of nanofiber diameters when the diameters are smaller than the wavelength of light. Both hand measurement of images and computational image analysis are useful and practical. Measurements of the intensity of laser light scattered by a nanofiber promises a less cumbersome method to determine the diameter of nanofibers, but this method is not yet fully developed.

Safety

Electrical shock hazards are minimal if the maximum current available from the high voltage power supply is limited to a few hundred microamperes. Large, electrically isolated conducting materials such as metal or solution reservoirs can accidentally form large capacitors. If such a capacitor is charged to a high voltage by the supply, a serious spark or shock could occur. The possibility of forming and charging a capacitor must be recognized and avoided.

The fire hazard of flammable solvents can be limited by keeping the amount of solvent small. Larger quantities of solvents require appropriate precautions

to prevent fire. Scale-up of the electrospinning processes requires careful engineering for safety.

Dangerous accumulations of explosive vapors must be avoided since sparks can occur at any time and sometimes occur in unexpected places. Noxious vapors can be avoided with adequate ventilation or efficient solvent recovery.

BIOMEDICAL APPLICATIONS OF ELECTROSPUN NANOFIBERS

Scaffolds for Tissue Engineering

Nanofibers offer many ways to make highly porous scaffolds to support and guide tissue growth. Nanofibers that provide biodegradability, bioresorbability, and biocompatibility can be made. The highly porous nature of scaffolds of nanofibers allows cell migration and growth as well as transport of nutrients and metabolic waste.^[33] Nanofiber technology will take its place alongside solution casting, gel casting, gas saturation, three-dimensional printing, and the like^[34] as a way to produce scaffolds useful for tissue engineering. By electrospinning a solution of poly(D,L-lactide-co-glycolide) (PLGA) in a solvent mixture (1:1) of tetrahydrofuran (THF) and N,N-dimethylformamide (DMF), Ko et al.^[8] made a scaffold structure in the form of an electrospun fiber sheet of 92% porosity with pore sizes ranging from 2 to 465 μm , as shown in Fig. 4A. The cells lived and divided in this structure, which pushed nanofibers aside to make room for the increasing number of cells. Bowlin et al.^[9] made a scaffold structure of electrospun collagen nanofiber. They seeded aortic smooth muscle cells into an electrospun collagen scaffold. Within seven days, the scaffold was densely populated with the smooth muscle cells (Fig. 4B).

Although the goal of producing a clinically useful tissue scaffold is not yet realized, electrospinning provides a practical approach. A wide variety of polymers can be used. Process parameters can be adjusted to produce nanofibers of different diameter and sheet density. Intricate designs of scaffolds, which require choice and control of the pore size distribution, mechanical properties, and biochemical properties of the scaffold, can be realized with nanofibers.

Nanofibers for Controlled Release of Drugs

Controlled delivery systems are used to improve therapeutic efficacy and safety of drugs by delivering them at a rate dictated by the need of the physiological environment to the site of action.

A new method to prepare drug-delivery matrix by electrospinning was recently reported and patented.^[10,35,36] Poly(lactic acid) (PLA), poly(ethylene-co-vinyl acetate) (PEVA), or their 50/50 blend were electrospun from a chloroform solution that contained a suspension of fine particles of tetracycline hydrochloride. Short-time, drug-release experiments showed that electrospun fibers of PLA, PEVA, or their 50/50 blend have a higher release rate than a comparable film. Electrospun mats of PLA exhibited a release rate about six times higher than that of films with similar compositions. The PEVA mats exhibited a release rate that was about 10 times higher than that of the comparable film after an 80-hour test. The diffusion path of drug from the nanofiber reservoir into the test liquid was much shorter than for the film.

The morphology, porosity, and composition of drug-release matrices can be controlled to optimize the release rate and release period. Drug-release systems made by the electrospinning process could be used not only for human health but also for the protection of crops or forest plants against disease and insect pests. Nanofibers loaded with pesticides can be applied by

Fig. 4 (A) SEM image of electrospun poly(D,L-lactide-co-glycolide) (PLGA) scaffold structure composed of randomly oriented nanofibers, scale = 10 μm . Scale = 10 μm . (Reproduced with permission from Ref. [9]. Copyright (2002) American Chemical Society.)

electrospinning nanofibers onto electrically grounded plants. In this method, the plants capture the pesticides efficiently with minimal environmental pollution. Pesticides can be released from the nanofibers gradually over a relatively long time to shield crops or plants from disease. Pesticide retained in nanofibers on the plant leaves can kill insects that eat the leaves.

Wound Dressing

An ideal wound dressing provides: 1) a moist environment; 2) protection from secondary infections; 3) adequate gaseous exchange; 4) absorption of wound fluids; 5) painless and easy removal; and 6) prevention of secondary contamination.^[37] Winter^[38] showed that an occlusive wound dressing that maintains a moist wound environment accelerates healing.

Electrospun nanofibers provide a practical approach to improve wound dressings.^[6,7] Wound dressings can be produced for individual patients according to the location, size, and nature of the wound. The electrospun nanofiber membranes are porous and permeable to gases such as O₂, CO₂, and water vapor. Appropriate process parameters can control the pore size of the membrane and the surface area per unit mass to maintain a moist environment under the wound dressing and control the exchange gases or vapors. Antibacterial drugs can be carried with nanofiber. The surface area of the dressing can be increased even more by making highly porous nanofibers.^[39] The dressings can be made to be biodegradable, bioresorbable, and biocompatible by using appropriate polymers. Nanofiber wound dressings are flexible, conformable, and easy to apply. Complete removal of the dressing, which can be painful, may not be needed.

COATED NANOFIBERS

Nanofibers can be coated with other polymers, metals, carbon, or semiconductors. Ceramic nanofibers and tubes can be made from electrospun polymer nanofibers. Physical vapor deposition,^[4] plasma-enhanced physical sputtering,^[40] chemical vapor deposition,^[3] and the sol-gel process^[41] can be used to modify the surface chemical and physical properties of nanofibers. The applications of such coated nanofibers in biotechnology remain to be investigated. Some examples of coated nanofibers are described here.

Metal and Ceramic Coating

Subnanometer thick coatings of high purity metal can be deposited by physical vapor deposition or plasma-enhanced physical sputtering technique. A 10 nm-thick

Fig. 5 Optical microscope image of nylon-4,6 coated with platinum by plasma-enhanced physical sputtering technique. The insert is a transmission electron microscope image of a platinum-coated nylon-4,6 nanofilament.

aluminum coating on poly[N,N'-(1,3-phenylene)]isophthalamide nanofibers, as reported by Liu et al.,^[4] was obtained by physical vapor deposition aluminum-coating technique. Subsequently, the aluminum-coated poly[N,N'-(1,3-phenylene)]isophthalamide nanofibers were converted into Al₂O₃ ceramic nanotubes by heating in air. Figure 5 shows platinum-coated nylon-4,6 membrane prepared by plasma-enhanced physical sputtering platinum coating of polymer nanofibers.

Coating with a Second Polymer

The chemical vapor deposition coating technique is very suitable for coating electrospun nanofibers with poly(p-xylylene) (PPX) or its derivatives poly(p-chloroxylylene) (PPX-C) or poly(α -bromo-p-xylylene). Poly(α -bromo-p-xylylene) can be converted into PPV, an electroluminescent polymer, by heating to 200°C. The chemical vapor deposition PPX-coating technique allows a hole-free coating to be formed on the substrate at room temperature and was used by Greiner et al.^[3] to form PPX-coated electrospun fibers. PPX is thermally stable, solvent-resistant, and biocompatible. The PPX-coated polylactide electrospun nanofibers were transformed into PPX nanotubes by thermal degradation or solvent-extraction removal of PLA.^[3] Because of the biocompatibility of PPX, these nanotubes are candidates for use in controlled release of drugs.

CONCLUSION

Nanofibers are promising candidates for biomedical applications. The mechanical, surface, and biochemical properties of nanofibers span a large and useful range. Their high tensile strength, which is combined with

flexibility and high surface area per unit mass, provide many possibilities for the design of new therapeutic materials, devices, and systems. Electrospinning of polymer nanofibers provides a broadly applicable method for producing nanofibers for needed research and development of these possibilities.

INTRODUCTION

Endoscopy is a medical tool at the forefront in the diagnosis and treatment of human diseases. Endoscopes, inserted through orifices such as the mouth, nose, anus, and urethra, play an instrumental role in the management of diseases of the oropharynx, esophagus, stomach, small intestine, colon, pancreatobiliary tree, larynx, bronchial tree, and urinary system. This article will focus on the use of endoscopes for optical diagnostic purposes in the gastrointestinal (GI) tract. It will present the fundamental concepts of endoscopy, including the optical and mechanical components of a typical endoscope. It will review current endoscopic imaging modalities as well as introduce emerging and novel endoscopic imaging technologies.

The field of endoscopy continues to evolve with the aid of technological innovations and development. Early endoscopes consisted of simple rigid tubes that provided limited views of a few easily accessed organs.^[1] Recent developments have substantially enhanced the capabilities of endoscopes. For example, fiber optic imaging bundles have allowed for the development of flexible instruments that may be guided through tortuous organs to visualize deeply into the body. The development of miniaturized semiconductor detectors have enabled substantial improvements in image resolution and a reduction in instrument size. Conventional endoscopy is based on the detection of diffusely reflected white light from tissue surfaces to reveal neoplasms.^[2] Recent advancements in optical imaging take full advantage of light's properties such as its spectral content and coherence to improve contrast and resolution. Ultrasound imaging has been combined with endoscopy to enable visualization beyond the tissue surface. Novel imaging modalities such as fluorescence imaging and optical coherence tomography (OCT) provide even more informative images. Technological improvements that are enhancing the capability of endoscopes to

visualize, diagnose, and treat human diseases are revolutionizing the practice of medical endoscopy.

ENDOSCOPE COMPONENTS

An upper GI endoscope will be used to illustrate the basic components of an endoscope. An upper GI endoscope enables visualization of the esophagus, stomach, and duodenum. A schematic diagram of the individual components of the endoscope is shown in Fig. 1. The distal tip houses the optics required for illumination and collection of endoscopic images, multipurpose instrument channels, and conduits for providing air, water, and suction.^[2] The bending section consists of a set of user-operated hinges that allow the distal tip to deflect at angles as high as 270°. The insertion tube is encased in a rugged plastic. The proximal end of the endoscope contains an article port into a multipurpose instrument channel, the control knobs for manipulating the hinges in the distal end, a lock for maintaining tip deflection, controls for air, water, and suction, and switches for capturing and storing images. The endoscope is connected to a video processor unit through an umbilical device, which contains the light guide, electrical connectors, and supply lines for air, water, and suction. Endoscope length varies according to the length of the targeted lumen. The total length of the upper endoscope is about 1.5 m.

The Distal Tip of Endoscope

The distal end of an endoscope contains the optics for image acquisition. A cross-sectional view of a forward-viewing endoscope is shown in Fig. 2A, illustrating the location of the objective and illumination lenses, air/water conduit, and detector. A corresponding end-view is shown in Fig. 2B, showing that identical illumination

Fig. 1 A basic endoscope.

sources are located on either side of the objective, in this case, to uniformly illuminate the image. The large instrument channel is useful for the delivery of tools such as biopsy forceps, electrical cautery tools, balloon dilators, diagnostic brushes, etc. The instrument channel also acts as the suction tube. The objective generally contains several optical elements such as a diverging lens, intermediate lenses, a pupil, and an achromatic lens for imaging large fields of view and large spectral ranges with minimal aberrations. The air/water channel directs water across the outer surface of the objective to clear debris, or air to insufflate and expand the organ being examined. The first endoscopes used an optical fiber imaging bundle to transmit images to the proximal end of the endoscope for direct viewing through an eyepiece by an endoscopist. Advancements in semiconductor technology have led to the development of video endoscopes in which miniature charge-coupled device (CCD) arrays have replaced the imaging bundles. These CCD arrays are small enough to be positioned in the distal tip directly behind the objective lens.

The Imaging Lens

The objective lens of the endoscope is designed to image a large field of view with high resolution. As it is very difficult to achieve both of these requirements with a simple lens, endoscopes utilize multiple lenses to form an image. The design of these lens systems is complex, and is usually done with an optical ray-tracing program. An example of an optical train of lens elements required to produce an endoscopic image is shown in Fig. 2A. The angle between a ray of light and the normal to the objective is defined as θ . A diverging lens (negative focal length) is utilized to image a large angle θ and therefore to maximize the field of view. A pupil is located behind the objective lens to spatially reject extraneous internal reflections. A series of intermediate lenses, rather than one optical component, helps to focus the image onto the detector with minimal aberrations. An achromatic lens corrects for chromatic aberrations so that all colors in the visible spectrum are precisely focused at the detector. The focal length of the objective is different at the

Fig. 2 The distal tip of a conventional video endoscope. (A) Side view showing illumination and detection optics. (B) End view.

center of the image than at the periphery, causing barrel distortion in the image.^[3] For an imaging system with barrel distortion, image magnification is higher at the center of the image than at the edges. The endoscopist can maximize the resolution of a region of interest by placing it in the center of the image where the density of image pixels is the highest (owing to increased magnification).

The Insertion Tube

An exposed cross section of the insertion tube is shown in Fig. 3. The outer layer consists of a durable plastic covering capable of withstanding caustic bodily fluids such as gastric acid and bile as well as the disinfectants used to sanitize the instrument after each use. Under the covering, a wire mesh runs along the length of the tube to provide structural rigidity. Under the mesh, helical steel bands maintain the round shape and provide further mechanical protection. The contents of the insertion tube may include a light guide, imaging bundle, angulation control wires, air and water pipes, a hollow instrument channel, and electrical wires to a CCD camera. The stiffness of the endoscope is designed to vary along its length to facilitate insertion into the GI tract. The distal end can be manipulated to produce the large bending angles that are needed for visualization of tissues located behind the endoscope (retroflexed view), as well as for aiding the endoscopist in traversing tortuous internal organs such as the intestines.

Air, Water, and Suction

A set of buttons and valves are located on the proximal end of the endoscope to deliver air and water or to suction intraluminal contents. Air supplied by a pump within the video processor unit may be emitted from a nozzle on the distal tip. Air is introduced into a lumen such as the colon or stomach to expand the mucosal folds for improved visualization. Air may also be

Fig. 3 The contents of the insertion tube include the light guide, imaging bundle, angulation control wires, air and water pipes, and instrument channel. Mechanical support is provided by a wire mesh and steel bands.

suctioned from a distended lumen for decompression. Water may be delivered through a nozzle on the distal tip, and over the surface of the objective to remove obstructing debris. Intraluminal contents such as fluid or stool are aspirated through the endoscope to a collection bottle via an external suction pump. The umbilical cord to the video processor unit contains connections for the light source, water supply, suction pump, and electrical power.

Manipulating the Endoscope

The angulation control of the distal tip is performed by the left hand of the endoscopist, leaving the right hand free to hold and manipulate the insertion tube. These angulations are produced by a durable set of guide wires that deflect the distal end in four directions. If desired, a brake can be applied to lock the position of the deflection. The second, third, and fourth fingers grip the proximal end of the instrument against the palm, leaving the left thumb to control the up/down knob and the left index finger to operate the air/water and suction valves. The right hand is used to torque and advance the insertion tube, to insert accessories down the instrument channel, to control the right/left knobs, and to activate remote switches.

Endoscopes are available with varying points of deflection, diameters, and instrument-channel sizes. These endoscopes are designed for specialized procedures, many of which are experimental. The exciting pace of advancements in endoscopic technology and development suggests that the tools and procedures described in this review will likely undergo further refinements.

Endoscopic Tools

A diverse set of tools are available for performing diagnostic and therapeutic endoscopic procedures such as standard biopsy, polyp removal (polypectomy), tumor resection, and hemostasis. These tools are generally inserted through the instrument channel of an endoscope. Biopsy forceps are often used to obtain samples of GI mucosa or diminutive (<2mm) polyps for histopathological analysis. Larger polyps may be removed by the use of snares that frequently utilize electrocautery to burn through tissues. For more effective and safe removal of sessile, flat, or depressed polyps, endoscopic mucosal resection is employed. Saline solution is injected with a sclerotherapy needle in the submucosa to elevate and separate the lesion from the underlying muscularis layer. Conventional snares and electrocautery devices may then be used to remove the lesion. Clip application is increasingly used in GI endoscopy, particularly in the treatment of GI bleeding and the closure of mucosal defects such as perforations,

anastomotic leaks, and fistulas. They are also used for radiographic marking to direct fluoroscopic stent placement and to target surgical, interventional radiologic, or radiation therapy. Argon plasma coagulation is used therapeutically to cauterize lesions or vasculature by the delivery of a large electrical current through ionized argon gas. There are many valuable tools in the armamentarium of endoscopic accessories. Further refinement of accessory technology and design will continue to strengthen the safety and efficacy of diagnostic and therapeutic endoscopy.

Non-GI Endoscopy

Endoscopy is often used to describe a host of related technologies outside of the GI tract. A brief listing of other common endoscopic modalities will be provided here. In laparoscopy, a small incision is made in the abdominal wall through which a laparoscope is inserted to visualize and perform procedures in the abdominal and pelvic region with minimal invasion. During laparoscopy, carbon dioxide gas is used to insufflate the abdominal region, separating the organs for better visualization. Coronary angioscopes are used to visualize the interior of blood vessels for diagnosing coronary lesions. A transparent balloon is inflated at the tip of the device to provide a clear imaging path to the vessel walls by displacing the blood, which is optically dense. Bronchoscopes are used for close examination of the bronchial-alveolar tree to perform a diagnostic lavage and biopsy. Scopes are also used by otolaryngologists in the naso-oral pharynx (laryngoscopy), by urologists in the bladder and urinary tract (cystoscopy), and by gynecologists in the uterus (hysteroscopy). As with colonoscopy, polyps may be removed and tissue may be cauterized. In short, endoscopic technologies are finding widespread use in an increasing number of medical areas. The overwhelming majority of endoscopic procedures, however, are performed in the GI tract.

ENDOSCOPIC IMAGING

Illumination

A variety of light sources such as metal halide, halogen, and xenon lamps may be used to provide endoscopic illumination. These light sources can provide incident powers of up to 300 W or more at incident wavelengths over the visible and near-infrared spectral regions. Because of the intense heat generated by these light sources, spectral filters are used to block the infrared portion, allowing only visible light to be delivered at the distal tip. The endoscope's light guide consists of an incoherent fiber optic bundle that has a large numerical

aperture (NA) lens at the proximal end to maximize the amount of illumination light coupled from the light source into the light guide. A diverging lens at the distal end is designed to illuminate the field of view of the imaging objective. The individual optical fibers in the light guide have high NAs and are made as large as possible in diameter, without compromising their flexibility and durability, to produce the highest possible packing fraction and illumination efficiency.

Image Detection

In early years, image detection was first performed by the eye of the endoscopist viewing the proximal end of a fiber optic imaging bundle through an eyepiece. Later, a camera was attached to the eyepiece to detect the image and display it on a video monitor. While this method is simple and effective, there are several limitations to fiber-based imaging.^[4] For example, a Moire pattern (interference artifact) is produced by the superposition of the image from the fiber optic bundle and the detector array of the camera. Also, the fiber optic imaging bundle is inefficient in collecting light, requiring high-power light sources. The number of optical fibers packed into the bundle, which affects the image resolution, is limited by instrument size and stiffness. Additionally, individual fibers may break over time, creating gaps in the image. In modern video endoscopes, a miniaturized CCD array located directly behind the objective lens detects the image and overcomes many of these shortcomings.

Image Resolution

The image resolution defines the level of detail that can be clearly seen on an endoscopic image. The transverse resolution is the smallest distance that two objects located perpendicularly to the optic axis (along the surface of the tissue) can be distinguished while the axial resolution defines the smallest distance that two objects located along the optic axis (into the tissue) can be distinguished. For conventional white light endoscopy (WLE), only the transverse resolution parameter is relevant because the light detected is reflected from the tissue surface and does not penetrate below. In other endoscopic methods where the light detected has penetrated with depth into the tissue, such as endoscopic ultrasound (EUS) and OCT, the axial resolution is also relevant. Barrel distortion introduced by the objective lens, as discussed earlier, causes the image resolution to vary across the field of view. Thus, endoscopes are characterized by an average transverse resolution. In Fig. 4, a set of plots shows the average transverse resolution of endoscopic images as a function of distance, d , varying from 5 to 75 mm, the typical range of

Fig. 4 Plots showing the average transverse resolution of endoscopic images as a function of distance varying from 5 to 75 mm. N_r is the total number of resels in the imaging system.

working distances. The total number of pixels (resolution elements), N_r , varies from 50,000 to 200,000, and reflects typical values found in fiber optic and video endoscopes. The total number of pixels is about 50,000 for fiber optic endoscopes (limited by the number of fibers) and about 100,000 to 200,000 for video endoscopes. Because more pixels can be packed into a CCD array than optical fibers in an imaging bundle, the average resolution for video endoscopes is generally better when imaging similar fields of view. As shown in Fig. 4, the average transverse resolution for both fiber optic and video endoscopes is submillimeter over the depth of focus and improves as the distal end of the endoscope is moved closer to the tissue surface.

ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY

Conventional endoscopes are too large to directly probe the pancreatic and bile ducts. However, a procedure

called endoscopic retrograde cholangiopancreatography (ERCP) is commonly used to visualize these sites with X-rays. In ERCP, a cannula is inserted into the papilla, the site where the pancreatic and common bile ducts join, and contrast is injected. This contrast is viewed with X-rays onto an external fluoroscopy monitor. Because the papilla, located within the ampulla of Vater, is on the side wall of the duodenum, there is not enough space for a forward-viewing endoscope to maneuver and perform the cannulation. Instead, a side-viewing endoscope, or duodenoscope, is used. The optics for a side-viewing endoscope are designed for imaging tissue located parallel to the axis of the endoscope. In Fig. 5A, a cross-sectional view shows an illumination bundle that is curved to deliver light to the side of the endoscope. The objective collects returning light from the side using a prism to reflect the image to the detector. Furthermore, the side-viewing endoscope has a forceps raiser located in the instrument channel to elevate the catheter during cannulation, as shown in the side-view in Fig. 5B. Only one illumination lens is located on the distal tip. Side-viewing duodenoscopes are about 120 cm in working length, and have a variety of instrument channel sizes, ranging from 2.8 to 4.0 mm. The larger diameter channels are useful for special instruments used in therapeutic biliary endoscopy, such as for endoscopic sphincterotomy, stone extraction, and stent placement. In Fig. 6, a radiograph shows the position of a duodenoscope with contrast agent illuminating the bile and pancreatic ducts. A filling defect in the cystic duct is because of a gall stone.

EUS

EUS combines endoscopy with ultrasound, using a miniaturized ultrasound transducer attached to the distal tip. Ultrasound images are collected with a transducer placed in close proximity to the structure being imaged.^[5] High resolution is obtained with EUS because

Fig. 5 (A) A cross-sectional view of a side-viewing endoscope shows the optics aligned to view images in the radial direction. (B) A side-view shows one illumination lens and a forceps raiser, utilized to help guide cannulation.

Fig. 6 A radiograph showing the position of a duodenoscope with contrast agent illuminating the bile duct (left arrow) and pancreatic duct (right arrow). The existence of a gall stone is preventing contrast agent from entering the cystic duct, creating a filling defect.

obstructing layers of bone and gas are avoided, allowing for higher acoustic frequencies to be used. In addition, high resolution of the GI wall can be obtained by having the ultrasound transducer placed directly on the wall. The clinical applications of this technology include determining the grade and stage of tumors and guiding fine needle aspiration (FNA) for tumor cytology. Two modes of scanning—radial sector and linear array—are often clinically used in a complementary fashion.^[6,7]

Radial Sector Scanning

Radial sector scanning provides ultrasound images in the plane oriented perpendicular to the axis of the endoscope. A radial sector echoendoscope uses a rotating acoustic mirror that scans images in sectors of 360 or 180°. They are available with 7.5 and 12 MHz transducers that have a focal distance of 30 and 25 mm and

an axial resolution of 200 and 120 μm , respectively, and a penetration depth of about 100 mm. The oblique-viewing echoendoscope, shown in Fig. 7A, has a small radial sector echoprobe attached at the distal tip. Radial scanning is usually performed as a preliminary step to determine the exact size, location, vascularity, and consistency of a lesion. An example of a 360° radial sector scan of the esophagus is shown in Fig. 8A. The layers of the wall, mucosa (m), submucosa (sm), and muscularis propria (mp) can be seen.

Linear Array Scanning

Linear array scanning provides ultrasound images in the plane oriented parallel to the axis of the endoscope, and is useful for guiding FNA procedures. A linear array scanning echoendoscope uses an array of transducers that provides a wedge-shaped image in sectors of 100 to 180°. They are available with 5 and 7.5 MHz transducers that have variable focal distances. The linear array can also provide color-flow mapping and Doppler imaging to locate blood flow in vessels for identifying landmarks and for assessing vascular invasion in tumors. In addition, this scanning mode provides continuous real-time visualization of a needle during EUS-guided FNA for cytology. The oblique-viewing echoendoscope, shown in Fig. 7B, has a curved linear array transducer located on the distal tip with a FNA needle protruding from the instrument channel. Fig. 8B shows an endosonographic view of an EUS-guided FNA of a periaortic lymph node. An arrow points to the needle used for aspiration.

WIRELESS CAPSULE ENDOSCOPY

In addition to video endoscopes, the development of miniaturized detector technology has allowed for images to be collected with a wireless capsule.^[8,9] The optics and electronics are contained within a small capsule, the size of a large vitamin pill, which can be swallowed and passed through the GI tract in several hours. There are no cables, wires, or optical fibers. This method of endoscopy is particularly suited for imaging

Fig. 7 (A) A mechanical radial EUS endoscope tip. (B) A curved linear array EUS endoscope tip with FNA needle protruding from the instrument channel.

Fig. 8 (A) A radial EUS image of an esophageal mass (on the right side of the wall, mucosa (m), submucosa (sm), and muscularis propria (mp) can be seen. (B) EUS-guided FNA of a lymph node. An arrow points to the needle used for aspiration.

regions of the GI tract that cannot be easily reached by conventional endoscopes, such as the small bowel. The illumination light is provided by light-emitting diodes. Images are collected by a complementary metal oxide silicon detector that produces images of comparable quality to a CCD detector but with greatly reduced power consumption. The images are transmitted from within the body by radio telemetry to aerials worn around the waist, and are stored on solid-state media.

In current devices, images are delivered at a rate of two frames per second. The capsule passes through the human GI tract in an average time of 80 (range of 17–280) minutes. An example of an endoscopic image collected with the wireless capsule is shown in Fig. 9, where an arteriovenous malformation has been found in the jejunum. The anatomic location of the capsule within the small bowel is determined by calculating the time of travel within the small bowel relative to the total small bowel transit time and the strength of the transmitted signal. The wireless capsule has potential for diagnostic use in occult GI bleeding.

NEW AND DEVELOPING IMAGING TECHNOLOGIES

A variety of endoscopic imaging technologies are under development and show great promise, warranting a brief description of their principles and results.

High-Magnification Endoscopy

High-magnification endoscopy visualizes the details of the mucosal surface to differentiate between malignant and benign tissue.^[10,11] While most raised mucosal lesions such as polyps are easily identified with a conventional endoscope, there is increased evidence for the existence of flat lesions with malignant potential.^[12] These lesions have a subtle appearance on WLE. High-magnification endoscopes have special intermediate

lenses that can be inserted into the optical train of the objective to attain image magnifications as high as 170X, although most instruments operate at a magnification around 35X. In the high magnification mode, the depth of field is usually significantly reduced, and the endoscope must be placed very close to the mucosal surface. Also, the field of view decreases significantly, and the images are susceptible to motion artifacts. These endoscopes are often combined with high-resolution CCD detectors to provide transverse resolution as fine as 10 μm . In comparison, the human eye has a transverse resolution of approximately 125 μm . Conventional video endoscopes have CCDs with 100,000 to 200,000 total pixels. The transverse resolution varies with distance as shown in Fig. 4. High-magnification endoscopes can have total pixels as high as 850,000. High-magnification endoscopes are often used in combination with chromoscopy.

Fig. 9 Wireless capsule image of an arteriovenous malformation (shown by an arrow) in the jejunum.

Fig. 10 (A) White light image of Barrett's esophagus in the distal esophagus. (B) A high-magnification view of the Barrett's epithelium.

An example of high-magnification endoscopy is illustrated with images taken of Barrett's esophagus, a premalignant condition for esophageal adenocarcinoma. In Fig. 10A, a standard endoscopic image is shown of the distal esophagus. The arrow points to a tongue of Barrett's esophagus (salmon pink) extending up into normal esophagus (light pink). In Fig. 10B, the Barrett's epithelium is visualized at high magnification. The magnified view shows a fine pit-patterned appearance. These pit patterns have a high correlation with the identification of Barrett's esophagus on histology.

Narrow Band Imaging

Narrow band imaging (NBI), comprising modified optical filters used in the light source of a videoendoscope system, has been applied to enhance image contrast.^[13] In brief, the videoendoscope light source unit consists of a xenon lamp and a rotating disk with three optical filters. The rotating disk and monochrome CCD are synchronized to sequentially generate images in three spectral bands. Using all three bands, a single color endoscopic image is synthesized. The image displayed on the monitor depends greatly on the spectral

characteristics of the optical filters. For example, NBI units have been developed with optical band pass filters at 500, 445, and 415 nm (with a FWHM band pass of 30 nm). In this case, the shorter wavelength falls within the hemoglobin absorption band. Colorectal neoplasms have been shown to alter normal capillary patterns. An NBI system may enhance capillary pattern imaging, thus increasing the ability to detect small or flat and depressed colon polyps. To illustrate the contrast enhancement that NBI affords, Fig. 11A shows a polyp imaged with conventional white light and the same polyp imaged with an NBI system in Fig. 11B.

Chromoscopy

Chromoscopy is an endoscopic technique that involves the application of tissue stains to highlight regions of interest in the mucosa, and is often used in conjunction with high-magnification endoscopy.^[14] The use of these methods is becoming more common for detecting flat lesions with malignant potential, which are not apparent on conventional endoscopy. There are two common types of stains: contrast and vital stains. Contrast stains such as indigo carmine and cresly violet collect

Fig. 11 (A) White light image of an adenomatous polyp. (B) A narrow-band image of an adenomatous polyp, showing improved contrast.

within the surface defects of the lesion and enhance the color contrast. These dyes are useful for identifying flat adenomas and carcinoma in situ in the colon and stomach. They are not absorbed by the mucosa and thus produce no systemic effects to the patient. Vital stains such as Lugol's iodine, methylene blue, and toluidine blue bind to the tissue and produce a chemical change. Lugol's solution contains iodine and potassium iodide and reacts with glycogen to produce a brown-black color. This dye is used to enhance lesions such as squamous cell carcinoma and high-grade dysplasia of the esophagus, which are poor in glycogen. Methylene blue is absorbed by the cytosol of the epithelium of the esophagus, small intestine, and large intestine. This dye is particularly useful for staining the intestinal metaplasia associated with Barrett's esophagus, which turns a bright blue color and exhibits a granular structure. Toluidine blue binds to the nucleus of cells and thereby highlights mucosa with increased DNA synthetic activity. This dye is also used for enhancing regions of Barrett's esophagus to screen for high-grade dysplasia. An example of chromoscopy in which indigo carmine has been applied to detect a small depressed tumor in the colon is shown in Fig. 12. On conventional endoscopy, these tumors exhibit a faint reddish or whitish color, subtle vascular abnormalities, and a slight deformity in the mucosal surface. In Fig. 12A, a sessile polyp is imaged with a slightly depressed lesion located on the top surface. The depression is not well visualized under standard white light colonoscopy. After indigo carmine is sprayed onto the lesion, the borders of the lesion are more clearly defined and the surface appearance is more clearly depressed as shown in Fig. 12B.

Endocytoscopy

Chromoscopy has been combined with high-magnification imaging for *in vivo* pathological diagnosis based on cellular and subcellular morphology of surface

tissues, a technique referred to as endocytoscopy.^[15] In this technique, an imaging device is passed through the instrument channel of a standard endoscope. An observation of nuclear-to-cytoplasm ratios, as well as cell density and staining characteristics, allows for delineation between superficial mucosal tissues that are normal or dysplastic.

Fluorescence Imaging

The endoscopic techniques discussed previously provide images of structural changes in the tissue. New endoscopic methods collecting fluorescence can determine biochemical and molecular changes in the tissue. Autofluorescence can occur from endogenous molecules such as aromatic amino acids, NADH, FAD, and porphyrins. Fluorescence can also be produced by exogenously administered drugs such as hematoporphyrin derivative and 5-aminolevulinic acid (5-ALA)—a technique known as photodynamic diagnosis. Both of these fluorescence methods are used to identify cancer at an early stage.

Autofluorescence

Autofluorescence images can be collected with either a fiber optic or video endoscope. Because no exogenous drugs are administered, these images can be acquired during routine endoscopy, and the patients do not experience photosensitivity after the procedure. However, the fluorescence produced from endogenous molecules is much weaker than that from exogenous agents or from diffuse reflectance, by a factor of 1000 or more, and a laser is required for excitation (illumination). With a fiber optic endoscope, fluorescence can be separated into two or more spectral bands to ratio the images, which corrects for spatial nonuniformities. The optimal spectral regimes for collecting images are determined by fluorescence spectra collected from

Fig. 12 (A) An slightly depressed lesion on the top surface of a sessile polyp, imaged in the colon with standard colonoscopy. (B) The depression is best visualized using chromoscopy with indigo carmine.

Fig. 13 (A) WLE image of the distal esophagus in a patient with Barrett's esophagus. (B) A corresponding autofluorescence image shows a bluish/purple color on the right side. Biopsy specimens revealed carcinoma in that region. Initial WLE did not reveal the lesion, which is indicated with an arrow in each image.

E

single-point optical fiber probes. An intensified camera is generally required for image detection owing to the low signal levels. A video endoscope can also be used to collect fluorescence. Because the CCD detector is located directly behind the objective, the fluorescence signal is much more intense. Image-processing algorithms are required to correct for spatial nonuniformities, and to identify regions of disease.

An example of an autofluorescence image of a flat colonic adenoma is shown in Fig. 13, along with a corresponding white light endoscopic image of the same region.^[16] This example demonstrates the improved ability to localize neoplastic mucosa with autofluorescence imaging. A xenon light source with a rotary RGB band pass filter sequentially illuminates the mucosa with red, green, and blue light at 20 Hz. Two CCD detectors are utilized, one to collect a white light image (by combining the RGB reflectance signals) and one to collect autofluorescence and reflectance signals from the individual RGB illumination phases. An image-processing algorithm combines the autofluorescence and reflectance signals to provide the high-contrast image shown in Fig. 13B. In these images, normal mucosa and nondysplastic Barrett's esophagus appear green whereas neoplastic lesions appear bluish/purple. In addition to premalignant tissue in other areas of the GI tract, autofluorescence imaging has demonstrated the potential to detect lesions in the bladder, head and neck, larynx, lung, and nasopharynx.

Photodynamic imaging

Photodynamic imaging collects fluorescence generated from externally administered agents that are internally converted and selectively taken up by cells exhibiting elevated metabolic activity. A promising agent is 5-ALA, a porphyrin substrate in the heme biosynthetic pathway, which induces the formation of protoporphyrin IX (PPIX), a compound with high fluorescence efficiency. 5-ALA has demonstrated potential to detect

pre-malignant tissue in the bladder, colon, esophagus, and oropharynx. Excess exogenous application of 5-ALA leads to a three- to sixfold higher intracellular accumulation of PPIX in areas of high-grade dysplasia and malignant lesions compared to the surrounding mucosa. PPIX fluorescence is excited by blue light (peak of 405 nm), and the emission is red at wavelengths above 600 nm. ALA can be administered orally for systemic distribution, and the drug is cleared in about 48 hr, and can produce mild skin photosensitivity and transient elevation of liver enzymes. An example of white light and photodynamic imaging of fluorescence with 5-ALA is shown in Fig. 14.^[17] Six or seven hours prior to upper endoscopy with a fiber optic endoscope, patients ingested an ALA solution at a dose of 15 mg/kg body weight. The light source was a 300 W short-arc violet lamp, with fluorescence at wavelengths above 600 nm being detected with a CCD camera attached to the fiber optic endoscope. The images indicate an improved ability to distinguish an esophageal carcinoma that is not easily detected in this case with WLE.

OCT

OCT performs cross-sectional imaging in a manner similar to that of EUS, except that the coherence (phase) property of light rather than the backscattering behavior of sound is used.^[18] Moreover, OCT has up to 10 to 100 times better axial resolution than EUS at a penetration depth of up to 1 mm. OCT is a technology that is being developed to assess tissue histopathology in vivo—a goal that is often termed “optical biopsy.” OCT has demonstrated the ability to distinguish layers of mucosa in the GI tract with the potential to detect precancerous lesions such as dysplasia. The OCT, in its most basic form, uses an interferometer to analyze light as it is reflected from a layer of tissue in one optical path to light traveling along a reference path of nearly equal length. Because a low-coherence light source is used, an interference signal is only generated when the path

Fig. 14 (A) WLE image of a region containing esophageal carcinoma, which is not noticeable under WLE. (B) A corresponding image showing ALA-induced fluorescence (red) at the site of the tumor.

lengths are matched to within the coherence length of the source (typically on the order of $10\ \mu\text{m}$). As the length of the reference arm is scanned, different tissue depths are probed, enabling vertical image sections to be acquired. As shown in the schematic diagram in Fig. 15A, light from a low-coherence light source, $22\ \text{mW}$ at $\lambda = 1300\ \text{nm}$, is coupled into a single mode optical fiber and divided by a beam splitter to the scanner and reference arms of a Michelson interferometer.^[19] Contrast is provided by variations in the reflectance of cellular and extracellular material present in each tissue layer.

In the OCT system described, the transverse and axial resolutions at $\lambda = 1300\ \text{nm}$ are approximately 25 and $8\ \mu\text{m}$, respectively, and the light penetrates on the order of a millimeter into the tissue. The images are

acquired in a manner similar to radial sector scanning in EUS with image dimensions of 600×600 pixels in depth with a frame rate of up to four revolutions (images) per second. In Fig. 15B, the radial OCT image shows the layers of normal esophagus.^[19] OCT imaging has also demonstrated potential for other diagnostic purposes such as the identification of premalignant tissue in the lung, endometrium, and cervix, measurement of blood flow rates via the Doppler effect, and the characterization of atherosclerotic plaque in coronary arteries.

In Vivo Confocal Microscopy

An histologic analysis by trained pathologists is currently the most reliable method of diagnosing

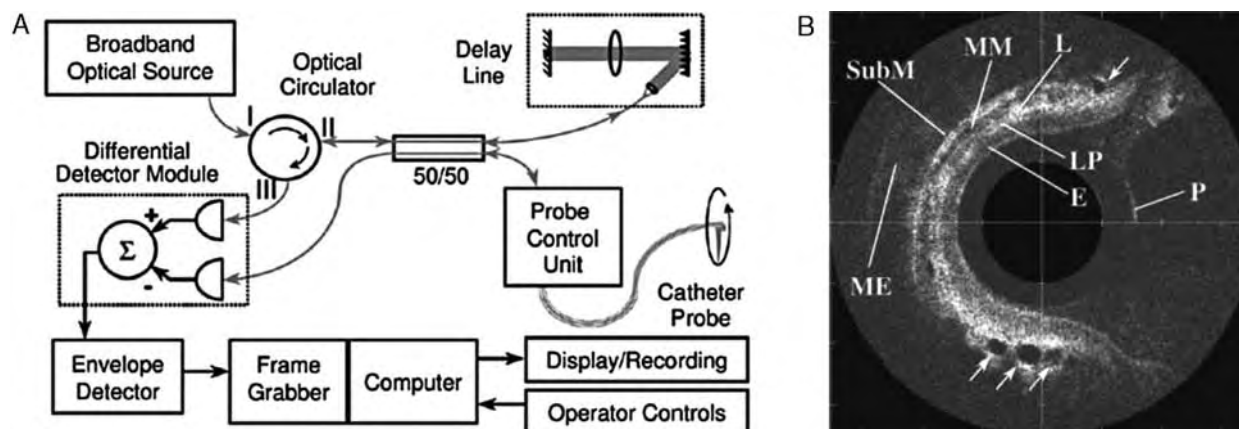

Fig. 15 (A) A block diagram of an endoscopic OCT system. The OCT catheter probe constitutes one arm of the Michelson interferometer (at the 50/50 coupler) whereas the rapid-scanning delay line is the other arm. Grey lines in the diagram are optical and black lines are electronic. (B) A single 4 frame/sec endoscopic OCT image with a radial image depth of $2.5\ \text{mm}$ and 600×600 pixels constructed from 1000 (430-pixel) radial "A-scans." The outer surface of the probe sheath is labeled P. Mucosal structures are labeled as squamous epithelium (E), lamina propria (LP), muscularis mucosa (MM), submucosa (SubM), and muscularis externa (ME). Arrows correspond to blood vessels and glands. Bright inclusions in the lamina propria may correspond to lymph nodes (L).

Fig. 16 (A) Confocal endomicroscopic image of rectal mucosa, obtained with fluorescence contrast from intravenous fluorescein injection. (B) Corresponding histology (H&E) showing 1. goblet cells; 2. crypt lumen; 3. lamina propria; and 4. nuclei.

malignancy. Recent technologies such as OCT strive to provide an “optical biopsy” that is in situ and in real time with the same diagnostic capability as histopathology. Confocal microscopy is an optical-sectioning technology, which differs from OCT in that spatial filtering techniques are utilized, rather than coherence gating techniques, for providing optical sectioning and the rejection of out-of-plane scattered light.^[20] This allows for incoherent fluorescence to be used in conjunction with confocal techniques. Much work has been done to develop exogenous optically labeled molecules, which specifically target and bind to biomarkers of neoplasia, in a field known as functional or molecular imaging. The development of in vivo confocal microscopes that are endoscope compatible holds great potential for powerful biomarker-assisted imaging strategies for the early detection of cancer in hollow organs. Various research groups and companies are developing confocal endomicroscopes as clinical tools.^[21] Fig. 16A shows an in vivo confocal image acquired with an endomicroscope developed by Pentax Corporation.^[22] Fluorescence contrast is obtained through the intravenous injection of sodium fluorescein in the patient. The axial (in plane) resolution of the confocal device is $7\ \mu\text{m}$ whereas the lateral resolution is $0.7\ \mu\text{m}$. The excellent resolution and contrast of the image compares well with histology performed on biopsy specimens, shown in Fig. 16B. The potential for technologies such as this, to provide optical histology in vivo, could be of great diagnostic utility, as well as for guiding surgical procedures in real time.

CONCLUSIONS

The field of endoscopy is undergoing vast technological development, with new innovations promising to radically improve the capabilities of endoscopes in the near future. These technological improvements are diverse

and interdisciplinary. Advances in semiconductor technology have allowed detectors to become miniaturized, and have led to the development of video endoscopes and wireless capsules. These endoscopes can view larger areas with higher resolution. At the same time, the diameters of insertion tubes are becoming smaller in size, improving patient comfort. The addition of ultrasound technology to endoscopy has allowed structural information to be collected beyond the tissue surface to depths of several millimeters and even into adjacent tissue structures. New methods are being developed to obtain even more diagnostic information from tissue. OCT provides morphologic information with subcellular resolution for real-time histopathology. Fluorescence spectroscopy and confocal microscopy, using exogenous fluorophores and photosensitizers, have the potential to reveal biochemical and molecular information below the tissue surface. Magnification and chromoscopy provide high-resolution details about the mucosal surface. The wireless capsule is providing endoscopic images from previously uncharted territory such as the small bowel. Active research and development is revolutionizing the practice of diagnostic and interventional endoscopy.

Ergonomics

Brian N. Craig

Department of Industrial Engineering, Lamar University, Beaumont, Texas, U.S.A.

INTRODUCTION

Ergonomics is an interdisciplinary field that incorporates principles from engineering, anatomy, biomechanics, physiology, medicine, anthropometry, human factors, psychology, and safety. Ergonomics, simply stated, is the study of work. Ergo means work, and nomos means to study. More formally, ergonomics can be defined as the science and practice of designing systems to fit people. As a science, it involves the analysis of human performance capabilities, limitations, and other characteristics to develop human-system interface technology in the form of ergonomic design principles, guidelines, specifications, tools, and methods. As a practice, ergonomics applies human-system interface technology to the analysis, design, test, evaluation, standardization, and control of systems to reduce human error and improve human and system performance, safety, health, comfort, productivity, quality, efficiency, and quality of life.^[1]

Working to maximize the effectiveness, efficiency, and safety of human-system interfaces, ergonomics can be viewed as a science of performance. Therefore, ergonomics is also defined as the design/redesign of tools, tasks, equipment, environments, software interfaces, pedagogic approaches, and organizations that enhance performance with many of the principles contributing directly to contemporary business and production management philosophies as well as inventory management systems.

OVERVIEW

Ergonomics is most often recognized as a discipline related to the primary prevention of work-related musculoskeletal disorders (WMSDs); therefore, the purpose of this article is to acquaint the reader with the current status of ergonomics initiatives, discuss WMSD risk factors, discuss elements of an effective ergonomics program, and introduce various ergonomic assessment tools. Work-related musculoskeletal disorders, e.g., muscle strains of the back, shoulder, neck, etc., are generally associated with the manufacturing sector of the economy; however, workers in the service sector and office workers also experience musculoskeletal

discomfort. Therefore, this article will also include a section addressing the principles of office ergonomics.

MAGNITUDE OF WORK-RELATED MUSCULOSKELETAL DISORDERS

According to the Bureau of Labor Statistics (BLS), in excess of 4 out of 10 injuries and illnesses resulting in days away from work in 2001 were sprains or strains, which most often involve the back.^[2] The BLS definition of days away cases is defined as the sum of lost work day cases and restricted work day cases. Even though these trends have been decreasing, these findings are consistent with the previous 10 years of BLS data. The trunk, which includes the shoulder and back, was the most affected part of the body and accounted for 36.5% of the cases. Cases of overexertion and contact with objects and equipment remained the leading cause of a disabling condition.^[2] Also, according to the BLS, the median number of days away from work in 2001 for all cases was six days. At 25 days, carpal tunnel syndrome (CTS) is associated with the most median days away from work. At 18 days, repetitive motions is the most frequent event or exposure associated with a median number of days away from work. The wrist and shoulder injuries resulted in median days away of 13 and 12 days respectively.^[2]

It is estimated that 1 out of every 3 spent for workers' compensation costs is spent on WMSDs, which result in employers paying 15 billion in workers' compensation.^[3] Additional costs associated with these WMSDs, such as training new workers, employee absenteeism and turnover, lost productivity, and lost wages may result in a total cost of 45 billion per year.^[3]

CURRENT ERGONOMIC INITIATIVES

The Occupational Safety and Health Administration (OSHA) proposed a final rule for an Ergonomics Program Standard on November 14, 2000.^[3] The standard became effective on January 16, 2001. This standard, however, was short-lived and was rescinded by the United States Senate on March 6, 2001. Currently, OSHA has assembled a National Advisory Committee on Ergonomics and unveiled a Four-Pronged,

Comprehensive Approach on Ergonomics.^[4] OSHA's four-pronged approach provides for guidelines, enforcement, outreach and assistance, and research.

According to OSHA, ergonomic-related injuries/illnesses are on the decline, and it is the goal of OSHA to accelerate the decline.^[4] A major advantage of the four-pronged approach over the repealed Ergonomic Program Standard is the emphasis on program flexibility and avoiding a one-size-fits-all approach.

Guidelines

OSHA is in the process of developing industry-specific guidelines for a number of industries that are based on current incidence rates and available information about effective and feasible solutions. In March 2003, OSHA released the first industry-specific Ergonomics Guidelines for Nursing Homes^[5] and is currently developing Ergonomics Guidelines for Retail Grocers and for Poultry Processing. In April 2003, OSHA announced plans to develop Ergonomics Guidelines for the Shipyard Industry.^[4] Furthermore, OSHA will encourage other industries to develop ergonomic guidelines to meet their own specific needs.

Enforcement

The primary goal of OSHA is the reduction of injuries and illnesses in the workplace, and, under the OSH Act's General Duty Clause, employers must keep their workplaces free from recognized serious hazards, including ergonomic hazards. According to OSHA, enforcement efforts will not be focused on employers who have implemented effective ergonomic programs or are making good-faith efforts to reduce ergonomic hazards. However, OSHA will conduct inspections for ergonomic hazards and issue citations under the General Duty Clause and issue ergonomic hazard alert letters when appropriate.^[4]

Outreach and Assistance

OSHA will provide assistance to businesses, particularly small businesses, and help them proactively address ergonomic issues in the workplace. OSHA will also provide advice and training on the voluntary guidelines and implementation of a successful ergonomics program. OSHA is developing a set of compliance assistance tools, including Internet-based training and information, to support understanding of guidelines and how to proactively define and address ergonomic problems (Table 1).

Research

OSHA will work closely with the National Institute for Occupational Safety and Health (NIOSH) and through the National Occupational Research Agenda (NORA) process to encourage ergonomic research in needed areas.

For additional information, visit <http://www.cdc.gov/niosh/homepage.html> and <http://www2.cdc.gov/NORA/default.html>. While there is a large body of research available on ergonomics, there are many areas in which additional research is necessary, including gaps identified by the National Research Council and the Institute of Medicine.^[6]

WORK-RELATED MUSCULOSKELETAL DISORDERS RISK FACTORS

Low Back

Due to the prevalence of low back pain and its associated cost, much of the ergonomic research has focused on the low back. Low back pain is an intricate interaction between the affected person and the multitude of potential risk factors that have been linked to occupationally related low back pain. The internal and external risk factors, whether personal, non-occupational, occupational, and/or psychosocial in nature, are dynamic, interdependent, and subject to debate. In addition, personal abilities, skills, attributes, buffers, and thresholds of individuals are also dynamic in nature. Thus, the dose of the injuring agent may vary widely from person to person.

Research has associated musculoskeletal disorders to personal risk factors, including low maximal aerobic power,^[7-12] high body fat/body mass index,^[8,13,14] low levels of flexibility,^[15-17] low strength capabilities,^[18-23] low levels of exercise/physical activity,^[21,24] smoking,^[13,25,26] low general overall muscular fitness,^[16,22,27,28] age, gender,^[13,29-31] and anthropometrics.^[32] However, there are also studies that have failed to demonstrate some of these associations.

In an occupational environment, workers may perform jobs that require high-frequency lifting and lowering, high forces, extended reaches, frequent bending and twisting along with static postures and carrying. There have been several investigations of the relationships manual materials handling may have with occupational musculoskeletal injuries, specifically low back injuries.^[13,33,34] Occupational injuries have been associated with high physical workloads,^[13,30,33,35,36] body motions and postures,^[13,37] and length of employment.^[38] In addition, many nonoccupational risk factors of equivalent magnitude exist at home, work, and play.^[39,40]

Table 1 OSHA's ergonomic outreach and assistance

Outreach and assistance	Examples	Description
OSHA Ergonomic eTools	Baggage handling Beverage delivery Computer workstations Grocery warehousing Healthcare Poultry processing Sewing	Stand-alone, interactive, Web-based information to address ergonomic hazards.
Cooperative Programs	Alliances	OSHA's Alliance Program is a tool for employers, trade or professional organizations, employees, and labor organizations to collaborate with OSHA in effectively sharing information on the usefulness and feasibility of their ergonomics programs within their own sectors.
	Onsite consultation program	OSHA's Onsite Consultation Program is a free service, particularly for small businesses involved in high-hazard industries or involved in hazardous operations.
	Strategic partnership	Organizations can enter into Strategic Partnerships with OSHA to address specific safety and health issues, including ergonomics.
	Voluntary partnership programs	Voluntary Partnership Programs recognizes and promotes effective safety and health management. VPP participants are facilities that have designed and implemented outstanding health programs.
Training and Education	OSHA training institute (OTI) and OTI Education Centers	Provides training in a wide variety of occupational safety and health topics.

There is increasing evidence between the relationship of job and work-related psychosocial risk factors and occupational injury/illness.^[41] Research indicates a 50% increase in health care expenditures for workers that report high levels of stress.^[42] Back pain and discomfort have been associated with job task dissatisfaction,^[36,43-45] psychological job demands,^[36] an employee's lack of social support from supervisors and/or colleagues,^[36,46-48] frequency of job problems,^[36] increased job pressure,^[38] monotonous work,^[38] and lack of job control.^[47]

Upper Extremity Disorders

Currently, the most common method to analyze the ergonomic exposures of a job for the upper extremities involves the use of generic risk factors. These generic contributing conditions include force, repetition, posture, vibration, localized compression, and other considerations.

Not all WMSDs are related to work activities. Other factors such as personal characteristics, nonoccupational, and psychosocial factors have also been associated with ergonomic-related injuries and illnesses.

However, when analyzing jobs or work tasks that may be associated with upper extremity disorders, conditions most commonly considered consider include, but are not limited to:

1. Awkward Postures, e.g., prolonged work with hands above the head or with the elbows above the shoulders; prolonged work with the neck bent; squatting, kneeling, or lifting; handling objects with back bent or twisted; repeated or sustained bending or twisting of wrists, knees, hips or shoulders; forceful and repeated gripping or pinching.
2. Forceful Lifting, Pushing/Pulling, and Carrying, e.g., handling heavy objects; moving bulky or slippery objects; assuming awkward postures while moving objects.
3. Prolonged Repetitive Motion, e.g., keying/keyboarding; using tools or knives; packaging, handling, or manipulating objects.
4. Contact Stress, e.g., repeated contact with hard or sharp objects, such as desk or table edges.
5. Vibration, e.g., overuse of power, pneumatic, or impact hand tools.
6. Other Factors, e.g., cold temperatures and poorly fitting gloves.

ELEMENTS OF AN ERGONOMICS PROGRAM

There are several key elements of a successful ergonomics program. The first and most important is true management commitment up to and including integration of ergonomics into production and management systems. The following provides the minimal elements of a successful ergonomics program.^[49]

1. Management commitment.
2. Employee participation.
3. Training and education.
4. Job hazard identification, including design, redesign, worksite analysis, and prioritization.
5. Job hazard prevention and control (implementation).
6. Follow-up and continual improvement.
7. Medical management and health promotion.

For additional information on ergonomic program effectiveness, the reader is encouraged to review McSweeney et al., "Ergonomic Program Effectiveness: Ergonomics and Medical Intervention."^[50] For more information about Elements of an Ergonomics Program, download the NIOSH document "Elements of an Ergonomics Program" at <http://www.cdc.gov/niosh/ephome2.htm>.

ERGONOMIC ASSESSMENT TOOLS

Although there are numerous job hazard analysis techniques offered in the literature, OSHA chose to include eight job hazard analysis tools in Appendix D of the Ergonomics Program Rule.^[3] These tools included the revised NIOSH Lifting Equation, the psychophysical tables published by Snook and Ciriello, the Strain Index, Appendix B of the Washington State Ergonomics standard, Rapid Upper Limb Assessment (RULA), Rapid Entire Body Assessment (REBA), the General Motors risk factor checklist, and the threshold limit value (TLV) for hand-arm vibration. The first four of these tools are briefly presented in this article along with the University of Michigan's Three-Dimensional Static Strength Prediction Program[™] (3DSSPP) along with checklists and surveys.

The 1991 Revised NIOSH Lifting Equation

The 1991 Revised NIOSH lifting equation is an improvement over the 1981 NIOSH lifting equation. Compared to the 1981 lifting equation, the 1991 equation allows for evaluation of asymmetrical lifting tasks, accounts for lifts with less than optimal hand-object couplings, and provides guidelines for a larger range of

work durations and lifting frequencies.^[9] It is also based on previous physiological, psychophysical, biomechanical, and epidemiological research.

The equation for calculating the recommended weight limit (RWL) is based on a multiplicative model that provides a weighting for each task variable. The weightings are expressed as coefficients that are used in the model to decrease the recommended load constant, i.e., maximum load weight to be lifted. The revised lifting equation established six multipliers that range from zero to one and the load constant as 51 pounds. The six multipliers include the horizontal multiplier (HM), vertical multiplier (VM), distance multiplier (DM), frequency multiplier (FM), asymmetry multiplier (AM), and coupling multiplier (CM). These six multipliers and load constant result in the recommended weight limit (RWL), as shown in the following equation.

$$RWL = (Load\ Constant) \times (HM) \times (VM) \\ \times (DM) \times (FM) \times (AM) \times (CM)$$

The RWL value is used to determine the lifting index (LI). The LI is the ratio of the actual load weight to the RWL. It is the LI that provides a relative estimate of the physical stress associated with manual lifting jobs and is given in the following equation:

$$LI = Load\ Weight / RWL$$

Whether a LI greater than one constitutes a risk is still a subject for debate. Waters et al.^[9] note that it is not possible to quantify the precise degree of risk associated with the increments in the LI. There is uncertainty about whether a LI of one is a reliable threshold for differentiating between an increase in risk and no increase in risk for some fraction of the working population.^[9] Despite the lack of research studies, it is reported that lifting tasks with a LI more than one poses an increased risk for lifting-related low back pain for some fraction of the workforce.^[9] The LI is considered a useful tool for prioritization for job redesign and job design.

The revised lifting equation continues to have limitations, including assumptions of two-handed, smooth, continuous lifting motion; unrestricted lifting posture; adequate foot traction; moderate ambient environment; lifting stable objects; and an object length less than 25 inches. It assumes that a smooth continuous lowering motion can be treated as lifting, other manual handling activities are minimal, and no unexpected heavy loads are present. It also assumes the worker is not lifting while carrying, pushing, or pulling, and the lifting is not done while seated or kneeling.

For more information about the scientific construct and precise use of the revised lifting equation, review the 1994 *Applications Manual for the Revised NIOSH*

Lifting Equation,^[51] or visit the Web site at <http://www.cdc.gov/niosh/pdfs/94-110.pdf>.

Snook & Ciriello's Liberty Mutual Maximum Acceptable Weights and Forces Tables

The Liberty Mutual Research Center has attempted to develop guidelines for the evaluation and design of manual handling activities based on a psychophysical approach.^[52] The results of the experiments conducted by Liberty Mutual have been compiled into a set of tables that depict gender-specific maximum acceptable weights and forces for lifting, lowering, pushing, pulling, and carrying tasks.^[52] The psychophysical approach refers to the method of conducting laboratory studies in which workers control an object's weight or force according to their perceptions of acceptable levels of exertion or fatigue. The worker can adjust the weight or force of the object according to his or her own capabilities and limitations, which thereby establish a maximal acceptable weight of lift, lower, or carry, or maximal acceptable push/pull force.

These maximum acceptable weight tables are intended for job design and hazard assessment.^[52] Whenever the strength requirements of a job exceed the maximum acceptable weights/forces for the worker, the worker may be at increased risk for overexertion injury. Although use of the maximum acceptable weights and forces tables has not undergone significant validation, Snook and associates estimate that up to one-third of compensable low back pain incidents may have been related to performing exertions that exceeded the maximum acceptable weight of 75 percent of females.^[53] Although these tables were derived from data gathered from simulated industrial tasks, such as lift, lower, push, pull, and carry, there is currently no data for twisting and lifting/lowering, type of grasp, duration of job (one hour versus eight hours), one-handed lifting, or sitting and lifting. For more information, visit the following Web site at <http://hsc.usf.edu/~tbernard/ergotools/#oshasuggested>.

The Strain Index

The Strain Index evaluates a job's level of risk for developing a disorder of the distal upper extremity (DUE).^[54] The DUE is defined as the hand, wrist, forearm, and elbow. Through a semiquantitative method, jobs are evaluated by analysis of six task variables, including intensity of exertion, duration of exertion, exertions per minute, hand/wrist posture, speed of work, and duration per day.

The Strain Index involves the direct measurement of duration of exertion, efforts per minute, and duration per day with estimation of intensity of exertion, hand/

wrist posture, and speed of work. The output of the Strain Index method is an SI score. Using the Strain Index involves five steps: 1) collect data on the six task variables; 2) assign ordinal ratings for each task variable (based on their data); 3) determine the multiplier values for each task variable (based on their individual ratings); 4) calculate the SI score (the product of the six multiplier values); and 5) interpret the result.^[54] The right and left sides are analyzed separately.

Interpretation of the SI score is the last step. According to the research, data suggest that an SI score of 5.0 best discriminates between jobs with and jobs without a history of workers developing DUE disorders.^[54-57] An SI of 5.0 can be considered a point value, but the authors suggest the following SI score interpretation. Strain Index scores less than or equal to 3.0 are probably safe. SI scores greater than 3.0, but less than 7.0 may be hazardous. SI scores greater or equal to 7.0 are probably hazardous.^[54] The Strain Index does not consider stresses related to localized mechanical compression and recommends this risk factor to be considered separately. For more information, visit the following Web site at <http://hsc.usf.edu/~tbernard/ergotools/#oshasuggested>.

Washington State Appendix B

The Washington State Department of Labor and Industries published its Ergonomics Rule in May 2000.^[58] Appendix B of that rule outlines specific criteria for analyzing jobs. The primary purpose of this job hazard analysis tool is to reduce employee exposure to specific workplace hazards that can cause or aggravate WMSDs. According to this rule, a WMSD hazard is a physical risk factor that exceeds the criteria in Appendix B.^[58]

Washington State's Appendix B is primarily a checklist to determine if employers possess jobs that are identified as caution zone jobs.^[58] Caution zone jobs are jobs or tasks in which an employee's typical work includes any of the following generic risk factors: awkward postures; high hand force; highly repetitive motions; repeated impact; heavy/frequent/awkward lifting; or moderate to high vibration.^[58] According to the rule, an employer has a choice of analyzing and reducing WMSD hazards using a general performance approach or a specific performance approach.^[58] The general performance approach allows employers to choose their own methods and criteria for analyzing jobs and reducing WMSDs as long as it is as effective as other recommended and widely used methods, such as the Strain Index, RULA, and REBA. If an employer chooses the specific performance approach, each caution zone job needs evaluation for specific physical risk factors that are specified in Appendix B of the ergonomics rule.

Washington State's Appendix B is based on epidemiological evidence of relationships between physical risk factors and WMSDs.^[58] The predictive and external validity of the checklist and its components have not been reported. For more information about Washington State Appendix B, visit the Web site at <http://www.lni.wa.gov/wisha/regs/ergo2000/AppendixBfinal5-19-00.pdf>.

The University of Michigan's 3-D Static Strength Prediction Program

The University of Michigan's 3-D Static Strength Prediction Program™ (3DSSPP) is a job hazard analysis tool that predicts compressive forces acting on the lower lumbar discs.^[37] The 3DSSPP is a computer software program that predicts the proportion of the population that is capable of performing an exertion with reference to various static strength norms and identifies the joint(s) that limits the capacity to perform the task.^[37]

To use the 3DSSPP, a job analyst describes and observes a worker performing a job. The computer software input data includes: 1) the magnitude and direction of the load; 2) whether one or two hands are involved; 3) the general anthropometry of the people to be analyzed; and 4) the postural angles of the body.^[37] The output screen includes graphical and tabular predictions describing the percentage of the male and female populations that are expected to have sufficient static strength at each major joint, the L5/S1 disc compression forces exerted by men and women, and the static coefficient of friction required not to slip along with a statement as to whether the task being performed would result in a loss of forward or backward balance.^[37]

The back compression design limit (BCDL) of 770 pounds does not predict the probability of injury. The BCDL is a job design criterion level that is similar to NIOSH's recommended L5/S1 maximum disc compressive force criteria of 770 pounds.^[37] This design limit is set at 770 pounds because research has suggested that most workers lifting loads below the compressive force criteria were at little risk of lifting-related low back pain.^[9] The criteria for good job design are loads requiring less than 770 pounds of disc compression force and within the static strength capability of 75% of female workers and 99% of male workers.^[9]

Validation studies of the 3DSSPP have been conducted by Chaffin et al.^[59] and Chaffin and Erig.^[60] Research has suggested that the 3DSSPP appears to accurately predict the percent of the population that is capable of performing a large variety of different types of maximal static exertions using the population strength norms in the model,^[61] however, the reader is reminded that the physical capacities of workers vary

depending on other personal, occupational, non-occupational, and psychosocial factors not entered in the model. For more information on the biomechanical basis for low back pain, the reader is encouraged to review Garg, "Occupational Biomechanics and Low-Back Pain."^[62]

Checklists and Surveys

A common tools used for conducting exposure assessments are workstation checklists and body part discomfort surveys. Even though subjective are not known to predict risk of injury, workstation checklists tools provide a quick method of evaluating workstation design, work postures, and work activities. Similarly, even though body part discomfort surveys are subjective and not specific to discomfort arising from the work environment, they may be helpful in some circumstances.

Checklists

In general, checklists are used to itemize certain aspects of the work environment for comparison to recommended criteria. In their most basic form, these checklists simply address the issue of whether or not a particular workstation incorporates specific objects or designs. For example, a line item on a checklist may be as straightforward as "Is Your Seat Pan Height Adjustable? (Yes or No)", or "Does the Operator Perform Intensive Keying for Four or More Hours per Day? (Yes or No)." These basic checklists are primarily initial screening tools used to determine if there needs to be a more detailed workstation exposure assessment. There are numerous checklists available to assess a variety of work environments.^[49]

It is important to remember that checklists are a limited collection of questions and criteria. No single checklist can anticipate the wide variety of complex situations that may be encountered in the work environment. Therefore, checklists should be considered simple screening tools that are used to assess current conditions of the workplace. They do not predict a worker's risk of developing a WMSD.

Surveys

Body part discomfort surveys ask workers to rate the intensity of discomfort for various body parts, such as the feet, lower legs, hands, wrist, lower back, and neck, on a categorical or continuous scale. These results can be applied at an individual level to identify opportunities for workstation evaluation or intervention, or they can also be applied collectively to prioritize work areas

2. Rate the backrest cushion comfort

that need more detailed ergonomic assessments. Other surveys may also be similarly constructed, such as in the case of chair comfort questionnaire. An excerpt from such a survey is given in Fig. 1.^[63]

OFFICE ERGONOMICS OVERVIEW

The purpose of this section is to provide the reader with general knowledge about ergonomic principles for office furniture and workstation design and layout. Some of the voluntary standards and guidelines available for designing proper office workstations will also be mentioned.

Adjustability

The key to worker performance, injury/illness reduction, and improved quality of work life in the office environment is adjustability of the chair and the workstation to accommodate most—if not all—of the users. Since there are variations in most human anatomical characteristics, designing for a range of body sizes and working postures instead of the average person allows for greater workstation adjustability.

Anthropometry is the science of anatomical human measurement. Many ergonomic textbooks provide tables of standardized anthropometric data for a variety of human characteristics.^[64,65] Anthropometric data includes distributional information regarding physical attributes for generalized populations. Examples of such data include standing and seated stature, shoulder and hip breadth, buttock-knee length, and hand span. The design of an ergonomic chair is one example of applied anthropometry. A well-designed ergonomic chair should have the following adjustments to accommodate the 5th percentile female up to the 95th percentile male:^[66,67]

1. Seat pan height adjustment with waterfall front.
2. Seat depth adjustment.
3. Backrest height adjustment.
4. Seat pan angle adjustment, which includes tension adjustment.

5. Backrest angle adjustment that is independent of the seat pan angle.
6. Armrest width adjustment.
7. Armrest height adjustment.
8. Armrest rotation.
9. Adjustable lumbar support.

Furniture and equipment that comprise the modern office workstation include—but are not limited to—the work surfaces, chairs, footrests, monitors, and input devices. The successful design of a workstation depends on the proper interface of the furniture and equipment with the person and his or her work tasks.^[65] Several textbooks cover specific design criteria such as ranges of adjustability; equipment locations, such as heights, distances, etc.; clearances; and zones of reaching.^[65,66]

Generally, when a worker's hands are on the keyboard, the elbow should be in an angle slightly greater than 90° and his or her hands are aligned with the forearm with minimal wrist deviation.^[66] The backrest should conform to the contour of the lower back. The operator is seated all the way back in the chair to properly support the back.^[66] The operator's neck should be comfortably erect approximately 15° forward flexed. The knees are slightly lower than the hips, and the trunk-thigh angle is slightly greater than 90°.^[66] The feet should remain flat on the floor or supported by a footrest.^[66]

The desk should be a thin work surface in order to provide necessary thigh clearance and should preferably have an adjustable surface height with adequate area and depth to support the operator's computer(s) with all needed peripherals, books, telephone, files, etc., at the correct height, orientation to the operator, and distance from the operator. The monitor, depending on its size, should be placed directly in front of the operator on the desk surface at approximately 18–30 inches from the operator. The top of the viewable screen is no higher than the operator's horizontal eye height.

The keyboard should be directly in front of the operator with the pointing device immediately adjacent to the keyboard and located at the same height as the keyboard. To assist in avoiding eyestrain, the operator should make sure that his or her vision is checked by an optometrist or ophthalmologist. Also, light sources should primarily be indirect and nonglare producing. Finally, each operator should periodically rest his or her eyes by looking into the distance. In addition, telephone headsets and document holders should be provided if needed.^[66]

Environmental design includes principles related to lighting, noise, and temperature. There are numerous textbooks and guidelines the reader can consult for more information on office ergonomic principles and guidelines related to these environmental factors.^[64,65,67,68]

Guidelines and Standards

There have been several efforts to generate guidelines for ergonomic office environments, most notably ANSI/HFS 100-1988^[67] and the BSR/HFES 100-2002 (Draft).^[68] These documents provide voluntary guidelines for office environments and offer detailed criteria for workstation design, chair design, general office layout, and monitor features. The purpose of these guidelines is to maximize comfort. It should be noted that, due to the age of the 1988 guideline, many details contained in that document may not be necessarily consistent with current knowledge, theories, or issues regarding the design of office equipment. The 2002 document is still in draft form. However, these guidelines do provide a good starting point for implementing ergonomic designs in an office environment. Copies of ANSI/HFS 100-1988 and the BSR/HFES 100-2002 (Draft) can be obtained on the HFES Web site at <http://hfes.org/Publications/ANSI-HFS-100.html> and <http://hfes.org/publications/HFES100.html>, respectively.

CONCLUSION

This article provides the reader with an understanding of the current status of ergonomics initiatives, provides a general discussion on WMSD risk factors, discusses elements of an effective ergonomics program, and introduces several ergonomic assessment tools. The key principles of office ergonomics are also presented. In addition, numerous references throughout the article and a list of 20 additional references are given at the end of this section. Even though many of the major topics were covered, many topics were not covered. Many of these topics can be found in the references throughout the text as well as in the following list:

Excitable Tissue, Electrical Stimulation Of

Dominique M. Durand

Neural Engineering Center, Department of Biomedical Engineering, and Department of Neurosciences, Case Western Reserve University, Cleveland, Ohio, U.S.A.

E

INTRODUCTION

Two of the most vital organs in the body, the brain/nervous system and the heart comprise excitable tissue. Patients with disorders in either of these organs can have severe deficits. Although rehabilitation and neural regeneration can provide some improvement,^[1,2] the amount of restoration provided to the patients has been limited. Electrical stimulation of cardiac tissue has been particularly successful to restore function in the heart with implanted pacemakers, and electrical stimulation of the nervous system can provide functional restoration to neurologically impaired individuals. By placing electrodes within excitable tissue and passing current through these electrodes, it is possible to activate pathways in the brain as well as cardiac and skeletal muscles.

Neural prostheses refer to applications for which electrical stimulation is used to replace a previously lost or damaged neural function. Electrical stimulation has been applied to restore neural function in several neural systems.^[3,4] The most successful neural prosthesis is the cochlear prosthesis. Electrical stimulation of the auditory nerves can restore hearing in deaf patients.^[5] Other applications include phrenic nerve stimulation for patients with high-level spinal cord injury to generate diaphragm contractions and can restore ventilation;^[6,7] and electrical stimulation of the visual cortex^[8] or the retina^[9] to restore vision and stimulation of upper/lower extremities.^[10] There are also several applications of electrical stimulation in the brain such as deep brain stimulation of thalamic nuclei to decrease tremor in patients with Parkinson's disease.^[11] Some applications are therapeutic instead of restorative, such as electrical stimulation of the vagus nerve to reduce seizure frequency in patients with epilepsy.^[12,13]

Stimulation of cardiac tissue has generated significant therapeutic benefits. A cardiac pacemaker is a stimulator capable of restoring the normal rhythm of the heart in patients suffering from cardiac disorders such as arrhythmia and heart block.^[14] The sophistication of pacemakers has increased dramatically in the recent years. Starting from the simple asynchronous (free running), synchronous (synchronized to the patient's heart beat) for patients with incomplete heart

block, rate-responsive pacemakers (frequency of pacing varies with metabolic demand) and pacemakers with defibrillators have been released.

BACKGROUND

Electrical excitation results from the interaction between extracellular electric fields and cellular membrane as described by the cable equation.^[15] The interaction can be analyzed by determining the voltages and electrical fields generated by the electrode using the solution of Maxwell equations. The relationship between the applied extracellular field and the transmembrane voltage is described by the source term in the cable equation and is derived below (section "Fundamental Principles of Electrical Stimulation"). The effect of waveform of the stimulation pulse, the electrochemistry taking place at the electrode interface and the tissue damage are also reviewed (section "Membrane-Electric Field Interaction"). In the last section ("Electrode Tissue Interface"), the stimulation of neural tissue is emphasized and stimulation of various other excitable tissues such as skeletal muscles and cardiac tissue are discussed.

FUNDAMENTAL PRINCIPLES OF ELECTRICAL STIMULATION

Anatomy and Physiology

Axonal excitation by applied current is effected when the transmembrane current generated by the electrode depolarizes the membrane sufficiently to activate the sodium channels located in high density within the cell membrane. Once activated, the sodium current will further increase until the membrane reaches an unstable fixed point. This is the point at which a full action potential (~ 100 mV) will develop. Once started, the action will propagate unattenuated either along nerve fibers or cardiac tissue.

Although the dynamics of membrane channels play a major role in the excitation properties of excitable cells, the sodium channels are almost completely closed

at the resting potential. Therefore, the passive properties of the membrane contribute significantly to the determination of the membrane voltage along the axons and to the site of the excitation. The transmembrane voltage is the difference between the intracellular voltage and the extracellular voltage. This extracellular voltage is generated by the current of the electrode and can be estimated with a reduced set of Maxwell equations, the quasistatic formulation.

Electric Fields in Volume Conductors

Although the volume conductor clearly contains material with a high dielectric constant (cell membrane for example), its capacitive properties can be generally neglected when the frequency is below 10 kHz.^[16] Similarly, the inductive properties can be neglected at these low frequencies. Therefore, the volume conductor surrounding the neural excitable tissue can be assumed to be purely resistive with a resistivity varying between 50 and 500 Ωcm in most applications. The resistivity of the volume conductor can vary at different locations or in different directions and is defined at each point of the volume by a resistivity tensor. If the resistivity is the same in all directions, the volume is isotropic. If the resistivity is the same at all points of the volume, then the volume is homogeneous. A simpler solution of the Maxwell equations can be derived for this type of volume conductor and applications.

Quasistatic formulation of Maxwell equations

For frequencies under 10 kHz, both the capacitive and inductive properties can be neglected and a simplified set of equations can be used to calculate the voltage and current in volume conductors.^[16]

$$\text{Conservation of charge: } \nabla \cdot \mathbf{J} = 0 \quad (1)$$

$$\text{Gauss's law: } \nabla \cdot \mathbf{E} = \rho/\varepsilon \quad (2)$$

$$\text{Ohm's law for conductors: } \mathbf{J} = \sigma\mathbf{E} \quad (3)$$

$$\text{Electric field: } \mathbf{E} = -\nabla V \quad (4)$$

where \mathbf{E} is the electric field (V/m) defined as the gradient of the scalar potential V , \mathbf{J} the current density (mA/m^2), the conductivity (inverse of resistivity) in S/m , ρ the charge density in C/m^3 , ε the permittivity of the medium (F/m).

Equivalence between dielectric and conductive media

The current density \mathbf{J} at any point is the sum of a source term \mathbf{J}_s and an ohmic term \mathbf{J}_Ω .

$$\mathbf{J} = \mathbf{J}_\Omega + \mathbf{J}_s = \sigma\mathbf{E} + \mathbf{J}_s \quad (5)$$

Using Eq. (1):

$$\nabla \cdot \mathbf{J} = \nabla \cdot (\sigma\mathbf{E}) + \nabla \cdot \mathbf{J}_s = 0 \quad (6)$$

Assuming an homogeneous volume conductor, $\nabla \cdot (\sigma\mathbf{E}) = \sigma(\nabla \cdot \mathbf{E})$ therefore:

$$\nabla \cdot \mathbf{E} = -\nabla \cdot \mathbf{J}_s/\sigma \quad (7)$$

$$\text{As } \mathbf{E} = -\nabla V,$$

$$\nabla^2 V = \nabla \cdot \mathbf{J}_s/\sigma = -I_v/\sigma \quad (8)$$

where I_v is a volume source current in A/m^3 and ∇^2 is the Laplacian operator. The volume current I_v can be calculated from the knowledge of the distribution of sources in the volume conductor. This equation is the equivalent of the Poisson equation derived for dielectrics:^[17]

$$\nabla^2 V = -\rho/\varepsilon \quad (9)$$

Using the following equivalence:

$$\rho \iff I_v$$

$$\varepsilon \iff \sigma$$

the solution of the Poisson equation for dielectric problems can be applied to the calculation of the current and voltage distribution in volume conductors.

Monopole point source

For the monopole source, the current density \mathbf{J} at any point in the medium located at a distance r from the source can be obtained simply and is equal to the total current crossing a spherical surface with radius r divided by the surface area

$$\mathbf{J} = \frac{I}{4\pi r^2} \mathbf{u}_r \quad (10)$$

where \mathbf{u}_r is the unit radial vector, and r the distance between the electrode and the measurement point. The electric field is then obtained from Eq. (3)

$$\mathbf{E} = \frac{I}{4\pi\sigma r^2} \mathbf{u}_r \quad (11)$$

The electrical field is the gradient of the potential. In spherical coordinates

$$\mathbf{E} = -\frac{dV}{dr}\mathbf{u}_r \quad (12)$$

The potential at point P measured with a reference electrode located at infinity is

$$V = \frac{I}{4\pi\sigma r} \quad (13)$$

Both the current density \mathbf{J} and the electric field \mathbf{E} have a radial distribution with an amplitude inversely proportional to the square of the distance to the source. The potential decay is inversely proportional to the distance. At $r=0$, the potential goes to infinity and this singularity can be eliminated if the electrode is modeled as a sphere with a radius a . Eq. (13) is then valid on the surface of the electrode $r=a$ and for $r>a$.^[18]

Assuming the medium to be homogeneous and linear, using superposition, Eq. (13) can be generalized to n monopolar electrodes with a current I_i located at a distance r_i from the recording point. The voltage is then given by

$$V = \frac{1}{4\pi\sigma} \sum_i \frac{I_i}{r_i} \quad (14)$$

For an axon located in the volume conductor at a distance d from the source I_s (Fig. 1A), the voltage along the axon is given by the following equation and is plotted in Fig. 1B ($d=1$ cm and $I_s=1$ mA)

$$V = \frac{1}{4\pi\sigma\sqrt{d^2 + x^2}} \quad (15)$$

The longitudinal component of the electrical field (E_x) is biphasic and plotted in Fig. 1C.

Bipolar electrodes and dipoles

Using Eq. (14), it is possible to calculate the voltage generated by a current source and a current sink separated by a known distance d . The potential at point P (assuming that the voltage reference is at infinity) is given by

$$V = \frac{1}{4\pi\sigma} \left(\frac{1}{r_1} - \frac{1}{r_2} \right) \quad (16)$$

where r_1 and r_2 are the distance between the measuring points and the electrodes. When the distance d between the two electrodes is small compared to the distance r ,

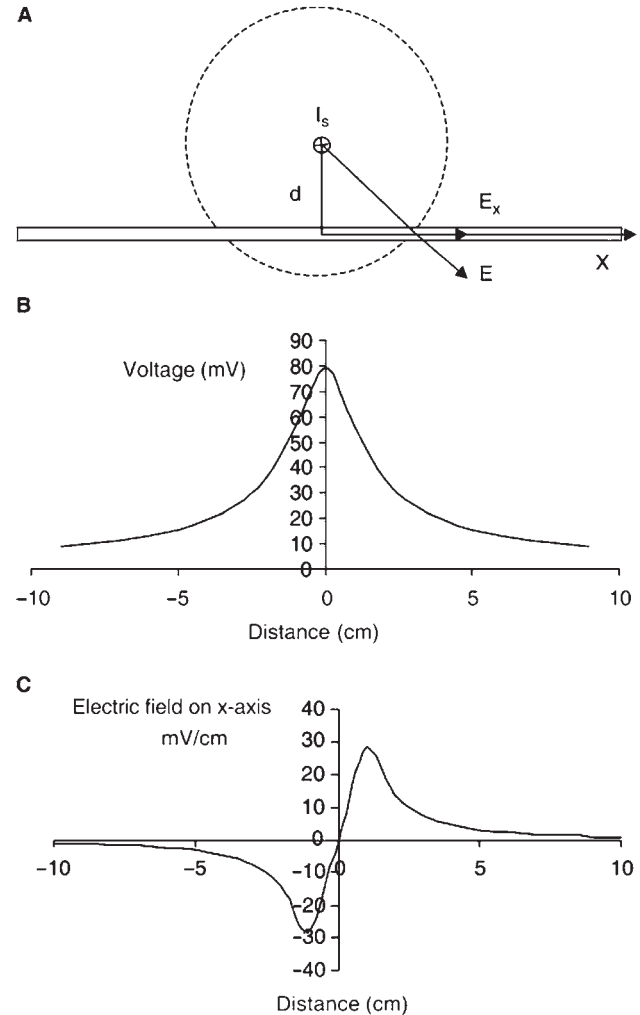

Fig. 1 Electrical stimulation of a fiber. (A) An electrode is located at a distance d from the axon and an anodic stimulus is applied to the electrode. The current flows outside and inside the axon generating depolarization of the membrane. Action potentials are generated underneath the electrode and propagate both orthodromically and antidromically. The fiber is activated by the longitudinal component (E_x) of the electric field \mathbf{E} . Extracellular voltage (B) and electric field (C) generated by 1 mA and measured along an axon located at 1 cm from the electrode (resistivity of the medium is assumed to be $100 \Omega \text{cm}$).

the equation for the potential reduces to

$$V = \frac{Id \cos \theta}{4\pi\sigma r^2} \quad (17)$$

where θ is the angle between the dipole axis and the point of measurement. There is an equipotential line ($\theta=0$) passing between the two electrodes. Therefore, an axon or nerve located along this line (transverse excitation) has a very high threshold for excitation. The voltage generated by a dipole is inversely

proportional to the square of the distance between the source and the recording site. Because the voltage decays rapidly compared to a monopole, the dipole is a much more selective method of stimulation. However, the current threshold for a dipole is significantly higher than for monopoles. The ratio of the monopole voltage to the dipole voltage is proportional to r/d and d is much smaller than r .

Inhomogenous volume conductors

Biological volume conductors are highly inhomogenous and the complexity of the volume conductors requires in most cases numerical solutions using finite element or finite boundary methods. However, the effect of the boundary between two layers of various conductivities can be studied in a simple configuration. Consider two volume conductors region 1 and 2 with conductivities σ_1 and σ_2 separated by an infinite plane. A monopolar electrode is placed in region 1 and potentials are recorded in the same region. Solving for the boundary conditions at the interface, it can be shown that the inhomogenous volume conductor can be replaced by a homogenous volume with conductivity σ_1 by adding a mirror current source with an amplitude equal to^[18]

$$I' = \frac{\sigma_1 - \sigma_2}{\sigma_1 + \sigma_2} I \quad (18)$$

The voltage is then given by Eq. (14) for region 1 only. In the case where layer 1 is a volume conductor such as the body and 2 is air ($\sigma_2 = 0$), the mirror source I' is equal to I . If the stimulation electrode is located at the interface, the zero-current boundary condition is satisfied by simply doubling the amplitude of the current. Similarly, if the recording electrode is located on the surface, the zero conductivity layer will double the size of the recorded potentials. If layer 2 is a perfect conductor ($\sigma_2 = \infty$), the current density must be normal at the boundary. The condition is satisfied if $I' = -I$. This image theory is only applicable in simple cases, but can be useful to obtain approximations when the distance between the recording electrode and the surface of discontinuity is small thereby approximating an infinite surface.^[19]

MEMBRANE-ELECTRIC FIELD INTERACTION

The interaction between the extracellular voltage and axons can be studied with a simple passive membrane model (Fig. 2A).

The membrane resistance is modeled as the rest conductance of the sodium, potassium, and leakage

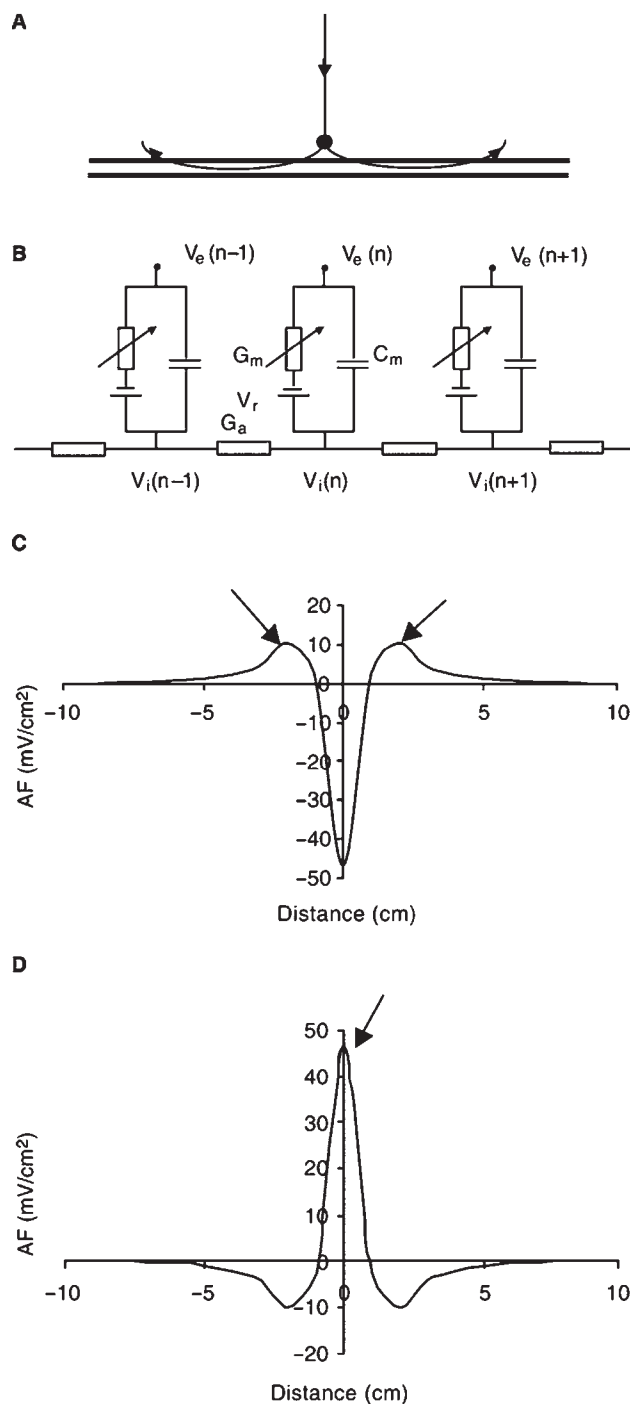

Fig. 2 Activating function for the electrical stimulation of a fiber: (A) The current lines generated by an anode enter the axon underneath the electrode. The current leaves the fibers in the distal regions. Electrical model of the membrane and axonal component of the fibers. (C) Activating function for an anode. The maximum positive value of the function shows the location of depolarization (excitation) of the fiber and is indicated by the two arrows. (D) For a cathode, the maximum value of the activating function is at the origin and is much greater than in (C). Therefore, cathodes have a lower threshold than anodes.

channels using compartmental analysis.^[20] Current flowing from the outside to the inside of the cell increases the voltage across the membrane and causes hyperpolarization. When current flows from the inside to the outside, the membrane is depolarized (Fig. 2).^[21]

A quantitative analysis of the interaction between electric fields and neural tissue can be derived by combining the passive membrane model with the extracellular voltage (V_e) generated by stimulating electrodes. The model makes several assumptions.^[22] Assuming that the presence of the fiber does not affect the extracellular voltage, the extracellular voltage can be calculated using the equations previously derived. A passive electrical model of the axon can be built and the circuit can be solved using numerical methods for compartmental analysis.^[23] These methods have been analyzed using neuronal simulation packages such as Neuron.^[24] Each compartment in Fig. 2B models a length Δx of the cell. Applying Kirchoff's law at each node and taking the limit when Δx goes to zero, one obtains the following inhomogenous cable equation^[25,26]

$$\lambda^2 \frac{\partial^2 V_m}{\partial x^2} - \tau_m \frac{\partial V_m}{\partial t} - V_m = -\lambda^2 \frac{\partial^2 V_e}{\partial x^2} \quad (19)$$

λ is the space constant of the fiber and is determined by the geometric and electric properties of the axon

$$\lambda = \frac{1}{2} \sqrt{\frac{R_m d}{R_a}} \quad (20)$$

where R_m is the specific membrane resistance, R_a the axoplasmic specific resistance, and d the diameter of the axon. The time constant of the axon is given by

$$\tau_m = R_m C_m \quad (21)$$

where C_m is the specific membrane capacitance. The source term of the cable equation is negative and is the product of the square of the space constant with the second spatial derivative of the extracellular voltage. At the onset of a pulse ($t=0$), the voltage on the cable is equal to zero and the change in voltage is proportional to the second-order spatial derivative of the extracellular voltage also known as the activating function $AF(x, t)$ ^[27]

$$\frac{\partial V_m}{\partial t} = \frac{\lambda^2}{\tau_m} \frac{d^2 V_e}{dx^2} \Big|_{t=0} = \frac{\lambda^2}{\tau_m} AF(x, t) \quad (22)$$

The amplitude of the activating function $AF(x, 0)$ is plotted in Fig. 2C and D for a 10 μm axon stimulated by a 1 mA anodic and cathodic current respectively

located 1 cm away from the axon. A positive value of $AF(x, 0)$ indicates membrane depolarization, while a negative value indicates hyperpolarization. The membrane polarization calculated from this equation can be predicted by simply examining the current flow pattern in and out of the axon. This analysis is valid only at the onset of the pulse, because during the pulse, currents will be distributed throughout the cable and will affect the transmembrane potential.^[28] However, for short pulses, these effects are small and the shape of the transmembrane voltage can be predicted using the activation function source. This analysis is valid for long axonal structures with uniform membrane. However, when cell bodies, dendrites, and more realistic axons are simulated, the site of excitation is strongly influenced by the distribution of sodium channels and a more detailed analysis is required to predict the site of excitation.^[29]

Activation of Myelinated Axons

The cable equation derived above needs to be modified for myelinated fibers because the presence of a myelin sheath around the axon forces the current to flow in and out of the membrane only at the nodes of Ranvier. Therefore, the action potential also jumps from node to node (Saltatory conduction). The interaction between myelinated fibers and applied fields can be described using the model shown in Fig. 1A with R_m and C_m replaced by R_n and C_n , respectively. In this simple model, the myelin sheath is assumed to have an infinite resistance. Therefore, R_n and C_n represent the membrane resistance and capacitance at the node of Ranvier only, respectively.

$$R_n = \frac{R_n^s}{\pi dl} \quad C_n = C_n^s \pi dl \quad (23)$$

where R_n^s and C_n^s are the specific membrane capacitance and resistance at the node, d is the inner fiber diameter, and l the width of the node. The axoplasmic resistance R_a is defined as:

$$R_a = \frac{4R_a^s L}{\pi d^2}$$

where R_a^s is the specific axoplasmic resistance and L , the internodal distance. The cable equation for a myelinated nerve can be derived using Kirchoff's law

$$\frac{R_n}{R_a} \Delta^2 V_m - R_n C_n \frac{\partial V_m}{\partial t} - V_m = -\frac{R_n}{R_a} \Delta^2 V_e \quad (24)$$

Δ^2 is the second difference operator ($\Delta^2 V = V_{n-1} - 2V_n + V_{n+1}$), and R_a represents the resistance between

two nodes. The source term for this equation

$$\left(-\frac{R_n}{R_a}\Delta^2 V_e\right) = -\frac{R_n^s}{R_a^s}\frac{d}{4\rho L}\Delta^2 V_e$$

is not explicitly dependant on the axon diameter because $d/L = d/D \times D/L$ ($= 0.007$), where D is the outside diameter of the axon and l is constant. However, because the distance between the node increases with the diameter of the fiber, the second-order difference does indeed depend on the of diameter of the axons.

Effect of Polarity of Applied Stimulus

Activation of axons is determined by the amplitude of the membrane depolarization. The polarity of the membrane polarization can be predicted directly from the sign of the activating function (positive sign indicates depolarization). This activation function is plotted in Fig. 2 and it is clear from the figure that the membrane depolarization (see arrows) generated by the cathode is greater than the depolarization generated from the anode (Figs. 2C and D). Note also that the polarity of the stimulus affects the location of the excitation. Cathodic excitation will produce excitation directly under the cathode, whereas anodic excitation will produce excitation at two sites located away from the anode (see arrows in Fig. 2D). However, the location of excitation also depends on the largest density of sodium channels. For example, anodic stimulation of cortical pyramidal cells has a lower threshold than cathodic stimulation, when applied to the surface of the brain.

Effect of the Space Constant of the Axon

The source term of the cable equation is proportional to the square of the space constant λ . λ^2 is proportional to the diameter of the fiber^[20] for unmyelinated fibers and to the square of the diameter for myelinated fibers.^[19] Therefore, in both cases, the source term is higher for fibers with larger diameters and, therefore, large diameter fibers have a lower threshold. As λ^2 is also dependent on the electrical properties of the axons, it is possible to predict that fibers with a larger membrane resistance or lower axoplasmic resistance will also have lower thresholds.

Recruitment Order of Fibers

The physiological recruitment order by the central nervous system (CNS) is to first recruit the small fibers followed by large ones. As previously indicated,

electrical stimulation recruits large fibers first. Therefore, electrical stimulation produces a recruitment order opposite to the physiological and this effect is known as the reverse recruitment order. Several techniques have been developed to recruit small fibers before large fibers. The first technique uses anodal block, whereby axons activated under the cathode are blocked when passing underneath the anode. This blocking effect requires a long pulse (about 400 μ sec) to maintain hyperpolarization of the membrane. By decreasing the amplitude of the current, the small diameter fibers are first released from the anodic block. Further reduction of the amplitude activates the larger fibers^[29] restoring a normal recruitment order. Another more recent technique places an array of contact along the nerve. When the contact separation of the electrodes is equal to the internodal distance of fiber of a given diameter, the activation function for that fiber is reduced and the fiber does not fire.^[30] By adjusting the polarity and the electrode distance, it is possible to reverse the recruitment order of the nerve activation.

Electrode–Tissue Interface

At the interface between the electrode and the tissue, the charge carrier must change between electrons in the metal and ions in the tissue. This exchange is carried out by chemical reactions that can modify the chemical milieu around the electrode, produce neural damage, and change the impedance. Moreover, the shape of the waveform can influence the threshold for activation as well as the corrosion of the electrode.

Effect of Stimulation Waveform on Threshold

Strength–duration curve

It has been known for a long time that it is the time-change in the applied current and not the continuous application of the external stimulus that can excite. Direct currents cannot excite and even in small amplitudes can cause significant tissue damage. It has also been observed experimentally that the relationship between the pulse width and the amplitude suggests that the total charge injected is the important parameter. The relationship between the amplitude and the width of a pulse required to bring an excitable tissue to threshold is shown in Fig. 3.

The amplitude of the current threshold stimulus (I_{th}) decreases with increasing pulse width (W) and can be modeled by the following relationship^[30]

$$I_{th} = \frac{I_{rh}}{1 - \exp\left(-\frac{W}{T}\right)} \quad (25)$$

Fig. 3 Strength-duration (A) and charge-duration (B) curves for excitation of neurons. The time constant, chronaxie, and rheobase currents are 1 msec, 0.7 msec, and 1 mA, respectively.

The minimum current amplitude required to cause excitation is known as the rheobase current (I_{rh}). T is the membrane time constant of the axon if the axon is stimulated intracellularly. For extracellular stimulation, T is a time constant that takes into account the extracellular space resistance. The relationship between current amplitude and pulse width can also be derived theoretically using the cable equation by assuming that total charge on the cable for excitation is constant.^[31] The pulse width required to excite the tissue with an amplitude equal to twice the rheobase current is known as the chronaxie (T_{ch}) and is equal to $0.693T$. This strength duration curve can also be modeled by the following simpler equation

$$I_{th} = I_{rh}[1 + (T_{th}/W)]$$

Charge–duration curve

The threshold charge injected $Q_{th} = I_{th} \times W$ is plotted in Fig. 3B and increases with the pulse width.

$$Q_{th} = \frac{I_{rh} W}{1 - \exp(-\frac{W}{T})} \quad (26)$$

The increase in the amount of charge required to fire the axon with increasing pulse width is owing to the fact that for long pulse durations, the charge is distributed along the cable and does not participate directly to raising the membrane voltage at the excitation site. The minimum amount of charge Q_{min} required for stimulation is obtained by taking the limit of Q_{th} ^[32] when W goes to zero and is equal to $I_{rh} \times T$. In practice, this minimum charge can be nearly achieved by using narrow, current pulses. Short pulses have other advantages; they increase the spatial selectivity of stimulation^[33] and fiber diameter selectivity.^[32]

Anodic break

Excitation generated by cathodic current threshold normally takes place at the onset of the pulse. However, long-duration, subthreshold, cathodic or anodic current pulses have been observed experimentally to generate excitation at the end of the pulse. This effect has been attributed to the voltage sensitivity of the sodium channel. The sodium channel is normally partially inactivated at rest. However, when the membrane is hyperpolarized during the long duration pulse, the inactivation of the sodium channel is completely removed. Upon termination of the pulse, an action potential is generated because the inactivation gate has a slow time constant relative to the activation time constant and cannot recover fast enough.^[34] This effect can be observed with an anodic or cathodic pulse because both can generate hyperpolarization. Anodic break can be prevented by avoiding abrupt termination of the current. Pulse shapes with slow decay phases such as exponential or trapezoidal decay shapes have been successfully used.^[35]

ELECTROCHEMISTRY OF STIMULATION

Conduction in a metal is carried by electrons, while in the tissue, current is carried by ions. Although capacitive mechanisms have been explored, capacitive electrodes capable of storing enough charge for stimulation have not yet been developed. Therefore, most electrical stimulation electrodes rely on the Faradaic mechanisms at the interface between the metal and the tissue. Faradaic mechanisms require that

oxidation and reduction take place at the interface.^[36] Faradaic stimulation mechanisms can be divided into reversible and nonreversible mechanisms. Reversible mechanisms occur at or near the electrode potential and include oxide formation and reduction and hydrogen plating. Irreversible mechanisms occur when the membrane is driven far away from its equilibrium potential and include corrosion, hydrogen, or oxygen evolution. Those irreversible processes can cause damage to both the electrode and the tissue because they alter the composition of the electrode surface and can generate toxic products with pH changes in the surrounding tissue. During charge injection, the electrode potential is modified by an amount related to the charge density (total charge divided by the surface area). To maintain the electrode potential within regions producing only minimal irreversible changes, this charge density must be kept below maximum values.^[37] The maximum charge density allowed depends on the metal used for the electrode, the stimulation waveform, the type of electrode used, and the location of the electrode within the body.

Stimulation Waveform

Common biphasic waveforms for stainless steel or platinum use a cathodic pulse followed by an anodic phase. An example of a square balanced biphasic waveform is shown in Fig. 4 and can be easily implemented using a capacitor and switches. This waveform ensures that the charge is balanced because a capacitor is inserted in series with the tissue to be stimulated and the charge injected is then reversed by discharging the capacitor.^[38] Biphasic cathodic-first waveforms have a higher threshold than monophasic waveforms because the maximum depolarization induced by the cathodic pulse is decreased by the following anodic pulse.^[34] A delay can also be added between the cathodic and anodic phase as shown in Fig. 4. However, this time delay can also prevent adequate charge reversal and can be dangerous to the electrode and the tissue. An alternative method is to decrease the maximum amplitude of the anodic phase but increase its duration. This waveform can also be damaging to the electrode because the charge is not reversed fast enough following the cathodic pulse. The various waveforms have been ranked for their effect on tissue damage, corrosion, and threshold of activation.^[19,36]

Electrode Damage

Corrosion of the electrode is a major concern because it can cause pitting, metal dissolution, and tissue damage. Corrosion occurs at the anodic phase of the stimulation during oxidation. Therefore, by using

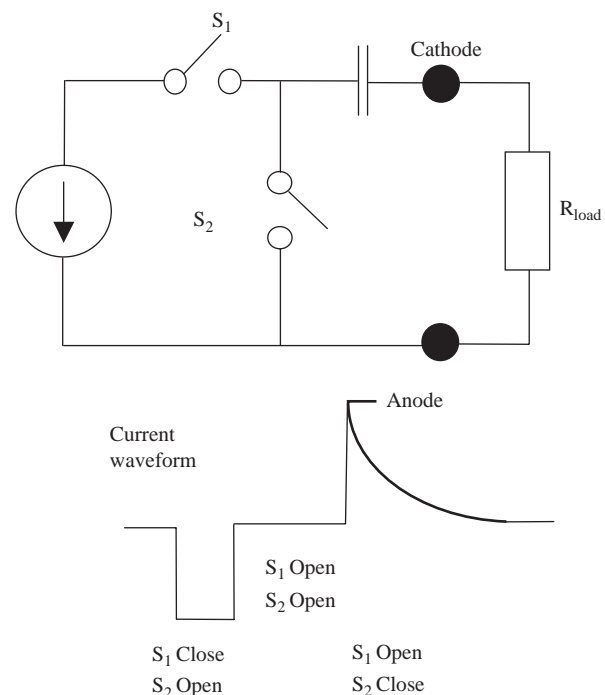

Fig. 4 Method for generating biphasic cathodic-first stimulation waveform. S_1 is closed and a square negative pulse is generated through the load. S_1 is then opened, and when S_2 is closed, the charge stored in the capacitor is discharged and produces the anodic phase.

cathodic monophasic or cathodic-first biphasic waveforms, corrosion can be avoided or minimized. The monophasic anodic waveform must be avoided because it will cause corrosion. Because for most applications, cathodic stimulation has a lower threshold than anodic stimulation (Fig. 2), the monophasic cathodic waveform will be a preferred stimulation waveform as it minimizes both the current to be injected and the corrosion. However, because the current only flows in one direction, the chemical reactions at the interface are not reversed and the electrode is driven into the irreversible region potentially generating tissue damage. A biphasic waveform will avoid both corrosion and tissue damage if the electrode potential is maintained within reversible regions.^[36]

Tissue Damage

Successful restoration of function with electrical stimulation requires that activation of the excitable tissue be carried without causing damage. Tissue damage has been divided in two categories: passive and active. Passive damage refers to surgical trauma and the lack of biocompatibility. Active damage is associated with the effect of current passing through the

electrode, such as physiological and electrochemical processes.^[39]

Surgical access to the implant site can cause significant trauma involving stretching or compression of the tissue. Postsurgical trauma can also trigger compression injury by swelling of the tissue in the presence of electrodes. Moreover, damage to the vascularization of the tissue can induce hypoxic damage. Although mechanical damage can occur, recovery of function and normal histology has been observed.^[40]

The biocompatibility of the material implanted within the tissue also controls the response of the tissue. Both the metal electrode and the insulation material can contribute to the foreign tissue response. This response consists of inflammation and encapsulation of the foreign material by a layer of collagen. This layer forms 3–4 week following the implant and usually remains thin (about 75 μm) unless relative movement of the implant and the tissue is allowed.

A likely cause of tissue damage is the chemical reaction at the interface between the electrode and the tissue. Electrodes operating in the irreversible region can cause significant tissue damage because these processes can modify the pH of the surrounding tissue and generate toxic products. Balanced biphasic waveforms are preferred as the second phase can completely reverse the charge injected into the tissue. Waveforms that have the most unrecoverable charge are the most likely to induce tissue damage. The fact that electrical stimulation can cause damage directly by overdriving the tissue was obtained from experiments reporting a lesser amount of damage when activity in the peripheral nervous system was blocked by lidocaine.^[41] The mechanisms underlying this effect are still unclear, but could include damage to the blood–nerve barrier, ischemia, or a large metabolic demand on the tissue leading to changes in the ionic concentration, such as calcium and potassium concentration both intra- and extracellularly.

STIMULATION OF EXCITABLE TISSUE

Stimulation of Brain Tissue

Electrodes can be placed on the surface of the brain and directly into the brain to activate CNS pathways. Experiments with stimulation of electrode arrays made of platinum and placed on the surface of the brain indicate that damage was produced for a charge density between 50 and 300 $\mu\text{C}/\text{cm}^2$, but that the total charge/phase was also an important factor and should be kept below 3 μC .^[42,43] Intracortical electrodes with a small surface area can tolerate a charge density as high as 1600 $\mu\text{C}/\text{cm}^2$ provided that the charge/phase remains below 0.0032 μC .^[44] More recently, studies

have shown that prolonged stimulation by electrode cortical arrays can significantly decrease the excitability of the neural tissue.^[45]

Stimulation of the Peripheral Nerve

The electrodes used with peripheral nerves are varied and include extraneural designs such as the spiral cuffs or helix electrodes^[46] with electrode contacts directly on the surface of the nerve, or intraneural designs placing electrode contacts directly inside the nerve.^[47,48] Intraneural electrodes can cause significant damage because electrodes are inserted directly into the nerve through the perineurium but have excellent selectivity. Extraneural electrodes are relatively safe because the designs such as the spiral^[49] or helix,^[41] both round designs are self-sizing and allow swelling without compression. However, the selectivity of a round electrode design is not as high as it could be as it is difficult to excite fascicles in the middle of the electrode without first activating axons located in the periphery.^[50] New electrode designs aimed at producing selective stimulation by recruiting only small portions of the nerve have been proposed.^[51,52] An electrode array has been designed to place electrodes directly into the nerve through the epineurium and the perineurium.^[53] Another design takes advantage of the plasticity of the nerve and reshapes the nerve cross section into a flatter configuration. With this flat interface nerve electrode design, electrodes can be placed close to the fascicles without damaging the perineurium.^[40,54] Damage in peripheral nerve stimulation can be caused by the constriction of the nerve as well as neuronal hyperactivity and irreversible reactions at the electrode.^[55]

Stimulation of Muscle Tissue

Muscle tissue can be best excited by electrodes located on the nerve innervating the muscle.^[56] However, for some applications, electrodes can be placed directly on the surface of the skin (surface stimulation),^[57] directly into the muscle (intramuscular electrode),^[58] or on the surface of the muscle (epimysial electrode).^[59] The current thresholds are higher when compared to nerve stimulation unless the electrode is carefully placed near the point of entry of the nerve.^[38] Stainless steel is often used for these electrodes and is safe below 40 $\mu\text{C}/\text{cm}^2$ for coiled wire intramuscular electrodes.^[60]

Stimulation of Cardiac Tissue

Stimulation of cardiac tissue differs in several respects from the stimulation of the nervous system. Nerve

stimulation must be localized to stimulate only a single nerve or a single fascicle. In contrast, stimulation of the heart in any appropriate region will activate the whole heart through the syncytium. Therefore, the electrode design is simpler and the timing or the pulses is of crucial importance to provide appropriate contraction patterns and avoid the set of parameters (timing and amplitude) that can cause fibrillation (vulnerable window). As all cells in the heart are similar in shape and size, the stimulation system does not need to consider issues dealing with fiber diameter recruitment and fatigue. Most electrodes are placed in the endocardium with a reference located on the stimulator. This monopolar stimulation can generate excitation by inducing intracellular voltage (V_m) that depends on the size of the electrode, the conductivity, the current, and the space constant. An approximate formula for the relationship between intracellular voltage V_m (mV) and extracellular current I_a (mA) is given by:^[61]

$$V_m = 34 \times I_a$$

Magnetic Stimulation of Excitable Tissue

Time-varying magnetic fields can induce electric fields in conducting media. Although the conductivity of biological tissue is much lower than that of metals, it is still a good conductor. Moreover, because the conductivity is so much lower than in a metal, the magnetic field can penetrate easily within excitable tissues such as brain or heart tissue. The varying magnetic field B can then induce an electrical field E inside the tissue. The cable equation for magnetic stimulation is given below:^[62]

$$\lambda^2 \frac{\partial^2 V_m}{\partial x^2} - \tau_m \frac{\partial V_m}{\partial t} - V_m = \lambda^2 \frac{\partial E_x}{\partial x}$$

This equation is very similar to that obtained for electrical stimulation and indicates that the nerve is excited by the first spatial derivative of the component of the induced electrical field longitudinal with the axon. The mechanism of action of the magnetic stimulation shares similarities with electrical stimulation.^[63] However, there are several important differences,^[64] which are not reviewed in this article.

CONCLUSIONS

Electrical stimulation of excitable tissue has been highly successful as indicated by the broad application of devices such as the cardiac pacemaker and cochlear

prostheses. Yet it is also clear that the potential for these stimulation devices has not been realized. The sales in the area of neurotechnology^[65] are predicted to be \$7.2 billion in 2004–2008. Cardiac applications are also increasing rapidly as well as combined cardiac and neural applications. The challenge to researchers is to design better electrodes that can 1) be integrated within the tissue and 2) provide a functional interface with the excitable tissue. Recent advances in technology have made it possible to interface directly with the brain.^[66] Yet the mechanical and material properties of the electrodes are still not adequate for long-term implants. In the peripheral nervous system, new designs capable of intimate contact between nerve and electrodes has been shown to be selective for fascicle stimulation^[53,67,68] and for recording.^[69,70] This ability of placing electrodes closer to axons also allows fiber diameter selectivity^[71] for improving the recruitment order of the nerve fibers. Yet cardiac stimulation technology is more mature with significantly larger clinical impact. Neural engineering is by comparison to cardiac engineering still maturing and offers great potential for new discoveries to help patients suffering from a wide range of disorders such as spinal injury, epilepsy, or stroke.

Extracellular Matrix Scaffolds

Stephen F. Badylak

McGowan Institute for Regenerative Medicine, University of Pittsburgh, Pittsburgh, Pennsylvania, U.S.A.

INTRODUCTION

The extracellular matrix (ECM) is a complex mixture of structural and functional proteins that are arranged in a unique, three-dimensional ultrastructure that is specific to each tissue and organ. These proteins serve many functions, including the provision of structural support and tensile strength, provide attachment sites for cell surface receptors, and act as a reservoir for cell signaling factors that modulate diverse host processes such as angiogenesis and vasculogenesis, cell migration, cell proliferation and orientation, inflammation, immune responsiveness, and wound healing. Stated differently, the ECM is a vital, dynamic, and indispensable component of all tissues and organs and is nature's natural scaffold for tissue and organ morphogenesis, maintenance, and reconstruction following injury. For these very reasons, the ECM is an excellent scaffold for tissue engineering applications. Unfortunately, it is not yet possible to recreate the ECM by synthetic methods. Therefore, ECM scaffolds must be prepared by processes that utilize a mammalian—usually xenogeneic—tissue source and methods that produce an acellular, sterile device for medical and surgical applications.

OVERVIEW

With the discovery that the ECM was necessary for the conversion of myoblasts to myotubes^[1] and structural proteins such as collagen and glycosaminoglycans played a functional role in salivary gland morphogenesis,^[2] it became apparent that the ECM was more than a passive bystander in the events of tissue and organ development and the pathophysiologic host response to tissue injury. Cytokines, growth factors, and potent functional proteins were found to reside within the ECM. The ECM was quickly recognized as a critically important conduit for exchange of information between cells. The concept of dynamic reciprocity between the ECM and intracellular cytoskeletal and nuclear elements has become widely accepted.^[3–5] Selected forms of the ECM have been successfully used as a scaffold for tissue engineering applications in recent years in both preclinical animal

studies and human clinical applications. The success is likely due to the structure-function relationships of this naturally occurring bioscaffold and its lack of recognition as a foreign material against which an inflammatory or fibrotic reaction must be raised. Both the three-dimensional ultrastructure and the composition of the ECM scaffolds are likely important in the biologic remodeling response.

The ECM is not a static structure. The composition and structure of the ECM are a function of age of the host, the location within specific tissues and organs, and the physiologic demands of the particular tissue.^[6–8] For example, the ECM that constitutes the basement membrane of epithelial tissues and organs, such as the liver, is an excellent substrate for cell growth, especially epithelial cell growth. These basement membrane ECMs tend to be comprised of proteins, including laminin, collagen type IV, and entactin, which are not nearly as abundant in ECMs that derive from submucosal tissue sources. In contrast, the ECM derived from submucosal tissues is often well vascularized, contains primarily type I collagen and site-specific glycosaminoglycans, and a wide variety of growth factors, including basic fibroblast growth factor (bFGF), vascular endothelial cell growth factor (VEGF), and epidermal growth factor (EGF). In other words, even though all ECMs share the common features of providing structural support and serving as a reservoir of growth factors and cytokines, their composition and structure can be markedly different.

The ECM presents its growth factors efficiently to resident cell surface receptors, protects the constituent growth factors from degradation, and modulates the synthesis^[9–12] of these growth factors by the local cell population. In this manner, the ECM affects local concentrations and biologic activity of growth factors and cytokines and makes the ECM an ideal scaffold for tissue repair and reconstruction. In one sense, the ECM can be considered as a localized, controlled release biomaterial that is regulated by host homeostatic control mechanisms. The consequence of the differences between the basement membrane versus submucosal tissue source of the ECM upon in vivo tissue remodeling when these ECMs are used as scaffolds for tissue repair has yet to be determined.

COMPONENTS OF THE EXTRACELLULAR MATRIX THAT SUPPORT TISSUE RECONSTRUCTION

Scaffolds for tissue reconstruction and replacement must have both appropriate structural and functional properties for the intended application. Many synthetic scaffolds are coated with one or more biologically derived components of the ECM, such as fibronectin or collagen type IV, in an attempt to make them more cell friendly. The distinction between structural and functional proteins is becoming increasingly difficult. Domain peptides of proteins originally thought to have purely structural properties have been found to have physiologically significant and potent modulating effects upon cell behavior. For example, the RGD peptide that promotes adhesion of numerous cell types was first identified in the fibronectin molecule,^[13,14] a molecule originally described for its structural properties. Biologically active peptides have since been identified in other dual function proteins including laminin, entactin, fibrinogen, types I and VI collagen, and vitronectin.^[15] Thus, the inclusion of biologically derived components within or upon synthetic scaffold materials affords both structural and functional properties that generally favor a constructive host response (Table 1).

The ECM is a degradable bioscaffold for tissue reconstruction when presented in its natural state. The structural and the functional components of these scaffolds must be thought of as transient due to the rapid rate of degradation of ECM scaffolds in vivo.^[16,17] Once again, the concept of ECM scaffolds as temporary controlled-release vehicles for naturally occurring growth factors is attractive.

The most abundant protein within the ECM is collagen. More than 20 distinct types of collagen have been identified, and the type and relative amounts of each that reside within the ECM are tissue-specific. The primary structural collagen in mammalian tissues is type I collagen. This protein has been well characterized and is ubiquitous across the animal and plant kingdom.^[18] Collagen has maintained a highly conserved amino acid sequence through the course of evolution and, for this reason, allogeneic and xenogeneic sources of type I collagen have been considered to have low antigenic potential. Bovine type I collagen is perhaps the most widely used biologic scaffold for therapeutic applications. Purified forms of collagen are typically chemically cross-linked prior to clinical use; thus, this renders them biologically inert.

Collagen types other than type I exist in naturally occurring ECM, albeit in much lower quantities. These alternative collagen types each provide distinct

Table 1 Major structural components of scaffolds derived from extracellular matrix collagens

Collagen type	Role
I,III	Most abundant collagenous protein that is responsible for the formation of collagen fibrils
IV	Protein forming a basement membrane network structure that permits other basement membrane components to interact; allows for cell attachment
VI	Basement membrane protein responsible for the attachment of the cells as well as anchoring the collagen fibers, nerves, and blood vessels to the surrounding connective tissue
VII	Basement membrane protein responsible for anchoring of fibrils to basement membrane
<i>Glycoproteins</i>	
Fibronectin	Adhesive glycoprotein that interacts with many ECM components; most notable of which is the ability to interact with a cells' fibronectin receptors which results in cell adhesion and migration
Laminin	Adhesive glycoprotein responsible for cell adhesion and migration in the basement membrane; pivotal role in cell surface receptors, both integrins and nonintegrin receptors
Nidogen/Entactin	Pivotal glycoprotein in basement membrane that binds to laminin; paramount for the connection of the networks of laminins and collagen type IV in the basement membrane
Thrombospondins	Adhesive glycoproteins that binds calcium and heparin; modulate cell attachment, migration, and proliferation
Vitronectin	Adhesive glycoprotein that binds to collagens and heparinlike glycosaminoglycans and acts as a cell adhesion molecule; regulates proteolytic degradation of matrix.
<i>Proteoglycans</i>	
Perlecan	Most abundant proteoglycan found in the basement membrane; binds to cell surface and ECM proteins
Decorin	Basement membrane proteoglycan that binds to (decorates) collagen fibrils present in the ECM

mechanical and physical properties to the ECM and contribute to the utility of the intact ECM—as opposed to isolated components of the ECM—as a scaffold for tissue repair. For example, type IV collagen is present within the basement membrane of all vascular structures and is an important ligand for endothelial cells. Thus, collagen type IV is frequently used as a coating for scaffolds intended to have a blood surface interface. Type VII collagen is an important component of the anchoring fibrils of keratinocytes to the underlying basement membrane of the epidermis. Type VI collagen functions as a connector of functional proteins and glycosaminoglycans to larger structural proteins such as type I collagen, which helps to provide a gellike consistency to the ECM. Type III collagen exists within selected submucosal ECMs, such as the submucosal ECM of the urinary bladder, in which less rigid structure is demanded for appropriate function. The diversity of collagens and their distinctive spatial organization is likely responsible for the distinctive biologic activity of ECM scaffolds when placed *in vivo*. This complex composition and structure is also an exemplary representation of the difficulty in recreating such a composite *in vitro*. The ECM is a source of numerous types of collagen, and the relative concentrations and orientation of these collagens to each other provide an ideal environment for cell growth both *in vitro* and *in vivo*.

Laminin is a complex adhesion protein found in the ECM, especially within ECM derived from basement membrane structures.^[19] This trimeric cross-linked polypeptide exists in numerous forms that are dependent upon the particular mixture of peptide chains, (such as $\alpha 1$, $\beta 1$, and $\gamma 1$).^[20,21] Laminin plays a particularly important role in the formation and maintenance of vascular structures and appears to be important in the development of embryonic stem cells. When considering the ECM as a scaffold for tissue repair, laminin is one of the principle reasons that the ECM is an attractive option for vascular reconstruction.^[22,23] Vascularization of scaffolds for tissue repair is one of the rate limiting steps in the field of tissue engineering. Proteins such as laminin and type IV collagen are receiving close attention as an important component of endothelial cell-friendly scaffold materials.

Fibronectin is a major component of ECM and is second only to collagen in quantity within the ECM. As stated earlier, fibronectin has both structural and functional roles *in vivo*. Fibronectin exists both in soluble and tissue isoforms and possesses many desirable properties of a tissue repair scaffold, including ligands for adhesion of many cell types.^[24,25] The fibronectin component of the ECM scaffold derived from the porcine small intestinal submucosa (SIS) and urinary bladder submucosa (UBS) has been shown to be partially responsible for the adhesion of endothelial

cells during *in-vivo* remodeling of these xenogeneic bioscaffolds.^[26,27] The cell-friendly characteristics of this protein have made it an attractive ligand for use as a coating protein upon various synthetic scaffold materials to promote host biocompatibility.

Vitronectin, a multifunctional glycoprotein, binds to components in the ECM such as collagens, glycosaminoglycans, and plasminogen activation inhibitor-1. In addition to binding to ECM components, vitronectin can also control cell attachment, spreading, and migration due to the presence of the Arg-Gly-Asp (RGD) sequence in vitronectin. Not only is vitronectin a key player in ECM scaffold's response to cells, but it can also regulate proteolytic degradation of the matrix through binding to plasminogen activation inhibitor-1.^[28] Vitronectin may play an important role in wound healing^[29] since vitronectin is intimately involved with integrin $\alpha_v\beta_3$, which plays a paramount role in angiogenesis.^[30]

Glycosaminoglycans (GAGs) are important components of ECM and play important roles in binding of growth factors and cytokines, water retention, and the gel properties of the ECM. The heparin-binding properties of numerous cell surface receptors and growth factors such as fibroblast growth factor family and vascular endothelial cell growth factor make the heparin-rich GAGs attractive components of scaffolds for tissue repair. The GAG components of the ECM scaffolds include the naturally occurring mixture of chondroitin sulfates A and B, heparin, heparan sulfate, and hyaluronic acid.^[31] Hyaluronic acid has been extensively investigated as a scaffold for dermal reconstruction and a carrier for numerous cell types and growth factors.

The characteristic of the intact ECM that distinguishes it from other scaffold materials is its diversity of structural proteins and associated bioactive molecules and their unique spatial distribution. Although cytokines and growth factors represent a very small component of the ECM composition, they are potent modulators of cell behavior. Many different growth factors reside within the ECM, including VEGF, EGF, bFGF, keratinocyte growth factor (KGF), transforming growth factor beta (TGF-beta), hepatocyte growth factor (HGF), and platelet-derived growth factor (PDGF). These factors often exist in multiple isoforms, and each has its specific biologic activity. Purified forms of growth factors and biologic peptides have been investigated in recent years as therapeutic means of encouraging blood vessel formation (VEGF), inhibiting blood vessel formation (angiostatin), stimulating deposition of granulation tissue (PDGF), and encouraging epithelialization of wounds (KGF). However, true controlled release of these proteins has been difficult to achieve, and the inability to turn the factor on and off as needed during

the course of tissue repair has limited the success of this approach. An advantage of utilizing the ECM in its native state as a scaffold for tissue repair is the presence of all of the attendant growth factors and their inhibitors in the relative amounts that exist in nature and, perhaps most importantly, in their native three-dimensional ultrastructure. To date, it is not possible to recreate the structure of the native ECM *in vitro*. It is important to note that almost all attempts to chemically cross-link naturally occurring ECMs has resulted in destruction of the constructive scaffold remodeling properties. Cross-linking invariably changes the host response to one of chronic inflammation, frustrated degradation of the scaffold, and a fibrotic reaction.

SOURCES OF EXTRACELLULAR MATRIX AND HOST RESPONSE

ECM exists in all tissues organs. However, sufficient ECM for use as a therapeutic bioscaffold can be harvested from relatively few sources. The dermis of the skin, submucosa of the small intestine and urinary bladder, pericardium, basement membrane and stroma of the decellularized liver, and the decellularized Achilles tendon are all potential sources of ECM. The methods used to process the material will determine its size, shape, practical utility, and the host response (Fig. 1).

Chemical and nonchemical means of cross-linking ECM proteins have been utilized extensively in an

Fig. 1 Extracellular matrix can be engineered to many different forms. The upper left picture shows a multi-laminated (4-ply) sheet. The lower left picture shows a single-layer lyophilized sheet. The picture in the lower right shows a gel form of ECM. The picture in the upper right shows a powdered particulate form that can be shaped into any three-dimensional configuration.

effort to modify the physical, mechanical, or immunogenic properties of naturally derived scaffolds.^[32] Chemical cross-linking methods generally involve aldehydes or carbodiimide. Photochemical means of protein cross-linking have also been investigated. The end result of most chemical cross-linking methods is the transformation of a biologically interactive scaffold material into a relatively inert bioscaffold material. The host response to purified collagen of ECM that has been heavily cross-linked is typically encapsulation of fibrous connective tissue, inhibition of scaffold degradation, and inhibition of cellular infiltration into the scaffold. The physical properties of ECM are often enhanced or strengthened by cross-linking, but mineralization of such cross-linked materials is a common long-term complication. These properties are counter-intuitive to many current approaches in the field of tissue engineering, especially those approaches in which cells are seeded upon scaffolds prior to or at the time of implantation.

The intact, nonmodified ECM or purified components of the ECM, such as collagen, fibronectin, or hyaluronic acid, are currently being investigated as cell-friendly scaffolds or scaffold coatings. These proteins and glycosaminoglycans promote cell infiltration and rapid scaffold degradation, deposition of host-derived neomatrix, and, eventually, constructive tissue remodeling.

EXTRACELLULAR MATRIX SCAFFOLDS FOR TISSUE REPAIR

The ECM plays an important role in embryonic stem cell (ESC) development, tissue differentiation, and organogenesis. The ability of the ECM ligands to modulate cell phenotypes and cell behavior also likely has important implications for other biologic processes such as inflammation, immunity, and wound healing. It is well accepted that developing fetuses and newborns heal wounds differently—generally better—than mature individuals and certainly more quickly and efficiently than aged individuals. It is plausible that the composition and structure of the ECM is at least somewhat responsible for the differences noted in the wound healing process as a function of age. Recently, scaffolds derived from naturally occurring—usually porcine-derived—ECM have been used for therapeutic applications.

There is abundant literature on the use of modified ECM scaffolds, especially chemically cross-linked biologic scaffolds, for tissue repair and replacement. Porcine heart valves, decellularized and cross-linked human dermis (Alloderm™), and chemically cross-linked purified bovine type I collagen (Contigen™) are examples of such products currently available

for use in humans. Similarly modified ECM scaffolds have been used for the reconstitution of the cornea, skin, cartilage and bones plus nerve regeneration.

Porcine-derived ECM scaffolds that have not been modified, except for the decellurization process and terminal sterilization, have been successfully used for the repair of numerous body tissues, including musculotendinous structures,^[33,34] lower urinary tract reconstruction,^[35–40] dura mater replacement,^[41,42] vascular reconstruction,^[43–45] and the repair of full- and partial-thickness skin wounds.^[46] The remodeling process in all of these applications has been remarkably similar. Immediately following implantation in vivo, there is an intense cellular infiltrate consisting of equal numbers of polymorphonuclear leukocytes and mononuclear cells. By 72 hours after implantation, the infiltrate is almost entirely mononuclear cell in appearance with early evidence for neovascularization. These mononuclear cells have not been definitively characterized to date. Between the third and fourteenth day, the number of mononuclear cells increases, and vascularization intensifies. There is also a progressive degradation of the xenogeneic scaffold with an associated deposition of host-derived neomatrix. Following the fourteenth day, the mononuclear cell infiltrate diminishes, and there is the appearance of site-specific parenchymal cells that orient along lines of stress, i.e., a microenvironmental factor.^[47] These parenchymal cells consist of fibroblasts, smooth muscle cells, skeletal muscle cells, and epithelial cells that depend upon the site in which the scaffold has been placed. It has been shown that circulating, marrow-derived progenitor cells participate in this remodeling process when ECM scaffolds are used.^[48] Environmental factors, such as mechanical loading, have also been shown to be important in the remodeling of ECM scaffolds.^[44] Of note, there is an absence of tissue necrosis and scar tissue formation during the remodeling of these xenogeneic ECM scaffolds.

ECM scaffolds derived from the urinary bladder submucosa (UBS) have been used for reconstruction of the lower urinary tract and has shown remodeling and healing that is atypical for adult mammals.^[49–54] The UBS scaffolds have been either allogeneic or xenogeneic in origin and have been used either alone or with cultured autologous cells. Sections of urethra, ureter, and urinary bladder have shown near normal reconstitution with formation of organized and innervated smooth muscle. There is a substantial body of literature developing that supports the use of intact ECM as a scaffold for tissue repair. More than 150,000 human patients have now been implanted with xenogeneic ECM scaffold derived from the porcine small intestinal submucosa for a variety of applications.

SUMMARY

The extracellular matrix is a complex structure that exists in dynamic reciprocity with the resident cell population. The ECM plays a critical role in cell, tissue, and organ development, including the development and differentiation of embryonic stem cells. The cause-effect relationship between the ECM and cell behavior and the ECM and biologic events such as organogenesis, inflammation, and wound healing is only partially understood. However, this naturally occurring scaffold has many attractive features that have at least, to date, been difficult to match with synthetic materials.

Eye Tracking: Characteristics and Methods

Daniel C. Richardson

Michael J. Spivey

Department of Psychology, Cornell University, Ithaca, New York, U.S.A.

INTRODUCTION

Eye movements are fundamental to the operation of the visual system. The term eye movement research relates to a patchwork of fields more diverse than the study of perceptual systems, however. Due to their close relation to attentional mechanisms, eye movements can provide insight into cognitive processes such as language comprehension, memory, mental imagery, and decision making. Eye movement research is of great interest in the study of neuroscience and psychiatry, as well as ergonomics, advertising, and design. Since eye movements can be controlled volitionally, to some degree, and tracked by modern technology with great speed and precision, they can now be used as a powerful input device, and they have many practical applications in human-computer interactions.

CHARACTERISTICS OF EYE MOVEMENTS

Eye movements are arguably the most frequent of all human movements.^[1] Large ballistic scanning movements called saccades typically occur 3–4 times every second. As one early researcher put it, “there seems to be an almost ceaseless twitching, as if rest for more than an instant were the one thing not to be endured.”^[2] Indeed, virtually all animals with developed visual systems actively control their gaze using eye or head movements.^[3] This frenetic movement is a consequence of the enormous amount of visual information that is available to an organism. Rather than devote resources to processing it all in detail, evolution appears to have selected a solution whereby small portions of the visual world are inspected in a rapid sequence.^[4] Consequently, the human eye monitors a visual field of about 200 degrees, but receives detailed information from only 2 degrees.^[5] This region, about the size of a thumbnail at arm’s length, is called the fovea. It is jerked around at speeds of up to 500° a second, during which its sensitivity drops to near blindness levels.^[6,7] During the 200–300 milliseconds it is at rest, however, over 30,000 densely packed photoreceptors in the fovea provide high-acuity color vision.

HISTORY AND METHODS

The first data regarding eye movements were obtained either through introspection or by the experimenter observing a subject’s eye, using a mirror, telescope, or peephole. These methods were dubious, of course, because any feature of the eye being studied could be obscured by the eye doing the studying. The first significant advance, therefore, was the invention of mechanical devices that would translate the eye’s movements into permanent, objective records of its motion.^[8]

At the end of the nineteenth century, eye movement research served a pressing theoretical need. As Delabarre wrote, “[m]any problems suggest themselves to the psychologist whose solution would be greatly furthered by an accurate method of recording the movements of the eye.”^[9] Phenomena such as visual illusions and aesthetic preferences were commonly explained away in terms of eye movements, and yet there were few data beyond introspection to support these hypotheses. In some of the first empirical studies, Javal^[10] used mirrors to observe the eye movements of subjects while reading, and was the first to note that the eyes moved in a series of “jerks.” These fixations were counted by placing a microphone on a closed eyelid while the subject read monocularly. Each time the bulge of the moving cornea bumped the microphone, a saccade could be counted, according to Lamare and Javal.^[11] An approximate measure of the location of these fixations could be obtained by inducing an afterimage in the subject’s eye with a bright light, and then asking subjects to report the location of the afterimage as they read.^[12]

Such observational methods, however, were limited by the accuracy and memory of the person making the observations.^[13] An objective record of the motion of the eyes was required. Since “plaster of Paris will attach itself firmly and immovably to any moist surface,” Delabarre^[9] was able to fix a small, moulded cap to a sufficiently “cocainized eye.” A wire ran from the cap to a lever, which drew the horizontal movements of the eye on the smoked surface of a kymograph cylinder. With his lids propped open, the subject (usually Delabarre himself) could read text through a hole drilled in the cap. It was reported that the cap “will not detach itself

until it becomes thoroughly soaked with tears.” Delabarre writes, “As to whether there is any danger to the eye to be feared from using it in this manner, I cannot say with assurance.” He reports that he was able to record his own eye movements for up to an hour, and suffered no ill effects after a week’s recuperation.

Huey^[14] simultaneously developed a similar mechanical method to study the behavior of subjects reading an article in the magazine *Cosmopolitan*. By varying the distance between the subject and the text, he found that “the number of jerks was shown to be a function of the matter read rather than of the arc described by the eye’s rotation.” Although the temporal resolution of his apparatus was too poor to measure the speed of the eye movements, he conjectured that they may be so fast that “we really do not see foveally what we read except at the few points on the ordinary line where the eye pauses.”

Huey and Delabarre were able to gain valuable first insights into the function and characteristics of eye movements, yet their mechanical devices were criticized for impeding motion and straining the eye. To overcome these flaws, Dodge and Cline^[15] invented a device to produce “a group of what we may justly claim to be the first accurate measurements of the angle of velocity of the eye movements under normal conditions.” Dodge’s method, as it became known, used photography to record the movements of the eye accurately and noninvasively, and the same basic technique continued to be used into the 1970s.^[8]

If the eye were a perfect sphere and rotated about its center, a light ray would be reflected at a constant angle despite rotations. Given that the eye has neither of these characteristics, however, the reflection of a ray of light bouncing off the bulge of the cornea will move as the eyes move. In Dodge’s first device, a vertical line of light was bounced off the cornea and fell on a horizontal slit. Behind this slit was a photographic plate that moved vertically, regulated by the escape of air from a cylinder. When developed, this plate showed time on the y -axis and horizontal motion of the eye on the x -axis.

Further developments in the 1920s, in labs at Chicago and Stanford, allowed two photographic recordings to be made simultaneously. In this way, head position could be recorded by reflecting a light off a bead on a pair of spectacles,^[16] or the horizontal eye movements of one eye could be recorded with the vertical movements of another, producing the first two-dimensional eye movement records.^[17] Later technology allowed the reflection beam from a single eye to be split, its vertical and horizontal components measured and recombined in the form of a fixation dot recorded on a film reel. This methodology allowed researchers, including Buswell,^[18] to produce some of the first two-dimensional scan paths of subjects inspecting images. Although a thread of research continued for a couple of

decades investigating the relationship between mental imagery and eye movements,^[19–23] the vast bulk of eye movement research in the first half of the century investigated the processes, habits, and individual and cultural differences involved in reading.^[11,24–27]

The 1960s saw a renaissance of the turn-of-the-century, invasive techniques of Delabarre^[9] and Huey^[14] for recording eye movements. Researchers found that rather than using sticky plaster of Paris, a device could be tightly clamped to the eye using suction. Yarbus^[28] used a tiny valve to withdraw fluid from under a contact lens, and Fender^[29] found that sodium bicarbonate would osmose through the tissue of the eye and create negative pressure. A tiny plane mirror could be attached to the surface of the contact lens, and its reflection could be recorded in much the same way as a corneal reflection. To avoid a tear film clouding the lens, researchers also mounted the mirrors on stalks that protruded out from the eye.^[29] As well as reflecting with mirrors, these stalks could produce their own light source if fitted with small lamps^[30] or glowing radioactive tritium.^[31] Finally, a nonoptical method employed a scleral search coil: a contact lens embedded with two orthogonal wire coils that would perturb a magnetic field surrounding the subject’s head.^[32] Due to the discomfort produced by these contact lens methods, all have dropped out of use except the last, and that is primarily used in animal research.

In the early 1970s, a host of techniques were developed in which the eye was scanned with a television camera, and certain distinct features were electronically detected and localized. These methods are most sensitive to high contrast, and so one technique scanned the image of the eye for the limbus, the boundary between the white sclera and the coloured iris. If small electronic photoreceptors are aligned near the limbus, their output will vary according to the amount of white sclera exposed. This method will give a very rapid measure of horizontal eye movement.^[33] Unfortunately, the iris is large and often obscured by the eyelid, and vertical eye movements in particular are difficult to track with this method. An alternative is to scan for the lack of reflectance from the pupil (dark-pupil tracking), although there can be low contrast between this black circle and dark-brown irises. If the pupil is lit directly from the front, the light will bounce off the back of the retina and appear very bright (bright-pupil tracking), as it does in poorly taken flash photographs. This bright circle can then be more easily detected by a scanning technique.^[34]

All the methods described so far for recording eye movements are more precisely stated as methods for recording movements of the eye in relation to the head. In order to infer where the subject was looking in the world, researchers needed to ensure that the head was absolutely stationary, by employing severe methods of

Fig. 1 The corneal reflections produced by different eye-head positions. The corneal reflection appears as a bright white dot, just to the side of the pupil (A). The relative positions of the pupil and the corneal reflection change when the eye rotates around its vertical (B) and horizontal (C) axes. This relationship does not change, however, when the head moves and the eye is stable (compare A and D).

restraint. These draconian means were obviated by the innovation, in the 1970s, of simultaneously measuring two optical characteristics of the moving eye. Since these features behaved differently under head movement and eye rotation, their differential could be used to calculate the point of regard, the place in the world where the subjects was actually looking (Fig. 1). Although such devices still needed to restrain the head with a bitebar or chinrest, they allowed slight movements of the head to be deconfounded from eye movements, and so produced more accurate gaze tracking.

As described above, Merchant and Morrisette^[34] employed a scanning method to detect the center of a brightly lit pupil. The same technique was also used to find the smaller, brighter corneal reflection. Since the position of the corneal reflection in relation to the center of the pupil remains constant during head translation, but moves with eye rotation, point of regard can be extrapolated. Like contemporary systems,^[35] the Honeywell oculometer was able to calculate what location on a screen was being fixated, while being so noninvasive that the subject was often not aware of its presence in the room.

A similar logic lay behind the development of the dual Purkinje image eye tracker.^[36] Light bouncing off the eye produces a series of reflections. The first, and the brightest, is the corneal reflection. A second image is reflected off the rear surface of the cornea, and another two by the front and rear of the lens. These four Purkinje images all have different motions in relation to eye rotation. The dual Purkinje image eye tracker measures the disparity between the first and the fourth images by adjusting a series of mirrors with servomotors until the two images are superimposed upon electronic photoreceptors. The degree to which the mirrors have to be moved is directly related to eye rotation and is independent of head translation, although the head still must be held in place with a chinrest or bitebar so that the eye can be detected by the equipment. The

advantage of the Purkinje eye tracker is that since it is limited only by the speed of the servomotors, it is remarkably fast and accurate. The continuous analog signal was sampled at a rate of 300 Hz in initial incarnations, and modern computers can sample at up to 1000 Hz.

The balance between obtaining a high-precision record of an observer's point-of-regard and allowing natural head and body movements is where much of the technological advancement in eye-tracking takes place in the current state of the art. Whereas systems like the dual Purkinje eye trackers require that a subject's head be immobilized by a chinrest or bitebar, new headband-mounted eyetrackers point an additional scene camera at the subject's field of view from the subject's perspective, thus allowing point-of-regard to be superimposed on the scene camera's image regardless of where or how the subject moves^[37-39] (Fig. 2). Recent table-mounted remote optical eye trackers have also been developed that allow some natural head movement while the

Fig. 2 A subject wearing a light, head-mounted eye tracker. The eye monitor, with crosshairs on the pupil and corneal reflection visible, is shown at the top right. The view from the scene camera, with the subject's point of gaze superimposed, can be seen at the bottom right.

subject sits in front of a computer screen for two-dimensional stimulus presentation.

One particularly important, and frequently used, method in eye tracking concerns not just the eye tracker itself but also the yoking of the eye-position signal with real-time stimulus presentation: gaze-contingent display paradigms. The visual system receives highly detailed information from the small part of the visual field that the eye is fixating at that moment, and yet the target for each detailed fixation is planned on the basis of information gathered from low-resolution peripheral vision. This relationship between peripheral information and saccades has intrigued researchers. Its influence could only be assessed, however, if subjects were instructed to hold their eyes still, or if stimuli were presented tachistoscopically before an eye movement could occur. The next advance in eye movement research came when a cluster of researchers in the 1970s were able to overcome these limitations by coupling the system that was measuring eye movements with the system that was presenting stimuli to the subjects.^[40–42] During the 30–50 milliseconds that the eyes take to saccade to a new location, the visual system's sensitivity is greatly reduced. To trigger a change in the visual stimulus during that brief period, the saccade must be detected within a few milliseconds of onset, the appropriate stimulus change calculated by the computer, and the screen display refreshed. Using a limbus reflection system that sampled eye position every millisecond, McConkie and colleagues^[41,43] were able to produce saccade-contingent display control. In such experiments, the characters of a line of text could be changed while a subject was reading, and hence the amount of information that a subject detected peripherally could be assessed.

The advent of gaze-contingent paradigms was a highly significant advance in eye movement research. It has had a far greater impact, perhaps, in its practical applications. The technology provides not merely a device a scientist can use to study a subject's eye movement behavior, but also a way for the subject's eye movement behavior to manipulate a device.

CONCLUSION

Dodge and Cline's^[15] revolutionary invention allowed researchers, for the very first time, to make a permanent, objective record of a subject's eye movements using a noninvasive method. Although eye tracking techniques were refined in the following decades, there were no comparable breakthroughs until the advent of digital technology and image processing in the 1970s. Such advances have placed fewer constraints on experimental subjects, with the result that modern researchers are able to record the eye movements of freely moving

subjects carrying out everyday tasks. We speculate that further developments will produce smaller, cheaper eye trackers that may well populate a range of human-computer interfaces. The potential ubiquity of such devices underscores the need for a solid understanding of the cognitive and perceptual processes that govern human eye movements.

INTRODUCTION

In this brief review of the research fields and practical applications of eye movement technology, we will begin by considering studies of the relationship between eye movements and attentional mechanisms. Typically, in such experimental paradigms, a subject is required to fixate one location and direct their attention to another while psychophysical and neuropsychological measures are taken. We will then examine how the relationship plays out as observers view more complex, natural scenes. The relationship between visual perception and language has historically interested researchers, and we will review studies of eye movements during spoken language comprehension and production, as well as during the more specialized case of reading. In addition to perceptual demands, language processing is a cognitive task, and we shall see how eye movements are also implicated in cognitive processes such as memory, imagination, reasoning, and decision-making. Perhaps as a result of this tight integration with a spectrum of perceptual and cognitive processes, eye movements are richly intertwined with behavior in a variety of task domains, from social interaction to jet plane navigation. Moreover, differences between the eye movements of individuals can reveal differences in aptitude, expertise, and even pathology.

SPATIAL ATTENTION AND SCENE PERCEPTION

Attending to a location in space aids processing of a stimuli at that location,^[1] and has neural correlates, such as modulating the activity and sensitivity of neurons across the visual cortex.^[2] The link between attending to a location and launching a ballistic eye movement (a saccade) to it is intuitive, yet it is equally clear that while fixing the eyes on one location, spatial attention can be directed to other locations. This spotlight of covert attention^[1] was thought to be a mechanism behaviorally and neurally dissociable from

eye movement control. However, it is highly likely that spatial attention and saccade planning are closely coupled during natural, unconstrained eye movement.^[3] There is behavioral evidence that covert attention directed in one direction can lead to deviations in orthogonal saccades,^[4] and there is neuropsychological evidence from single-cell recordings suggesting that attention and eye movement systems utilize overlapping neural networks.^[5] Moreover, planning a saccade toward a location improves processing at that location, regardless of whether or not the saccade is launched.^[6–8] Indeed, evidence shows that microstimulation of neurons in the frontal eye fields can cause both a saccade to a certain location^[9] and, with a lower level of stimulation, an absence of eye movement—but improved stimulus detection at that location.^[10,11]

How are these coupled mechanisms of attention and eye movement deployed when a scene is viewed? Early eye movement recordings showed that a subject's fixations would center on interesting or informative areas of the image, leaving blank or uniform regions uninspected.^[12] These findings have been recently replicated on a large scale. Wooding and colleagues installed an autonomous eyetracker in a public museum in London, and collected data from over 5000 subjects looking at works from the National Gallery.^[13,14] They too found that only a small set of regions in a work of art were reliably fixated by viewers. Contemporary research aims to quantify what determines such regions of interest, and has identified two main components.^[15] First, statistical properties of the image such as high spatial frequency^[16,17] and local contrast^[18] have been found to be closely correlated with fixation likelihood. These “bottom-up” properties can be analyzed to produce a salience map of any given image, which may correspond to a neural representation in the visual cortex.^[19,20]

A second influence on scene perception comes “top-down,” from knowledge, memories, beliefs, or goals that the viewer may bring to the image. In an early demonstration of this effect, Yarbus^[21] presented various subjects with Ilya Repin's painting *An Unexpected Visitor*, and asked them different questions,

such as “What are the ages of the people in the painting?” “What had the family been doing before the visitor arrived?” and “How long had the visitor been away?” The scanpaths differed dramatically according to the question. The semantic content of the scene itself can also attract attention. If there are out-of-place objects in a scene, such as a farmyard animal in a hospital, these anomalies are frequently fixated.^[22]

In order to scan a scene efficiently, some form of short-term memory for saccade location must be retained.^[23,24] It is not clear exactly what kind of memory representation is constructed from these successive fixations.^[25–28] Although observers are surprisingly poor at detecting large changes across scenes under some circumstances,^[29–33] there is evidence that eye fixation patterns are related to this form of scene recognition.^[34–36]

Eye movements have contributed to our understanding of the functioning of the visual system and attentional mechanisms. They have also provided insight into abnormal brain functioning. In the early years of eye movements research, Diefendorf and Dodge^[37] observed a deficit in smooth-pursuit eye movements in patients with praecox dementia. The relationship between this disorder, now known as schizophrenia, and eye movements was rediscovered in the 1970s.^[38,39] During a saccade the eye moves in a rapid ballistic motion, but the human eye can also rotate slowly and smoothly when tracking a moving object. Schizophrenic patients, however, find it difficult to maintain these smooth-pursuit movements, and they launch more predictive saccade eye movements than control subjects. On tasks that demand such predictive eye movements, however, schizophrenic subjects perform faster than controls.^[40,41] In an antisaccade task, subjects must inhibit an eye movement toward a suddenly appearing stimulus and make a saccade in the opposite direction, something that schizophrenics find relatively difficult.^[42–44] Schizophrenics also show different exploratory eye movements and scanpaths when viewing faces and stimuli with emotional valence.^[45,46] These eyemovement differences are of great interest to researchers attempting to relate schizophrenia to dysfunction in specific brain mechanisms,^[47] and to clinicians diagnosing and treating the disorder. For example, abnormalities in eye movements can be seen by the age of six in children susceptible to schizophrenia, more than ten years before the highest risk for onset of psychosis.^[48]

READING

The general characteristics of eye movements during perception have been studied in great depth during the process of reading.^[49,50] In general, eye fixations during

reading last approximately 200–250 milliseconds.^[51] Reading saccades span on average about two degrees of visual angle, although this can be better expressed here in terms of a span of seven to nine letter spaces, since the number of letters covered remains largely invariant despite differences in text size or distance.^[52] The chances of an individual word being fixated vary according to whether it is a content word (85%) or a function word (35%),^[53] and in relationship to the length of the word, with two- or three-letter words being skipped 75% of the time, but eight-letter words fixated almost always.^[54] Eye movements also vary as a function of the legibility of the text,^[55–57] syntactic difficulty of the text,^[58–60] conceptual difficulty of the text,^[61–63] and whether it is being read silently or out loud.^[64]

Saccades typically land between the beginning and the middle of a word.^[65] A reader will gather information from text at and around this fixation point. The size of this perceptual span has been investigated using a gaze-contingent paradigm.^[66] The text appears normal at the reader’s fixation point and within a window of a certain character length, but beyond that the text is garbled. With a small window, reading is impaired. Reading is unaffected, however, when the window extends 3–4 letters to the left of fixation and 14–15 letters to the right, suggesting that there is a perceptual span of around 18 characters centered asymmetrically around the fixation point.^[67,68] This asymmetry in the perceptual span is reversed for languages that are printed left to right,^[69] and rotated for those that run vertically.^[70] Although readers typically move their eyes forward when reading, approximately 10–15% of saccades move backward, fixating previous letters or words. These regressive saccades are thought to be related to difficulties in processing an individual word, or difficulties in processing the meaning or structure of a sentence. In these cases, readers can accurately refixate the part of the text that generated confusion.^[71,72]

These features of eye movements during reading—gaze durations, saccade lengths, and occurrence of regressions—can be used to infer moment-by-moment cognitive processing of a text by the reader.^[73] Details of the cognitive processes of pronoun resolution and co-reference, word frequency, lexical ambiguity, syntactic ambiguity, and discourse factors can all be gleaned from analyses of eye movement patterns. Rayner^[49] has reviewed the research in this area. For this reason, eye movements can reveal significant differences between individuals, as well as being an important data source about language processing. Differences in eye movement patterns can be distinguished between fourth- and fifth-graders, successful and unsuccessful third-graders or undergraduates, dyslexics and nondyslexics, and even graduate students

and professors.^[74–78] As a consequence, the study of eye movements while reading has considerable practical applications in education psychology.^[79]

LANGUAGE IN A VISUAL AND SOCIAL CONTEXT

Language use, more often than not, occurs within rich visual contexts, and the interplay between linguistic processes and visual perception is of increasing interest to psycholinguists and vision researchers.^[80] Eye movement research provided some of the first compelling demonstrations of the real-time interdependence between spoken language processing and visual perception.^[81] In these paradigms, a subject wears a headband-mounted eyetracker and typically follows spoken instructions to move objects around on a table or on a computer screen. One of the important findings with this paradigm demonstrated how spoken word recognition is an incremental process, at the timescale of milliseconds, that is profoundly influenced by the visual context. For example, subjects facing a display containing a bag of candy, a candle, an envelope, and a spoon, and being instructed to pick up the candy, occasionally look first at the candle (because of the overlap in the first few phonemes between “candy” and “candle”) and then at the bag of candy to pick it up.^[82] When the object with the phonologically competing name—candle—is not present in the display, subjects look more accurately and more quickly to the bag of candy. (The same results are found with a wide variety of objects and object names, e.g., penny and pencil, towel and tower.) The timing of the eye movements suggests that, in a sufficiently constrained visual context, spoken word recognition can be achieved in the listener before the word has even finished being spoken. This kind of real-time interaction between visual and linguistic processing is also seen in eye movement patterns during syntactic processing,^[83] spoken language production,^[84] and even natural, unscripted conversation.^[85]

Eye movements also reveal social characteristics and processes of face-to-face communication. Humans are remarkably sensitive to changes in where others are looking. Gibson and Pick^[86] demonstrated that a subject can detect a one-millimeter displacement of a viewer’s gaze away from the bridge of the subject’s nose, which is at the limit of the visual acuity of the eye. The gaze direction of others is a powerful attentional cue, yet is only beginning to be studied empirically.^[87] In analysis of face-to-face communication, however, research has mainly focused on one variable—eye contact between a speaker and a listener. Mutual gaze has two consequences. First, it correlates with many interpersonal factors, such as attractiveness,

authority, and perceived sincerity.^[178] Secondly, the timing of mutual gaze is used to coordinate dialogue. Bavelas and colleagues^[88,89] found that, a listener typically will look more at the speaker than vice versa, but the speaker will periodically cast looks at the listener, creating a period of mutual gaze. At this point, the listener is likely to respond with a nod or “mhm,” prompting the speaker to continue. In this way, eye movements are employed as part of the composite signal used in the collaborative act of conversation.^[90]

MEMORY, IMAGERY, AND DREAMING

Because of their selective and rapid sampling of the visual world, eye movements must recruit memory processes in order to build up some representation of the visual world.^[91] Conversely, it has also been found that memory processes often recruit eye movements.^[92] Richardson and Spivey^[93] demonstrated that subjects will systematically fixate particular empty spaces when questioned about the semantic content of a linguistic event that had previously taken place at that location. Subjects were presented with video clips of four people relating short pieces of factual information. The clips appeared in each of four regions of a grid. While viewing an empty grid, subjects answered a question about one of those facts. The location which had previously been associated with that information received significantly more fixations. This result holds even when the locations move around before the question period, and parallel behavior has been shown in infants as young as six months.^[94] These results suggest that the location of cross-modal events is spatially indexed by the brain, so that relevant locations can be refixated when a memory of the event is activated.

Contemporary neuroscience suggests that memory representations recapitulate perceptual processes to some degree.^[95–98] Researchers have long been intrigued by the relationship between eye movements during a perceptual experience and eye movements that occur when one remembers, imagines, or dreams about that experience. Early empirical investigations found that the frequency of eye movements increases during mental imagery, particularly that of a spatial nature,^[99–103] and an increase in rapid fluttering of the eyes while sleeping correlates with vividness of dreams.^[104–106] A specific account of this relation during picture recognition, known as scanpath theory,^[107] held that a mental representation of a given perceptual experience is composed of a sequence of sensory and motor activities. A picture is recognized partially by replaying the memory of this sequence of eye movements and visual stimulation

and comparing it to the present stimulus. The predictions of this model were borne out by the finding that scanpaths of subjects inspecting an abstract pattern bore a strong similarity to scanpaths of subjects looking at a blank display and recalling the pattern.^[108]

Recent work suggests that eye movements are engaged not only by a memory of a specific perceptual experience, but also by cognitive acts of imagination. Spivey and colleagues^[92,109] asked subjects to listen to short narratives describing events extending either horizontally or vertically (for example, a story about a train pulling out of the station and a story about the apartments in a 40-story building). Subjects' eye movements were recorded while they looked at a blank white screen, or while their eyes were closed. The directionality of saccades corresponded to the directionality of the narratives, suggesting that lower-level motor actions such as eye movements can accompany higher-level cognitive processes. This is because motor actions may be fundamental components of the mental state, rather than being separate functions that are triggered by a mental state.

The notion of a systematic relationship between eye movements and mental activity has percolated into a wider realm, where it has devolved into a series of popular myths and dubious therapeutic techniques. Bandler and Grinder^[110] proposed the theory of neurolinguistic programming (NLP). They observed that when patients were visualizing they tended to look up, when they remembered sounds they looked horizontally, and when they looked downward and to the left they were "accessing their feelings." NLP theory stated that these eye movements to particular locations corresponded to areas of the brain that were being used. Although Bandler and Grinder's observations, theories, and grasp of neuroanatomy have been discredited,^[111-116] NLP is still the basis of a large therapeutic industry.

There have also been claims that eye movements can be used to help alleviate the symptoms of post-traumatic stress syndrome. Shapiro^[117,118] developed the technique known as eye movement desensitization and reprocessing, whereby patients recalled a traumatic episode while following a moving stimulus (such as the therapist's hands) with their eyes. The claim is that this looking behaviour would disrupt the eye movement pattern associated with the traumatic memory, diminishing the visual aspect of the memory and desensitizing the patient to the memory. It is hotly contested whether such methods produce objective improvements.^[119,120] Although they have been empirically shown to help some patients,^[121-123] it could be the case that improvement is due to the general therapeutic practices employed, rather than to the specific effect of eye movement manipulation.^[124]

EYE MOVEMENTS IN THE SERVICE OF COMPLEX TASKS

The research we have discussed so far investigates relatively passive acts of perception and information processing. But eye movement research can inform the study of more complex behaviors, such as selecting a commercial product, playing cricket, or flying a jet plane. In these cases, eye-tracking technology can reveal what different sources of information the subject is using, how frequently they are sampled, and how they affect decisions.

Consumer behavior rests on an interplay between immediate perceptual factors and decision-making processes that can be seen in eye movement behavior. Early in its development, it was realized that eye movement technology could be used to identify factors that determine the amount of attention allocated to different advertisements.^[125-127] Indeed, when advertisements are placed next to vital traffic signs, their over-effectiveness and distracting qualities can also be seen in eye movements.^[128] Such measures have predictive value, since it is the case that gaze durations between competing advertisements correlate with later product choice.^[129,130]

Good visual design is important in a wide range of activities. The eye movements of radar operators,^[131,132] gunners,^[133] and pilots^[134,135] have been recorded and used to evaluate operator skill and equipment design. Similarly, a range of studies employed eye tracking to study the effectiveness of different instrumentation panels,^[55,136-140] and later, different computer-to-user interfaces.^[141-144] Such research has even been used to investigate the ways in which people experience Japanese formal gardens.^[145]

Clear instrumentation, efficient perception, and rapid decision-making are crucial while driving or piloting a vehicle. Early research indicated that eye movements away from the direction of heading were related to steering errors of pilots,^[146] and that saccade frequency was employed as a measure of fatigue in long-distance truck drivers.^[147] Finer analyses investigated what information sources people use, and how frequently they were sampled during different driving conditions.^[148-151] Particularly difficult perceptual/motor tasks, such as cornering, have come under close scrutiny. One or two seconds before average car drivers enter a curve, they direct their gaze to the tangent point on the inside of each bend and leave it there for approximately three seconds.^[152] The direction of the tangent point relative to the car heading is a good predictor of the curvature of the road. Although this anticipatory behavior is not present in novice drivers,^[153,154] in professional race-car drivers it is advanced to the point that the head is rotated proportionally to the estimated car rotation speed,

such that the head is brought in line with the expected tangent points.^[155]

Differences in oculomotor responses between professional and amateur athletes^[156,157] can be seen, and saccadic performance has been claimed to correlate with batting averages in little-leaguers.^[158] More specific analyses have examined differences in scanpaths between novices and experts. For example, skilled golfers are less likely to look at the club during putting, and more likely to look at the ball and the hole.^[159] Land and McLeod^[160] studied the scanpaths of cricket batsmen, who have to judge the trajectory of a fast bowl with an unpredictable bounce and spin based on half a second of viewing time. The batsmen fixated the ball at its time of release and then made a saccade to where they anticipated the bounce. The better batsmen were faster at making this predictive eye movement.

Eye movements not only reveal the strategies of highly trained sportsmen; they can also reveal the more mundane strategies we employ while carrying out everyday tasks, such as making a sandwich. Land and Hayhoe^[161] found that eye movements are tightly linked with moment-to-moment goals and subtasks. This is in contrast to the passive perception of a static scene or picture, when eye movements may be drawn by areas of high contrast or spatial frequency.^[15] Such task-related fixations have been examined in detail using the block-copying task developed by Ballard, Hayhoe, and colleagues.^[162–164]

In these eye tracking experiments, subjects were given the job of constructing a pattern of colored blocks. The pattern was displayed in the model area of a board. Participants took blocks from the resource area, and copied the pattern in the workspace area. The participants' hand actions were recorded, and a headband-mounted eyetracker recorded their eye movements to obtain a window on the strategy used in the task. One method participants could use was to look at the model area and memorize the pattern; each block in turn could be located in the resource area, and then placed in the workspace. A second method, less memory-intensive, would be to remember the color and location of one block from the model, collect it from the resource area, place it in the workspace, and then consult the model again for the next block. The strategy most often used by participants, however, entailed the minimal possible memory demands. Participants would commonly fixate the model, then fixate and pick up a correctly colored block from the resource area, fixate the model again, and then place the block in the workspace. Thus, two fixations per block were made on the model—one to extract color information and one to extract relative spatial location information.^[162] This is a strategy of indexing, whereby just the location of an object is maintained in working

memory, and other properties can be “looked up” as they are needed.^[163] In a computerized, gaze-contingent version of the block-copying task, the color of a block was changed during a subject's saccade.^[164] The subjects rarely noticed this property change, further demonstrating that subjects rely on fixating external information rather than mentally storing it.^[165]

INTERACTIVE APPLICATIONS

The relationship between eye movements and cognitive processing has been employed as a tool to improve ergonomic design and computer interfaces.^[166] The emergence of gaze-contingent eye tracking has allowed eye movements to be further employed as a means to interact with such systems.^[167] Since fixations indicate what parts of the visual world are salient to the user, eye movement information can be used to tailor visual displays. Regions that are not fixated can be rendered at a far lower level of detail,^[168–170] and hence eye tracking can be used to make valuable computation shortcuts. Given the speed and frequency of naturally occurring eye movements, and their close relation to perceptual and cognitive processing, they also have the potential to be an efficient and expressive input device.

In the first applications of this technology, eye gaze replaced the hand-operated mouse, allowing users to select icons and menus in a graphical user interface. It takes very little training for naïve users to employ their gaze as a means to control a computer.^[171] Although gaze is also faster than a mouse, there is no clear equivalent of a button press. Blinks were found to be unnatural for users, so dwell times were used as a selection criterion. Initially, this led to the so-called Midas touch problem: Users could not distinguish between items they wanted to visually inspect and items they wanted to select, so everything they looked at would be chosen. If a long enough dwell time is used, typically 600–1000 ms, this can be avoided. If the dwell time is very carefully calibrated to be just longer than a normal fixation, then users report an eerie sense that the system knows what they want to do before they do.^[172]

This technology can be employed by users who are unable to operate standard input devices because of physical disability.^[173] One such application is eye typing, in which users can enter characters by fixating on the keys of a virtual keyboard.^[174] There are currently limitations to such implementations. Accuracy issues determine the size of buttons on the screen, such that a whole alphabet cannot always be employed at once.^[173] It can take severely disabled users many months to learn this form of interaction,^[175] because they have had little experience actively controlling devices. The speed of eye typing is typically a character a

second.^[176] In order to be a successful, real-time communication tool, eye typing systems have been developed in which the user selects a word or phrase from a hierarchical menu.^[177]

CONCLUSION

Eye movements are driven both by properties of the visual world and by processes in a person's mind. Uniquely poised between perception and cognition, eye movements are an invaluable tool for psychologists. Compared to the single data point provided by a button-press reaction time, the eye movements of a subject can provide researchers with a rich, dynamic data source concerning the temporal dynamics and psychological processes that led up to the response. These properties are also of great value to designers and engineers, because they allow for detailed measurements of how a user is interacting with a device. Since the technology has become highly efficient, such information can now be fed back into devices in real time, and the movements of a user's eyes can be used to issue commands or tailor computational processes. Although such applications are currently in their infancy, this most frequent of all human behaviors could turn out to provide the most fluid and expressive interface between humans and computers.

Fabrics

Frank K. Ko

Fibrous Materials Laboratory, Department of Materials Science and Engineering, Drexel University, Philadelphia, Pennsylvania, U.S.A.

INTRODUCTION

Fabrics are fibrous structures manufactured by the interlacing, interlooping, intertwining, or direct bonding of oriented or random, discrete or continuous, fibers into 2-D or 3-D textile assemblies. Textile surgical implants are fibrous structures placed into the human body for a period of time to perform a specific clinical function. Surgical implants can be classified according to their end uses or by their functions. Based on the location of use in the body, surgical implants can be categorized as cardiovascular and thoracic implants, orthopaedic implants, or implants for plastic and constructive surgery. The functions of these implants can include replacement of parts of the anatomy, such as hip and joints; simulation of a congenitally absent portion of the anatomy, such as facial prostheses; correction of congenital, traumatic, or pathological deformity (spinal plates); and rectifying an organ's mode of operation (pacemaker), as well as therapeutic functions and drug delivery.

In this article, the wealth of fiber architecture in fabric forms and their characteristics, which are critical for the selection and design of implants for surgery, are introduced. A review of the basic components of fabrics and the various classes of fabric structures is provided. The characteristics of the various fabrics are illustrated in performance maps, and potential applications of fabrics for tissue engineering scaffolds are illustrated.

OVERVIEW

Even though the use of surgical implants dates back to ancient Egyptian days, the modern use of surgical implants did not begin until the 19th century. The use of textile- and fabric-based surgical implants has greatly expanded since the development of synthetic fibers in the 1940s and 1950s. Some well-established textile surgical implants include artificial arteries, hernia mesh, sutures, bone fixation plates, hip joints,^[1,2] and more recently, material for the regeneration of tissues and organs.^[3,4]

It is well established that the fundamental building blocks of living systems are fibrous in nature. From the

1.5-nm double-helix strand of DNA molecules (including cytoskeleton filaments with diameters around 30 nm) to sensory cells such as hair cells and the rod cells of the eyes, fibers form the extracellular matrices—the multifunctional structural backbone—for tissues and organs.^[5] Whereas collagen fibrils constitute the structural backbone of connective tissues such as tendons and ligaments, specific junctions between various cells conduct electrical and chemical signals that result from various kinds of stimulation. The signals direct normal functions of the cells such as energy storage, information storage and retrieval, tissue regeneration, and sensing. Figure 1 illustrates the hierarchical fibrous nature of biological tissues.^[5] The architecture of these natural fibrous structures is a blueprint for the design and fabrication of replacement body parts and the creation of scaffolds for tissue regeneration.

Man-made or regenerated fibrous structures in fabric form are attractive candidates for surgical implants. Because of their large length-to-diameter ratio and flexibility, metallic, ceramic and polymeric materials in fibrous form can be organized into textile structures in linear, two-dimensional, and three-dimensional structures. The enormous possibilities of combinations of material properties and structural geometry can result in structures exhibiting one or more of the following characteristics:

- High strength-to-weight ratio.
- High voluminosity.
- Controlled modulus, extensibility, flexibility, pliability.
- Conforming behavior.
- Reactive or nonreactive to body environment.
- Controlled porosity and permeability.
- Ease of suturing, clamping, or joining.
- Compatible surface texture for tissue adhesion.
- Structural similarity to body tissues and organs.

Available fibers can range from the very strong aramid or gel-spun polyethylene to the extremely extensible elastomers. The properties of some of the candidate fibers are shown in Table 1.^[6] The stress-strain behavior of a wide range of fibers tested in ambient and physiological conditions is shown in Fig. 2.^[7,10] As a result of their higher molecular orientation, the tensile

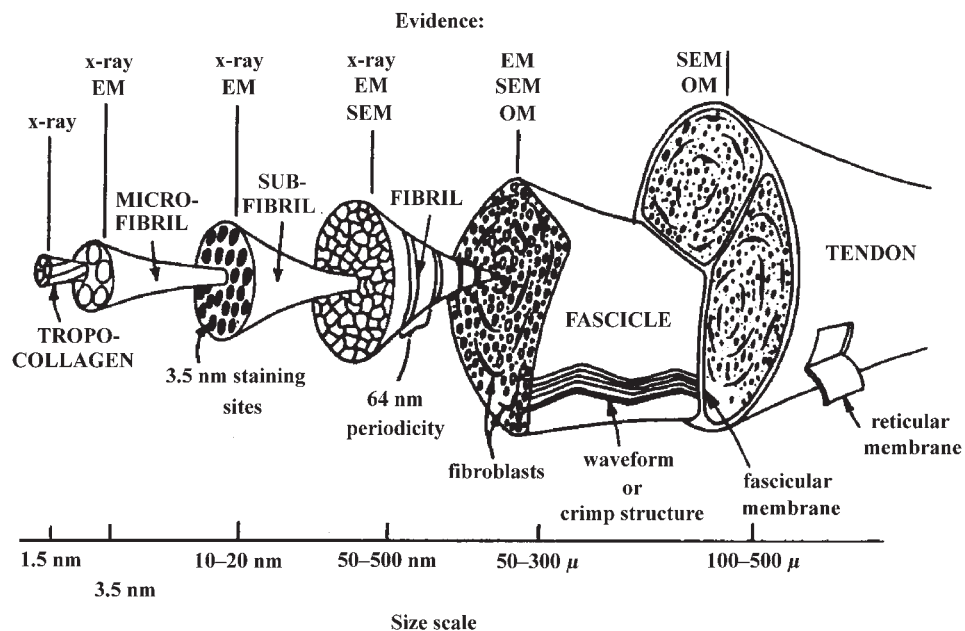

Fig. 1 Hierarchical organization of fibrous structures of biological tissues. (From Ref. [5].)

properties of the high-tenacity fibers are quite insensitive to the physiological environment.

Although biomaterials that are nonreactive to body environment are desirable for some surgical applications, the emergence of tissue engineering has resulted in a trend in surgical implants toward materials that respond to the body environment in a programmable manner. A large number of absorbable polymers have been developed in recent years. These absorbable polymers serve a temporary purpose: Once the wound or fracture heals, the implant, suture, or other structure disappears. Table 2^[8] gives a summary of some of the synthetic absorbable polymers and their applications.

The various fibers can exist in monofilament, multifilament (with or without twist), textured, and staple fiber forms to create a wide variety of surface geometries and extensibilities. Figure 3a illustrates the different types of linear fibrous assemblies available for use. In Fig. 3b, the stress-strain behavior of the various linear fiber assemblies is illustrated.^[9]

The fibers or yarns can be converted into a tremendous array of 2-D and 3-D fabric structures, as shown in Fig. 4.^[10] An implant designer can utilize, for example: 1) highly covered and bulky nonwoven structures; 2) dimensionally stable plain-weave fabrics; 3) weft-and-warp-insertion warp knits (warp-knitted structures with inserted linear yarns integrated into the fabric during fabric formation, along the machine direction (warp) and across the machine direction (weft), respectively); and 4) highly conformable weft knits and braids, as well as net-shaped three-dimensional fabrics, which provide a means to organize fibrous networks similar to the structural features of various body parts.

STRUCTURAL COMPONENTS OF FABRICS

Textile Units

Fabrics are characterized by fiber material (polyester or polylactidglycolic [PLAGA]), fiber geometry (crimp,

Table 1 Properties of candidate materials for prostheses

Fiber	Tenacity (g/denier)	Breaking elongation	Young's modulus (g/denier)
Polytetrafluoride (Teflon)	1	45%	5
Polyester (Dacron 55)	6	30%	30
Polyamide (Nylon 65)	6	45%	20
Aramid (Kevlar 29,49)	22	3-6%	450-1000
Acrylic (Orlon)	2.5	25%	10
Stainless steel (315 L)	3	1%	300
Polypropylene (Olefin)	5	50%	30

cross-sectional shape, fineness), yarn geometry (monofilament or textured multifilament), fabric construction (woven, knit, braid), and fabric weight (mass per unit area). Similar to soft biological tissues, the compressible nature of fibrous assemblies makes it difficult, if not impossible, to precisely measure the dimension of

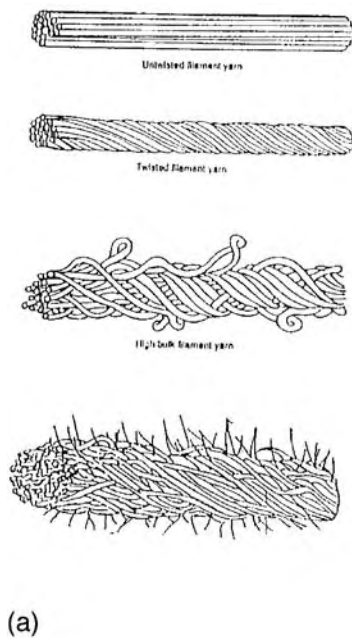

fibrous materials. The cross-sectional area of fibers and linear fiber assemblies are more conveniently expressed in terms of the traditional textile unit of linear density: the denier. One denier is the thickness of a fiber with mass of one gram per 9000 meters. Alternatively, the linear density can be expressed as the SI unit kg/m, or

Table 2 Absorbable Fibers

Composite-PLA/PGA, ceramic and carbon fibers	Bone fixation Bone repair
Polyester-amides	Suture
Isomorphic copolyoxalates and polyalkylene oxalates	Suture Controlled-release device Surgical aid
Polyethylene oxide- polyethylene telephthalate copolymers	Artificial artery Tendon

tex. The equivalent cross-sectional area or specific cross-sectional area has the following expression:^[11]

$$A_{sp} = \frac{\text{tex}}{10^5 \times \text{density}} \text{cm}^2 = \frac{\text{denier}}{9 \times 10^5 \times \text{density}} \text{cm}^2 \quad (1)$$

With the specific cross-sectional area expressed in terms of linear density, one can obtain the specific stress and other quantities in mechanics by normalizing of force by A_{sp} (to obtain force/area [MPa or psi]) or by linear density, such as force/linear density (g/denier; g/tex; N/tex). For fabric structures (planar and 3-D assemblies), the normalization of properties can be carried out using the following relationships for specific stress:^[12]

$$\frac{N}{\text{tex}} = \frac{\frac{\text{force (N)}}{\text{width (mm)}}}{\text{fabric areal density (g/m}^2\text{)}} \quad (2)$$

$$1 \text{ N/tex} = 1 \text{ GPa/density (g/cc)}.$$

Fibers

A textile fiber is an entity of matter that is processable in a textile manufacturing process and characterized by slenderness, flexibility, and a high length-to-diameter ratio greater than 1000:1. Beside flexibility, the unique characteristic of textile fibers is a combination of strength, light weight, and toughness. As shown in Fig. 2, the strength of fibers ranges from 1 g/den* to 40 g/den for super-high-strength fibers, with elongation ranging from 1% to several hundred percent for elastomers.

Depending on chemical composition and internal structure, fibers have different stress-strain properties. The stress-strain curves of natural and man-made fibers

shown in Fig. 2 exhibit the wide range of material properties available at our disposal.^[10] It is of interest to observe that the fiber with the best combination of strength and toughness is spider silk.^[13]

Yarns

A yarn is a linear assembly of discrete textile fibers or continuous filaments in a form suitable for knitting, weaving, or intertwining in order to form textile fabrics. Depending upon the nature of the fiber (natural or man-made, long or short, fine or coarse) and the end-use requirements, various yarn formation systems are used. The fiber material properties and the resulting yarn geometry (twist, denier, etc.) determine the performance properties of a yarn and, consequently, dictate the processing methods and the intended applications.

Yarns can be classified according to their form, by the formation system, and by physical properties and

performance characteristics (Fig. 3). The three basic forms of yarns are:

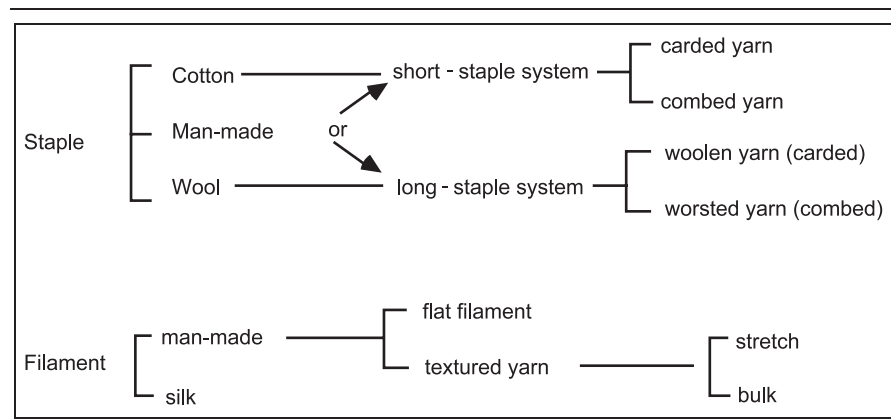

- Monofilament, a solid, single strand of unlimited length.
- Multifilament, a multitude of continuous-filament fibers twisted or textured together.
- Staple (spun), a yarn made from staple (discrete-length) fibers; spun yarn.

Table 3 provides a summary of the various types of yarns produced by different yarn formation systems. For more information on the manufacturing technology of yarns, readers are referred to the texts by Goswami et al.^[14] and Kaswell.^[15]

FABRIC STRUCTURES AND PROPERTIES

There is a large family of fiber architectures available for surgical implants (Fig. 4).^[16] The design and selection of these fiber architectures for surgical

Table 3 Classification of yarns based on yarn formation systems

implants or tissue engineering scaffolds can be carried out on the fiber level as well as on the fabric structure level. These fabrics can be made from yarns (yarn-to-fabric structures) or directly from fibers (fiber-to-fabric structures), resulting in a wide range of dimensional scale, fiber tortuosity, and fabric porosity as characterized by the fiber volume fraction-orientation map described in the section on fabric performance characteristics.

Yarn-to-Fabric Structures

In the family of yarn-to-fabric structures, it can be seen that interlooped structures such as weft knits tend to be more porous, more voluminous, and bulkier and thicker. Interlaced structures such as woven fabrics tend to be less porous, less bulky, and thinner. The performance of these fabrics is determined to a great extent by the linearity and interlacing density of the yarns in the fabrics. For example, the weft knits have high extensibility and are extremely comfortable and compressible. As a result of the openness of the loop geometry to a knitted structure, weft knits are highly permeable. The high linearity of the multiaxial (non-crimped) warp knit structure allows only limited extensibility and low toughness. The permeability of woven and multiaxial warp knit fabrics is lower than that of weft knit fabrics because of the high coverage. In general, based on structural geometry, the family of yarn-to-fabric structures can be classified into two major groups: 2-D planar fabrics and 3-D fabrics (wherein more than two yarns are placed in the through-thickness direction).

Structural Geometry of 2-D Fabrics

Woven fabrics

Fabricated by the interlacing of yarns, woven fabrics can be produced in hundreds of possible combinations. From the in-plane fiber orientation point of view, woven fabrics can be divided into biaxial and triaxial woven structures. Biaxial weaves consist of 0° and 90° yarns interlaced in various repeating patterns or topological unit cells. The three basic weave geometries from which many other patterns evolve are the plane, satin, and twill weaves. A schematic diagram for the various views of these three basic weaves is shown in Fig. 5. These three fabrics are distinguished by the frequency of yarn interlacing and the linearity of the yarn segments. The plane weave has the greatest number of interlacing yarns and the satin weave has the least number of yarns interlacing, with the twill weave somewhere in between. Accordingly, the plane weave has a higher level of structural integrity and

Fig. 5 Three basic weaves.

greater ductility as a result of the crimp geometry produced by yarn interlacing. On the other hand, the satin weave has the highest level of fiber-to-fabric strength and modulus translation efficiency due to the low level of yarn interlacing and high level of yarn linearity. The low level of yarn integration in the satin weave also allows freedom of yarn mobility, which contributes to higher fiber packing density and consequently to higher fiber volume fraction.

Although cane weaving for cane chairs has been known for a long time, a machine-made triaxial weave wasn't available until Norris Dow's development of triaxial machine weaving in the early 1970s.^[17] The unique feature of triaxial weave is the $90 \pm 60^\circ$ hexagonal yarn orientation in one plane, resulting in a high level of in-plane shear resistance. High levels of isotropy and dimensional stability can be achieved with triaxial weave at very low fiber volume fraction. Figure 6 shows a schematic diagram of two triaxial-weave geometries.

Fig. 6 a. Structural geometry of triaxially woven fabrics (basic weave). b. Structural geometry of triaxially woven fabrics (biplane weave).

Fig. 7 Weft-knitted structures.

Knitted fabrics

Knitted fabrics are interlooped structures wherein the knitting loops are produced by the introduction of the knitting yarn either in the cross-machine direction (weft knit), as in Fig. 7, or along the machine direction (warp knit), as in Fig. 8, producing a large number of stitch geometries. By controlling the stitch (loop) density, a wide range of pore geometries can be generated. Because of their interlooped nature, the maximum fiber packing density of knitted structures is lower than that of the woven fabrics. The high level of conformability and porosity of weft-knitted fabrics makes them ideal candidates for vascular implants.

Braided fabrics

By intertwining three or more yarn systems together, braided fabrics can be produced in flat or tubular form (Fig. 9). The bias-interlacing nature of the braided fabrics make them highly conformable and shear resistant. To enhance reinforcement in the 0° direction, triaxial braiding can be employed to introduce 0±θ yarns, as shown in Fig. 10. Because of the torque-free nature of braided fabrics, they are used extensively for sutures and are increasingly being considered for orthopaedic applications, such as ligaments and tendons.

Fig. 8 Warp-knitted structures.

Structural Geometry of 3-D Fabrics

The structural geometry of the 3-D fabrics will be discussed according to the four basic methods of textile

Fig. 9 2-D braided structures.

Fig. 10 Triaxially braided structure.

manufacturing: weaving, orthogonal, knitting, and braiding.

Woven 3-D fabrics

Three-dimensional woven fabrics are produced using the multiple-warp weaving method, which has long been used to manufacture double and triple cloth for bags, webbings, and carpets. Fabrics have been successfully woven with as many as 17 layers. Various fiber architectures can be produced by the weaving method, including solid orthogonal panels (Fig. 11a), variable-thickness solid panels (Fig. 11b), and core structures simulating a box-beam (Fig. 11c) or trusslike structure (Fig. 11d). Furthermore, by proper manipulation of the warp yarns, as exemplified by the angle-interlock structure (Fig. 11e), the through-thickness yarns can be organized into a diagonal pattern. To provide in-plane reinforcement in the bias direction, a new process was developed by Dow^[17] as an extension to the triaxial weaving technology, producing multi-layer triaxial fabrics as shown in Fig. 12.

Fig. 12 3-D triaxial weaves (dow).

Orthogonal 3-D fabrics

Pioneered by aerospace companies such as General Electric,^[18] the orthogonal 3-D fabric technology was developed further by Fiber Materials Incorporated.^[19] Progress in automation of the orthogonal 3-D fabric manufacturing process has been made in France by Aerospatiale^[20,21] and SEP,^[22] and in Japan by Fukuta at the Research Institute for Polymers and Textiles.^[23,24] The structural geometries resulting from the various processing techniques are shown in Fig. 13.^[16] Figures. 13a and 13b show the single-bundle

Fig. 11 3-D woven fabrics. (a) Solid shape; (b) variable thickness panel; (c) Box beam; (d) Truss structure; (e) Angle interlock.

XYZ fabrics in a rectangular and cylindrical shape. Figure 13c demonstrates the multiple-yarn bundle possibilities in the various directions. In Fig. 13d the multidirectional fiber placement in the plane of the 3-D structure is shown. Although most of the orthogonal 3-D structures consist of linear yarn in all of the directions, introduction of the planar yarns in a nonlinear manner, as shown in Fig. 13e, f, and g can result in an open lattice, or a flexible and conformable structure. Some of these 3-D lattice structures have been used for producing scaffolds for composite bone implants.^[24]

Knitted 3-D fabrics

Three-dimensional knitted fabrics are produced by either warp knitting or weft knitting. An example of a weft knit is the nearly net-shaped structure knitted under computer control by the Pressure Foot[®] process^[25] (Fig. 14). In a collapsed form, this preform has been used for carbon-to-carbon structures. The unique feature of the weft-knit structures is their conformability and their highly porous nature. When additional reinforcement is needed in the 0° and 90° directions, linear laid-in yarns can be placed inside the knitting loops, as shown in Fig. 14.

Multiaxial warp (MWK) fabric

MWK systems consist of warp (0°), weft (90°), and bias ($\pm\theta$) yarns held together by a chain or tricot stitch through the thickness of the fabric, as illustrated in Fig. 15.^[26] The major distinctions of these fabrics are the linearity of the bias yarns, the number of axes, and the precision of the stitching process. Depending on the number of guidebars available and the yarn

insertion mechanism, the warp-knit fabric can consist of predominantly uniaxial, biaxial, triaxial, or quadraxial yarns. The Mayer Textile Corporation, utilizing a multiaxial magazine weft insertion mechanism, produces the latest commercial nonimpaled MWK fabric. The attractive feature of this system is precision yarn placement, with four layers of linear or nonlinear bias yarns plus a short fiber mat arranged in a wide range of orientations. Furthermore, stitches are formed without piercing through the reinforcement yarns (hence the term, nonimpaled) at a production rate of 100 meters per hour. Another MWK is the impaled LIBA system shown in Fig. 16. This fabric has six layers of linear yarns assembled in various stacking sequences and

Fig. 14 3-D knitted fabrics (pressure foot[®]).

Fig. 15 Multiaxial warp knit (MWK).

stitched together by knitting needles piercing through the yarn layers.

3-D braided fabrics

Three-dimensional braiding technology is an extension of the well-established 2D braiding technology, wherein the fabric is constructed by the intertwining or orthogonal interlacing of two or more yarn systems to form an integral structure. A wide variety of solid, complex structural shapes can be produced in this manner, resulting in 3-D interconnected fibrous structures.^[27] Figure 17 shows two basic loom setups in circular and rectangular configurations. The 3D braids are produced by a number of processes, including the

track and column method (Fig. 18), the 2-step method (Fig. 19), and a variety of displacement braiding techniques. The basic braiding motion includes the alternate X and Y displacement of yarn carriers, followed by a compacting motion. Formation of shapes is accomplished by properly positioning the carriers and joining various rectangular groups through selected carrier movements. The 3-D braided structure has been used for various orthopaedic implants, and more recently for tissue-engineered ligament scaffolds.^[28]

Fiber-to-Fabric Structures

Fiber-to-fabric structures are generally known as nonwoven fabrics. The simplicity of the manufacturing process—by direct conversion of fibers to fabrics, thus bypassing the yarn formation stage—has great appeal to the apparel and medical textile industries because of the high productivity and cost savings. A majority of surgical gowns are made from nonwoven fabrics. One of the obstacles preventing more extensive use of nonwovens for primary garment applications is the lack of drapability/conformability, or the paperlike nature, of nonwoven fabrics. There is an increasing variety of fabrication processes for nonwoven fabrics. Of the two major classes of nonwovens, chemically and mechanically bonded nonwovens, the mechanically bonded systems (such as needled felts) and spunlaced systems tend to be more voluminous, bulkier, thicker, and nonporous. The chemically bonded nonwovens tend to be more paperlike, thin, low in bulk, and less porous. As a result, the mechanically bonded nonwovens are more permeable, more compressible, and have higher extensibility. The toughness of nonwoven felts is a complex interaction of bonding density, fiber tenacity, and fiber orientation. Because of the high strength of the continuous filaments and the strength of the bonds, a spunbonded system features high levels of shear resistance, tear resistance, and toughness. Needled felt made from strong fibers (e.g., Kevlar), on the other hand, can be quite tough and capable of

Fig. 16 Multiaxial warp knit (MWK): LIBA system.

Fig. 17 3-D braiding equipment and net-shaped structures.

arresting fragments from a ballistic projectile when a sufficient level of entanglement is created in the manufacturing process.

Since the 1950s, many of the textile structures illustrated in Fig. 3 have been used for surgical implants, with considerable success. Some of the structures and their respective applications are summarized in Table 4. These fibrous structures are mostly from nonabsorbable polymers consisting of fibers larger than 10 μm in diameter, although some microfibers are increasingly being used. Unfortunately, these fibers are developed primarily for clothing rather than for medical applications. Recently, with the rediscovery of the electrostatic spinning process, a new family of nonwovens and yarns consisting of ultrafine fibrils have been fabricated, with fiber diameters ranging from a few nanometers to a few micrometers. The extension of the basic building block of a fabric to the nanoscale has created new design options for numerous medical fabrics. One method that is capable of direct formation of nanofiber-based yarns and fabrics is the electrospinning process. Electrospinning technology has been detailed in numerous publications,^[29] and a brief description is provided here.

Electrospun yarns and fabrics

The electrostatic spinning (electrospinning) process is a simple, nonmechanical process developed over sixty years ago.^[30] Because of its simplicity and its capability of generating nanoscale fibers from polymer solutions and melts under ambient conditions, there has been a revival of interest in the electrospinning process to create structures that have ultrahigh surface

areas.^[31–33] In the electrospinning process, as illustrated in Fig. 20, an electric field is generated between an oppositely charged polymer fluid and a collection screen. A polymer solution is added to a glass syringe that has a capillary tip, and an electrode is placed in the solution, with another connection made to a

**Fig. 20** The electrospinning process.

ground-fiber-collecting metal screen. As the electrical potential is increased, the charged polymer solution is attracted to the screen. When the voltage reaches a critical value, the electric field overcomes the surface tension of the polymer cone formed on the capillary tip of the syringe and a jet of ultrafine fibers with diameters ranging from 2–500 nm is produced. As the charged polymer jets are splayed, the solvent in the fiber quickly evaporates and the fibers are accumulated randomly, or laid parallel on the surface of the collection screen. This results in a porous, nonwoven film, or a yarn composed of nano- to micron-scale fibers. Varying electric field strength, polymer solution concentration, and duration of electrospinning can control fiber diameter and film thickness. In addition, coelectrospinning can be carried out by mixing one or more kinds of functional nanoparticles, nanoplatelets, or nanotubes during solution preparation, resulting in ultrafine nanocomposite fibers that have a multitude of electronic and structural functions.^[34]

FABRIC PERFORMANCE CHARACTERISTICS

Fabric performance characteristics are a result of the interaction between fiber (material properties), yarn and fabric geometry, and finishing treatment. As outlined earlier, textile structures in fabric form can be characterized in terms of geometric and performance properties. The performance maps provide an overview of the range of behavior of various fabrics as a function of four geometric parameters and four performance parameters.

The geometric parameters include:

1. Porosity: the amount of open space in a unit volume of the fabric. As the fiber diameter and yarn diameter increase, the structure tends to be porous. The porosity of a fabric is inversely proportional to the areal coverage, or cover factor, of a fabric. A porous fabric tends to be lighter and more permeable.
2. Surface texture: the surface geometry of a fabric, characterized by the smoothness of the surface, which in turn is governed by fiber and yarn diameter. Modular fiber or yarn lengths are the geometric repeating units of the fabric.
3. Voluminosity: a reflection of the bulkiness of a fabric for a given areal density (mass per unit area). A fabric tends to be more voluminous if the fiber and yarn diameter is larger and the freedom of fiber mobility in the geometric repeating unit is high. Voluminosity is directly related to fiber thickness, in that a voluminous fabric tends to be thick.
4. Thickness of the fabric: similar to voluminosity and related to fiber and yarn diameter. The larger the fiber and yarn diameter, the thicker and bulkier is the fabric.

The performance parameters include:

1. Permeability: the ease of air or liquid flow through a fabric. The permeability of a fabric is higher when the porosity of the fabric is high. Porosity and fiber volume fraction (1-porosity) are related to packing efficiency, which is influenced by fiber diameter and fiber cross-sectional geometry. Permeability is a strong function of fiber or yarn diameter for a given fiber architecture (fiber orientation).
2. Compressibility: the ability of a fabric to resist transverse (through the thickness) compression. A voluminous fabric tends to be more compressible. On the other hand, compressibility decreases with the stiffness of fiber and yarn, which is significantly influenced by fiber diameter. As fiber diameter increases, the bending stiffness and longitudinal compressive stiffness of the fiber increases geometrically.
3. Extensibility: a measure of the ability of a fabric to stretch and conform. Fabric extensibility is affected by fabric geometry and inherent fiber-bending elongation. A yarn that consists of finer fibers tends to have a higher potential for fabric extensibility.
4. Toughness: a measure of the durability of a fabric. As reflected in the areas under the stress-strain curve of a fabric, a high-strength fabric with high elongation at break usually produces high toughness. Fabrics having high compliance and extensibility are usually tougher.

Summaries of the geometric and performance properties of the yarn-to-fabric structures, and the fiber-to-fabric structures in the form of performance maps, are shown in Figs. 21–24. These performance

Fig. 21 Geometric properties of yarn-to-fabric structures.

Fig. 22 Performance properties of yarn-to-fabric structures.

maps show that the geometric parameters play an important role in the structural and physical properties of fabrics. One key geometric factor is the fineness of the component fiber.

FABRIC SCAFFOLDS FOR TISSUE ENGINEERING

In addition to traditional applications for surgical implant development, fabric structures are excellent candidates for the emerging field of tissue engineering, or regenerative engineering. As articulated succinctly by Vacanti and Mikos,^[36] the key challenges in tissue engineering are: 1) the synthesis of new cell adhesion-specific materials; and 2) development of fabrication methods for the manufacturing of reproducible

three-dimensional synthetic or natural biodegradable polymer scaffolds, with tailored properties. These properties include dimensional porosity, pore size distribution, and connectivity; mechanical properties for load-bearing applications; and rate of degradation. In this article, we introduce the large family of three-dimensional fiber architectures, as well as the range of fiber-size scales available for tissue engineering.

The geometry and size scale effect and their potential for tissue-engineering scaffolds are demonstrated through various fibrous structures.^[37] Specifically, experiments were carried out using osteoblasts isolated from neonatal rat calvaria and grown to confluence in Ham's F-12 medium (GIBCO), supplemented with 12% Sigma fetal bovine on polylacticglycoic acid (PLAGA) sintered spheres, 3-D braided 20 mm filament bundles, and nanofibrils.

Fig. 23 Geometric properties of fiber-to-fabric structures (nonwoven fabrics).

Fig. 24 Performance properties of fiber-to-fabric structures (nonwoven fabrics).

Four matrices were fabricated for the cell culture experiments:

1. 150–300 mm PLAGA sintered spheres.
2. Unidirectional bundles of 20 mm filaments.
3. 3-D braided structure consisting of 20 bundles of 20 mm filaments.
4. Nonwoven structure consisting of nanofibrils.

The porosity of the microsphere structure, the nanofibrous specimens, and the 3-D braided structures were characterized by mercury porosimetry measurement to determine their pore size distributions. Cells were seeded on the UV sterilized PLAGA matrices at a density of 100,000 cells per cm^2 . The osteoblasts were cultured on the matrices for durations ranging from one day to 21 days. These specimens were prepared according to established procedures by fixing in gluteraldehyde and dehydrating through a series of ethanol dilutions. The seeded cells were labeled with [^3H]-

thymidine, and the thymidine uptake was measured at 1, 3, 7, 10, and 11-day intervals.

Pore Size Distribution

The pore size and distribution of the various specimens were characterized using a Micrometrics Autopore III porosimeter. As shown in Fig. 25, a bimodal distribution of pores was observed for the 3-D braided structures, showing the existence of large interstitial pores on the order of 250 μm and interfiber pores having a diameter on the order of 30 μm . At the other extreme, as shown in Fig. 26, the nanofiber structures show a predominant concentration of pores with an average pore size of 14 μm . The pore surface of the nanofibrous structures was 0.823 m^2/g , an order of magnitude greater than that in the 3-D braided structure at 0.0045 m^2/g . The sintered spheres show a single-mode pore diameter distribution over the range

Fig. 25 Pore size distribution of braided structure.

Fig. 26 Pore size distribution of nanofibrous nonwoven structure.

of 200–600 μm, depending on the sphere diameter, as shown in Fig. 27.

Cell Proliferation

Cell proliferation was quantitatively measured by uptake of radio-labeled methyl [^3H] thymidine (Sigma, St. Louis MO). During the last 6 hours of cell incubation, 10 μCi of [^3H] thymidine was added to each sample well. Incubation was terminated by removal of the radioactive media. Cells were fixed to the matrices by soaking in methanol for 10 minutes. Samples were then rinsed twice with Hank's Balanced Salt Solution (HBSS). Uptake of [^3H] thymidine into cellular DNA was assessed by dissolution of the material in 2N perchloric acid. Uptake was measured using an EC&G-Wallac 1027 Beta scintillation counter.

The cell proliferation, as shown in Fig. 28, is expressed in terms of the amount of [^3H] thymidine uptake as a function of time. It can be seen that there is a consistent increase of cell population with time. The nanofibrous structure demonstrated the most proliferate cell growth whereas the tightly woven 3-D

braided structure showed the least proliferation. On the other hand, the cell growth, in fused microsphere structures is between that of the 3-D braid and the nanofibrous structures, showing a surprising drop after the 10th day.

Cell-Scaffold Architecture Interaction

Experimental results show that cell growth pattern is related to the relative dimensions between the components in the scaffold and the cells. Scanning electron microscopy pictures were taken from the cell-matrix systems, which were prepared in a series of Freon 113 dilutions (25%, 50%, 75%, and 100%). The SEM samples were sputter-coated with gold (Denton Desk-1 Sputter Coater). An Amray 3000 SEM using an accelerating voltage of 20 kV was employed to take the SEM photographs shown in Fig. 29. It can be seen that in responding to the large spheres, wherein the cells are more than $10\times$ smaller than the spheres (Fig. 29a), the cells tend to spread over the surface of the sphere before connecting to the adjacent spheres and eventually forming an interconnected cellular network. In the case

Fig. 27 Pore size distribution of sintered spheres.

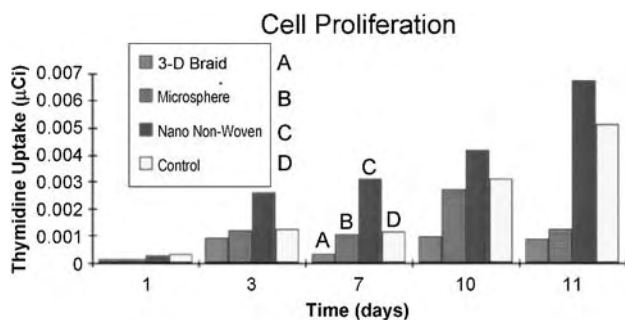

Fig. 28 Cell proliferation of fibrous scaffolding.

of 20 μm filaments in unidirectional bundles and 3-D braid (Fig. 29b), wherein the cells are about the same order of magnitude in dimension, the cell–matrix interactions appear to be similar. The cells tend to slide off the matrix at the moment of seeding. For those cells remain on the surface of the substrates they tend to grow around the filaments and bridge onto the adjacent filaments along the length of the fibers. The most intensive cell deposition was seen in the nanofibril nonwoven structure (Fig. 29c), wherein the cells are more than an order of magnitude larger than the individual fibrils. Extensive cell spreading was observed along the length of the fibrils and through the thickness. This suggests the feasibility of organizational cell growth.

This study showed that fiber-based scaffolds are capable of supporting cell attachment and proliferation. The use of fiber technology in tissue engineering holds several advantages over a number of nonfibrous 3-D structures. Mainly, the ability to impart high levels of structural organization to the matrix may allow for precise control of matrix structure. The 3-D braided and nonwoven matrices demonstrate a range of 3-D fiber architectures that can be designed and produced. The braided matrix consisted of highly organized PLAGA yarns woven into a 3-D structure. Although the nonwoven matrix was the result of randomly oriented microfibers, the structure was highly uniform.

Both the four-step, 3-D braiding technique and the electrospinning process are promising fabrication methods showing high levels of versatility. The use of hierarchical fiber architecture-based design enables the tailoring of a broad spectrum of substrates with a wide range of mechanical properties, and the creation of structures capable of supporting cell proliferation, as well as the microdiffusion of nutrients throughout the structure.

The ability to manufacture a variety of different matrices/scaffolds and the ability to maintain precise control over matrix fabrication are extremely important factors in the design of a tissue-engineered scaffold. Based on the results of the study reported in this article and in an increasing body of work,^[28,38] it seems that fiber-based scaffolds show promise as replacements for orthopaedic tissues, as well as for a broad range of biological tissues such as skin, arteries, muscles, and others.

SUMMARY AND CONCLUSIONS

This article provides an overview of the structural components of fabrics and a description of the various 2-D and 3-D fabrics, along with a gallery of the various fabric structures. The potential application of fabrics for scaffolds in the emerging field of tissue engineering is also reviewed in light of the development of nanofibers and nanofiber-based fabric structures.

Fibrous materials in fabric forms are an important structural backbone for surgical implants and tissue-engineering scaffolds. Analogous to natural tissues and organs, the fabric structures are organized into hierarchical fiber architecture, thus forming a scaffold for cell adhesion, migration, and proliferation.

Successful development of surgical implants and medical textiles requires a thorough knowledge of the structure and properties of fabrics. In addition to their use as surgical implants for the replacement or regeneration of body parts, fabrics are also important

Fig. 29 Cell-fiber architecture interaction: a, sphere; b, braid; c, nonwoven.

substrates for drug delivery and a wide range of medical textiles, including numerous hospital supplies ranging from nurses' uniforms to surgical gowns, drapes, and masks.

INTRODUCTION

The field of fiber optic biosensors (FOBSs) is an intensively active area of modern biophotonics technologies because these sensors are potential alternatives to conventional medical methods for diagnostics and monitoring of diseases. Fiber optic biosensors offer a minimally invasive, highly sensitive, and accurate means for measurement and control of various physical and biomedical quantities. Biosensor techniques and devices utilizing minimally invasive FOBSs technology are rapidly finding their way into the mainstream for early disease diagnostics, laser therapy, and in situ optical biosensing and bioimaging.

As a key component in FOBSs systems, biomedical optical fibers (OFs) are an attractive and extensively used medium for both effective laser radiation delivery and advanced biosensor design used in medical diagnostics and therapeutic devices. Optical fibers possess a number of unique properties, such as low attenuation losses, micrometer-scale core diameters, long interaction length, flexibility, immunity to external interference, electrically passive operation, delivery of nonionizing radiation, high sensitivity, and can be easily modified for multiparameter sensor measurements. These advanced features make the biomedical OFs an ideal medium for design and development of novel highly effective biosensing techniques and devices.

In this entry, we present the fundamental principles and features of the most significant and widely used fiber optic-based biosensors. This includes description of a basic FOBS system as well as key optical elements of this system, such as typically used biomedical lasers and incoherent light sources, various biosensing OFs including their advanced properties and critical parameters, and effective light modulator and detector FOBS systems. A major part of this entry is focused on current status as well as future trends in FOBSs applications. The vast variety of both conventional and recently developed FOBSs are summarized in three basic categories: passive (or intrinsic) FOBSs, active (or extrinsic, usually cellular/intracellular) FOBSs, and

direct FOBSs. Among these categories, we consider the ultimate advantages and specific limitations of some of the most effective and well-developed FOBS systems, such as fiber optic-based chemical, evanescent, combined, clinical, and nanobiosensors.

FUNDAMENTALS OF FOBSs

Principal FOBS Design

Biosensors are self-contained analytical devices that are capable of detecting and measuring biologically derived signals. A biosensor device is composed of a specific analyte (a biological sensing substance that needs to be measured), which is in direct spatial contact with a physical transducer that produces either discrete or continuous electrical signals proportional to the analyte concentration. Biosensors can be based on an extensive variety of transducer and detection approaches, such as electrochemical, thermometric, piezoelectric, magnetic, acoustic, optical, etc. Among these technologies, optical biosensors form a major group of biosensing techniques and devices that display specific advanced features in terms of sensitivity, minimal invasiveness, and immunity to all forms of external electrical interference. One of the most effective and extensively used optical biosensors is fiber optic-based biosensing system.^[1-6]

Fiber optic biosensors are analytical optical biosensor devices in which a fiber optic system is utilized as a key sensor component that provides both effective input/output laser radiation delivery and biosensing transduction. A principal design of a basic FOBS system is illustrated in Fig. 1. Using flexible fiber optic delivery links, the input laser emission is effectively and controllably transmitted to a remote biomedical analyte to be tested, and next, the output signal laser emission is returned to a detection system for extracting and analyzing essential biochemical information about the analyte's testing properties.

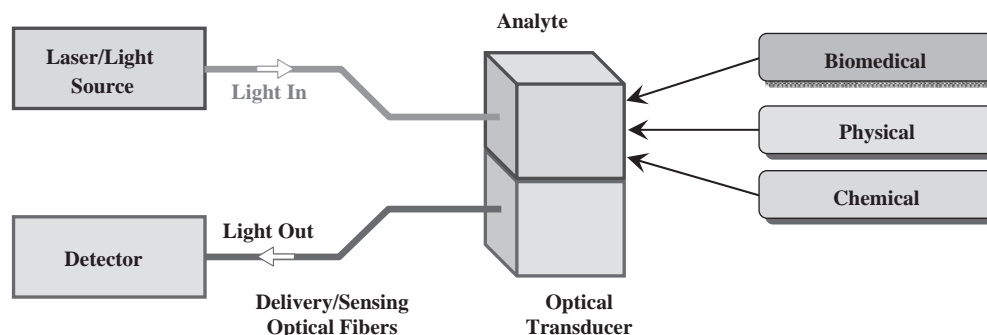

Fig. 1 A principal FOBS design.

Basic Components of a FOBS System

The principal FOBS design described (see Fig. 1) consists of the following basic components: a laser/light source, delivery/sensing OFs, an analyte, an optical transducer, and a detector. Fundamental features and critical parameters of these FOBS components are summarized below.

Laser/light source

A wide selection of both coherent (lasers) and incoherent (e.g., broadband lamps, light-emitting diodes) light sources is available for various FOBS applications. Depending on the specific requirements of a certain FOBS system, the laser sources should possess different features, for example, continuous-wave or pulsed (including ultrashort pulses) generation; a single narrow bandwidth wavelength or a tunable emission in a broadband spectral range; and emission in various spectral regions including the ultraviolet (UV), visible (VIS), and infrared (IR). For some FOBS applications, where a more portable and robust sensor design is required, incoherent light sources (e.g., light-emitting diodes) are preferable because of their significant advantages over other FOBS light sources, such as compactness, low power consumption, selective wavelength emission, simple operation, and relative inexpensiveness. To be able to use these laser/light sources in the FOBS setups they should satisfy specific requirements, the most important of which are intensity-stabilized emission (in some cases power fluctuation less than 0.5% is required), low noise, and compatibility with fiber optic components.

Delivery/sensing OFs

Optical fibers are a key component in FOBS systems because they demonstrate a number of unique features, such as low attenuation losses, effective delivery of nonionizing radiation, small core diameters, long

interaction length, flexibility, immunity to external interference, and enhanced sensitivity in sensor designs. Based on these advanced properties, the OFs play a crucial role in FOBS systems performing simultaneously several significant functions. 1) Flexible OFs provide effective delivery of both the input laser emission to a remote analyte and the output light signal to a detection system. 2) Optical fibers serve as biosensing transducers, which convert detection event into a measurable signal. This OF function can include either a passive mode (when the changes in the testing analyte's properties cause change of the sensing OF properties) or an active mode (when the OF tip serves as a biochemical probe including sensing reagents or molecules placed on the tip). 3) Optical fibers are used for the formation of laser emission with specific features, for example, special laser beam mode distribution (i.e., fundamental Gaussian beam profile using single-mode OFs), energy/power parameters, or spectral characteristics.

Depending on specific FOBS applications and design requirements, an enormous variety of both conventional and recently developed OFs are available. These OFs can be classified in various groups using different criteria. 1) Optical fiber material—silica glass, quartz, plastic, fluoride, chalcogenide, germanium-doped, silver-halide, etc. Silica glass and quartz OFs have low attenuation in the UV (spatially quartz OFs), VIS, and near-IR; however, these OFs have low numerical aperture and are fragile, which presents a safety concern. Plastic OFs have bigger aperture (for better coupling efficiency), and they are mechanically robust, flexible, and inexpensive, but have low UV transmission. The other OFs (fluoride, chalcogenide, germanium-doped, silver-halide) are specialized for mid-IR laser delivery and biosensing (e.g., for biochemical and temperature sensing). 2) Solid-core or hollow OFs—hollow OFs are basically utilized for either mid-IR or powerful UV, VIS, and near-IR laser delivery, but these OFs have poor bending attenuation losses. 3) Optical fiber mode distribution and core dimensions—small core diameter (3–10 μm) single-mode

or large core (50–1000 μm) multimode OFs. Single-mode OFs provide a smooth Gaussian beam profile for precise collimation and focusing, but the coupling efficiencies and absolute laser energy/power delivered is lower than those achieved with large core multimode OFs. 4) Optical fiber configuration—single-input/output OFs, OF bundles, or OF couplers. The single-fiber FOBS configuration ensures a relatively better signal-to-noise ratio than those of the OF couplers. However, the OF couplers combine various sensor functions (input laser coupling, spatial signal separation, and output coupling) in one single element.

Analyte

Target analyte or bioreceptor is the biologically sensitive component of FOBS systems (see Fig. 1) that needs to be measured. It is capable of producing a biochemical signal, which is converted by the transducer into an electrical response. The analyte may be a biological material (e.g., enzymes, protein, DNA, organelles, cellular structures, microbial cells, or bulk mammalian or plant tissue), a biologically derived material (created by biological engineering), or a biomimetic mimicking of bioreceptors.^[1–3] The bioreceptor should have direct contact with the transducing system so that the transmittance should be proportional to the reaction rate with a high range of linearity. Bioreceptors should also have a high sensitivity for the specific compound.

Optical transducer

Optical transducer is a FOBS component that converts detection event into either discrete or continuous measurable electrical signals proportional to the analyte concentration. Typically, OFs or other OF components used in FOBS systems serve as biosensing transducers. Depending on their principle of operation, these transducers can be summarized in three categories: 1) passive (or intrinsic) OF transducers—the changes in the testing analyte's properties affect the optical properties (e.g. intensity, spectral attenuation, and reflectance) of the sensing OFs, i.e., the light modulation is inside the sensing OF; 2) active (or extrinsic) OF transducers—usually, the OF tip serves as a biochemical probe that can involve sensing reagents or molecules placed on the tip and in this case, the light modulation is outside the sensing OF; and 3) direct OF transducers—the OFs are used as a plain transducer to deliver the input laser emission to a remote bulk tissue sample, to return the optical signal to the detection system, and to obtain direct information (e.g., fluorescence or absorption spectra, or reflectance) about the

tissue properties based on the changes in the tissue optical properties.

Detector

Fiber optic biosensor designs include various types of photodetectors. Typically, these FOBS components should satisfy a number of basic requirements, the most important of which are spectral response, sensitivity, noise, and response time. Photodiodes are usually preferable FOBS detectors because they need compact and simple circuits. In some cases, when more sensitive detectors are needed, photomultipliers with specific spectral response and sensitivity should be used.

Advantages and Limitations of FOBSs

Almost three decades have passed since the first fiber optic sensor, used to detect ammonia, appeared in 1976.^[7] Since then, these sensors have advanced both in their diversity and in their accuracy. Among the broad range of fiber optic sensor applications including industry, technology, and environment, the field of fiber optic-based biosensors has one of the best prospects in the future because the FOBSs demonstrate significant advantages that can be summarized as follows. 1) Fiber optic biosensors are non- and minimally invasive techniques and devices. There is no need to take away samples or alter the living system to make samples. 2) Fiber optic biosensors are completely immune to all forms of electrical and electromagnetic interferences, which make them safer than electrochemical biosensors. 3) They are self-contained and do not require external reference signals. 4) Because of low attenuation losses of the sensing OFs, the FOBS allow remote monitoring in hazardous environment and one could perform the sensor measurements from great distances only connected with small core diameter OFs. 5) Fiber optic biosensors system can be easily modified for multiparameter sensor measurement because they can respond simultaneously to more than one analyte. 6) Fiber optic biosensors can be miniaturized and are completely portable, which allows these sensors to be used for in vivo monitoring.

Besides these advantages, FOBSs exhibit specific limitations such as: 1) they usually have a limited sensor's life because of the biological character of their design, for example, biosensors with immobilized dyes have limited long-term stability; 2) they are composed of biological material, which causes problems in sterilization or may be inactivated by strong chemical compounds; 3) they have a limited dynamic range compared to electronic sensors; 4) they have limited sensitivity because the signal levels are proportional to

the small amount of immobilized biological material; 5) they are affected by daylight and light from other sources; and 6) they will work only if appropriate reagents can be developed.

Despite these difficulties, considerable efforts have been made recently to improve some FOBS features in terms of multianalyte capability, integration/miniaturation, implantable devices, and living cell/tissue monitoring.^[2,3,6]

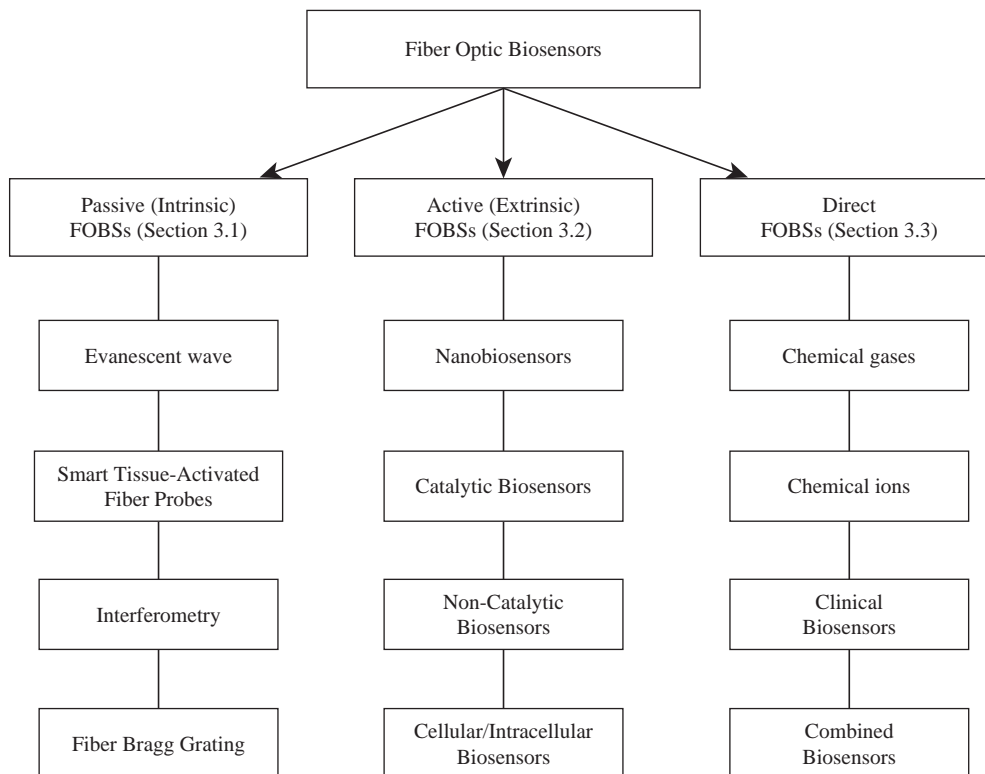

Classification of FOBSs

The enormous variety of both conventional and recently developed FOBSs can be classified using different criteria. For example, with regards to possible measuring principles and testing analyte's parameters, the FOBS classification may include the following categories: absorbance, luminescence, fluorescence, reflectance, scattering, ellipsometry, evanescence, etc. Using a different criterion related to the testing light characteristics, the classification may include the following FOBS types: intensity (or amplitude), frequency (or wavelength), polarization, phase-modulation, etc. However, a more complete classification (see Table 1) consists of three basic categories that are similar to the various types of optical transducers considered in the section "Optical Transducer."

1) Passive (or intrinsic) FOBSs, where the optical properties (e.g., intensity, spectral attenuation, wavelength, and reflectance) of the sensing OFs are modulated by the changes in the testing analyte's properties, that is, the light modulation occurs inside the sensing OF when an external perturbation causes changes in the boundary conditions for the OF. These passive FOBSs may include, for instance, evanescent wave, interferometric, smart FOBSs, etc. 2) Active (or extrinsic) FOBSs, where the OF tip usually serves as a biochemical probe that can include sensing reagents or molecules placed on the OF tip. In this case, the light modulation occurs outside the sensing OF when the testing analyte interacts with the sensing reagents. Basically, these types of FOBSs are related to cellular/intracellular biosensing. 3) Direct FOBSs, where the OFs are used for delivering both the input laser emission (with well-defined optical parameters) to a remote bulk tissue sample and the backward optical signal to the detection system. Next, by analyzing the acquired signals we can get direct information (e.g., fluorescence or absorption spectra, reflectance, or chemiluminescence) about the optical properties of the testing biomedical analytes. These three basic FOBS categories are illustrated in Table 1 and among these categories, some of the most effective and well-developed FOBS systems will be considered in the next section.

Table 1 A. basic FOBSs classification

FIBER OPTIC BIOSENSOR APPLICATIONS

Based on the FOBS fundamental principles and properties described in the section “Fundamentals of Fiber Optic Biosensors,” these fiber optic-based biosensors have been studied and developed for a broad range of biomedical applications. The most effective and well established of these FOBS applications can be summarized into three major categories, identical with the classification presented in the section “Classification of FOBS,” which are passive, active, and direct FOBSs.

Passive FOBSs

Fiber optic biosensor systems operate in a passive sensing mode when the optical properties of the laser/light emission inside the sensing OFs (e.g., light intensity, refractive index, reflectance, spectral attenuation, etc.) are modulated by changes of the analyte–fiber boundary conditions. This FOBS principle is commonly applied for large groups of FOBSs including evanescent wave, smart tissue-activated, and interferometric FOBSs.

Evanescent wave FOBSs

The fundamental waveguiding principle of OFs is based on the effect of total internal reflectance. However, under conditions of total internal reflectance, the transmission coefficients for the transverse electromagnetic field are nonzero, that is, although the light energy is totally reflected, an electromagnetic field penetrates from the interface to the lower refractive index medium. This field, called evanescent wave, decays exponentially with distance from the surface, typically over a distance, which is about a quarter of a wavelength. Decay of the evanescent wave field has been characterized by the penetration depth, d_p , the distance from the interface at which the intensity falls to $1/e$ of its value at the interface, which is defined by the dependence.^[7–9]

$$d_p = \frac{\lambda}{2\pi(n_1^2 \sin^2 \theta_i - n_2^2)^{1/2}}$$

where λ is the light wavelength, θ_i is the incidence angle of light entering the core/cladding boundary, and n_1 and n_2 are the core and cladding refractive indexes, respectively. The evanescent wave FOBSs are based on this evanescent wave phenomenon. Because of the limited penetration depth of the evanescent wave, detection is a surface-sensitive measurement, which has been exploited by a number of biosensor types, such as surface plasmon resonance sensors, interferometers, resonant mirrors, etc.

An effective technique for enhancing the evanescent wave effect is to modify a conventional cylindrical OF by introducing a double-tapered section along the fiber length (see Fig. 2). It will result in decreasing the incident angle of the internally propagated laser beam as well as in increasing the number of reflections inside the fiber. This will create a much larger area of evanescent waves into a medium in which the OF is immersed or the tissue it touches. It has been found that the sensitivity is almost linearly dependent on the reciprocal value of the fiber diameter (D) at the pressed zone. This phenomenon has been used by a few research groups to measure the concentrations of various components in biological media. For example, Katzir’s group, which is developing FOBS applications based on silver-halide OF in the IR range, has measured various blood components (e.g., total protein and cholesterol).^[8] Lucas’s group has used its chalcogenide-based OFs to measure cell metabolism information by attaching their evanescent wave FOBS to tissue.^[9] DNA or protein molecules were immobilized inside the air holes of a two-dimensional photonic band gap OF and specific capture of DNA or protein molecules was obtained. Evanescent wave sensing of the specific binding events by fluorescence detection was analyzed.

Smart tissue-activated FOBSs

A large group of passive FOBSs is based on modulation of reflectance properties of the sensing OFs used. Recently, a simple approach for an on–off switching modulation of reflectance/transmittance properties of so-called smart tissue-activated OF probes has been demonstrated (see Fig. 3A).^[11,12] It is a single-fiber

Fig. 2 A double-tapered sensing fiber for evanescent wave spectroscopy.

Fig. 3 An FOBS arrangement of (A) using a spatially shaped smart tissue-activated OF tip that provides either a total internal reflectance (B) or frustrated total internal reflectance (C). *Abbreviations:* BS, cube beam-splitter; PM, power meter; O, 10× microscope objective.

delivery/sensing technique based on the principle of frustrated total internal reflectance at the fiber–tissue boundary caused by the refractive index change of the surrounding medium. The key element of the system is the fiber tip shown in Figs. 3B and 3C. To get the on–off switching mode, the OF tip has a specially shaped angled (usually 45°) prism-type profile. Because of the effect of frustrated total internal reflectance, the angled tip acts as a smart, tissue-activated fiber probe. It provides a safe way for laser delivery, which includes only two states of tissue illumination. 1) The first is the off-state or no-tissue illumination mode. In this case (see Fig. 3B), the fiber tip is out of the tissue area, i.e., the surrounding medium is the air that leads to total internal reflection of the forward laser beam at the fiber–tip–air boundary. As a result, the laser emission is backreflected at the angled tip and the tissue area is not illuminated. 2) The second is the on-state or maximum tissue illumination mode. Here (see Fig. 3C), the angled OF tip is placed on the absorbing tissue area, which has a refractive index that is significantly larger than that of the air and close to the refractive index of the OF core. Then, the critical angle for total internal reflection increases and becomes greater than the shaped angle of the OF tip. Thus, the OF tip becomes transparent (or tissue-activated) for laser emission because of the frustrated total internal reflectance. The forward laser emission passes through the OF tip and the energy is coupled into the absorber. In this way, the smart fiber optic probe can recognize the absorbing tissue area and the on–off switching mode of the laser power delivery into the precise tissue area is achieved. The smart OF delivery/sensing system provides a high

spatial resolution in the micrometer and sub-micrometer range ($<2\mu\text{m}$) when the OF tip is moved toward the absorbing tissue area. The results obtained confirm the technique’s potential for on-the-spot laser delivery and sensing (when the backreflectance signal is analyzed), which can be applied for precise tissue diagnostics and laser treatment.

Recently, an attractive type of passive FOBS system has been demonstrated based on fiber optic Fabry–Perot interferometer.^[13] This interferometer is assembled on a single-mode fiber tip by multilayered coatings using an electrostatic self-assembly technique. This biosensor has applications for a precise breath gas analysis. Another FOBS based on modulation optical characteristics of the delivery/sensing OF is fiber Bragg grating FOBS.^[4] The operating principle of these sensors involves implantation of fiber gratings with specific properties into the sensing OF. These biosensors are typically used for precise measurement of temperature and strain.^[14,15]

Active FOBSs

When the biochemical sensing reactions employed for analyte testing possess no intrinsic optical properties, biosensors use an indicator/reactant for indirectly generated optical changes. In this case of active biosensing, the specific response of various indicators is monitored. These indicators might be either chemically (dyes) or biologically (enzymes, antibodies, and proteins) sensitive interfaces. In general, the indicators are

immobilized at the sensing OF tip and they interact with the light guided by OF nanobiosensor probes.

Indicator FOBSs

Indicator-based FOBSs depend on the recognition properties of the most biological components. These components are responsible for the generation of the sensing signal monitored by the FOBS detecting elements. The FOBS biological components can be divided into two categories: catalytic and noncatalytic.^[1,2,5,6]

The catalytic biosensors include enzymes, microorganisms, subcellular organelles, and tissue. These are also known as metabolism biosensors and can be used for continuous-monitoring metabolites by achieving a steady-state concentration of a transducer-detectable species. Enzymes are still indispensable and the most commonly employed biological components of FOBSs because of some their essential advantages, such as high sensitivity and selectivity, fast response time, and potential for multiparameter sensing. However, in some cases the use of enzymes is not feasible because they might be unstable. Then, the use of microorganisms, cells, and subcellular organelles are referable as they usually contain natural and more stable enzymes. The most commonly applied enzymes in FOBS systems are the oxidoreductases, which catalyze the oxidation of compounds using oxygen; the esterases, decarboxylases, and deaminases, which produce acids, CO₂, and NH₃, respectively; and the hydrolases, which catalyze the hydrolysis of compounds. The enzyme-based FOBS systems operate using various optical measurement methods, such as absorbance and reflectance, fluorescence, and chemiluminescence.

The noncatalytic or affinity FOBSs are based on specific binding between the target molecules and the bioreceptors (for instance, antibodies, antigens, nucleic acids, or hormone receptors), which causes physicochemical changes that will be measured by the transducer. These types of biosensors are applicable to single-use disposable devices for measurement of hormones, drugs, toxins, cancer markers, and viruses.

Fiber optic nanobiosensors

Nanotechnology is an emerging growth field in modern science and technology. Over the past several years, rapid progress in nanotechnology has led to the development of novel optical nanobiosensors, which are sensors with dimensions on nanometer scale. This has opened up new horizons for single-cell and intracellular sensing and measurements.^[16–19] After the first optical nanosensor application for intracellular monitoring in 1992, there has been a great impetus to obtain

quantitative chemical information at the cellular and intracellular level in the nanometer scale range.^[16] In this range, optical sensing and imaging techniques have a major drawback related to the fundamental “Rayleigh resolution limit” that is theoretically half the wavelength of the operating radiation. An effective way to avoid the resolution limit is a novel fiber optic-based nanobiosensor approach. It includes the use of a fiber nanometer-sized probe with a specially sharpened tapered tip. The tip is covered with a metal coating except at its very end where a small light-transmitting aperture, having diameter from 20 to 1000 nm, is formed. Such nanobiosensors have potential for direct probing and chemical analysis within individual cells and within the subcellular organelles. Laser emission having specific characteristics can be injected into the cell membrane, mitochondria, and other absorber side inside the cell. Fiber optic nanobiosensors have recently been developed for intracellular measurement of pH, calcium, oxygen, and absorption of glucose molecules by living cells. Because of some unique properties of the nanobiosensor fiber probes, including minimally invasive monitoring, micro- and nanoscale dimensions, effective laser delivery over relatively long distances, flexibility, immunity to external interference, and potential for multiparameter sensing, the fiber optic-based nanobiosensors demonstrate high sensitivity, fast response time, reproducibility, and long-term stability.

Direct FOBSs

Fiber optic biosensor systems operate in a direct sensing mode when the analyte–transducer biochemical reactions lead to products and intermediates that possess specific optical properties (e.g., absorbance, reflectance, fluorescence, luminescence, etc.), which can be directly (without any indicators unlike the active FOBS, see the section “Active Fiber Optic Biosensors”) monitored by the biosensor, that is, these FOBS measure directly a native optical quality. Among the wide variety of available direct FOBSs techniques, two major groups of well-developed and commercialized FOBSs are considered below: direct chemical and combined FOBSs.

Chemical FOBSs

The principles of chemical FOBS systems are based on a direct monitoring of various optical parameters and characteristics of the analyte to be tested, such as absorbance, reflectance, fluorescence, refractive index change, or light scattering, and aimed at measurement of different chemical components, such as oxygen, pH, carbon dioxide, ammonia, blood gasses, glucose,

etc.^[1-6]. Both the commercially available and the recently developed chemical FOBS techniques and devices can be classified into several major categories as follows:

1. Gas FOBSs, which include basic monitoring and measuring of oxygen and other blood gases. Oxygen biosensors or oximetry is a large group of FOBS techniques utilized for measurement of the degree of oxygen saturation, which refers to the amount of oxygen carried by the hemoglobin (the oxygen-carrying pigment) in relation to its maximum capacity. This parameter is measured optically by exploiting the different absorption spectra of deoxyhemoglobin (Hb) and oxyhemoglobin (HbO₂) in the VIS/near-IR region. The measurement is performed at two specific wavelengths: one, in the VIS (e.g., around 660 nm) where there is a large difference in light absorbance between Hb and HbO₂, and the other, in the near-IR (e.g., >805 nm), where there is no significant difference between the Hb and HbO₂ absorbance. A disadvantage of this method is its limited potential for the measurement of gas mixtures with oxygen concentrations larger than 20%, as routinely used in anesthesia. An improved non-invasive biosensor technique for oxygen monitoring is pulse oximetry. It is based on continuous monitoring of arterial oxygen saturation. This technique is a rapidly growing practice in clinical medicine because of its capability to provide continuous, safe, and effective monitoring of blood oxygenation at the patient's bedside without the need of a preliminary calibration. With regard to the blood gases, FOBSs, the research and development efforts are focused on effective disposable and, in particular, intravascular FOBSs that can provide continuous information on different gas concentrations, including oxygen and carbon dioxide partial pressures, and pH.
2. Ion FOBSs, which involve all types of inorganic ions, such as proton (pH), cations, and anions. Biosensors for pH monitoring are among the earliest and the best-established FOBS systems. The interest in these biosensors is due to the importance of precise pH measurement, which is directly related to accuracy in the diagnosis of properly functioning organs and systems within the body. Currently, fluorescence and absorption spectroscopy are the most widely used techniques for pH measurements in biomedical applications. In comparison to the fluorescence approach, the absorption biosensors are simple and easy to use, but not as sensitive. Absorption FOBS systems are also difficult to miniaturize. In contrast, the fluorescence method is more sensitive and can be used

for small-size sensors and/or low-concentration measurements. Further developments of the pH biosensors for practical use are focused on the design of novel OF probes with improved parameters (e.g., providing an accuracy of >0.001 pH units) and potential for pH imaging inside living cells using fluorescence nanobiosensors.

3. Clinical FOBSs, which, in addition to the gas and ion FOBS systems described, include other important types of biosensors, such as glucose, pharmaceutical, DNA, and cholesterol FOBSs. Development of non- or minimally invasive methods for blood glucose sensing in human subjects is a problem of major importance for clinical laboratories. Among a large number of various approaches applied for noninvasive glucose detection, optical sensing techniques, including FOBS systems based on absorption, fluorescent, and Raman spectroscopy, and polarimetry, have predominantly been investigated because of their advantages, such as no dependence on chemical reactions or enzymatic lifetimes and no fluorescent molecule relating specifically to glucose. Recently, near-IR and mid-IR spectroscopy has been also studied as an alternative noninvasive technique with a number of potential advantages: no required reagents, multicomponent chemical sensing from a single spectrum, and existence of spectral windows where hemoglobin, melanin, and water absorption intensities are low. However, more precise determination of specificity and calibration is needed, and yet no commercialized noninvasive glucose product is available.

F

Combined FOBSs

The use of a single-sensor method provides basically only relative measurements of the analyte's properties. In many cases, for either absolute measurements or comparative analyte testing, combined sensor methods should be utilized. Recent research efforts have been focused, for instance, in combining various FOBS techniques with high-resolution bioimaging systems, such as near-field and confocal microscopy, and optical coherence tomography.

A combined FOBS technique for direct sensing and monitoring of single-cell and intracellular components is shown in Fig. 4A. This design combines simultaneously a dual-nanobiosensor-probe technique and a high-resolution near-field microscopy that provides direct spectroscopic measurements and monitoring of cellular/intracellular components. It is a dual-probe arrangement that includes two identical nanobiosensor channels. One channel is used for precise delivery of the input light emission from either a coherent laser

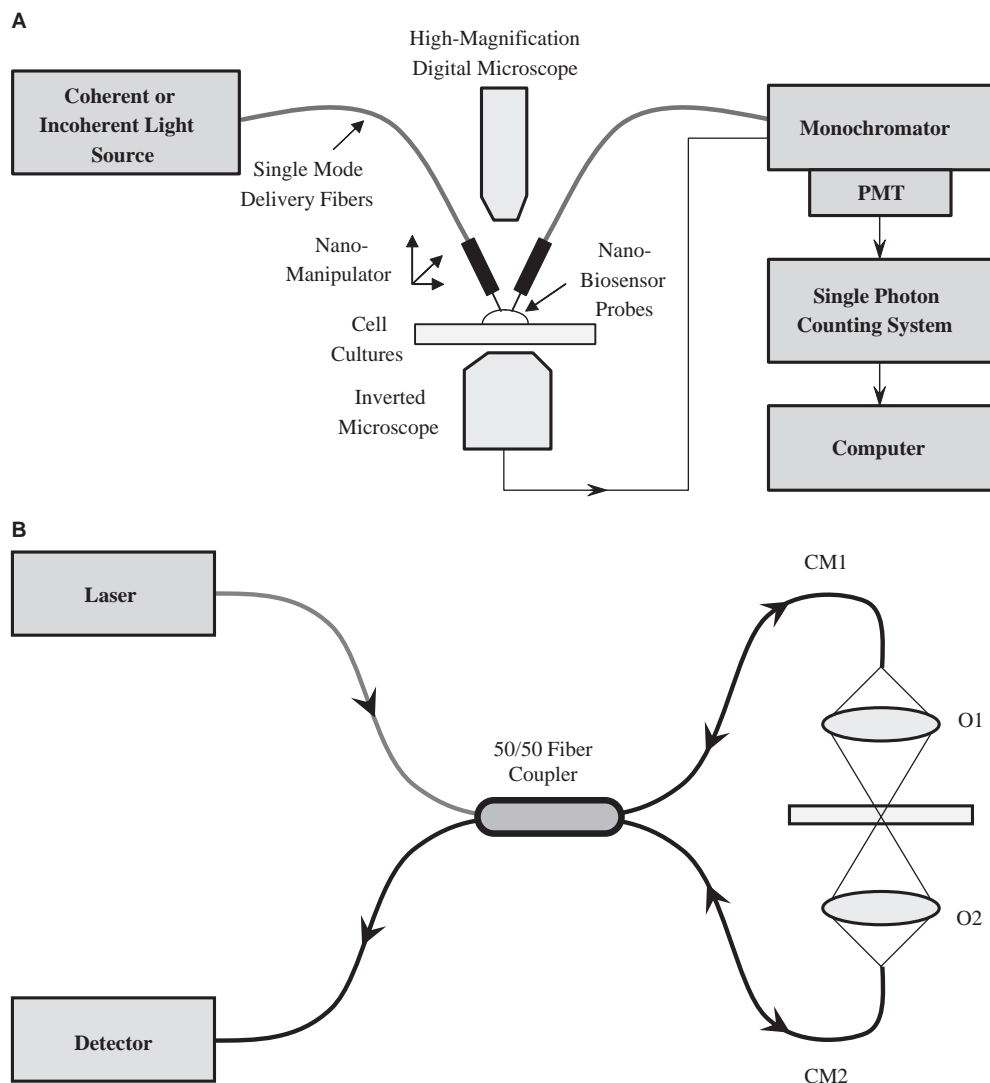

Fig. 4 Principal designs of a combined dual-nanobiosensor-probe setup (A) and a combined dual-confocal FOBSs (B).

source or a broadband incoherent source covering the UV, VIS, and near-IR spectral range. The second channel is used for detecting the output signals from the sensing of various cellular chemical components. In both the channels, small core diameter (3–10 μm) single-mode (for specific laser wavelengths) OFs equipped with tapered nanoscale tips are used as nanobiosensor probes. In addition, the nanobiosensor design is compatible with an ultrasensitive detection technique based on near-field microscopy. In this case, the input OF tapered nanobiosensor probe is used to inject light into specific parts of a living cell and the signal spectra from a near-field spatial zone are detected using a high-numerical-aperture ($\text{NA} > 1$) microscope. The ultimate advantage of the near-field technique equipped with nanosensor probes is the potential for breaking the subwavelength diffraction limit for high-resolution microscopic and broadband

spectroscopic analysis of single-cell components. Moreover, the combined FOBS technique (Fig. 4A) is compatible with a number of basic spectroscopic methods, such as absorption, fluorescence, and Raman spectroscopy.

A noninvasive combined dual-confocal FOBS technique for multiparameter sample sensing is illustrated in Fig. 4B.^[20,21] This is a dual-confocal sensor system that includes two identical confocal microscopes (CM1 and CM2) used as independent confocal sensor channels. The microscopes are based on a fiber optic-type apertureless confocal arrangement that excludes either the input or the output aperture, unlike the conventional pinhole-type confocal microscope. The combined dual-confocal FOBS design provides direct measurement in absolute units of refractive index and thickness of optically transparent and non-transparent media. Because of the typically high spatial

sensitivity of the fiber optic-based confocal approach, the dual-confocal sensor ensures high accuracy in spatially locating the image confocal points and objects ($<1\ \mu\text{m}$), and therefore simultaneously measuring the refractive index and thickness in absolute units. Such a system can be potentially used for precise measurement of optical properties of the various tissue layers and determining small changes in these properties between cancer and noncancer tissue areas.

CONCLUSIONS

Fiber optic biosensors have been under development for 30 yr. Nonetheless, the technology continues to evolve with new breakthroughs in optics, biochemistry, bioengineering, and nanotechnologies. Recent study and development efforts have been focused on significant improvement of some FOBS critical features including multianalyte detection potential, integration/miniaturation, and living cell/tissue monitoring.

INTRODUCTION

Fibrin clots are self-assembling biopolymer networks with important properties that can be exploited in the design of novel biomaterials. This article will summarize key aspects of the biochemical, biomechanical, and biological properties of fibrin clots formed by human plasma-derived fibrinogen, thrombin, and associated proteins. Also, recent work exploring new applications for fibrin-based biomaterials will be highlighted focusing on the delivery of therapeutic agents and cells for wound-healing and tissue-regeneration applications.

OVERVIEW

The process of fibrin clot formation is diagrammed in Fig. 1. Fibrinogen is a plasma protein composed of two sets of three polypeptide chains ($A\alpha$, $B\beta$, γ) that are linked by disulfide bridges.^[1,2] The $A\alpha$, $B\beta$, and γ chains have 610, 461, and 411 amino acid residues, respectively. The rod-shaped fibrinogen protein is approximately 45 nm long with two compact outer D domains each joined by flexible-coiled coil segments to the inner E domain.^[3] The conversion of fibrinogen to fibrin is catalyzed by the serine protease thrombin, generated by activation of prothrombin during the blood coagulation cascade. Thrombin binds to the central E domain of fibrinogen and catalyzes the removal of two sets of small N-terminal fibrinopeptides, FpA and FpB, from the $A\alpha$, and $B\beta$, chains, respectively. The resulting fibrin monomers then self-associate in a half-staggered manner (22.5 nm repeat spacing) with the end D domain of one molecule interacting with the central E domain of another to form linear

protofibrils. These protofibrils further self-assemble into branched fiber bundles, resulting in the formation of a characteristic biopolymer gel material with an open three-dimensional porous network structure.

The structure of a fibrin clot as seen by scanning electron microscopy (SEM) is shown in Fig. 2A. The fibrin network structure and porosity are clearly evident. A higher magnification view of an individual fiber bundle as seen by transmission electron microscopy (TEM) is shown in Fig. 2B. The 22.5-nm repeat pattern indicating the well-ordered assembly of the fibrin monomers within the fiber can be seen (arrow). The fibrin clot shown in Fig. 2 was prepared from a commercially available fibrin sealant product. However, the structural characteristics of the fiber network are similar to clots formed in vitro from purified fibrinogen samples or under more physiological conditions that mimic the formation of plasma clots in vivo. This represents a key aspect in the versatility of fibrin-based biomaterials. The overall structure of the biopolymer gel is determined primarily by the thrombin-mediated conversion of fibrinogen to fibrin and the subsequent self-assembly of the fiber network. The presence of other naturally occurring accessory proteins, e.g., factor XIII, fibronectin, and plasminogen, can then be used to add important biomechanical and biological properties to the final fibrin-based biomaterial with relatively small effects on the overall physical structure.

HISTORY OF FIBRIN-BASED BIOMATERIALS

The development of fibrin-based biomaterials has been closely linked with the use of fibrin sealant preparations. Fibrin sealants are products currently approved

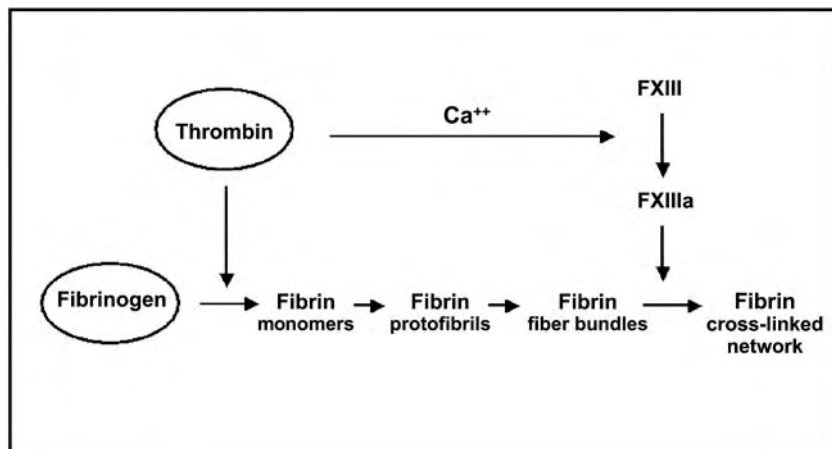

Fig. 1 Diagram of fibrin clot assembly.

for use in surgical procedures to achieve rapid hemostasis and to seal tissue surfaces together.^[2] They consist of two human plasma-derived components: 1) a highly concentrated fibrinogen complex composed

primarily of fibrinogen and fibronectin along with catalytic amounts of factor XIII and plasminogen and 2) thrombin and calcium ions. The rapid mixing of the two components produces a fibrin-based biopolymer that acts as a strong, bioresorbable adhesive coating especially useful in surgery on soft tissues and organs. Surgical procedures where fibrin sealant products are used include cardiovascular, thoracic, neurological, and reconstructive techniques. Fibrin-based preparations for the experimental development and testing of new biomaterials can be readily prepared from the fibrinogen complex and thrombin components of fibrin sealants.

The natural blood coagulation process provides the starting paradigm for how bleeding can be stopped, tissue parts sealed together, and normal wound healing achieved through the use of fibrin-based biomaterials. It took until the beginning of the 19th century to develop the first scientific concepts of the blood coagulation process. In 1905, P. Morawitz presented his model of blood coagulation, which at that time was partly based on hypothesis. He correctly perceived that by the action of calcium ions and tissue fluid, the prothrombin present in blood is converted into active thrombin, which in turn converts fibrinogen into fibrin.^[4] In 1909, S. Bergel postulated, based on animal experiments, that the physiological function of fibrin is not only to stop bleeding and seal wound edges together, but also to stimulate subsequent wound healing. He recommended the use in surgery of a fibrin-powder preparation prepared from equine or bovine blood.^[5] As early as 1915 and 1916, E. G. Grey^[6] and S. C. Harvey^[6] used fibrin tampons and fibrin patches to control bleeding from parenchymatous organs. In 1943, R. T. Tidrick and E. P. Warner,^[6] as well as E. P. Cronkite,^[6] reported on the use of either citrated human plasma or human fibrinogen clotted with bovine thrombin for the fixation of skin grafts in humans. Although these early attempts already suggested the basic advantages of using fibrin for wound

Fig. 2 Electron micrographs demonstrating the key structural features of fibrin clots. A) The overall clot structure including the branching of individual fibers to form an open three-dimensional porous network structure as seen by SEM. B) The 22.5-nm repeat spacing (arrow) of individual fibrin protein monomers making up the assembled fibers as seen by TEM. The clot was prepared with the fibrinogen complex and thrombin components of the Fibrin Sealant product Tisseel^R at final concentrations of 50 mg total protein/ml and 2 U/ml, respectively.

closure, such as excellent tissue tolerance, improved wound healing, and complete in-vivo adsorption, there was a relatively high rate of failure due to poor adhesive strength and durability of the fibrin preparations. The reason was probably the lack of sufficiently concentrated fibrin solutions together with the lack of insight into the underlying biochemistry of the new method. Thus, none of the authors reported the use of calcium chloride or of a fibrinolysis inhibitor in the fibrin-sealant mixture, which are now known to be essential for quality and efficacy in sealing applications.

It was due to these unsatisfactory results that the new technique was not pursued further for some thirty years. Instead, other approaches to achieve hemostasis by use of fibrin in combination with thrombin were investigated. In 1944, E. A. Bering, Jr.^[7] reported on the preparation of fibrin foams to be used as hemostats in combination with thrombin. In 1968, M. Gerendás^[8] described in a review article the preparation and clinical application of bovine-derived fibrin foam, fibrin powder, and fibrin films, as well as a novel slowly resorbable fibrin implant material. The latter was obtained from a mixture of fibrin powder and plasticizer (polyvalent alcohol) under high pressure and temperature in specific molds. A variety of implants were produced and excellent clinical results were reported, including in hip arthroplasty to cover the femoral head and in the regeneration of cartilage.

In parallel with these developments, ongoing basic research led to a better understanding of the reactions of coagulation and fibrinolysis. In 1948, the fibrin stabilizing factor (fXIII) was discovered by K. Laki and L. Lorand, followed by numerous studies on the biochemical and biological properties of this enzyme, including the importance of the fXIII-mediated cross-linking of fibrin to the mechanical strength and resistance to fibrinolytic degradation of the fibrin clot.^[9] A new era in the use of fibrin sealants began in 1972, when H. Matras and coworkers^[10] successfully used a highly concentrated human plasma-derived fibrinogen solution in combination with fXIII, thrombin, and calcium chloride to seal severed nerves in animal experiments. In 1973, H. P. Spängler^[11] used such a preparation for the first time clinically in an emergency situation in heart surgery to successfully stop severe bleeding that could not be controlled by other conventional means.

The efficacy of this biomaterial in heart surgery as well as other surgical applications opened the way for the development of the first commercial fibrin sealant, Fibrinkleber Human Immuno^R, which entered the market in 1978, followed by an improved version in 1980 available under the trade names Tisseel^R and Tissucol^R in different countries. Further developments of this product have included the continued

enhancement of viral safety profiles and the improvement of handling properties without compromising the required biochemical and physiological properties. Due to its pioneering position, this product may well be regarded as the conceptual prototype of fibrin sealant products now approved or under development.^[12] Fibrin sealant preparations have a long history and continue as an important platform in the development of innovative biomaterials.

FIBRIN CLOT STRUCTURE AND BIOMECHANICAL PROPERTIES

Many factors such as the ratio of thrombin to fibrinogen, the ionic strength and divalent cation concentration of the medium, or the presence of certain plasma proteins, e.g., serum albumin, regulate the rate of fibrin polymerization, and thus, the resulting clot structure.^[1,13-15] The rate of release of the fibrinopeptides FpA and FpB, as well as other factors affecting the lateral association of the fibers, regulate fiber thickness, degree of branching, and clot porosity.^[16] These possibilities to regulate fibrin formation and assembly can be employed to control the physical structure of the final fibrin-based biomaterial and have been shown to be important for wound healing applications.^[17-19]

Examples of different fibrin clot structures that can be prepared by varying some of these parameters are shown in Figs. 3 and 4. In Fig. 3, SEM micrographs are shown for fibrin clots formed using two different thrombin concentrations, A) 25 U/ml or B) 0.25 U/ml, to clot a fibrinogen complex preparation (5 mg total protein/ml). The fiber structure formed was much finer at the higher thrombin concentration with less porosity and many more branch points compared to the thicker, more laterally associated fibers at the lower thrombin concentration. In Fig. 4, fibrin clots were formed at three different salt concentrations, A) 0.07 M, B) 0.13 M, or C) 0.20 M, using the same fibrinogen complex protein (22.5 mg/ml) and thrombin (75 U/ml) concentrations. As the salt concentration was increased, thinner fibers with more branch points were formed leading to a fibrin network of lower porosity.

Fibrin clots are biopolymers with viscoelastic physical characteristics. The structure and composition of the final clot directly affect the biomechanical properties as measured by elastic modulus, breaking strength, and adhesiveness. Measurements of the mechanical properties are useful in predicting the performance of a fibrin-based preparation under shear force conditions in vivo.^[2] The elastic modulus increases as a power log of the fibrinogen concentration, as shown with fibrin clots formed from purified fibrinogen.^[15] An increase of elastic modulus, tensile

Fig. 3 The effect of varying the thrombin potency on fibrin clot structure. Thrombin at A) 25 U/ml or B) 0.25 U/ml was used to clot a fibrinogen complex preparation at 5 mg total protein/ml (final concentrations). Note the relatively thinner individual fibers and decreased overall porosity for the fibrin clot formed using higher versus lower thrombin potency.

strength, and adhesiveness, as a function of fibrinogen concentration, has also been seen for clots formed from fibrin sealant preparations.^[2,20]

Factor XIII-mediated cross-linking of the fibrin monomers that make up the fiber bundles also contributes considerably to the strength characteristics of the fibrin network. In the presence of thrombin and calcium ions, fXIII is activated to fXIIIa and catalyses the formation of covalent bonds between fibrin chains, resulting in the formation of both γ - γ and α - α chain polymers.^[1] This stabilizes the fibrin network and creates an insoluble fibrin clot, i.e., one that is insoluble in solutions of chaotropic agents such as monochloroacetic acid or urea. The elastic modulus increases as a function of the fXIII content, as shown with fibrin formed from purified fibrinogen. fXIII can increase the elastic modulus fivefold under physiological conditions.^[21] This has also been seen for clots formed from fibrin sealant preparations^[2,20] where α - α polymer formation has been shown to contribute greatly to the tensile strength.^[22] The ionic strength of the fibrin sealant formulation can also affect the degree of cross-linking.^[6] The change in elastic modulus seen

Fig. 4 The effect of varying the salt concentration of the medium on fibrin clot structure. The NaCl concentration during clot formation was A) 0.07 M, B) 0.13 M, or C) 0.20 M. The clots were prepared with the fibrinogen complex and thrombin components at final concentrations of 22.5 mg total protein/ml and 75 U/ml, respectively. Note the relatively thinner individual fibers and decreased overall porosity in the fibrin clot as the salt concentration of the medium increases.

with increasing levels of fXIII does not seem to correlate with significant changes in the clot structure. Similar fiber thickness was seen for clots formed with and without various levels of fXIII.^[20] Fiber mass-to-length ratios were shown to be similar with and without fXIII, but an increased density of fibers in the network was seen with the addition of fXIII.^[23]

FIBRIN BIOMATRIX FOR TISSUE REGENERATION

An appropriate biomatrix is a key structural element for tissue regeneration since a provisional extracellular matrix is required to support the highly organized

Fig. 5 Human dermal fibroblast cell adhered to and growing on a fibrin clot surface as seen by SEM. The clot was prepared with fibrinogen complex and thrombin components at final concentrations of 5 mg total protein/ml and 5 U/ml, respectively. The human dermal fibroblast cells were seeded onto the clot surface and then grown under standard cell culture conditions for 24 hours at 37°C.

remodeling and repair processes involved in forming new tissue. Fibrin-based biomaterials provide a biocompatible physical structure and many of the important biological activities needed for successful tissue regeneration. Fibrin is the natural provisional matrix for wound healing and tissue repair. The fibrin clot provides a structural scaffold for the adhesion, proliferation, and migration of cells important in wound healing (see, for example, Fig. 5). Also, fibrin and the associated proteins making up a physiological clot have intrinsic biological activities that support, and in some cases control, the cellular differentiation important in wound healing. Finally, fibrin clots are readily remodeled and resorbed through normal fibrinolytic processes as cells deposit the tissue-specific extracellular matrix components during the regeneration of functional tissues.

Biological Activities of Fibrin(ogen) and Associated Proteins

The first function of fibrin(ogen) in the overall process of blood coagulation and wound healing is to rapidly control bleeding at the site of injury. Once hemostasis is achieved, the fibrin clot serves as the foundation of a complex provisional matrix both to initiate and support subsequent tissue repair.^[24,25] The fibrin(ogen) protein has several specific domains that actively control cell behavior during wound healing. The fibrinopeptides FpA and FpB released by thrombin during clot formation, and fibrin degradation products resulting later during fibrinolysis, are chemoattractants and activators of leukocytic cells. The clot provides a physical scaffold for the migration of neutrophils and monocytes into the wound as part of the initial inflammatory response to protect the injured tissue.

Fibrin has peptide domains that facilitate cell adhesion to the clot, serving as binding sites for integrin receptors on cells involved in tissue repair. Similar binding sites on proteins associated with the clot (fibronectin), or deposited during extracellular matrix remodeling (collagens), play primary roles in cell migration. The release of Fibrinopeptide B from the β -chain of fibrinogen exposes a new N-terminal peptide domain on fibrin that serves as a unique binding site for the vascular endothelial cell surface receptor VE-cadherin.^[26] Fibrin-specific signaling through this receptor causes the vascular endothelial cells in injured blood vessels to migrate, proliferate, differentiate, and form new blood capillaries. The fibrin clot then serves as the physical scaffold for this angiogenesis at the wound site. The resulting neovascularization is critical for successful tissue regeneration.

The biological activities inherent in the final clot are not limited to fibrin, but include a complex mixture of other proteins that bind to the fibrin matrix.^[1] This is true both for physiological fibrin clots and for those made from fibrin sealant preparations. Thrombin remains bound reversibly to fibrin after the clot forms and is protected from inhibition by plasma factors such as antithrombin III. Thus, the fibrin clot is a storage matrix for thrombin that could affect wound healing through interactions with protease-activated receptors (PAR) present on epithelial, fibroblast, endothelial, leukocytes, and mast cells.^[27] Factor XIIIa, which stabilizes the clot by covalently cross-linking fibrin monomers, also cross-links other plasma proteins to fibrin. The most important of these are the plasma-derived proteins fibronectin, which is also normally present in fibrin sealant preparations, and α_2 -antiplasmin and plasmin activator inhibitor 2 (PAI-2), which help to control subsequent fibrinolysis of the clot.^[1] The cross-linked plasma fibronectin then provides specific receptor binding sites for cells involved in wound healing (keratinocytes, fibroblasts, vascular endothelial cells) to adhere to and migrate through the fibrin matrix, thus playing a role similar to fibronectins present in the extracellular matrix of tissues.^[28]

The biological activities inherent in fibrin-based biomaterials can be enhanced by incorporating novel therapeutic agents to control cell proliferation, migration, or differentiation during tissue regeneration. Certain growth factors, e.g., basic fibroblast growth factor (bFGF), the insulin-like growth factor-1/insulin-like growth factor binding protein-3 complex (IGF-1/IGFBP-3), and the vascular endothelial growth factor isoform VEGF₁₆₅, specifically bind to fibrin(ogen).^[1,29] These bioactive proteins can be delivered using fibrin-based biomaterials without further modifications.^[30,31] Other therapeutic proteins or drug molecules that do not specifically bind can be added to the biomaterial

preparations and delivered by freely diffusing from the biopolymer matrix.^[32] However, this latter approach does not allow for careful control over the timing or extent of delivery. Methods are being developed to modify either the fibrin-based matrix or the bioactive substance such that therapeutic proteins, drugs, or DNA can be delivered in a controlled manner.^[33,34]

Applications of Fibrin-Based Materials in Tissue Regeneration

Applications for fibrin-based biomaterials in tissue regeneration include the delivery of tissue-specific cells in order to stimulate the wound healing process. The regeneration of damaged skin based on the combined use of keratinocytes and a fibrin matrix was first described in 1988.^[35] Keratinocytes isolated from skin biopsies were cultivated under physiological conditions and then applied as keratinocyte/fibrin matrix suspension, resulting in the neof ormation of epidermal tissue.^[36] Pellegrini et al.^[37] have shown that the relative percentage of epidermal stem cells found in vivo is maintained when isolated keratinocytes were cultivated on a fibrin matrix and that the subsequent transplantation efficiency for the keratinocytes when applied as an autograft was high, reproducible, and permanent. The use of fibrin microbeads is another approach to deliver fibroblasts for skin regeneration^[38] and might be useful for other cell types as well.

In addition to skin wound-healing applications, further investigations have been done in vitro as well as in vivo to combine fibrin-based biomaterials with other tissue-specific cells. Wechselberger et al.^[39] showed that cultured urothelial cells could be successfully transplanted via fibrin glue onto a prefabricated structure. Based on this approach, Bach et al.^[40] were able to show the in-vivo formation of a new multilayered urothelium at the site of transplantation. Taken together, both studies point out the promising potential for an urothelial cell/fibrin matrix suspension in urethral reconstruction procedures. In a recent study, Wechselberger et al.^[41] extended the use of cell/fibrin matrix suspensions to the delivery of tracheal epithelial cells and preadipocytes. Other cell types including chondrocytes,^[42] human myofibroblasts,^[43] and osteoprogenitor cells,^[44] have also been grown in fibrin gels and tested for tissue regeneration applications.

The combination of fibrin-based biomaterials with other biomaterials provides possibilities for tissue regeneration approaches, either to add additional biological activities or to improve the biomechanical properties of the composite matrix. The combination of fibrin-based preparations with inorganic bone ceramics, e.g., hydroxyapatite and β -tricalcium phosphate,

has been tested in preclinical and clinical orthopedic procedures. It has been shown that a fibrin matrix enhances the osteogenic properties of the ceramic materials including osteointegration, bone remodeling, and new bone formation.^[45,46] These effects may be explained by a stimulatory effect of the fibrin matrix on osteoblastic precursor cells and mesenchymal cells to enhance osteogenesis. The ability of the fibrin matrix to promote angiogenesis and vascular development is another important property of fibrin-based biomaterials in the context of bone regeneration.

F

CONCLUSION

The ultimate goal of tissue regeneration therapies is the controlled formation of entire tissue and organ systems in vivo, thereby avoiding the problems of donor transplant shortages and tissue rejection reactions. One barrier to tissue regeneration strategies is the complexity and variety of the cells required for the task, whereas another is the limitation of the biomaterials currently available. Fibrin-based biomaterials can address problems involved in the uniform distribution of cells and nutrients throughout the scaffold, the delivery of growth factors and cytokines to induce specific cellular growth, migration, and differentiation responses, and revascularization of the newly formed tissue. In addition, the proven hemostatic and tissue-adhesive properties of fibrin sealants can be utilized in applying the fibrin-based biomaterials in vivo, while the inherent wound-healing properties of fibrin clots can enhance the successful integration of the constructs. Continuing advances in fibrin-based biomaterials including methods for delivery of cells and therapeutic agents provide a basis for creating the next generation of biomaterials^[47] designed to achieve site-directed stimulation of tissue regeneration processes.

INTRODUCTION

When injury occurs, the clotting process is triggered, and, within a few minutes, hemorrhage ceases. Fluid blood is converted to a solid plug by the production of the three-dimensional fibrin polymer matrix. The importance of this event has been recognized for greater than a century, and efforts to utilize exogenous fibrin to aid hemostasis in bleeding patients have been attempted for virtually the same length of time. Over the past 30 years, these efforts have resulted in products whose appropriate utilization appears to be of benefit in a variety of clinical and surgical settings. In addition, the importance of fibrin for appropriate wound healing and the potential to utilize this biological matrix to deliver drugs, growth factors, and even cellular components have been increasingly realized. This brief review will summarize the evolution of fibrin clinical products, the evidence for their efficacy, and the recent trends toward new applications.

BACKGROUND

Coagulation Pathway and Fibrin Formation

Early in the 20th century, Morowitz brought to an end the first epoch of coagulation research when he correctly postulated that the addition of material released from damaged tissue to blood would result in the formation of the enzyme thrombin.^[1] Once formed, thrombin cleaves fibrinogen which results in the spontaneous production of the fibrin clot. Prior to this hypothesis, parameters, such as changes in temperature and exposure to air, were offered as potential explanations for the mysterious solidification of blood upon its removal from the body. Dr. Morowitz's rudimentary pathway served as the framework for the vast amount of research that resulted in the discovery of multiple clotting factors and their placement in a

logical sequence that was subsequently described as the clotting cascade (Fig. 1A). This work continues, and recent modifications of the mechanism serve to emphasize the critical role played by platelets and the importance of the thrombin burst (Fig. 1B) for normal hemostasis.^[2]

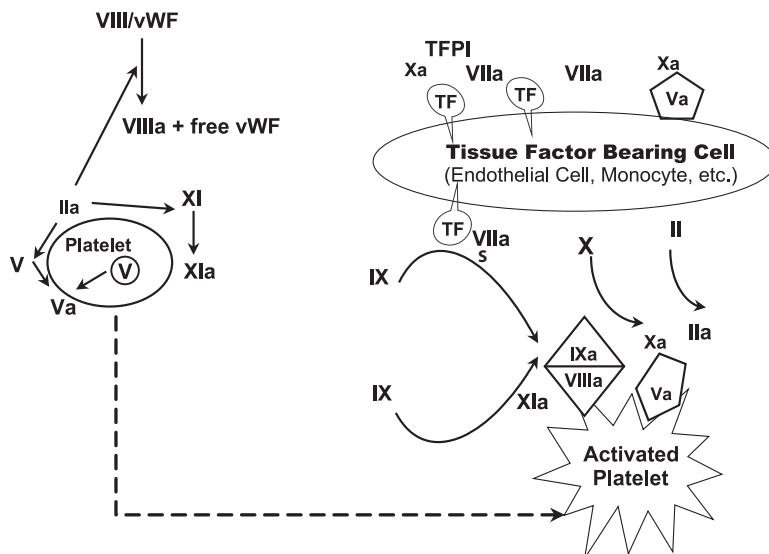

Once thrombin is formed, irreversible activation of platelets occurs. Fibrinogen is converted to fibrin monomer, and factor XIII is activated. Fibrinogen is composed of six extended polypeptide chains representing three distinct types— α , β , γ . Each of which is present as a pair ($\alpha_2\beta_2\gamma_2$). Fibrinogen's molecular shape is that of an extended, slightly bent rod containing two identical end nodules called D domains and one central nodule called E domain. Thrombin activates fibrinogen by cleaving two sets of peptides, fibrinopeptides A and B, from the amino terminal ends of the α and β chains. Due to the folding of the molecule, these peptides are removed from the central E domain. Upon removal of the fibrinopeptides, the new molecular species, which is termed fibrin monomer, spontaneously assembles into protofibrils and, subsequently, into fibers of the fibrin network (Fig. 2). The initial assembly is solely accomplished by hydrogen bonding. Such structures are inherently weak and subject to rapid removal by the fibrinolytic system. This situation is rectified by the introduction of covalent bonds between the assembled fibrin molecules through a process of transglutamination mediated by activated factor XIII. Factor XIII normally circulates as a pro-enzyme, but it is activated by thrombin during clotting (Fig. 2).

Development of Fibrin as a Clinical Agent

While our understanding of the coagulation apparatus continues to evolve, the potential for using fibrin to promote hemostasis in bleeding patients was recognized early on. In 1909, Bergel first reported use of

Panel A

Panel B

Fig. 1 Panel A: the clotting cascade emphasizing the intrinsic, extrinsic, and common pathways. Panel B: the new cascade emphasizing the critical roles of tissue-presenting cells and platelets in the initial activation and critical burst of thrombin production.

dried plasma as a source of fibrinogen and fibrin fleece as an aid to control hemorrhage in surgery.^[3] In 1915, Grey used fibrin patches to stop bleeding during cerebral surgery,^[4] and, in 1940, the adhesive properties of fibrin were exploited to reapproximate peripheral nerves.^[5] In 1944, the process of mixing fibrinogen with thrombin to prepare a fibrin adhesive to anchor skin grafts was described.^[6] For the next 30 years, the use of dry fibrin continued to be intermittently reported, but enthusiasm for the material was hindered by the variable quality of the product and the potential complications of viral exposure. Interest was renewed in the mid-1970s with the development of commercial processes for isolation of large quantities of virally inactivated fibrinogen. Subsequently, multiple products were developed and placed into clinical practice in Europe, Japan, and Canada (Table 1).

Fibrin's Desirable Properties

Fibrin adhesives, such as sealants, glues, etc., have multiple properties that make them desirable as hemostatic agents and tissue repair matrices. Since these fibrin products are of human origin, they are biocompatible and biodegradable. Since they are the normal injury repair matrix, they do not induce an inflammatory response, foreign body reaction, extensive fibrosis, or tissue necrosis. There is increasing evidence that fibrin sealants promote tissue growth and repair^[7] and may actually promote new vessel formation.^[8]

Commercially Available Products

Several companies have developed fibrin products for clinical use (Table 1). While these products have been

Fig. 2 Activation of fibrinogen and steps in the formation of the fibrin network.

available in Europe, Canada, and Japan for a number of years and in worldwide use for greater than a decade, their introduction in the United States occurred only recently. The delayed U.S. Federal Drug Administration (FDA) approval stemmed from concerns over viral safety and the FDA requirement that each component contained in the materials must add substantial benefit. In 1978, due to reported transmission of the hepatitis B virus, the FDA revoked the license to use fibrinogen concentrates in the United States. Since the majority of commercial fibrin adhesives started from human cryoprecipitate or Cohn Fraction I, concerns persisted despite the development of several effective viral inactivation treatments. The ever-increasing volume of literature regarding the use of fibrin products in multiple types of surgeries prompted the use of homemade fibrin sealants by many U.S. medical facilities.^[9-11] These locally produced materials were of variable quality and generally produced by combining cryoprecipitate with bovine thrombin and calcium—with or without the addition of an antifibrinolytic agent. U.S. fibrin glues, while effective in some clinical settings, carried several undesirable characteristics. First, the amount of fibrinogen and other proteins, such as factor XIII, fibronectin, etc., used to make the clots varied due to variations in cryoprecipitate used. Fibrinogen

concentration is a critical determinant in the structural properties of the formed fibrin. Second, the bovine thrombin typically used in U.S. fibrin was contaminated with bovine factor five. In some patients, exposure to bovine factor five produced antibodies that cross-reacted with human factor five, which led to acquired factor five deficiencies.^[12] Such deficiencies resulted in severe bleeding in some patients. Third, no simple quality control measures were typically employed to test the properties of the fibrin formed. Finally, although generally safe, cryoprecipitate from other humans continued to carry some risk of viral exposure. Virally inactivated human thrombin has become available through commercially available fibrin sealant kits; however, it is still not available as a stand-alone product. Whereas procedures for producing autologous fibrin glue that uses virally inactivated human thrombin have been developed,^[13] the pressure to proceed along these lines has recently decreased with FDA approval for the use of Tisseel[®] (Baxter-Immuno AG, United States of America) in the United States.

Production and Composition of Commercial Fibrin Adhesives

Components generally found in all fibrin adhesive products include fibrinogen, which is from concentrate; thrombin, which is initially bovine and later human, calcium; and a fibrinolytic inhibitor, which is mostly bovine aprotinin (Table 1). The fibrinogen is of human origin and initially isolated from frozen plasma. The first isolation procedure involves either thawing of the frozen plasma at 2°C (cryoprecipitate) or precipitation of plasma proteins with 10% ethanol (Cohn fraction I). The later process tends to yield materials enriched with fibronectin and factor XIII. This starting material is further purified by additional precipitation steps. Once purified and concentrated, the protein mixture undergoes viral inactivation with one of several processes including two-step vapor heat (at 60°C and 80°C), pasteurization, or solvent-detergent treatment. Viral inactivation is followed by additional purification and concentration steps, sterile filtration, and lyophilization. While the final concentrations of fibrinogen and factor XIII vary between products (Table 1), all products contain at least 70 milligrams of fibrinogen and 10 units of factor XIII per milliliter. Most products use bovine aprotinin as the antifibrinolytic, and all use virally inactivated human thrombin. Some products are packaged and supplied as vials of lyophilized protein concentrates. When reconstituted, one vial yields a solution of fibrinogen, factor XIII, and aprotinin. The other yields a thrombin plus calcium solution. The separate solutions are rapidly mixed through a variety of devices. One device yields a spray to cover

large surface areas while a dual-syringe device allows production of a significant amount of clot directly on an affected area.^[14] Recently dried, preformed fibrin bandages have been developed for direct application in the setting of massive hemorrhage.^[15]

CLINICAL APPLICATIONS FOR FIBRIN SEALANTS

Problems with the Evidence for the Clinical Utility of Fibrin Sealants

While the literature on the use of fibrin sealants is extensive, it is of relatively poor quality. Most trials have been uncontrolled and have employed differing products that use a variety of protocols to assess effectiveness. These difficulties have resulted in a number of instances in which trials designed to address the same clinical question have resulted in absolutely opposite conclusions. Trials testing the effectiveness of fibrin sealant for reducing seroma formation in breast surgery found that fibrin sealant was effective^[16] and ineffective.^[17] Trials testing whether fibrin sealant could reduce fistula formation in pancreatic surgery found that it did^[18] and did not.^[19] Trials testing the ability of fibrin sealant to reduce bleeding in patients with hemophilia undergoing tooth extraction were both positive^[20] and negative.^[21] Finally, despite several series that indicated that fibrin sealants improved the take and adhesion of skin grafts, a controlled trial failed to demonstrate benefit.^[22] With these conflicting results in mind, the following sections briefly summarize results from the literature.

Use in Neurosurgery

The properties and ease of application of fibrin sealants have led to their use in several neurosurgical applications. They have been used as an adjunct to suturing and reduce cerebrospinal fluid (CSF) leaks. The local inflammatory effects seen with suturing may be avoided theoretically with the use of fibrin sealants. The technically difficult access to microvascular anastomoses during transnasal surgeries makes the role of fibrin sealants attractive for enhancement of hemostasis intraoperatively and prevention of post-operative hemorrhage. Unfortunately, the literature on fibrin usage in neurosurgery consists mainly of small series and case reports plus a few randomized clinical trials.

Al-Yamany described a series of 25 patients who underwent 29 transcortical approaches for the resection of intraventricular and/or paraventricular lesions. None of the 25 patients developed a clinically

symptomatic subdural fluid collection after the application of fibrin sealant at the time of the procedure. Additionally, none of the patients developed new seizure activity or experienced progression of a pre-existing seizure disorder.^[23] Lee reported 26 patients undergoing neurosurgery for various intracranial conditions, including brain tumors, lipomyelomeningoceles, arteriovenous malformation, and dural tear.^[24] A commercially available fibrin sealant formulation was applied in conjunction with Teflon, cotton, or muslin pieces to reinforce aneurysmal clippings in nine patients. No recurrent bleeding or adverse reaction was reported during a 25-month follow-up in the group receiving fibrin sealant.

The potential role of fibrin sealant as biomaterial and drug delivery systems in neurosurgery has been investigated in animal models. Iwakawa evaluated fibrin sealant as an intraspinal delivery system for application of glial cell line-derived neurotrophic factor (GDNF) for regeneration of cut dorsal root in adult rats. When compared with nerves treated with GDNF-free fibrin sealant, rats treated with GDNF embedded in fibrin that was directly applied to the cut dorsal root experienced enhanced nerve regeneration into the spinal cord. These results suggest a possible role for fibrin sealant as a therapeutic drug delivery system in neurosurgical patients.^[25]

Use in Oral Surgery

Patients who are on long-term anticoagulation therapy or have hemorrhagic disorders such as hemophilia have increased risk of hemorrhagic complications with oral surgery. For patients on long-term anticoagulation therapy, it must be temporarily discontinued to reduce risk of bleeding perioperatively. Such intervention may increase risk of thrombosis and depending on the initial indication for anticoagulant therapy, may be particularly hazardous. The use of fibrin sealant is appealing for such situations if the therapy cannot only reduce perioperative bleeding but also eliminates the need for the interruption of anticoagulant therapy.

Fibrin sealants may reduce the incidence of post-operative bleeding for patients with hemorrhagic disorders undergoing oral surgical procedures.^[20] Rokocz examined 80 patients with a history of hemorrhagic disorders, who were between the ages 3 of 75, that were undergoing dental extractions.^[20] One hundred thirty-five tooth extractions were performed without preventative factor replacement therapy. Complete initial local hemostasis was achieved with fibrin sealant application (Berioplast[®]) after extraction. Nine of 12 patients with severe hemophilia experienced secondary bleeding. In those patients with severe hemophilia,

improved hemostasis was achieved by increasing the concentration of aprotinin in the fibrin sealant compound along with the addition of swish and swallow tranexamic acid before and after extractions.^[20]

Fibrin sealant application may reduce the risk of postoperative hemorrhage for patients on chronic anticoagulation therapy undergoing oral surgery. Martinowitz reported no secondary bleeding in 40 patients on chronic anticoagulation therapy with preoperative INR values ranging from 2.5 to 4.5 who were treated with Beriplast[®] to attain postextraction hemostasis.^[26] Bodner reported similar results in 69 patients undergoing oral surgery who were on chronic anticoagulation with INR values ranging from 1.0–5.0.^[27] All patients were treated with fibrin sealant to achieve local hemostasis, and none of the patients interrupted anticoagulation therapy before the procedures. Minor postoperative bleeding occurred in only three (4.3%) patients.^[28]

Use in Endoscopy

Acute upper gastrointestinal (GI) bleeding occurs in more than 100 per 100,000 persons each year and can be associated with mortality rates approaching 15%. Subsequent bleeding episodes will occur in 5 to 30% of patients following the initial presentation.^[28] Endoscopy is an effective tool in visualizing the etiology of bleeding, and sclerotherapy can be used to stop active bleeding and prevent recurrence. Fibrin sealants seem an ideal therapy since they are composed of physiologic materials involved in coagulation and healing. In addition, fibrin sealants may be applied serially. This is a significant advantage over traditional agents that may lead to tissue necrosis and destruction with multiple applications.

Available literature indicated that fibrin sealants may be an effective therapy in achieving hemostasis and reducing risk of additional bleeding in patients with acute upper GI bleeding. Rutgeerts reported 805 patients with acute upper GI bleeding who were treated with endoscopy and local therapy with either polidocanol or fibrin sealant (Beriplast[®]).^[29] The trial was designed to detect the difference between a single injection with sclerosant polidocanol in the ulcer bed versus local therapy with a single application of fibrin sealant versus repeated application of fibrin sealant as prophylaxis once daily for five days after the initial bleeding episode. Repeated injections of polidocanol were not utilized due to the risk of tissue necrosis with subsequent injections. The group that received repeated applications of fibrin sealant experienced a 33.3% reduction in the risk of recurrent bleeding, which was a 40.8% reduction in treatment failure rates, and a lower incidence of clinically relevant bleeding

($p=0.011$).^[29] An additional subgroup analysis revealed a significantly lower risk of bleeding in patients with nonbleeding visible vessels who were treated with repeated applications of fibrin sealant. Although not reaching statistical significance, a trend toward lower risk of recurrent bleeding was seen in the group with spurting vessels who were treated with repeated applications of fibrin sealant.^[29] Zimmer et al. examined upper GI bleed secondary to esophageal varices and randomized patients to receive either fibrin sealant or polidocanol. Fibrin sealant therapy was superior with regards to rebleeding risk and overall mortality at 28 days follow-up.^[30]

While these studies indicated a positive benefit to using fibrin sealants in the setting of acute upper GI bleeding treated with endoscopy, other studies have shown conflicting data. In 2002, Lin et al. reported a trial involving 51 patients who were presenting with acute upper GI bleeding with either actively bleeding or nonbleeding visible vessels that was visualized with endoscopy. Patients were randomized to either sclerosis with endoscopic epinephrine injections or fibrin sealant application.^[31] The rate of rebleeding was significantly higher in the epinephrine group—56% versus 15% in the fibrin sealant group ($p=0.003$).^[31] The volume of blood transfusions, number of surgeries, length of hospital stay and mortality was not significantly different between the two groups. The trial concluded that fibrin sealant may achieve better initial hemostasis than epinephrine injections, but it does not change overall outcomes.^[31] Similarly, Heldwein examined the role of fibrin sealant for treatment of acute upper GI blood loss secondary to arterial bleeding.^[32] All patients were treated with either photocoagulation or fibrin sealant application, and all patients achieved initial hemostasis. However, there was no significant difference between the two groups with regards to incidence of rebleeding, ultimate hemostasis, or hospital mortality.^[32]

Use in Skin Grafting

Fibrin sealant therapy may have multiple benefits in the setting of skin grafting procedures. Blood loss during engrafting procedures in burn patients can be profound. Topical fibrin sealants may have an important role in minimizing hemorrhage during such procedures. These agents may improve engraftment in slightly infected wounds while the combination of fibrin sealant and sutures seal parenchymal surfaces better than suturing alone.^[33,34] When used alone, fibrin sealant resulted in a 95–100% successful skin engraftment in such difficult graft sites as eyelids and neck with no hematoma formation and a 50%

reduction in operative time.^[34] Future clinical applications in this setting are under investigation.

Use in Urologic Procedures

Few trials have examined the use of fibrin sealants in the urologic setting. In a 30-patient trial, postoperative application of fibrin sealant to the prostatic bed significantly reduced postoperative bleeding in patients undergoing transurethral resection of the prostate when compared to placebo.^[35] Although they remain largely experimental at this time, use of fibrin sealants for other urologic procedures, such as urethral anastomosis and closure of bladder fistulae, have been reported.^[36,37]

Use in Ophthalmology

Clinical applications of fibrin sealants in ophthalmology include repair of conjunctival wounds, sealing of lens perforation, eyelid surgery, lachrymal repair, and closing of corneal ulcers reducing the need for corneal implants. Fibrin sealants are appealing in this setting due to their performance in moist environments and the potential to avoid sutures.

Use in Abdominal Surgery

Despite good surgical technique, complications such as infection, abscess formation, and sepsis can arise due to bleeding and fluid leakage from suture sites and parenchymal tissue where sutures cannot be used. Fibrin sealant, when used in conjunction with sutures, staples, or collagen fleece, could decrease and prevent leaks as well as enhance healing after abdominal surgery. In a multicenter study of patients undergoing esophageal, gastric, colonic, or rectal resection, fibrin sealant was applied to closure sites in 37 patients. After two weeks, 30 patients (81.1%) showed no evidence of leakage upon radiological examination. Minor or major suture failure was recorded on seven anastomoses.^[38]

Hepatic and Pancreatic Surgery

Fibrin sealant provides a potentially effective therapy to achieve hemostasis of parenchymatous organs in which sutures alone may not control and may even aggravate bleeding and fluid leakage.^[39] Their properties make fibrin sealants suitable adjunctive hemostatic agents in liver resection, biopsy, and transplantation. In a study of 77 patients who underwent elective liver resection for benign and malignant lesions, Noun et al. reported significantly lower mean fluid drainage and bilirubin concentrations during

the three postoperative days in the group treated with a single dose of fibrin sealant. Additionally, the abdominal closure site was judged as dry in 97% of patients treated with fibrin sealant versus 81% not treated with fibrin sealant ($p=0.016$). There was no difference in postoperative morbidity and mortality between the two groups.^[40] In a study in which fibrin sealant was sprayed onto the cut liver surfaces of eight patients with hepatic cancer and cirrhosis who underwent hepatectomy, no postoperative bile leakage and abscess formation was noted.^[41] In laparoscopic liver biopsies, postpuncture bleeding was prevented by injecting fibrin sealant into or near the biopsy site.^[42,43]

Pancreatic fistulas are most commonly derived as complications of elective surgical procedures on the pancreas and as sequelae of pancreatitis or pancreatic trauma. They are also a leading cause of morbidity after pancreaticoduodenectomy.^[44] The application of fibrin sealant during pancreatic surgery has been used with varying degrees of success in preventing complications associated with fluid leakage, tissue necrosis, and fistula formation. In one study, Suzuki et al. reported a 25% decrease in incidence of pancreatic fistula formation after applying fibrin sealant to seal the pancreatic stump.^[45] However, in another study by D'Andrea et al. of 97 patients undergoing pancreatic surgery, no statistically significant differences in the incidence of fistula formation was seen between the control group and the group treated with fibrin sealant.^[46] Although differences between groups were not statistically significant, the incidence of pancreatic fistula was significantly lower than in the first study. Differences in success rates in these studies may be due to differences in fibrin sealant formulation, techniques of fibrin application, and/or differences in surgical technique.

Cardiovascular Surgery

Fibrin sealants have been used in conjunction with sutures in a wide range of cardiovascular procedures to limit perioperative bleeding and postoperative blood loss. Fibrin sealants have been used to promote hemostasis after femoral artery catheterization and in procedures such as vascular grafts, valve replacements, repair of septal defects, repair of vessel/heart chamber ruptures, and prosthetic implantations. Fibrin sealant as an adjunct to sutures has been used with a success rate of at least 94% in cardiopulmonary bypass procedures.^[47,48] In 1982, Borst et al. reported a trial of 340 patients undergoing extracorporeal circulation in which fibrin sealant was applied as an adjunct to sutures. Fibrin-presealed fabric was inserted in 60 heparinized patients. Perfect sealing was reported in 95% of these cases.^[47] Jackson et al. reported a case in which fibrin sealant was used as an adjunct to sutures

in a patient with heparin-induced thrombocytopenia that was anticoagulated with heparinoid. Fibrin sealant was applied at the mediastinal wound surfaces and the anastomosis graft site, and complete hemostasis was achieved at these sites.^[49] In a multicenter study of 333 patients undergoing re sternotomy or reoperation after cardiac surgery, Rousou et al. reported a 92.6% success rate for fibrin sealant (Tisseel[®]) in controlling bleeding within five minutes versus a success rate of 12.4% for other conventional topical hemostatic agents. Additionally, fibrin sealant also controlled 82% of bleeding episodes that were initially treated with other topical agents.^[50] In 1991, Seguin et al. evaluated the use of fibrin sealant in a study of three groups of patients ($n=42$) undergoing surgery to correct type A acute aortic dissection. Fibrin sealant was used in 18 patients to seal the aortic stumps and reinforce the suture sites. In the other two groups, intraluminal sutureless graft or a Dacron prosthesis was used to replace the ascending aorta. Fibrin sealant significantly ($p<0.05$) reduced perioperative blood loss as well as perioperative mortality.^[51] In 1994, Seguin et al. suggested the use of fibrin sealant in lieu of sutures for aortic valve repair in order to prevent bleeding from the aortic wall caused by suturing.^[52] In a study of 17 patients undergoing carotid endarterectomy, mean blood loss from the arteriotomy suture lines was reduced by 130 milliliters. Plus, the time to achieve hemostasis was reduced by 13.5 minutes in the group treated with fibrin sealant.^[53]

The results of experimental studies suggest that fibrin sealants may improve hemostasis after femoral catheterization. Ismail et al. and Kipshidze et al. have reported on the efficacy and safety of applying fibrin sealant percutaneously after cardiac catheterization.^[54,55] Both studies reported less bleeding from the access site and fewer complications related to the procedure. Fibrin sealants may also be an effective means to deliver antibiotics to reduce the risk of infection at vascular graft sites. In-vitro experiments and studies in animal models have demonstrated the potential of adding a variety of antimicrobial agents to fibrin sealant products. In a model system in which 5 mg/cm³ tobramycin was combined with a fibrin sealant product, a significant reduction in vascular graft infection and pseudoaneurysm formation was reported.^[56] When combined with fibrin sealant, dibekacin sulfate has also been reported to be effective as a means of preventing vascular infection without affecting the strength of the sealant.^[57]

Thoracic Surgery

Air leakage and hemorrhage leading to infections, pleural adhesions, fistula formation, and infections

continue to be common complications of thoracic surgery. These complications can be overcome by the use of fibrin sealants. Fibrin sealants have been successfully used in numerous thoracic procedures, including assisting sternal closure plus sealing bronchial stumps, tracheal anastomoses, and pulmonary lesions, after surgical dissection in pleurodesis/decortication, tumor resection, and lobectomy/pneumonectomy.

In 1993, Mouritzen et al. reported on the efficacy of fibrin sealant (Beriplast[®] P) in a study of 114 patients undergoing pulmonary resections and pneumonectomies. Fifty-nine patients received sutures alone, and 55 patients received fibrin sealant as adjunct to sutures. Decreased air leakage, fewer postoperative complications, improved airway tolerance pressure testing, and a reduction in hospital stay were reported in the patients treated with fibrin sealant after suturing.^[58] Two newer methods of applying fibrin sealant (Beriplast[®] P) in thoracic surgery have shown better adhesive properties than conventional methods. One method consists of rubbing thrombin solution in the lung tissue before applying fibrinogen. A second method involves soaking fibrinogen into an absorbable mesh and subsequently applying it to the lung. Both methods have shown satisfactory results. The second method, however, had higher adhesive properties and a shorter duration of air leaks in a 35-patient clinical trial.^[59] In another proposed application, applying large amounts of diluted fibrin sealant was no more effective than chemical agents in the treatment for intractable pneumothorax.^[60]

FUTURE DIRECTIONS

While the hemostatic properties of fibrin will undoubtedly continue to drive most applications, the potential to use fibrin as a delivery system for drugs and growth factors has been postulated and is being actively employed. In this setting, the fibrin network is implanted to deliver high drug concentrations directly to the area of interest. The potential to enhance blood vessel formation in areas of ischemic risk by implanting fibrin networks enriched with angiogenesis factor is but one example. Equally intriguing is the possibility of accomplishing gene transfer by the implantation of genetically altered cells embedded and growing in fibrin structures. These possibilities will be facilitated by new techniques for producing bioengineered fibrin matrices with predefined structural characteristics through processes such as electrospinning. The primary limiting step at the moment is the supply of absolutely safe starting materials. Fibrinogen has been cloned, and, once it can be economically produced in large enough quantities, the potential applications for fibrin matrices appear compelling.

CONCLUSION

Fibrin sealants are used worldwide as adjuvants to control hemostasis. Although the products vary somewhat in their composition, they all contain high concentrations of fibrinogen and thrombin. Fibrin sealants are biodegradable and tissue-compatible. They also do not appear to cause significant inflammatory response. Since all current products are made from human plasma, a major concern regarding their utilization continues to be the potential for transmission of disease-causing materials. These concerns may be met in the short term by development of autologous products and/or better methods of pathogen inactivation. In the long term, utilization of recombinant products could solve the problem. Since fibrin is the normal three-dimensional tissue repair matrix, fibrin sealants are prime targets for development as implantable drug and tissue delivery systems.

INTRODUCTION

Finite element analysis (FEA), also known as the finite element method, is a numerical solution technique that allows users to quantify how a field variable can vary in space within a particular geometry. These field variables in engineering problems can take the form of displacement in stress analyses, temperature in heat transfer/thermal analyses, velocity/pressure in fluid mechanics, and current in electromagnetics, for example. Problems can be time-independent or vary in time as well as in space. Coupling of more than one field variable into a finite element analysis can also be performed to provide answers to more complex problems.

BACKGROUND

Engineers, mathematicians, and physicists have all contributed to what we now know as FEA.^[1] The 1950s and 1960s saw some of the first applications of FEA in engineering. It was originally applied by the aeronautical industry to study aircraft wing behavior. Since then, it has provided information on such topics as stresses in structures (roofs, bridges, concrete, spacecraft, dams, foundations, etc), heat flow in rocket nozzles and internal combustion engines, temperature distribution in nuclear reactor components, and movement of fluid in containers and aquifers.^[2] In the bioengineering field, one might therefore envision applying FEA to understand the stresses that bones are subjected to in the body and the effect on the bone after total joint arthroplasty (such as implanting a total hip replacement); heat transfer and temperature patterns during heating and cooling (including cryopreservation) of different cells and tissues (skin, brain, liver, breast); or blood flow in normal arterial vessels and changes that occur to the flow in the presence of an atherosclerotic plaque. Thus, FEA has a broad application to a number of engineering problems.

One of the major reasons for the wide use of FEA is its versatility. There are virtually no restrictions on the geometry, boundary conditions, applied loading, or material behavior of the object under study.^[3] Different objects of different sizes and with different material

properties can be combined to analyze the behavior of an entire structure. Thus, FEA provides solutions to problems that could not be solved otherwise. The finite element structure also physically resembles the original structure rather than being an oversimplified shape. As FEA usefulness has caught on, the size of analyses has increased and continues to do so, thus demanding computer implementation of FEA procedures. It is fortunate that computer efficiency, power, memory, and storage capacity have dramatically improved over the last few decades and now allow complex finite element problems to be solved not only on supercomputers and mainframes but even on desktop computers. Hundreds of FEA software packages are commercially available (although only a few dozen are extensively used), making application of the technique even more widespread.

This article will focus on the steps involved in completing a finite element study and conclude with examples of FEA applications to bioengineering problems.

OUTLINE OF A FINITE ELEMENT PROBLEM

A finite element analysis progresses through three main stages: preprocessing, analysis, and postprocessing (Fig. 1). Each stage involves many substages, each of which are described in more detail later in this article. Any FEA begins with representing the physical problem by a mathematical model or idealization. This means essentially that the geometry of the physical problem, the properties of the material in the geometry, and the environment around the geometry (boundary conditions, applied loads) must be expressed mathematically.

PREPROCESSING

Geometric Information

This stage begins with the decision of whether a 1-D, 2-D, or 3-D representation will accurately reflect the

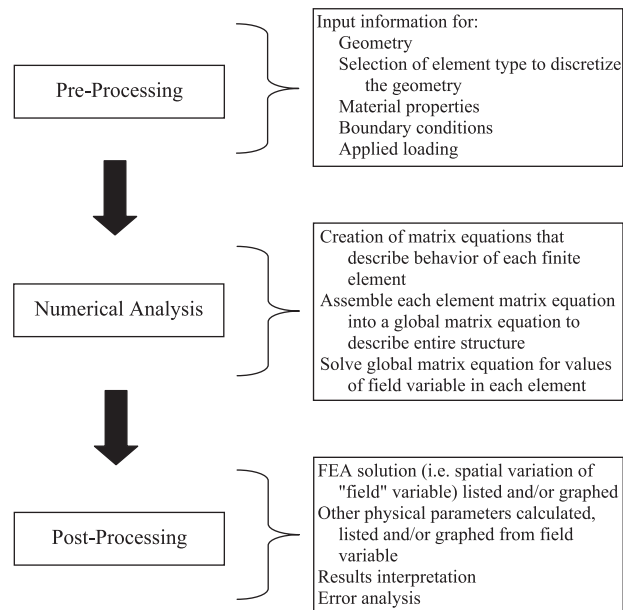

Fig. 1 General steps followed in a finite element analysis.

physics of the problem. Coordinate values are assigned to the geometry of the problem that serve as the initial input into the FEA software.

Discretization

A patchwork of finite elements that interconnect to form the geometry is then created (Fig. 2). The process of generating this finite element mesh is called discretization. If the space is one-dimensional, the elements may be bar elements to form trusses or beam elements to form frames, for example. If the space is two-dimensional, triangles or quadrilateral elements are most commonly used to discretize the space. If the space is three-dimensional, tetrahedral or brick elements may be implemented. Numerous types of elements (shell elements, plate elements, planar elements, 3-D solid elements, etc) often exist within various FEA software packages to lend versatility. It is also conceivable to discretize a geometry by combining two or more element types in one, two, or three dimensions.

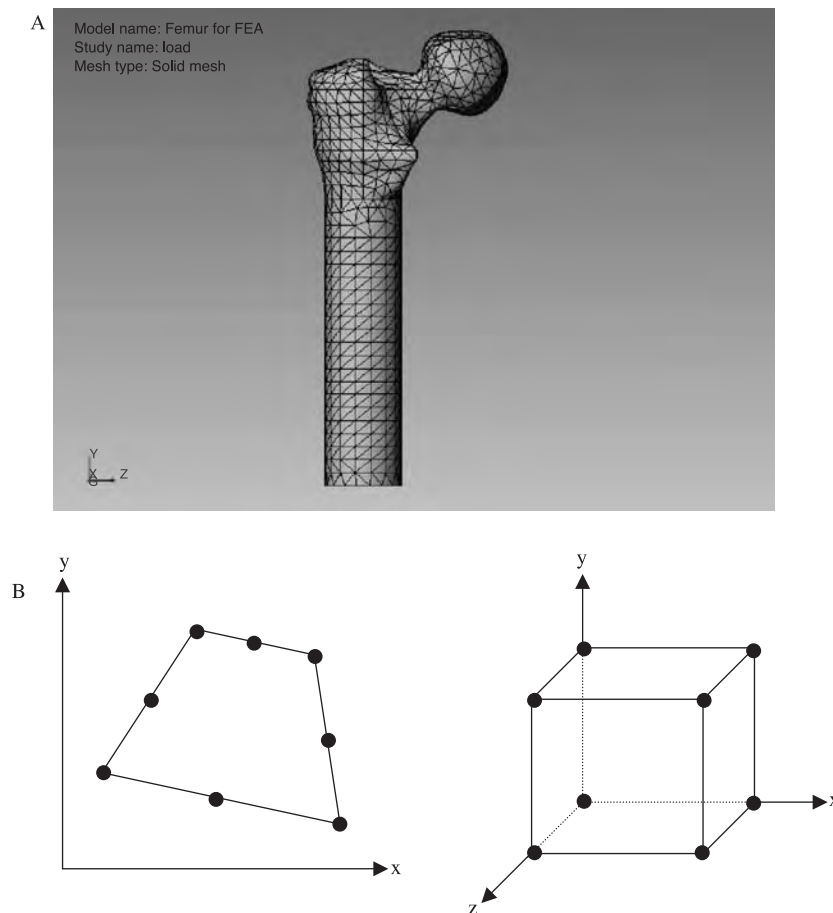

Fig. 2 A) The concept of discretization, or creating a patchwork of interconnected finite elements, is visually displayed on a solid model of the proximal femur or upper thigh bone. Model was created with SolidWorks 2001 Plus. B) Representation of two types of elements, 2-D (quadrilateral) and 3-D (brick) finite elements, defined with respect to a given coordinate system, which could discretize a given geometry. Black circles denote nodes, typically positioned at corners and/or edges, where the field variable of interest is specified.

The number of elements in the mesh and their size are dependent on the degree of spatial variation of the field variable that is expected for the given problem. If large variations are expected in some regions of the geometry, smaller and more elements would be used in those regions to better approximate the field variable. A mesh can also be refined (more and smaller elements) after an analysis if the results are not deemed accurate enough. As the number of elements (and thus nodes) in a given mesh increase, the FEA results typically converge to the true solution of the problem. An infinite number of elements is not computationally efficient or feasible, however, and thus mesh refinement is completed until the level of convergence and accuracy is acceptable.

All elements in a finite element mesh are connected to one another at specific locations within the element. These locations are designated as nodes; nodes are positioned at the corners of the elements, but additional ones may be included along the edges of the element or within the element's interior. The field variable associated with the problem is calculated at the nodes during the analysis stage. The number of nodes assigned to a particular element determines how the field variable can vary within that element. For example, elements with only corner nodes permit only linear variation of the field variable in any given direction (x, y, z) because two points in a specific direction define a line. If an element has corner nodes as well as mid-side nodes, then a quadratic variation is possible for the field variable (three points can define a quadratic curve). Connecting the nodes from element to element creates a piecewise interpolation of the field variable over the entire geometry of the problem.

Mathematical equations are used to express the interpolation (i.e., variation) of the field variable in an element. These equations are called interpolation, or shape, functions. Shape functions depend on coordinate direction(s) (x, y, z) and can be linear equations or quadratic equations, depending on the number of nodes within the element. To do so, each node is assigned its own shape function with the special feature that the shape function must have value 1 when the coordinates of the node are inserted into the shape function's equation and 0 when the coordinates of any of the remaining nodes are inserted into the equation. The shape functions then permit the field variable to be calculated at any location (x, y, z coordinates) within the element, simply by knowing the values of the field variable at the nodes for the element. Multiplying the shape functions by the nodal values of the field variable provides the value of the field variable anywhere in the element.

A one-dimensional example of a bar element is most useful to describe shape functions. Let this bar element have nodes only at the corners (i.e., ends) of the bar and be numbered 1 and 2. This element thus has two shape

functions, designated as N_1 and N_2 . The subscript refers to the node number that the shape function represents. For an element with four nodes, there would be four shape functions: N_1, N_2, N_3 and N_4 . For the two-noded bar element in this one-dimensional example, variation in only one coordinate direction (x) is allowed.

The shape functions that would represent this element are: $N_1 = (L-x)/L$ and $N_2 = x/L$. Note that when the coordinates of node 1 ($x=0$) are inserted into the equations, $N_1 = 1$ and $N_2 = 0$. When the coordinates of node 2 ($x=L$) are inserted into the equation, $N_1 = 0$ and $N_2 = 1$. Let the symbol u represent the field variable of interest in this problem; then u_1 and u_2 are the values of the field variables at the nodes. The expression $u = N_1u_1 + N_2u_2$ permits the calculation of the field variable anywhere along the length of the element u by inserting the coordinates of the position of interest into the shape functions. This multiplication can be represented as the matrix calculation $u = [N] \{u\}^e$, where $[N]$ is a row vector of the two shape functions for the element, $[N] = [N_1 N_2]$ and $\{u\}^e$ is a column vector of nodal values for the element $\{u\}^e = \{u_1 u_2\}^T$. The value of the field variable at the nodes can also be recovered from this equation, e.g. $u = u_1$ when coordinates of node 1 ($x=0$) are used and $u = u_2$ when coordinates of node 2 ($x=L$) are used.

This same approach is applied to shape functions for any element type in two- and three-dimensional geometries. Now, each shape function would depend on x and y (in 2-D problems) or on $x, y,$ and z (in 3-D problems). Let the symbols u and v represent the value of the field variable in the x and y directions, respectively, in a 2-D element. Then the matrix expression allows the calculation of the field variable anywhere in the element. The symbols $u_i, v_i,$ and w_i represent the value of the field variable at node i in the $x, y,$ and z directions. The repeating dots drawn into the matrix equation indicate that the matrix of shape functions continues similarly for the number of nodes within the element. This matrix equation can be more easily expressed as $\{u\} = [N] \{u\}^e$.

$$\begin{Bmatrix} u \\ v \end{Bmatrix} = \begin{bmatrix} N_1 & 0 & N_2 & 0 & N_3 & 0 & \dots \\ 0 & N_1 & 0 & N_2 & 0 & N_3 & \dots \end{bmatrix} \begin{Bmatrix} u_1 \\ v_1 \\ u_2 \\ v_2 \\ u_3 \\ v_3 \\ \vdots \end{Bmatrix}$$

Assignment of Material Properties

Because each element is defined individually, each element is assigned its own material properties. These material properties are specific to the problem under study, e.g., in thermal problems, the material property of thermal conductivity is important whereas in structural problems, Young's Modulus is important. These properties govern how the field variable is related to the forces driving the problem through relationships called governing, or constitutive relationships. These relationships are typically represented as differential equations. For example in one-dimensional thermal problems, the heat conduction equation $q = -Ak(dT/dx)$, is dominant in thermal problems. Here, q = heat flow; A = cross-sectional area; k = thermal conductivity; T = temperature (the field variable); x = axial coordinate; and dT/dx = differential of temperature in the x -direction. The equation states that the amount of heat flow through a bar depends on the size of the bar (area), its thermal conductivity, and the temperature gradient. In one-dimensional structural analyses, the linear form of the stress-strain relationship, $\sigma = E(du/dx)$, is dominant. In these equations, σ = axial stress; E = Young's Modulus; u = displacement (the field variable); and du/dx = differential of displacement in the x -direction or strain in the x -direction. The equation states that the amount of stress applied to a bar is linearly proportional to the strain (or displacement gradient) via Young's Modulus. If the geometry of the problem is greater than one-dimensional, then the stress-strain relationship is represented by $\{\sigma\} = [E] \{e\}$, where the stress vector, $\{\sigma\}$, contains normal and shear stresses in the coordinate directions; the strain vector, $\{e\}$, contains normal and shear strains in the coordinate directions; and $[E]$ is a matrix containing the material properties (including Young's Modulus).

As presented earlier, the value of the field variable anywhere in an element is determined by the shape functions and the matrix of shape functions through the matrix equation, represented in 1-D as $u = [N] \{u\}^e$. In order to implement the governing relationship and material properties into an analysis, it is necessary to calculate the gradient (differential) of the field variable, du/dx . This is accomplished by taking the derivative of the shape functions with respect to x . In structural analyses, this process creates a new matrix called the strain-displacement matrix, $[B]$. In 1-D, $[B] = [dN_1/dx \ dN_2/dx]$. Thus, $du/dx = [B] \{u\}^e$. In 2-D, there are two normal strains ($e_{xx} = du/dx$ in the x direction and $e_{yy} = dv/dy$ in the y direction), and one shear strain ($\gamma_{xy} = du/dy + dv/dx$). Thus, the strain-displacement matrix $[B]$ provides calculation of strains from nodal values of the displacement through

$$\begin{Bmatrix} du/dx \\ dv/dy \\ du/dx + dv/dy \end{Bmatrix} = \begin{bmatrix} dN_1/dx & 0 & dN_2/dx & 0 & dN_3/dx & 0 & \dots \\ 0 & dN_1/dy & 0 & dN_2/dy & 0 & dN_3/dy & \dots \\ dN_1/dy & dN_1/dx & dN_2/dy & dN_2/dx & dN_3/dy & dN_3/dx & \dots \end{bmatrix} \times \begin{Bmatrix} u_1 \\ v_1 \\ u_2 \\ v_2 \\ u_3 \\ v_3 \\ \vdots \end{Bmatrix}$$

or $\{e\} = [B] \{u\}^e$.

Boundary Conditions and Applied Loading

With the geometry, mesh, and material properties prescribed to the finite element model, boundary conditions and loads are assigned. Boundary conditions refer to specifying the environment the geometry is subjected to in space. These require designating the value of the field variable(s) at specific nodes within the geometry. In thermal problems, for example, a boundary condition may imply that the temperature is specified on one region within the geometry. In structural analyses, a region may be restrained from moving in a particular direction or forced to move a certain amount in a particular direction.

The applied loads are those physical quantities that cause the field variable of the problem to change from its original or equilibrium state. In thermal problems, the applied load could be a heat source delivering a flux of heat to the geometry on one of its regions. In structural analyses, the applied load could be a stress that results in forces on one of the regions of a geometry.

NUMERICAL ANALYSIS

This stage begins with the processing of all input information from the preprocessing stage and creating finite element matrix equations to represent the physics of the problem. The behavior of each element with its prescribed material properties is cast into matrix form using the laws of physics and a finite element formulation technique.^[1,3] In thermal analyses, the matrix would be called an element conductivity matrix, whereas in structural analyses, the matrix is referred to as an element

stiffness matrix. To illustrate this concept, let $[k]^e$ be the stiffness of an element in a structural analysis problem. This matrix is calculated by integrating the following matrix multiplications over the volume of the element, dV^e :

$$[k]^e = \int [B]^T [E] [B] dV^e$$

Recall that $[B]$ is the strain-displacement matrix, and $[E]$ is the matrix of material properties. Then $[k]^e \{u\}^e = \{f\}^e$ for each element. Here $\{f\}^e$ represents the load vector containing the forces acting on that particular element, as prescribed by the applied load.

It is rare in FEA that finite element integrals can be calculated exactly. More commonly, the integral must be numerically approximated by a mathematical quadrature. Gauss quadrature is frequently used in FEA to numerically integrate finite element equations but can be applied to numerically integrate any mathematical expression. The general manner in which this is accomplished is to calculate the value of the integrand (i.e., $[B]^T [E] [B]$ in the element stiffness matrix) at a specified number of locations within the element (Gauss points), multiply the value of each integrand at the Gauss points by a weighting factor, and sum up the contributions from all Gauss points. The accuracy of this numerical integration depends on the number of Gauss points specified and the complexity of the mathematical expression in the integrand (e.g., a ratio of polynomials is most common in FEA).

To illustrate the use of Gauss quadrature for numerical integration, consider the integral

$$\int \cos(x) dx$$

specified in one direction (x), with the definite limits of $x = -1$ to $x = 1$. Integrating this expression directly gives the exact value of $[\sin(1) - \sin(-1)] = 1.6829$. For this one-dimensional integration, the Table 1 lists possible Gauss points at different locations within the interval of the defined limits.^[3] As the number of Gauss

points increases, the percent error characteristically decreases, converging to the exact solution.

With the stiffness matrix and load vector known for each element, the contributions of all elements to the behavior of the geometry as a whole must be assembled. This is accomplished by knowing which elements are connected at which nodes and summing their individual contributions. This results in a global (i.e., representing the entire geometry) equation,

$$[K]\{U\} = \{F\}$$

Here, $[K]$ is the global stiffness matrix, assembled from the summed contributions of each element's stiffness matrix; $\{U\}$ is the vector of field variables at the nodes for the entire mesh; and $\{F\}$ is the global force vector, assembled from the summed forces acting on each element. With this global stiffness matrix $[K]$, the boundary conditions (or prescribed values of the field variable at the nodes) are imposed on the matrix. This alters some of the entries in the global stiffness matrix because it is not necessary to solve for those prescribed nodal values.

The set of simultaneous equations, $[K]\{U\} = \{F\}$, must now be solved to obtain unknown nodal values of the field variables within $\{U\}$. Direct solvers, such as Gaussian elimination, are most commonly implemented in an FEA software package to solve for the unknowns. Sometimes, iterative solvers become necessary due to the physics of the problem.

POSTPROCESSING

Display of Results

Upon completion of the numerical analysis stage, the values of the field variables at all nodes within the finite element mesh are known and can be provided to the user. Additional physical parameters such as gradients (of temperature or displacement for strain and then stress, for example) can also be calculated from the

Table 1 Possible Gauss points at different locations within the interval of defined limits

Order of Gauss quadrature	Location of Gauss points over the interval $\{-1 \text{ to } 1\}$	Weight factors	Value of numerical integration	Resulting error (%)
1	0	2	$2\cos(0) = 2$	18.84
2	$\pm 1/\sqrt{3}$	1	$1[\cos(1/\sqrt{3}) + \cos(-1/\sqrt{3})] = 1.6758$	-0.42
3	$\pm\sqrt{0.6}$	5/9	$5/9[\cos(\sqrt{0.6}) + \cos(-\sqrt{0.6})] + 8/9[\cos(0)] = 1.683$	0.006
	0	8/9		

Fig. 3 Schematic drawing of the geometry in Fig. 2A and plausible boundary conditions and applied loads acting on the geometry. Fixed (immovable) boundary conditions are represented by green arrows; pink arrows represent joint reaction forces acting on the femoral head and tension created by the abductor muscles on the greater trochanter. Finite element analysis was performed with CosmosWorks.

constitutive relationships specified by the mathematical model. With the improvement in computer graphics, graphical display is the most common approach to view results. The finite element information for the femur as described in Figs. 2 and 3 were numerically analyzed with an FEA software package to provide a representative picture of what a graphical display might resemble (Fig. 4).

Error Analysis

A vital step in any finite element analysis is to analyze the computed results critically and make decisions of

their accuracy. Care must be taken so that potential, controllable errors are eliminated. Error in this sense means disagreement between the finite element results and the exact solution of the problem. One difficulty in error assessment is that the exact solution is typically not known; this is the reason that an FEA was undertaken. Sometimes, an exact solution may be obtained on a simplified, but similar problem to which some comparison of the FEA results can be made. Or, experimental data might exist for the FEA problem and comparisons made. Thus, the finite element modeler must thoroughly review FEA results to ensure the highest accuracy has been obtained by the model.

Fig. 4 Graphical display of the deformed geometry (enlarged by a scale factor for descriptive purposes) from the finite element mesh of Fig. 2 under the action of the boundary conditions and applied loads of Fig. 3. The color contours within the geometry represent the magnitude of an averaged stress distribution (von Mises stresses in Pascals) that exists within the geometry. Note the color bar scale on the right; red represents areas under high stress (superior/inferior femoral neck, medial distal femur), while blue shading indicates areas of low stress. Finite element analysis was performed with CosmosWorks.

Sources of error can be classified into a few categories:^[3] modeling error, user error, software bugs, discretization error, and numerical error. Modeling error refers to how well the the mathematical model (geometry, material properties, boundary conditions, applied loading, etc.) represents the physical problem. Assumptions about the physical problem are made in the model out of necessity: Perhaps enough is not known about certain parts (boundary conditions, applied loads, for example) of the physical problem or material behavior must be approximated. Modeling error thus refers to those approximations of the problem that are done intentionally with the best representation applied to answer the question about the physical problem.

Errors made by the software user, once the mathematical model of the physical problem has been created, can be classified as user error. User error would include such issues as choosing the wrong element type to discretize the geometry (bar versus beam elements, for example), allowing element shapes/sizes to have poor aspect ratios or angles, not using an appropriate degree of numerical integration (quadrature), and mistakes in data entry. Another potential source of error is the existence of bugs in the software. Commercial vendors spend an extraordinary amount of time in debugging routines to eliminate this type of error, but software users should not be blind to the potential existence of software bugs.

Discretization error refers to how accurately the mesh and refinement in key regions of the geometry can capture the behavior of the object in the physical problem. The number of nodes per element (and thus the shape functions that define the piecewise interpolation within the geometry), the number of nodes in the entire mesh, and the number of elements in the geometry influence discretization error. Finally, numerical error classifies how the computer used for the FEA treats numbers. Information about numbers in the far decimal places is lost when the computer truncates or rounds off numbers. Additionally, as numbers are multiplied, divided, added, or subtracted, information may again be lost in the far decimal places. Thus, the number of decimal places stored should be as large as allowed by the computer.

A certain amount of error is expected in a finite element solution, as any FEA is an approximation of the physical problem. However, minimizing sources of error that can be controlled provides for a great degree of confidence in FEA results.

BIOENGINEERING APPLICATIONS

Some of the earliest applications of FEA to bioengineering problems were performed in the 1970s. The first symposium to present many of these applications occur-

red in 1980^[4] and covered a wide variety of topics. These included simulations of pulsatile blood flow in normal and abnormal arterial vessels, and numerous stress analyses of the lung, heart, normal and bioprosthetic heart valves, bone, and fixation devices for fractured bone. It is quite astounding to see the breadth of problems treated at that time with FEA still in its beginning stages of use. In these initial applications, it was more common for studies to use software that was internally developed rather than commercially available software.

Since these early applications, FEA in bioengineering has seen as dramatic a rise in use as in other engineering fields. Today, studies of similar problems originally described in 1980 remain, while new applications continue to appear. An important reason for the increasing use of FEA in all fields is the commercial availability of powerful FEA software with large element selections, extensive material models, and interactive preprocessing and post-processing graphical packages. Thus, the level of complexity of the problems and accuracy of the mathematical models have increased, particularly with respect to geometric representation and material behavior of the physical problem. Imaging techniques such as laser scanning, computed tomography (CT), and magnetic resonance imaging (MRI) are often employed to provide accurate, three-dimensional information about the shape and size of objects of interest. Numerous material models are incorporated into software packages that allow more realistic representation of the material behavior/properties of the physical problem. A few specific fields that have experienced extensive finite element applications will be highlighted. The clinical utility of FEA is growing.

Dentistry

Teeth are subjected to amazingly high forces of mastication (chewing) and yet are capable of withstanding these forces for many decades. Finite element simulations of a tooth during its normal function demonstrate how stresses and strains are distributed in the different layers of the tooth (enamel, dentin, etc.) and into the bone supporting the tooth.^[5] Finite element analyses of a tooth with a composite restoration (i.e., dental filling) illustrate how stress distributions are altered by the presence of the restoration and can provide comparative information on the behavior of the tooth with different materials for the composite. Thermal analyses of normal teeth and composite restorations while exposed to hot and cold environments (e.g., liquids)^[6] provide insight into the behavior of these physical systems.

Cardiovascular System

The cardiovascular system receives quite a lot of attention from finite element modelers. So many

life-threatening diseases can affect this system that stress analyses and fluid mechanics applications provide insightful information into normal function, function affected by disease, and the efficacy of treatment procedures. Blood flow through various vessels of the cardiovascular system is frequently analyzed. Coronary arteries provide the oxygenated blood to the heart itself and are critical elements in a normal heart. Stenosed coronary arteries can thus present major problems to the patient, the mechanics of which can be visualized with finite element simulations.^[7] Similarly, the aorta is the major conduit for blood leaving the heart to be distributed to the rest of the vascular system. Velocity patterns and shear stress distributions in the vascular wall of the ascending aorta can serve as predictive tools for the clinician.^[8] Some exciting work has been accomplished in modeling the heart itself. The left ventricle, the chamber of the heart responsible for forcing blood into the rest of the vascular system, has received much attention because of its importance. Models that simulate the mechanics of the normal left ventricle and an infarcted (due to heart attack) ventricle are enlightening.^[9-11]

Musculoskeletal System

Articular cartilage

Articular cartilage is the soft, connective tissue that covers the ends of long bones in joints. Its presence allows for smooth, painfree movement of our joints. Articular cartilage is very durable and can remain healthy for the length of one's life. This is in the face of enormous joint forces it is subjected to during activities of daily living. However, arthritis is a major health problem and destroys joint cartilage until severe disability results. FEA has been applied to study this tissue in order to understand various issues that contribute to its longevity and how the mechanics of articular surfaces become altered by the presence of damaged cartilage.^[12,13] To represent the material behavior of articular cartilage better, new mathematical models have been implemented in the study of this tissue, implemented coupled field variable analyses and new material behaviors.^[14,15] Simulations of surgical treatment of deteriorating cartilage have also been performed.^[16]

Bone and bone remodeling

Very exciting applications of FEA examine bone and bone remodeling. All biological tissues have the ability to remodel depending on the input signals they receive. For example, muscles adapt to increased activity (i.e., increased stress), such as weightlifting, by increasing their capacity and size. Muscles also respond to decreased activity (i.e., decreased stress), such as the zero

gravity experienced in space, by decreasing in capacity and size. The same is true with bone. However, bone is one of the few biological tissues whose potential for remodeling has been successfully described by mathematical models, some of which are called strain-adaptive remodeling theories. These remodeling theories have been put into practice with the finite element analysis to show how bone would change its geometry and/or material properties due to changes in applied loads/stresses that the bone experiences.^[17-19] The major effort in applying this combined FEA/bone remodeling theory is toward describing bone behavior around total joint replacements. A total joint implant can survive joint forces for many years, but loosening of the implant is a frequent occurrence, in part due to how the bone remodels around the replacement after implantation because of the changed stress environment experienced by the bone. The combined FEA/bone remodeling theory has the potential to serve as a clinical tool that allows the design engineer and clinician to predict where bone will remodel and how to design the implant, or implantation technique better, to extend the life of the total joint replacement.

CONCLUSION

This article has provided a basis for understanding a finite element analysis. Numerous books have been written with much detail on the technique and can be used for further reference. A small sampling of such books are given in the reference section.^[1-3,20-22] It must be remembered that FEA is an approximate solution technique used to solve a mathematical model. This mathematical model is an idealized representation of the actual physical problem under consideration. One can reap many benefits by knowing the behavior of the physical problem. Finite element results can show how a particular device will perform in its intended application. Inference can be made on whether it will perform adequately or fail. In a straightforward manner, geometry, material properties, boundary conditions, and applied loads can be varied in a finite element analysis to see how such design changes can alter the behavior of the problem. With attention given to the mathematical model and its incorporation into finite element equations, an accurate solution of the physical problem via finite element analysis can be obtained.

Flow Cytometry

J. Paul Robinson

Immunopharmacology and Biomedical Engineering, Purdue University, West Lafayette, Indiana, U.S.A.

INTRODUCTION

Flow cytometry is a technology that has impacted both basic cell biology and clinical medicine in a very significant manner. The essential principle of flow cytometry is that single particles suspended within a stream of liquid are interrogated individually in a very short time as they pass through a light source focused at a very small region. The optical signals generated are mostly spectral bands of light in the visible spectrum, which represent the detection of various chemical or biological components, mostly fluorescence. A key aspect of flow cytometers is that because they can analyze single particles/cells, it is possible to separate particles/cells into populations based upon a statistical difference of any of 10 to 20 variables that can be measured on each particle/cell. Using these statistical analyses, it is possible to separate these populations electronically and identify them using multivariate analysis techniques.

The most common detection system in flow cytometry uses fluorescent molecules that are attached by one means or another to the particle of interest. If the particle is a cell, such as a white blood cell, for example, the fluorescent probe might be membrane bound, cytoplasmic, or attached to nuclear material. It is a common practice to use monoclonal or polyclonal antibodies that recognize specific receptors on cells. By conjugating fluorescent molecules to these antibodies, it is possible to monitor both the location and number of these conjugated antibodies as they bind to cell receptors. Particles of almost any nature can be evaluated by flow cytometry. They can be very small, even below the resolution limits of visible light, because they can be detected by their fluorescent signatures. Similarly, depending on the structure of the flow cell and fluidics, particles as large as several thousand microns can be evaluated.

The key advantage of flow cytometry is that a very large number of particles can be evaluated in a very short time; some systems can run particles at rates approaching 100,000 particles per second while collecting 10 to 20 parameters from each particle. Finally, the principle of cell sorting in flow cytometry allows this technology to separate single particles/cells physically from mixed populations. Thus single particles can be physically placed into a defined location for further analysis and, if necessary, this process can be performed

under sterile conditions. This capability makes flow cytometry a valuable tool for rare event (1:100,000 or even 1:1,000,000) analysis.

In 1983 Shapiro noted that multiparameter flow cytometry was now a reality in the field^[1] because of the availability of commercial instruments. Since that time, the field has expanded well beyond anything that was then considered possible. Today's instruments have the capacity to measure 10–15 spectral bands simultaneously together with a variety of scatter signals. With modern computers it is possible to perform complex multiparametric analyses virtually instantaneously, allowing time to make sorting decisions after measurements are made. The result of this technology is that it is now possible to generate clinical diagnostic information rapidly from complex heterogeneous mixtures of samples such as human blood and to perform this in real time.^[2]

OVERVIEW

Basic Principles

The basic principles of flow cytometry arise from some very old ideas generated early in the 20th century and of course follow the principles of laminar flow defined by Reynolds in the late 19th century. Some 50 years later, Maldavan designed an instrument (although it is not clear that he actually constructed it) that could have identified single cells using a microscope and a photodetector.^[3] In the 1940s Papanicolaou demonstrated that he could identify as cancerous cells from cervical cancer by observing the staining patterns obtained by staining tissues with specifically designed stains.^[4] This suggested several directions of research, primarily using image analysis techniques for the identification of abnormal cells. The limited capability of computers and imaging technology at that time made this quite difficult and resulted in a movement toward single-cell analysis, as opposed to image processing and recognition. It was in the 1960s that Louis Kametsky began the drive to design and build single-cell analyzers. While working at IBM's Watson Labs, Kametsky was interested in using optical character recognition techniques to identify cancer cells. Because of the lack of computation, this became a difficult goal and in place

of image-based technology,^[5] Kamensky focused on single-cell analysis and the design of a cytometer that measured absorption and scatter and shortly thereafter added the ability to sort cells using fluidic switching.^[6] At the same time, Fulwyler was trying to solve a problem generated by the study of red blood cells using a single-cell analysis system. It had become apparent that a bimodal distribution of red blood cells observed using a Coulter volume detector suggested two different types of red blood cells, contrary to accepted medical understanding. Fulwyler had heard of Richard Sweet's development of high-speed chart recorders using electrostatic drop generation.^[7] Fulwyler visited Sweet's laboratory and essentially utilized this technology to design and build a cell sorter to separate red blood cells.^[8] Ironically, upon completion of the instrument, it took only a few hours to recognize that the supposed bimodal distribution was related to spatial orientation rather than to inherent red blood cell variability (Fulwyler, personal communication). Amazingly, this finding of great significance was never published since it was immediately obvious that sorting of white blood cells was an opportunity not to be missed. The history of the development of cell sorting is well covered by Shapiro.^[9]

Fluidic Systems

Reynolds formulated the relationship for fluid flow as $Re = vd\rho/\eta$ where Re is the Reynolds number (a dimensionless number), v the average velocity, d the tube diameter, ρ the fluid density, and η a velocity coefficient. Below a Reynolds number of 2300, flow will be laminar, a necessary factor for quality optical measurements in flow cytometry. Maintenance of nonturbulent flow requires careful design of fluidic systems in flow cytometers, particularly the flow cell components. Cells are hydrodynamically focused in a core stream encased within a sheath (Fig. 1). This sheath-flow principle was derived from the work of Moldavan and subsequently Crosland-Taylor,^[10] who designed a system similar to most used today in which an insertion rod (needle) deposits cells within a flowing stream of sheath fluid (usually water or saline), creating a coaxial flow that moves from a larger to a smaller orifice, creating a parabolic velocity profile with a maximum at the center of the profile. The general design of such a system is shown in Fig. 1. Because of the hydrodynamic focusing effect, cells that are injected through the injection tube remain in the center of the core fluid, thus allowing very accurate excitation with subsequent excellent sensitivity and precision of measurement within the flowing stream. There is a small differential pressure between the sheath and the sample (which is the core); the sample is 1 to 2 PSI above the sheath, forcing alignment

Fig. 1 Shown here is the basic structure of a typical flow cell. Sheath fluid flows through a large area and under pressure is forced into a much smaller orifice. In the center of the cell is an injection tube that injects cells or particles into the center of the flowing stream, forcing the cells to undergo hydrodynamic focusing, which will result in laminar flow if Reynolds number does not exceed 2300. Shown is the coaxial cross section of the sheath and core. B shows an alternative flow cell, an axial flow system typically used in microscope-based flow cytometers. In this system the laminar stream flows across a coverglass to a waste collector on the opposite side.

of cells in single file throughout the core. If the pressure is increased too much, the core diameter will increase, destabilizing the flowing cells and reducing the accuracy and precision of the measurement. If a highly accurate system is required, multiple sheaths can be used to create very stable flow streams, but this is generally not used in commercial systems.

A crucial component of the flow cytometer is the design of the flow cell, in which the fluid flows from a very large area to a very constrained channel. The velocity, which is proportional to the square of the ratio of the larger to smaller diameter, increases significantly within the smaller channel. Within this channel, the velocity profile is parabolic with a maximum at the center of the stream and almost zero at the walls of the vessel. This becomes a crucial issue in flow cytometry when biological specimens are used because these samples contain proteins, and surface binding will eventually increase turbidity and destroy the hydrodynamic nature of the flow. While Reynolds number remains less than 2300, laminar flow occurs. The acceleration at the core of the vessel is an important aspect of flow cytometers. Since particles are injected into the

center of the flowing stream, the highly accelerated central core creates spatial separation of particles within this rather long core stream. This separation creates the ability to analyze the signals from single cells more accurately. Once particles are accurately identified and are spatially separated within the core, it is possible to separate them physically in a process known as particle sorting (discussed later). An alternative system to the one described earlier uses axial flow where cells are shot onto the surface of a microscope objective with a regular nozzle to obtain laminar flow, flow across the objective in a laminar flow, and are extracted from the system on the other side of the objective. This is shown in Fig. 1B and is similar to systems designed by Harald Steen and others. There are several advantages of this system, such as high numerical aperture microscope objectives providing excellent resolution and signal to noise, and the ability to use a regular arc lamp for the light source. This system has extraordinary sensitivity for forward scatter and is the most sensitive system available. It was initially designed to be optimized for very small particles such as microorganisms.

Optical Systems

Most flow cytometers use lasers as excitation sources. In the earliest systems, mercury lamps were used; however, in the late 1960s relatively large water-cooled ion lasers were identified as the most desirable source of coherent light at 488 nm, the best excitation wavelength for fluorescein. These high-cost, large, and inefficient light sources shaped the design of the instruments themselves, making them enormous constructs often

taking 60 to 80 sq. feet of floor space and requiring high volume cooling water and high current levels. More recently, however, with the advent of solid-state lasers, the footprint of flow cytometers has been significantly reduced. Further, in the mid-1980s, there was an emerging market for flow cytometers that did not sort. These instruments were known as analyzers and are now commonly referred to as benchtop instruments. This is somewhat of a misnomer, as the third generation of sorters is almost indistinguishable from the benchtop analyzers of the past.

As already indicated, the key to the efficiency and sensitivity of current flow cytometers is the laser-based coherent light source. The chief criterion for selection of a laser is the excitation wavelength. The beam should be segmented in a transverse emission mode (TEM) of TEM 00, although in some circumstances a mixed TEM 00 and TEM 01 mode does not preclude the usefulness of such a beam mode (Fig. 2A). The excitation source must match the absorption spectra of the fluorochromes of interest. One reason that early systems used large water-cooled argon-ion lasers was that multiple lines could be obtained from these lasers. The argon laser was selected, as it was the only coherent source of excitation satisfactory for the most used fluorochrome in the field—fluorescein. The argon-ion laser could produce lines in the UV (350 nm), deep blue (457 nm), blue (488 nm), and blue-green (514 nm) regions, making this a very useful light source. The light source needs to be focused to a spot and a desired shape. This is accomplished by using a beam-shaping optic to obtain the desired crossed-cylindrical beam shape. For reasons explained in Fig. 2, the most desirable beam shape is an elliptical beam of

Fig. 2 As cells pass through the interrogation point, they create a pulse that can be characterized as shown above. At the point of entry into the laser beam, the pulse rises to a peak and holds for as long as the cell is in the stream. Once the cell begins to leave the laser beam profile, the signal returns to zero. The maximum signal is the peak, and the time taken for entry and exit of the beam is the time of flight (TOF). It is common to measure the total area under the curve (integral signal) for total fluorescence. Shown in B are the beam profiles most commonly used in flow cytometry. Most desirable is TEM 00; however, it is possible to mix the TEM 00 and the TEM 01 modes. In C are shown the definitions of each component of the signal from a cell passing through an elliptical beam.

approximately 15 by 60 microns. This produces a beam with a large, relatively flat cross-section that reduces the variation in intensity of the excitation spot should the particle move around within the excitation area. Reducing the beam even further would have the effect of slit-scanning the traveling particle.

Electronic Systems

Flow cytometers collect a lot of data very quickly. In fact, they are in a class of instruments that push the limits of data collection. For example, it is currently possible to collect at least 11 fluorescent spectral bands simultaneously together with at least two scatter signals on thousands of cells per second, creating a multivariate analysis problem.^[11] The key principle of flow cytometry is that every particle is identified individually and classified into a category or population member according to multivariate analysis solutions. Every particle that passes the interrogation point would be collected on every detector, which would cause a serious overload collection problem. To solve this, a circuit is included called a discriminator, which can be set to exclude signals lower than a preset voltage (Fig. 2C). On many current instruments it is possible to use discriminators on any or all detectors. That is to say, multiple detectors must register a preset signal level or nothing is collected by the data collection system. Once a discriminator setting is satisfied, this detector triggers the entire data collection system and all identified detectors will measure the signal. Frequently, for particles of bacteria to most animal cell size (1–20 microns), a forward-angle light-scatter signal is used to discriminate the presence of a measurable particle. However, it is also useful to use a fluorescence detector if one wishes to detect only particles of a certain level of fluorescence.

The most frequently recognizable detection system in flow cytometers is that of fluorescence. The initial detection system used in the earliest instruments was Coulter volume, based on the original patent of Wallace Coulter,^[12] whereby the principle of impedance changes was transferred from cell-counting instruments to flow cytometers. In addition to impedance, light scatter was also measured. Current systems have taken a rather complex pathway for the measurement of fluorescence.

Linear amplifiers produce signals that are proportional to their inputs, and while it is possible to amplify this signal, most immunofluorescence applications have huge dynamic ranges that are beyond amplification in the linear domain. For this reason, logarithmic amplifiers with scales covering three to five decades are required. This is particularly useful for samples in which some cells exhibit very small amounts of signal, while others have signals four orders of magnitude larger.

Detectors

It has become standard design to utilize a PMT for each spectral wavelength desired. In most pre-1990 instruments, a maximum of four or five spectral bands was collected. However, beginning in the last decade of the 20th century, it became evident that 5–10 spectral signatures were desirable. Each spectral band is collected by a PMT strategically placed within an optical system of which there are many current designs. Figure 4 shows several different optical layouts currently used in commercial systems. It is now evident that the biological requirements are in the range of 10–15 spectral bands. Next-generation systems will include either a vast number of PMTs, avalanche photodiodes, or multichannel PMTs, in addition to high-speed cameras. The disadvantages of the multichannel PMT is that detection sensitivity is reduced and it is not currently possible to adjust the sensitivity of each channel as can be achieved with individual PMTs. The advantage is that the complexity and number of optical components are reduced.

Most cytometers use photomultiplier tubes (PMTs) as detectors for both fluorescence and scatter. The pulse of a particle crossing the excitation beam will depend upon the beam shape, beam intensity, and particle size, as well as the velocity of the particle. Systems running at 10 m/s will cross a 10-micron beam in 1 microsecond, or a 5-micron beam in only 500 ns. The majority of instruments prior to publication of this article were designed around analog detection, rather than digital electronics. Essentially, once the threshold voltage is met (based on the discriminator circuit described earlier) the signal (usually 0–10 volts) is fed into an analog-to-digital converter (ADC) circuit, called a comparator circuit, whose purpose is to identify and signal the presence of a measurable signal that is used to trigger the rest of the detection systems. This is a binary decision only. Once a decision to collect is made, several measurements for each variable are made, such as peak, integral, and time-of-flight. There are several complications that can cause problems in the detection electronics. For example, if two particles pass the interrogation point at very close intervals, both signals must be aborted if this time is shorter than the reset time for the electronics. Another circuit is required to make this decision.

To further complicate the electronics, many systems use two or more laser beams delayed by a few microseconds. Each particle must be correctly analyzed by each laser, so data from the first beam must be stored while waiting for the same particle to pass the second beam, and so on. If the beam separation is large enough, several cells might be analyzed by the first beam before the first cell passes the second beam. This rather complex system is not necessary on simpler analysis systems, but it is absolutely necessary on more advanced

multilaser cell sorters. In addition, the time taken for all the analysis components is finite, which essentially sets the maximum analysis rate of the flow cytometer. The faster the system, the shorter the dead time must be. For example, to analyze 100,000 cells per second, a dead time of less than 10 microseconds would be necessary. In fact, depending on how many events must actually be analyzed to have 100,000 cells per second, the dead time would need to be considerably shorter.

Spectral Compensation

When a particle or cell contains fluorophores of multiple spectral bands, the identification and analysis become considerably more complex. For example, a detector with a band pass filter designed to collect fluorescence from FITC (525 nm) and another detector designed to collect signals at 550 nm (PE) will register photons in both detectors. It is impossible to determine which detector is detecting the real photons from FITC. This is not a problem if a single fluorophore is being collected, but when two or more fluorophores with close emission bands are present, it is necessary to identify which fluorophore was the real emitter of the photons. To achieve this, it is necessary to perform spectral compensation whereby a percentage of signal from one detector is subtracted from the other. As the number of fluorophores increases, so too does the complexity of the spectral compensation. A complex set of circuits must be designed that allows for a percentage of each signal to be subtracted from every other detector. Naturally, there are some instances where there is no overlap, but with six or seven detectors competing for signals from the narrow spectral emission range available from a single excitation source, it is absolutely necessary to compensate for spectral overlap. While this can be performed perfectly well in software off-line,^[13] if the goal of the analysis is to sort a certain population of cells physically, the compensation must be performed in real time between the time the cell passes the excitation beam and when the cell reaches the last time available for a sort or abort decision to be made. Compensation in flow cytometry is very complex and requires a large number of controls to establish appropriate compensations setting and photomultiplier voltages. As fluorescent dyes increase in number and spectral proximity, the need for complex spectral compensation circuitry also increases. This is far more complex than anything currently available in image analysis systems.

Cell Sorting

The principle of cell sorting was included in instruments designed by Fulwyler,^[8] Kamensky,^[6] and also

Dittrich^[14] in order to analyze a cell of interest definitively. It was Fulwyler, however, who identified the technique developed by Richard Sweet^[7] for electrostatic droplet separation for use in high-speed inkjet printers as the ideal technology for cell sorting. This evolved into the technique of choice for virtually all commercial cell sorters. This is shown in Fig. 2 and also Fig. 3. This idea was implemented into a commercial system by Herzenberg's group^[15] in the early 1970s. As already noted, the initial reason for Fulwyler's implementation was the desire to separate what were apparently two distinct populations of red blood cells that appeared on analysis based on Coulter volume measurements. The principle of electrostatic sorting is based on the ability to first identify a cell of interest based on measured signals, identify its physical position with a high degree of accuracy, place a charge on the stream at exactly the right time, and then physically collect the sorted cell into a vessel.

The technology of high-speed sorting has been recently well defined by van den Engh,^[16] who discusses in detail the complex issues. In brief, the speed and accuracy of a cell sorter are based on a number of factors. Firstly, despite the initial discussion pointing out that a fully stable laminar flow is required for accurate analysis, for cell sorting the stream must be vibrated by a piezoelectric device to generate droplets. As described by van den Engh, it is necessary to have high-speed electronics and to match the nozzle diameter, sheath pressure, and droplet generation frequency to obtain stable droplet generation and thus high-speed cell sorting. The principle that governs the generation of droplets has been characterized by Kachel;^[17] the wavelength of the undulations is $\lambda = v/f$, where λ = the undulation wavelength, v = the stream velocity, and f = the modulation frequency.

When $\lambda = 4.5d$ (d = exit orifice = stream diameter), the system is optimized for maximum droplet generation. Thus, the optimal generation frequency is given by $f = v/4.5d$. If a system is designed to accommodate this optimal droplet formation, as demonstrated by Pinkel,^[18] the jet velocity is proportional to the square root of the jet pressure. Thus, an optimal system to sort events at 20,000 Hz such that drops are separated by 4.5 stream diameters and flowing at 10 ms would make each drop 200 microns apart. As the number of sorted drops increases, the diameter must decrease, with the obvious conclusion that the speed of high-speed sorters will eventually be partially regulated by the size of the particle to be sorted and the velocity that the stream can achieve without destroying the sample. This is particularly important for biological particles such as cells.

High-speed sorters are essentially sorters that are designed to operate at sort speeds in excess of 20,000 particles per second. To accomplish this, higher pressures must be placed on the sample stream. When

Fig. 3 This figure shows the principle of electrostatic cell sorting based on Sweet's inkjet printer technology. In this figure, a stream of liquid intersects a laser beam (or multiple laser beams 1, 2, 3). The stream is vibrated by a piezo-electric crystal oscillator at frequencies from 10,000 to 300,000 Hz depending upon the orifice size, stream velocity, nature of the stream, and particle size. Typically 30–50,000 Hz is used to create droplets at the same frequency. Once a cell/particle is identified as desirable, a charge is placed on the stream that remains with the last drop (last attached drop) that leaves the stream. Using a computation method, this drop is sorted by being attracted toward a plate almost parallel with the stream and containing opposite charges in the vicinity of 5000 volts. Each droplet containing a desirable particle can be placed into one of several containers (shown is a four-way sorting system). In the center of the figure is a video image of the droplets strobed at the same frequency as the droplet formation. A shows the pulses of 3 different lasers as a particle passes by each beam separated in space. Thus, a particle will pulse from each laser a few microseconds apart. This way, signals from each laser can be individually analyzed. B is an alternative sorting system using fluid switching techniques. In this system the waste stream is blocked momentarily to allow a desired cell to pass into the sorting pathway.

systems exceed 40,000 cells per second, the key issue becomes analysis time—obviously the limiting factor since complex analysis must precede a sorting decision. The maximum speed of droplet formation is therefore not the limiting factor in design of a high-speed flow cytometer. As discussed in van den Engh,^[16] the primary issue is the high pressures that must be used to create very high-speed droplet formation. At droplet frequencies of 250,000/second, the jet pressure must approach 500 PSI, a significantly higher value than can be designed safely in most systems. Thus, if pressures are limited to around 100 PSI, a droplet rate of around 100,000 is closer to the realistic range. This then is the real limitation to current high-speed sorting systems.

Poisson statistics enter the equation at this time as well since it is impossible to predict exactly when any particle is going to pass the interrogation point. This adds uncertainty in the analysis and, as discussed

previously, it is crucial to ensure that no measurements take place as two cells try to pass through the interrogation point at or near the same time. Thus there is a relationship between particle concentration and coincidence detection.

Cell sorting has become a very important component of flow cytometry. In particular, the isolation of CD34 human hematopoietic stem cells by flow sorting specifically for transplantation purposes has revolutionized capabilities in transplantation.^[19] Naturally, to perform such a sort, all components of the instrument that come in contact with the cells must be sterile.

Another issue that relates to sorting is the potential dangers involved in sorting certain samples, particularly human samples that may be infected with AIDS, or more commonly, hepatitis virus. This is an area that can cause considerable tension between operators and researchers wanting to sort materials from infected

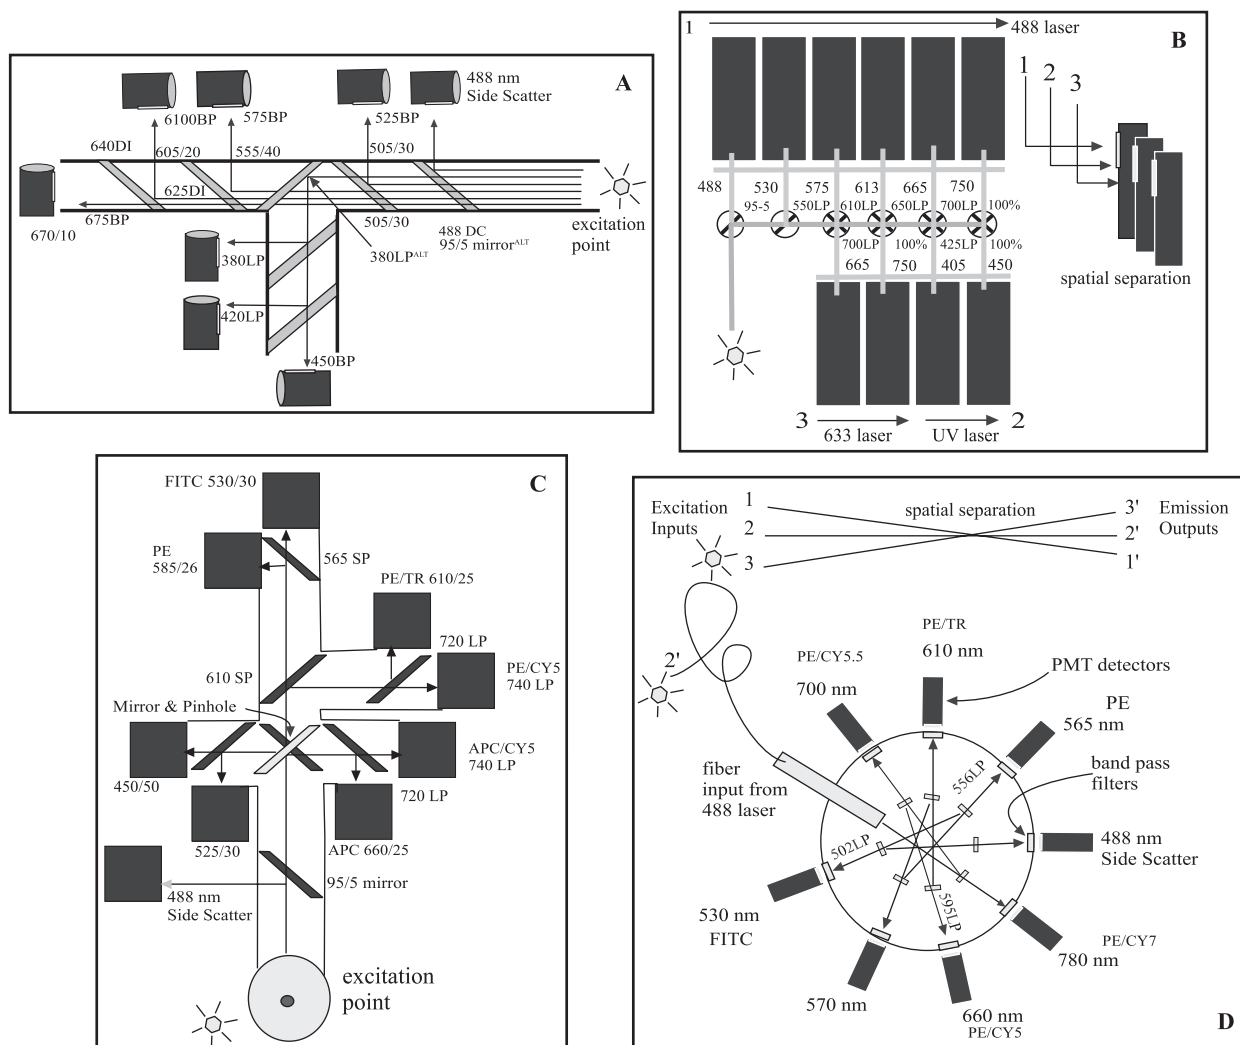

Fig. 4 A–D represent the optical tables of several commercial flow cytometers. A: Beckman-Coulter ALTRA showing the position of 8 PMTs; B shows the Dako-Cytomation CYAN instrument, which has 10 detectors placed in such a way that there are three beams with slightly different trajectories; C shows the Becton-Dickinson Vantage system in a typical configuration showing nine detectors; D is the more recent Becton-Dickinson ARIA system using an innovative PMT array with eight PMTs in a ring, which allows the emission signal to bounce around the ring. There are an additional six detectors on this system (not shown) that come from the first and third lasers (see diagram). In all cases A–D above, each PMT has a narrow bandpass filter immediately in front of the PMT in addition to the dichroic mirrors that are used to direct the various emission spectra.

patients. Because aerosols are generated in the normal operation of a flow cytometer, complex biosafety systems must be employed to reduce the potential of infection. There is a significant literature on the dangers posed by both microbes and carcinogenic molecules such as fluorescent dyes that are used to label many cells.^[20]

APPLICATIONS

Clinical Sciences

One of the largest applications of flow cytometry is in the clinical sciences, where the primary measurements

are of fluorochrome-conjugated antibodies bound to cellular receptors. This is generally referred to as immunophenotyping since many of the cell types being studied are immune cells such as lymphocytes. In fact, almost every possible human cell has been evaluated by flow cytometry. By far the most significant cell populations are peripheral blood cells such as red blood cells (RBC), white blood cells (lymphocytes, monocytes, and polymorphonuclear leukocytes), and platelets. Each of these populations presents some specific challenge in assay performance, but overall these cells are very amenable to flow analysis. A complex system of receptor identification has been developed within immunology to identify cellular receptors, which are referred to as Cluster of Differentiation (CD) antigens of which at

the time of writing there were 166 such classifications. These are based on similarity of antibody binding to specific receptors. Therefore, by conjugating fluorescent molecules to antibodies that recognize specific receptors, a population of cells binding that antibody and therefore that fluorescent molecule can be identified. With certain clinical syndromes, it is evident that a specific pattern will emerge when identifying which cells bind to certain antibodies. One of the most significant findings in the early 1980s was that the identification of certain subsets of human T cells was important for the monitoring of the clinical status of AIDS patients^[21]

(Fig. 5A and B). This significantly increased the utility of flow cytometry and drove the need for simple-to-operate, reliable clinical benchtop analyzers for basic two- and three-color immunofluorescence. These instruments now represent the great majority of flow cytometers in the field.

Cell biology

Some of the earliest studies of cell function investigated neutrophil function by measuring phagocytosis of microorganisms.^[22] This is an excellent example of the

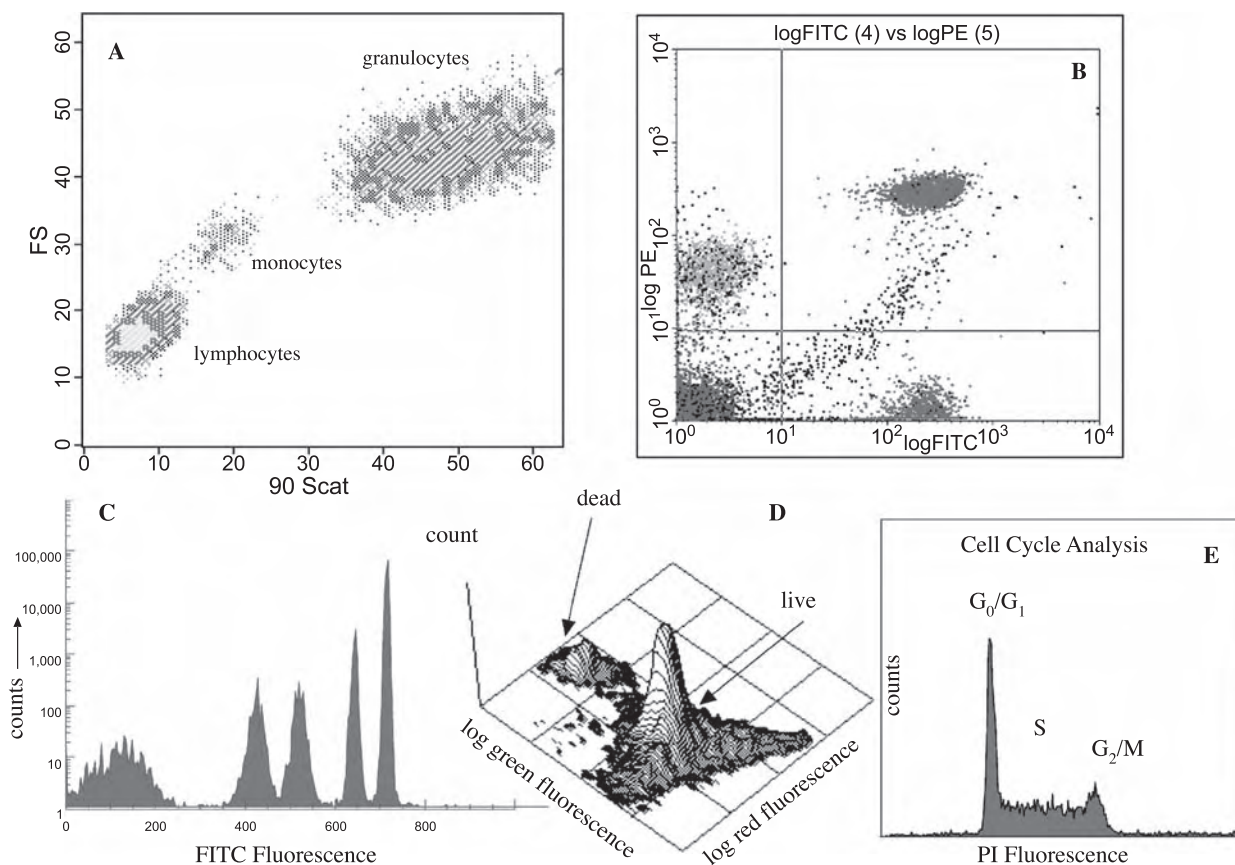

Fig. 5 A. When a cell passes through a laser beam, it scatters light. That light is measured on a detector and the resulting signal can provide information about the cells. Forward angle scatter (FS) is a measure of cell size. Side scatter (90° scat) is a measure of cellular components or granularity. In this dotplot of forward-versus-side scatter, human white blood cells can be differentiated without any other probes. Here is shown the separation of lymphocytes, monocytes, and granulocytes.

B. Gating strategies allow identification of populations of cells such as lymphocytes, shown in (A), the fluorescence emission of conjugated antibodies can be further separated to divide the lymphocytes into four distinct populations. In two-parameter space, the populations can easily be divided into four populations: those cells that are double negative, double positive, and single positive for each color. C. Calibration beads with fluorescent molecules attached to their surface are used to create quantitative measures for flow cytometry. This histogram has five peaks, the lowest peak being negative cells and the other four peaks represent four levels of fluorescence. From this histogram a standard curve can be obtained for quantitation of particles being labeled with this probe. D. This isometric display shows a plot of bacteria as observed by flow cytometry.

Pseudomonas aeruginosa is broth treated with 10× MIC of the antibiotic Imipenem for two hours and stained with BacLight Live/Dead kit. The log green fluorescence is Syto 9 and the log red fluorescence is PI. Positive PI fluorescence represents damage to the cell membrane, an indication of cell death. E. Propidium Iodide (PI) can also be used to study the cell cycle. In this case, the membrane is slightly damaged to allow penetration of the dye. PI binds to DNA in a stoichiometric manner such that there is a direct relationship between DNA content and PI fluorescence.

value of flow cytometry, which can identify individual cells by their size, structure, or specific identifiers such as cell receptors, and simultaneously measure the nature and number of microorganisms that were internalized via the process of phagocytosis. There are many applications of flow cytometry used for studying unique properties of cells that cannot easily be studied with any other technology. For example, real-time, single-cell production of oxygen radicals is frequently evaluated by using flow cytometry. There are a number of well accepted techniques from the earliest studies^[23,24] to more recent ones whereby both cells and organelles have been studied by flow cytometry.^[25,26] A huge number of applications exist in the field of DNA ploidy research (Fig. 5E). The ability to identify the rate of cell division and to monitor the effect of various therapeutic drugs is of great interest. Studies of the cell cycle by flow cytometry have provided a great deal of information on the nature of cell division and more recently apoptosis.^[27–29]

Microbiology

The study of microbes and their behavior is ideally suited to flow cytometry,^[30] however, there is an apparent disconnect between the capability of flow cytometry to answer microbial-related questions and its use in the field. Early studies quickly focused on the possibilities of developing flow-based assays for such time-consuming assays in the clinical environment as antibiotic resistance. With the growth of resistant organisms, determination of antibiotic resistance would be a desirable measure, but one that is rarely if ever performed outside the hospital environment. Even in the medical microbiology laboratory, it is still considered uneconomic, despite the clear demonstration that both organism identification and antibiotic sensitivity can be determined within a couple of hours. Unfortunately, the current cost far exceeds the pennies-per-test conditions set by current medical practices. This is definitely one of the potentials for microbiology-specific instruments that should markedly reduce testing costs for such applications (Fig. 5D).

Many studies of microbial kinetics have been performed using flow cytometry, including growth curves, reproduction studies, and metabolic requirements. In addition, exciting new studies are beginning to demonstrate new opportunities of flow cytometry together with advanced imaging tools for studying growth of microorganisms in complex 3-D environments such as biofilms.^[31]

Plant and Animal Science

Although a great majority of flow cytometry is related to human and laboratory animal systems, there are

some excellent examples of studies of plant systems. For example, it was recognized very early in the use of flow cytometry that cell cycle could be easily analyzed by flow cytometry,^[32] and this stimulated a number of cytometry-related plant-based studies.^[33] Pollen, for example, is perfectly suited to flow cytometry, as are plant chromosomes, even though they are somewhat more difficult to extract. A number of flow sorting experiments performed on plant systems to identify gene expression from transgenic tobacco plants^[34] demonstrated the efficacy of using this technology.

Pharmaceuticals

One of the more recent applications of flow cytometry is high-throughput screening. While there are many technologies that have far greater sample throughput, flow cytometry is one of the few technologies that can identify and analyze individual cells in multiple parameters. Recently, the concept of high-throughput cytometry was introduced, and initial reports suggest the possibility of achieving as many as 100,000 samples per day,^[35] something that approaches the needs of pharmaceutical manufacturers. The clear advantage of flow cytometry over other technologies, such as imaging cell-culture plates, is that with flow cytometry, a large number of parameters can be analyzed on each and every cell. The disadvantage is that flow cytometry, even with high-speed systems, is very much slower than automated image-processing systems.

Reproductive Medicine

Sperm analysis has proved the value of flow cytometry and especially the cell sorting capacity. There are several approaches to analysis of sperm. One utilizes the ability of DNA dyes such as Hoechst 33342 to bind to sperm DNA without inflicting damage,^[36] another uses antibodies to the H-Y antigen.^[37] The ability of flow cytometry to sort human sperm for sex selection raises a number of ethical questions. It is clearly well within the means of this technology to sex-select human sperm; although to date there are no published reports of this having been done, the topic is heavily discussed.^[38]

Calibration Issues

Because flow cytometry is defined as a quantitative technology, it is important to have calibration standards. These were primarily developed by Schwartz^[39] and others to allow reproducibility of clinical assays. Schwartz developed the concept of Molecule Equivalents of Soluble Fluorescein (MESF units). Using a mixture of beads with known numbers of fluorescent

molecules, it is possible to create a standard curve based on a least-squares regression based on the median fluorescence intensity of each bead population. This value is then converted into MESFs (Fig. 5C) from which comparisons can be made from different instruments or the same instrument on different days. Future instruments will most likely provide data in units such as MESFs rather than “arbitrary fluorescence values,” as are frequently observed in present-day publications. It would seem highly desirable to provide more quantitative data for comparison purposes.

CONCLUSIONS

The technology of flow cytometry has made a significant impact on many fields. There are few technologies that can evaluate so many parameters on such small samples in such short time periods. The principle of evaluating each and every cell or particle that passes through the laser beam and then producing a highly correlated data set is unique to flow cytometry. The combination with multivariate analysis and subsequent ability to separate cells physically by the process of cell sorting gives this technology some unique characteristics. It has been almost 40 years since flow cytometry first demonstrated its importance in medical research. Since that time, well over 60,000 publications have highlighted its usefulness. It was identified as one of the most important technologies in the early 1980s upon the recognition of AIDS. The ability of flow cytometry to identify and quantify the T cell population subsets CD4 and CD8 lymphocytes identified it as a most important technology in the diagnosis and monitoring of AIDS patients. Similarly, the ability of flow cytometry to make complex multivariate analyses of bone marrow to identify the CD34+ cells and subsequently sort and purify them has been a vital resource in transplantation immunology.

Foreign Body Response

John Hunt

UKBioTEC, U.K. Centre for Tissue Engineering, Clinical Engineering, University of Liverpool, Liverpool, United Kingdom

INTRODUCTION

The term foreign body response presents itself as a simple nontechnical phrase that belies its complexity, interactions, and possibly dependence with other host responses. In terms of materials and implanted materials, the search for definitions can be limited to the organism being mammalian and the foreign material being that which has been introduced by deliberate intervention into or onto the body to address an improvement in the quality of life for the host. In this context, *The Williams Dictionary of Biomaterials* defines the foreign body response as the “Overall response of a host to the presence of a foreign body.” This is necessarily substantiated with notes that develop this: “The foreign body reaction is neither a single event nor a simple process but a broad concept and multifactorial phenomenon.”^[1] The supplementary note provides a significant insight towards the breadth and depth of the foreign body response.

The foreign body response without a body could be described as inflammation and wound healing. The components and factors involved have the potential to interact, stimulate, and act in synergy, in parallel, or as positive and negative feedbacks. It is often unclear when implantation is significantly invasive (involving a full-thickness incision wound of the skin) at what point the host response becomes the foreign body response and should be attributed to the implant, or the response is in actual fact a result of the surgical procedure itself. This dilemma highlights the overlap and involvement of the same systems and components from the host. This is compounded by the dual effect the combination of surgery and the application of a material can have on the overall host response.

The foreign body response is the human body's first line of defense against invasion and can be short or long term (minutes to years). The invading object is termed a foreign body originating from outside of the host. This can include many temporary invasions, for example, dust particulates in the lung that stimulate the involuntary reflexes of coughing or the peristaltic motion and wavelike movements from the cilia of the epithelium that line the bronchioles of the respiratory tract when moving inhaled particulates out of the lung and air passages into the trachea for removal by swallowing,

coughing, or in saliva. These reflexes do have some significance for the introduction and application of some materials and these examples would particularly relate to asthma treatments, inhaled materials, and further-to-fast delivery vectors for pharmaceutical agents.

The most commonly encountered foreign body response in material terms relates to the invasion of tissues by implanted foreign materials and the host's methods for dealing with these. In basic evolutionary terms, this involves both innate (nonspecific) immunity and adaptive (specific or acquired) immunity mechanisms of increasing complexities to combat micro-organism invasion, infection, and wounding. A good example to relate the principles of the foreign body response first hand would be to consider a body's response to a splinter (macroscopic fragment of material).

From the evolution of our species, many of the mechanisms involved in our defense can be related to our animal needs and the fight-or-flight, life-or-death scenario of our ancestors. Fundamentally as animals, if we become ill or injured, the body's first priority is to enable us to maintain mobility to escape danger and then to recover quickly to acquire food. As a complex high society far removed from our animal origins, we are unsatisfied with some of the potential longer term outcomes of these impressive rapid repairs. They leave scar tissue (skin and soft tissue) and possibly misshaped bone (skeletal); a serious consequence of these two end stages is that they can result in the body being susceptible to further injury or with a shortened life expectancy due to long-term stresses induced on the body because of vigorous unguided healing. Modern medicine in most circumstances avoids these extremes and they generally rarely become a life expectancy issue. In material terms, prior treatment including good operating room preparation can in most circumstances stabilize the host, and the material can be deployed in safe, sterile conditions. Nevertheless, these points remain functional issues for both device and host.^[2]

WHAT IS INVOLVED IN THE FOREIGN BODY RESPONSE?

The foreign body response can involve and encompass many details from host responses that can be included

in other terms: blood-contacting devices, thrombus formation, and complement activation,^[3] stimulation of inflammation,^[4] recruitment of cells from blood,^[5] and the release of protein signaling factors that act both locally and systemically.^[6,7] A foreign body response to a material can equally include first instance (seconds) effects such as protein adsorption^[8] or much later effects, up to years after implantation, such as chronic granuloma.^[9] Each of the individual host response components affect the outcome and performance in material terms, and the potential of many factors as single events has been and continues to be researched and documented in increasing detail.^[10]

The foreign body response as a route to respond to a breach of the skin-tissue barrier, which is the host's front line of defense, is a good specific area in which to develop and discuss many of the significant aspects of the host's foreign body response. As the skin is breached, there is an immediate response, a fantastic and complex sequence of events are triggered to combat the inevitable loss of blood from the system. This is non-specific and acts effectively as a quick sealant system despite the complexity of the sequence of events. Platelets are activated and aggregate at the site of injury, forming a temporary platelet plug. Fibrinogen stimulates the platelets to clump and the platelets change shape to a flattened disclike morphology. A fibrin mesh forms by the activation of fibrinogen by thrombin to trap the platelets. There are two potential pathways which lead to the formation of a fibrin clot: the intrinsic (in the absence of tissue injury) and extrinsic (in response to tissue injury) pathways.^[11,12] The formation of a thrombus also effectively reduces the rate of invasion by microorganisms by limiting the free access to what many organisms find ideal material to live in and on.^[13]

The foreign body response in its first phases utilizes the host's innate defense mechanisms that have evolved to deal with the invasion of microorganisms and are triggered by changes in the hemostasis. The complement system comprises a set of proteins circulating in the serum of blood called the complement proteins. These exist in a stable (albeit fragile) inactivated state in normal circulating blood; they are very sensitive to change. Once activated, the complement system fires in a cascade in which one component activates the next, taking only minutes to coat materials or microorganisms.^[14] The binding of C3b (an activated component of complement) or IgG (immunoglobulin G) to the surface of a foreign bacteria or material labels the particle as nonhost and targets it for attack by phagocytic cells.^[15,16] The phagocytes form the next waves of the foreign body response and these are also termed inflammatory responses in other contexts.^[17] Escaping from the blood into tissue when the capillaries are damaged, inflammatory cells can have

autocrine and paracrine effects, activating themselves and also stimulating the recruitment from undamaged blood vessels with increased vascular permeability of further phagocytic cells and stimulating the release of factors from resident tissue mast cells.^[18] A significant role of the cells is to phagocytose (cell eat) material labeled as foreign or to phagocytose damaged cellular material. This response appears to be potentially quite specific and can be related to opsonization, but it has equally been shown that this response is nonspecific: Once these cells are activated, they will try to phagocytose most things in the area, as there is an abundance of IgG^[19] and activated complement.

Opsonization is the process of coating microorganisms with plasma proteins to increase their visibility as target molecules and to enhance the adhesion of phagocytic cells in preparation for phagocytosis. There are two main opsonins: IgG antibodies and C3b, which bind to the surfaces of microorganisms. Phagocytic cells have membrane receptors for IgG (Fc piece) and C3b. IgG antibody binds to microorganisms because the Fab portion recognizes bacterial epitopes. C3b binds because during activation of C3 a thiol bond is exposed that permits the formation of ester or amide bonds (covalent binding) with the bacterial surface structures.^[20]

Neutrophils and monocytes/macrophages are the two most important blood-derived phagocytic cells. Neutrophils and monocytes circulate in the blood and migrate into the tissues at the postcapillary venule through the process of diapedesis (monocytes are the immature circulating form of the macrophage cell). Initially they adhere to endothelium and then migrate through intercellular junctions. In the tissues, cells migrate toward foreign materials by chemotaxis, which is defined as directed movement along a concentration gradient of a chemical agent (for example, interleukin 8, IL-8). Phagocytes recognize their targets by specific sugar residues (e.g., mannose or Lipopolysaccharides), but binding is greatly enhanced if the organism is opsonized with IgG and or C3b. Phagocytes possess Fc and C3b receptors and there is cooperation between these receptors.^[21] A material or organism opsonized with IgG and C3b is more effectively phagocytosed.^[22-24]

PHAGOCYTOSIS OF MATERIAL

In the early phase, material is phagocytosed by large numbers of neutrophils, which are found in high numbers in normal circulating blood—in fact, they are the most abundant cells and get trapped in the coagulation response, and are also the fastest migrating cells—so they can move into an area from the cardiovascular system quickly. These nonproliferative cells are on a suicide mission to phagocytose bacteria; once engulfed, the phagocytic vacuole is fused with

lysosomal vacuoles in the cytoplasm. Lysosomal vacuoles contain many destructive and degradative agents. Lysozyme is an enzyme that specifically breaks down the cell wall of Gram-negative bacteria, effectively lysing the cell. These vacuoles also contain collagenase, neutral proteases, acid hydrolyses, and proteolytic enzymes, in fact: a good range of aggressive agents to attack bacteria cell membranes. These agents are nonspecific and the cell controls their action only by localization while the agents are contained within vacuoles inside the cell cytoplasm. If released into the extracellular fluid, these mechanisms can have significant implications for the host tissue. These cells also have the capacity to produce oxygen free radicals (electron-rich molecules) to compromise biological membranes by introducing free highly unstable and therefore reactive species into an area.^[25] These oxygen radicals are nonspecific and can react with the host tissue causing cell death and localized tissue damage, the evolutionary idea being to clear an area of invading microorganisms and infected tissue completely before they reproduce into a significant population. This free radical production and release also has much further reaching implications and can lead to accelerated degradation of implanted materials, or actually presents a means by which previously considered biostable materials can be demonstrated to degrade. So significant is this potential that ISO 10993 testing standards require materials to be tested for degradation in free-radical-rich solutions to evaluate this parameter.

After neutrophils have performed their phagocytic function, they themselves die and become debris that requires clearing from tissue. This leads on to the recruitment of a second slower moving phagocytic cell called the macrophage and this is the first cell that has been historically associated with a foreign body response.^[26] This cell can be long-lived in tissue, which is important only because a small percentage (<5%) have the potential to proliferate. The macrophage can exert significant effects in tissues by triggering many further responses.^[27] Equipped with the same innate mechanisms as neutrophils to phagocytose and release free radicals as well as degradative enzymes, these cells also come with the ability to present antigen to other cells and can be called antigen-presenting cells (APC) and be involved in the specific immune response to infection or invasion.

In an inflammatory context a sustained macrophage response is typical of a chronic inflammatory response and many implanted materials can and do endure a chronic inflammatory response for the duration of their implanted working life. In terms of a foreign body response, this sustained macrophage response to an implanted material forms the end-point foreign body response. This is the stage in the host response where for many scientists the foreign body response

begins,^[28] and this can be specifically attributed to the accumulation and persistence of macrophages in an area and their development into multinucleated giant cells. The multinucleated giant cell, or foreign body giant cell (FBGC) as it is also called, has been the subject of much research and debate and still remains poorly understood, perhaps due to its susceptibility to spontaneous lysis when compromised and further activated; these cells have been observed and been found to be absent in almost identical situations and experiments. The research debate about how these cells form and why they form also continues. There is good evidence and theory that foreign body giant cells exist in the context of the following explanation of their origins, and this term FBGC can perhaps be accepted: The macrophage like the neutrophil, when in contact with an unrecognized material or a material labeled as foreign by opsonization, will attempt to phagocytose the material. In the case of individual bacteria, this is easily possible but becomes more of a challenge for clustered populations and even more of a challenge in the context of the scale of many implanted prosthesis. Phagocytic cells actually perform the process of phagocytosis of a foreign material by enveloping it and forming a vacuole around it, which is derived from the cell's own plasma membrane and could be called invagination. The cell extends cytoplasmic extensions around the particle called pseudopodia and/or lamellapodia; these extend around the particle, remaining in contact with it as they develop. At some point, the cell hopes to meet itself around the other side and once again fuse its plasma membrane and complete the sphere that becomes an internalized vacuole that contains the material. The whole process is very similar to the way the single-celled eukaryotic animal the amoeba acquires its nutrients. Clearly, a single cell cannot stretch itself infinitely and there is a point at which it cannot increase in area any further. The macrophage and the neutrophil respond by attempting to achieve this process but if unsuccessful (frustrated phagocytosis), they will release their vacuole contents extracellularly and hopefully onto the surface of the target substance or material; attack then proceeds on the substance outside of the cell. This has critical implications for the cell and the surrounding host tissue. Many of the host defense mechanisms have the ability to affect living tissue and will attack the surrounding cells and matrix, breaking this up also and creating more debris.^[29] There is evidence that when macrophages contact materials, they can attach and form a sealed interface with the material and actually create an enclosed environment underneath themselves in which to release their vacuoles. This can be compared to the mechanism by which osteoclasts attach to the surface of bone and resorb it. In this case, macrophages will attempt impressive aggressive extremes and

can reduce the local pH to a strong acid pH of around 3. This is a very hostile environment indeed for most invading pathogenic microorganisms and certainly for some implanted materials. It has variable levels of success for implanted materials and these are, of course, material specific.^[30]

FOREIGN BODY GIANT CELL RESPONSE

We should return to the concept of the FBGC and develop this further. If macrophages that are going through this process of frustrated phagocytosis come into contact with each other, there is the potential for them to combine forces and their plasma membranes to fuse to form a double nucleated cell that has only one complete cytoplasm. This can continue to involve further adjacent cells and 6-, 10-, and even 20-nuclei giant cells have been observed; researchers have reported on FBGCs with over 200 nuclei. This is hard to accept; to actually be able to see and measure a single cell body of this size as one and determine that it is in fact a single whole unit would be very difficult. Given FBGCs' sensitivity to change and lytic response, FBGCs on this scale are unlikely to be observable.^[31] The macrophage and giant cell response can be the long-term end stage of the body's response to a material, and this situation can persist for years in a fragile balance that can be triggered to return to an acute inflammatory response by seemingly small changes in the material, maybe by factors such as the material's position, shape, or chemistry.^[6,32]

FIBROBLAST

Historically, in the context of the pursuit of a truly inert material, the end-stage acceptance point has often been the encapsulation of the material by fibroblasts and their extracellular matrix, which is predominantly collagen. This is a poor end point, in function and design terms but it has been the fate of many promising and actually widely used implanted devices. The macrophage and fibroblast in chronic inflammation will release chemotatic factors that will recruit fibroblasts to an area seemingly to accept the presence of a material that cannot be removed.^[33] It perhaps no longer carries a threat or stimulus in terms of carrying microorganisms, and many of the more aggressive nonspecific mechanisms are switched off in macrophages, and fibroblasts displace them as the principal cell and start laying down collagen-based extracellular matrix.^[34] This is predominantly type I and type III collagen, and the ratio varies depending on movement of the device and the age of the response, more type III being present at early time periods than later. There are

very few materials in which this can be accepted as the final biocompatible response,^[33] for example, pacemaker leads or the pacemaker driver unit although there are limitations even to these examples. In both cases, a positioning of the device in soft tissue is required, but the device itself has no mechanical or delivery implications that rely on holding tissue in position or articulating. This is somewhat oversimplified and can sometimes lead to a secondary set of inflammatory complications from physical irritation or possibly in other cases even carcinomas.^[35] An example of this fibrous encapsulation resolution point being a serious problem is in the region between the femur and the femoral stem component of a hip prosthesis. The thinnest layer of fibrous soft tissue in this region presents a zone in which loads cannot be transferred efficiently; slipping and movement under load can occur and progressive loosening follows. To complicate this example with other issues, it is not accepted by all research groups as to which comes first, the soft tissue or the loosening, and a good case could be presented for either scenario.^[36]

This complex scenario needs to be updated a little, however, and studies must begin to address the non-contacting form of cellular communication. In doing this, some of the detail becomes controversial because there is conflicting or parallel evidence.^[37] Cells communicate (on the cellular scale) over large distances in the human body using protein messages, signals, and cell-membrane-bound protein receptors.^[38] Cells also communicate with each other at a direct-contact level using proteins, but the two routes are not mutually exclusive. The potential to involve cells from any other part of the body in another part is clearly evident when cells can produce and release proteins into tissue that find their way into the cardiovascular and lymphatic systems and get transported around the body. There are many protein groups identified and many being redefined from previously classified ones.^[39] Growth factors, chemokines, and cytokines form the main groups with direct significance in the foreign body response, in addition to of course, the already mentioned complement proteins and the proteins that compose the coagulation cascade.^[40] The list of significant factors that could be mentioned is extensive and continues to be extended, but examples should certainly include platelet-derived growth factor, Interleukin-1, 4, 6, 8, 10, 12, and 15, Tumour necrosis factor α ,^[41] and transforming growth factors β -1 and 3.^[42,43]

WHAT IS THE FOREIGN BODY RESPONSE?

The first prerequisite: for a foreign body response is a material; the second is an initiation of the wound-healing inflammatory response. The third is persistence

in terms of time. Much of what has been discussed as being involved in the foreign body response also applies to the various phases of an inflammatory response and also to the phases of wound healing. The foreign body response exists only for as long as there is a foreign body present to be responded to. If one is not present, then the cellular response would be described as an inflammatory response. Much of the detail is identical and it is only at the point where the origin of the stimulus can be defined that the foreign body response finds a distinction and therefore perhaps a definition. In historical terms, the resolution of this in cell terms to fibroblast encapsulation of an implanted material signifies the final fate and best case acceptance of the material with the host. Even at this point comparisons can be found in inflammation at the chronic inflammation phase and subsequent fibrous encapsulation.^[44]

WHAT STIMULATES A FOREIGN BODY RESPONSE?

Even the smallest particulates from an implanted material can cause inflammation. If the particulates persist and with them inflammation, this will be termed the foreign body response at some time point and discussed in that context. This becomes much more significant from a materials perspective as the dimensions or complexity of a device increase,^[45] which leads to the bigger questions of what causes a foreign body response? What is required to stop it, or control it? The implications are considered much more serious if developing materials and implanting devices are said to provoke a foreign body response rather than inflammation. In reality, as discussed, there is very little difference.^[46] It is true that a material or device can fail due to the foreign body response and as such is a serious issue.^[47] A material can become completely encapsulated in many layers of fibrous tissue such that it becomes a rigid structure or hardened structure. This new structure may become inflammatory because of these new physical properties and start to manifest itself as a problem for the patient in terms of pain and or swelling. Another alternative is that the encapsulation effectively restricts movement of the material and the same scenario follows.^[48] The recurrence or stimulus to cause inflammation is a common issue for a presented failing device due to a foreign body response. The hardening of the soft tissue surrounding soft tissue breast prosthesis is perhaps one of the clearest examples of a device failing due to a foreign body response and the extremes that this can lead to. In these cases, in actual fact, there is often very little wrong with the material the device is made from, but it is a situation in which inflammation has

progressed to a point where there has been a significant amount of fibroblast activity and fibrous extracellular matrix tissue formation.^[49] This matrix has become less flexible than the surrounding tissue and therefore caused some mechanical mismatches to occur in the surrounding tissue, which have led to inflammation by irritation.

The body is very susceptible to mechanical stimulus and not particularly well adapted to constant abrasion/friction. Necessarily there are some exceptions such as articular cartilage, but in general, unless conditioned and hardened, even the skin when abraded will blister, delaminate, and break down. It is true that there are many factors in material terms that could affect inflammation in a stimulatory manner. Research has demonstrated the significance of implant size, shape, and form with respect to the host response.^[50] This has provided increasing insight into how materials could affect the host when contacting soft tissue.^[51] The issues are all too obvious: Soft tissue and hard implants present a serious problem in an environment where even the slightest mismatch in the transfer of forces is sufficient to cause inflammation, often by the simple mechanism of irritation by friction.^[52] Good stability and fixation are well understood for orthopedic applications, and even here materials demonstrate limitations in terms of stress shielding and bone resorption. In soft tissue, however, the importance and significance is often lost.^[53]

A body is in motion as a loose water-based structure, hung on a semirigid frame (skeleton); any obstruction to the smooth fluid motion within tissues and of tissues themselves will cause inflammation. The skeleton itself is vulnerable to attack by inflammation, but in normal circumstances the hard tissue of bone does not interfere with movements in the surrounding soft tissue. The term movement is not exclusive to contraction and relaxation in muscles; all tissues move or have the potential to be moved, stretched, or compressed.^[54] Our splinter example in the skin is the simple case with which to clarify the significance of even the smallest additional object in soft tissue. A fragment of material can be introduced into the skin and the wound completely healed over with no consequences of infection. The particle can go unnoticed until the skin in that area is compressed or moved, which results in the onset of inflammation, possibly pain if firing a nerve, but more likely pain will result as an indirect result of inflammation. In this case inflammation is caused by the material being moved differently compared to the surrounding cells and causing localized cellular damage, which actually breaks up the cells mechanically. The dead/dying cells stimulate the body's defense mechanisms and cells infiltrate to investigate and clean up, causing swelling and pain to follow.

Poly(lactic acid) (PLA) devices have been designed to be mechanically strong for a finite period of time to enable bone healing. The device then starts to degrade and becomes progressively weaker introducing increasing load and function to the healing bone and actually aiding in the complete bone healing. A positive design benefit is that because it is degradable, the device does not have to be removed. The devices have demonstrated good initial success as fixation devices, with good stabilization of the bone.^[55] Quite unexpectedly, though, at a later time, sometimes years, the degrading plate causes inflammation,^[56] irritation, and pain and the patient re-presents with swelling at the site of the plate. This has been attributed to a significant pH change in the surrounding tissue due to the degradation of the PLA to lactic acid^[57] or due to the release of particulates during the materials degradation.^[58,59] By either mechanism this would demonstrate the failing of a device by the onset of inflammation and irritation and certainly should be termed a significant foreign body response.^[60]

CONTROLLING THE FOREIGN BODY RESPONSE

There are pharmaceutical approaches to controlling inflammation and the foreign body response, but these have yet to be realized in terms of adding crucial secondary function to implanted materials. The introduction and successful delivery of a pharmaceutical agent as a secondary role from a device is more easily envisaged in tissue-engineering applications compared to applying delivery systems to materials that historically have been mainly inorganic solids and in general impermeable.

Materials are required that enable the surrounding tissue to move and to move the material as required in terms of temporary displacements. The concept of a significant inflammatory response and the resolution by collagen encapsulation is not an acceptable scenario for tissue-engineered devices, where good immediate and long-term communication between the introduced cells and the cellular support services of the host in terms of providing nutrients and removing waste is essential. The potential to trigger any component of the inflammatory response during implantation or application as well as part of the function is an ever present possibility that is brought to the forefront when the device or material is genuinely a foreign body. If the material does not cause localized cell damage by physically damaging the surrounding cells, a significant step forward will have been made towards avoiding the establishment of an environment that does not favor the foreign body response, though the

question of how to maintain a directed function will still be an issue.

CONCLUSION

From the instant a material is placed in contact with the body, there is the stimulation and onset of the foreign body response. What determines whether this will develop into something that will cause failure of the material itself or significant inflammation and discomfort depends on what is triggered in the inflammatory and wound-healing pathways and how prolonged the stimulus for this is maintained. There is a point at which the tissues of a body seem to give up aggressively combating a material, which is the final fibrous encapsulation. This is a very poor end point and should in a healthy body lead to its own set of stimuli that will perpetuate the inflammatory response.

Acute inflammation, chronic inflammation, and fibrous encapsulation all form part of the foreign body response. Blood coagulation, complement activation, and the production and release of growth factors and cytokines also form part of the foreign body response. These factors all have significance in other body functions and are not unique to a foreign material. The pathways and triggers can easily be initiated by other factors. These factors get attributed to a foreign body response only when there is a foreign body present as the defining stimulus.

The host's foreign body response is inevitable, and can as result of this be predicted and anticipated. Many of the factors considered detrimental in terms of inflammation and damage to the host and material themselves can be utilized and brought to bear positive and beneficial effects on the material and device or cell that they contain.^[61] Attempts to defeat the foreign body response have been met with little success. The efficient and correct progression is to utilize this response and develop and design materials accordingly.

Functional MRI: Applications

Hui Mao

Department of Radiology, Emory University School of Medicine, Atlanta, Georgia, U.S.A.

INTRODUCTION

The development of functional magnetic resonance imaging (fMRI) has made tremendous contributions to the field of neuroscience in advancing our understanding of brain functions. Functional magnetic resonance imaging is now widely accepted as a noninvasive tool for identifying brain regions that are associated with certain perceptual, cognitive, emotional, and behavioral functions, such as visual, sensorimotor, language, and memory. The most commonly used fMRI technique detects brain activities from MRI signal changes that are blood oxygenation level dependent (BOLD).^[1,2] Blood oxygenation level dependent MRI takes advantage of the paramagnetic properties of deoxyhemoglobin molecule, an endogenous MRI contrast agent in the blood, and its concentration change that is induced by the brain activation. With currently available MRI equipment, brain functions can be studied noninvasively at high spatial resolution of less than a millimeter and good temporal resolution of less than a second. Since its introduction in the early 1990s, applications of fMRI have grown continuously from studying various brain functions in the basic neuroscience research to assisting presurgical planning in neurosurgery and to providing additional diagnostic information in the clinical management of patients who have functional disorders due to neurological diseases and mental illness.^[3,4] These applications have brought us new knowledge of human brain functions, better understanding of brain diseases and disorders, and improvement in medical practices. Developing fMRI technology and applications has become an important area in the field of biomedical engineering, as it receives and facilitates the multidisciplinary efforts from neuroscience, physics, engineering, computer science, as well as clinical practices of neurology, psychiatry, neurosurgery, and more. This entry provides a brief review of current applications of fMRI and its potential development in the future.

MAPPING THE FUNCTIONAL BRAIN

Identifying the brain region that is responsible for a particular function is an important approach to the better understanding of how a human brain works and

the improvement of the diagnosis and treatment of brain diseases and disorders. Before neuroimaging methods become available, the knowledge of the functional localization of the human brain was largely obtained based on the studies of patients who suffered various functional disorders due to brain injuries and brain lesions or patients who underwent brain surgery for treatment. The relationship between the specific brain structure and its function was determined through the examination of the damaged area and the characteristics of the functional impairment. For example, an injury to the occipital lobe may cause various degrees of impaired vision, suggesting the occipital cortex is critical to the visual functions. In the surgical treatment of patients with severe brain diseases, such as epilepsy or brain tumor, the region that is affected by the disease has to be removed. In addition to giving patients neurological tests before the surgery, during the open-skull surgery neurosurgeons often carefully evaluate brain functions and their relations to the area that needs to be removed. By directly stimulating or inhibiting the targeted brain regions point by point, one can record the behavioral responses from the patient to obtain spatial localizations of certain functions. Functions as well as functional impairment of the patient can be further examined following the surgery. Developed by physicians, such as Paul Broca, whose name is used as the identification of one of the brain regions responsible for the language function, this approach allowed mapping the general functional organization of the human brain and is still practiced in the neurobehavioral and neuropsychological exams, and in the intraoperative functional tests. However, the use of this approach is not without some significant limitations. For example, it is not widely accessible for research because of the availability of the patients. As an intraoperative procedure, it can be time-consuming and can only cover limited areas of the brain. Furthermore, characterization of functional areas is done, in most instances, on patients with a certain degree of functional impairment, therefore some functional tests cannot be performed naturally. Because the spatial arrangement of functional areas can be altered or reorganized as results of the brain diseases and the plasticity of the brain, there is considerable concern that the information on the functional organization obtained from patients may not be represented correctly in the “normal” brain. Other

noninvasive and nonimaging brain mapping methods, such as electrophysiological recording methods of electroencephalography (EEG) or electromyogram (EMG), suffer from limited spatial resolution and brain coverage. Thus, the number of applications of functional brain mapping in research and clinical practices is very limited.

Although it has been known that increased neuronal activity leads to increases of regional cerebral blood flow (rCBF), regional cerebral blood volume (rCBV), and blood oxygenation, the fundamental biochemical and physiological mechanisms of these processes are still under intense investigation. Nevertheless, there is an empirical correlation between local neuronal activity in the brain and local physiological changes in hemodynamics. It has been generally accepted that brain activation, hemodynamics, and metabolic processes are coupled in both space and time. The coupling of the neuronal activity to the alterations in the vascular system is the basis for a number of functional or neuroimaging methods currently used in studying brain function, e.g., positron emission tomography (PET), single photon emission computed tomography (SPECT), and optical imaging and fMRI (Table 1).^[5,6] Development of neuroimaging methods provides the way to visualize and study the brain noninvasively in patients and healthy persons. Using neuroimaging methods, brain mapping can be done in the conscious state of a person, while the entire brain is examined to determine the functional organization and connections of the brain.

Methods of fMRI include various imaging techniques, such as arterial spin label (ASL) perfusion imaging and contrast agent enhanced dynamic imaging for measuring changes of rCBF, and magnetic resonance spectroscopic imaging for measuring changes of regional metabolic activity; however, the most

commonly used technique is based on the detection of BOLD signal change.^[7-9] Blood oxygenation level dependent fMRI allows robust detection of brain activation and can be readily performed on the MRI scanners conveniently available in many research and healthcare institutions. Increase in neuronal activity leads to a transient increase of local blood flow and blood oxygenation, which causes the change in the blood concentration of deoxyhemoglobin, a paramagnetic species that causes subtle change of magnetic susceptibility or T_2^* effect of proton transverse relaxation time of the brain tissues in the territory of the microvasculature. A statistical comparison of images obtained during an activated condition with images obtained during a control condition can be used to reveal activated brain regions that are specific to a particular mental task. It should be noted that BOLD signal is dependent on both the underlying physiological events and the imaging physics.^[10] The activation-induced BOLD signal measured with fMRI is considered to be an indirect measurement of the change in the blood deoxyhemoglobin concentration coupled with the local synaptic activity in the vicinity. Although it is sensitive, BOLD contrast is not a directly quantifiable measure of neuronal activity; for example, it does not have units of “ml/min” or “activity/sec.” However, measuring the time course of hemodynamic changes and the relationship between these physiological changes to the underlying neuronal activity will determine both the spatial resolution and the accuracy of the fMRI technique.^[11] After a decade of development, fMRI has now been widely recognized as one of the most desirable functional imaging methods with high spatial resolution and good temporal resolution for functional brain mapping when compared to other neuroimaging modalities.

Table 1 Comparison of some imaging modalities and their measurements

Imaging modality	Hemodynamic parameters measured	Contrast used for imaging	Spatial resolution (mm) ^a	Temporal resolution (sec)
PET	rCBF, rCBV	Radioactive tracer (¹⁵ O or ¹⁸ F)	5–20	0.06–0.12
SPECT	rCBF	Radioactive tracer (⁹⁹ Tc or ¹²³ I)	10–20	>0.3
Optical ^b (near infrared)	Blood oxygenation	Hemoglobin and deoxyhemoglobin	2–10	<1
fMRI	Blood oxygenation, rCBF	Deoxyhemoglobin or magnetically “labeled” blood	2–4	0.1–3

^aSpatial resolution is compared at in-plane resolution. A typical slice thickness used for fMRI exam is 4–5 mm.

^bOptical imaging, e.g., near-infrared spectroscopy, in particular, has technical limitation in brain coverage; however, it can measure deoxyhemoglobin concentration directly and quantitatively. It has attracted increased attention to develop this method for studying brain function.

LOCALIZING BRAIN ACTIVATION WITH BOLD fMRI

The image acquisition technique used for BOLD fMRI is the combination of the gradient echo method and single-shot echo planar imaging (EPI), designed for T_2^* weighted contrast and a rapid image readout. Using this technique, fMRI exams can be routinely performed at the field strength of 1.5–3 T with the temporal resolution of 1–3 sec, depending on the acquisition parameter of time of repetition (TR), and the spatial resolution of 2–3 mm (in plane voxel size). With higher field strength, more powerful gradient system, and parallel imaging technique, the spatial resolution and temporal resolution can be further improved.

As other neuroimaging modalities, fMRI experiments rely on the ability to detect time-dependent task-evoked signal changes and to extract regions of activation using statistical methods.^[12] Any area with signal changes that correlate with the neurological stimuli can be identified and compared with the anatomy of the brain. In general, there are two types of task paradigms used in fMRI studies: block (“boxcar”) design and event-related design. Block design uses a boxcar waveform that typically has a control condition, e.g., resting, and a task condition. However, it is also possible to test more than two conditions during one scan. Given instructions and stimuli, a person who receives fMRI scan will execute different tasks in different conditions that are alternating, while the MRI scanner records images over a period of time. Block design offers a relatively simple experimental method and robust detection of brain activation as the BOLD signal rising from the brain responses to stimuli in each block is accumulated in that block. Therefore, it is commonly used in clinical applications of fMRI, which are done mostly on the individual patient with restraints of the scan time and patient tolerance. In addition to its simplicity, block design is well suited to clinical fMRI, because the primary goal in most clinical applications is to specifically localize an activated brain region rather than to look for the pattern of connectivity throughout the brain. Event-related design is similar to the experimental designs used in the conventional electrophysiological and neurophysiological tests, such as event-evoked EEG or EMG. It uses very brief stimuli, typically <1 sec each in duration against a baseline control condition. Because most of the event-related design experiments use very brief stimuli, they can be used to track the flow of neural process through the brain. They can be also used to investigate differences in the onset of neural activity evoked by different types of stimuli. Furthermore, because the stimuli can appear randomly, they are statistically more efficient than blocked designs and can minimize the effect of mental preparation such as prediction and planning. Consequently, event-related

fMRI is considered as a more suitable approach to address a number of important cognitive questions that focus on the temporal behavior of the hemodynamic response.^[13] Today, most fMRI applications in studying cognitive processes use event-related experimental design. However, its application in clinical fMRI faces several technical challenges. First, complicated statistical models are often needed for deriving the functional maps, but this is becoming feasible with the inevitable increase in computer processing speed. Second, substantial validation and development remains to be done before event-related designs become widespread in clinical practice. Nevertheless, because event-related designs offer greater flexibility, they will likely gain wider acceptance in the future.

Postprocessing of fMRI data generally follows the steps of: 1) realigning the functional images recorded in the time series to correct for motion artifacts; 2) coregistering functional images to the anatomical images; 3) statistical analysis to correlate functional image time series to the design paradigm; and 4) superimposing a functional map on high-resolution images for anatomical assignments. Because data analysis of fMRI strongly relies on the statistical power, in many fMRI applications, results are obtained by averaging data from many individuals in the selected population and presented in the normalized standard brain atlas. This group analysis approach is very effective when studying group differences in brain functions and is widely used in research applications. However, because many clinical applications of fMRI are usually for investigating an individual patient case by case, it is not generally necessary, and appropriate in many circumstances, to normalize the images and functional maps to a standard brain atlas in those applications.

APPLICATIONS OF fMRI

Propelled by rapid advancement of MRI technology, applications of fMRI have been developed and are widely spread over many areas of neurosciences and clinical management of brain diseases and disorders. New applications and interventions based on fMRI are emerging continuously. Here, we attempt to highlight several major applications.

Studying Basic Functions and Functional Organization of the Brain

Perhaps, the most important application of fMRI should be attributed to its role in studying basic brain functions. Development of fMRI allowed opening up a window to the insights of the brain where our knowledge and understanding are still limited. Since it was

introduced, fMRI has been used mainly by neuroscientists to map brain functions and led to the tremendous growth of our knowledge about the brain in the past decade. In recent years, fMRI is applied largely in studying cognitive functions and functional organization of the brain.^[14,15] Cognitive functions or “higher-level functions,” such as memory, emotion, and perception, are processed by different but interrelated brain regions in a synergic fashion. Neuronal and physiological responses of cognitive activities are usually subtle and difficult to detect. The ability to simultaneously scan the entire brain with high spatial resolution and deep tissue penetration makes fMRI the desirable technique for neuroscientists to interrogate the complex neuronal network associated to cognitive functions.^[16] Functional magnetic resonance imaging not only can be used to test the classic views and hypotheses of cognitive functions that were obtained from studies of patients or animal models, but also makes significant additions to advance our understanding of

those functions. For example, Haist and colleagues used fMRI to investigate the activation pattern in memory consolidation, one of the important aspects of the memory function, using a test that subjects viewing the faces of people who were famous primarily within a particular decade, as well as faces of nonfamous people. They found the selective activation for famous faces in the hippocampus only for responding to the faces of famous people of the most recent decade, while activation in the entorhinal cortex was most prominent for faces of the most recent decade, but less prominent for faces famous in the less recent decade, and absent for the remote decades.^[17] This pattern of activation (shown in Fig. 1) is consistent with the once-debatable classic view of the prolonged memory consolidation initially derived from the study of patients with defects in hippocampal regions. Furthermore, new information obtained from their study suggested that the prolonged consolidation occurs in two stages, an initial, relatively brief stage mediated by the hippocampus and a more

Fig. 1 Brain activation patterns from the famous faces remote memory test and fMRI indicated the right hemisphere hippocampal activation (showed in the crosshairs). Images are shown in the neurological convention in which the right hemisphere is the right side of the image. (From Ref. [17].)

lasting stage mediated by the adjacent entorhinal cortex.

So far the vast amount of fMRI studies in cognitive functions have derived new information that advanced our understanding of brain functions and also brought some light to the mechanism of some brain diseases and disorders.

Improving the Diagnosis of Mental Disorders

Because of its close ties to neuroscience, fMRI has been used to investigate the neural basis of mental illness since fMRI was introduced. Most of the major psychiatric disorders, e.g., schizophrenia, major depression, and attention deficit hyperactivity disorder, appear to represent disordered neural systems widely distributed in the brain. Because of this, it is thought that there is more than one single brain region associated with a particular mental illness. Using fMRI, it is now possible to observe how cognitive tasks are performed. Such “in-action” information is not available from traditional neuropsychological tests. With proper experimental design, brain activation patterns identified by fMRI can reveal the mechanisms of the psychological processes, such as strategy or compensatory. Patients with psychological disorders may demonstrate different neural networks from normal controls as the cognitive processes in patients may be altered by specific neuropsychological deficits.

There are a few consistent findings that have emerged, which hold promise for the development of clinically useful fMRI in psychiatry. For example, the anterior cingulate cortex has become a focal point for the pathophysiology of major depression. There are some evidences suggesting that depression is associated with hyperactivity in this region and that effective pharmacological treatment is associated with a normalization of activity. Similarly, the anterior cingulate has been shown to be less active in schizophrenic patients.^[18] On the other hand, fMRI is very useful in testing existing hypotheses derived from the previous neuropsychological studies.^[19] The hypothesis of deficits in recruitment of frontal lobe structures during higher-level executive functions in attention deficit hyperactivity disorder (ADHD) patients has been confirmed with great specificity using fMRI. Rubia et al. demonstrated that the frontal lobe in ADHD adolescent patients exhibits task-specific hypoactivity during complex higher-level executive tasks, but appears normal during a lower-level finger tapping task.^[20] However, in all of these examples the difference between patients and controls was statistical. Using fMRI for individual diagnosis of mental illness is not state of the art. Because psychiatry does not currently have any reliable diagnostic test, the development of a reliable test that

could be used on an individual basis would represent a major breakthrough.

Assisting Neurosurgery in Presurgical Planning

The ability to noninvasively localize functional foci of the brain makes fMRI particularly useful for preoperative planning in neurosurgery. The primary use of fMRI is to identify cortical functional areas so that their functions can be preserved, if possible, during brain biopsy, resective surgery, neuroradiological embolization, or radiation therapy.^[21,22] When removal of such areas becomes necessary for the best of the surgical treatment, functional mapping can be used to determine the surgical margin and to assess the potential functional deficits so that other treatment options can be explored or proper postsurgery rehabilitation can be planned.

In the clinical management of brain tumor patients, fMRI can play an important role in mapping of eloquent functional areas to guide stereotactic biopsy and tumor resection, and to assess functional plasticity in relation to the lesion.^[23] One of the examples shown here involved a patient with a brain tumor located in the left parietal lobe. Surgical removal of the tumor posed the potential risk of impairing the movement of the right limbs. Functional magnetic resonance imaging was then used to identify the left hemisphere motor area as the tumor sits close to the left motor stripe that controls the right-hand side of the body. Patient was tested with a series of motor tasks including the right-handed sequential finger tapping, hand movement with the fist open and close, wrist flexion, etc. This exam allowed localizing the areas that control right-hand movements, as shown in Fig. 2, and identifying the possible surgical margin between the functional area and the tumor boundary. In the other case, a growing tumor is located in the left frontal area of a patient, an area important for many cognitive functions, including the language processes. Presurgical preparation included fMRI exam to determine the language area and its spatial relation to the tumor. This was accomplished by using a confrontation naming task, in which the patient was instructed to generate a sentence to name each animal shown in the picture in one condition while counting numbers in the other. The results from fMRI showed that the tumor appeared to infiltrate into the language areas (Fig. 3), revealing the risk of disrupting language function if the surgical treatment applies. There are, however, potential limitations of fMRI in the study of brain tumors. The presence of edema, tumor mass, and radiation-induced tissue damage affects the microvasculature surrounding the lesion. One must be careful, especially in the interpretation of data from an fMRI exam for the guidance

Fig. 2 Preoperative fMRI identified the left motor area of a patient who had a brain tumor located in the left parietal area. Motor activation was the response of a right-handed finger tapping. The activation map was overlaid on T1 weighted images of coronal (A), sagittal (B), and transverse (C) views as well as a three-dimensional rendering of the brain (D). The left motor area was found close to the tumor (indicated by arrows). Images are shown in the radiological convention in which the left hemisphere is in the right-hand side of the image.

of surgical procedures, especially for areas directly adjacent to tumors.

In the area of surgical treatment of epilepsy, there have been significant efforts made in developing fMRI method to replace the traditional intracarotid amytal procedure, also known as the Wada test. The Wada test involves inserting a catheter into the carotid of the patient to infuse anesthetic amytal to partially paralyze the selected part of the brain in order to localize the language and the memory areas. In comparison, fMRI provides not only a safe alternative but also a high spatial and anatomic resolution in localizing functional areas. In addition, fMRI procedure can be conveniently

done in conjunction with the routine preoperative MRI. Some studies have developed task paradigms, such as picture naming, word generation, or simple rhyme detection to determine hemispheric dominance for language in epileptic patients.^[24,25] Results derived from fMRI examinations were compared with those obtained on the same patients using the standard Wada test, stereotactic intracerebral EEG stimulations and recordings, as well as outcomes of the temporal lobectomy. These studies demonstrated that fMRI examination generates robust responses in the language areas and is feasible for determining hemispheric language dominance. As a result, fMRI has been used

Fig. 3 Functional magnetic resonance imaging was used to determine the left frontal language area and its relation to the tumor for a brain tumor patient in the planning of a biopsy. (A) A transverse sectional view of the brain showing the activated area in color and bright tumor mass in the T2 weighted image; (B) three-dimensional rendering of the brain with activated areas shown in color; and (C) a cutoff in the three-dimensional rendering view showing the bright tumor mass and its relation to the activated area. Images are shown in the neurological convention.

Fig. 4 A locked-in patient suffered from a brainstem stroke (highlighted in a T1 weighted sagittal image) (A) and demonstrated activated motor area in the posterior parietal lobule when performing the imagery finger tapping (B); blood oxygenation level dependent signal time course (C) was recorded in the area (indicated by an arrow), which was selected for implanting a neurotrophic electrode that extracts brain signals for interface with a computerized assisting device.

in many institutions for lateralization of the language area in presurgical planning for patients with temporal lobe epilepsy, although the complete replacement of the Wada test has not yet been accomplished.

Other neurosurgical interventions may use fMRI for functional guidance. For example, in the effort of developing brain–computer interface for patients who are quadriplegic or “locked-in” with loss of the means of communication, because of brain injuries or other neurological disorders, such as amyotrophic lateral sclerosis (also known as Lou Gehrig’s disease); fMRI can be used to identify the optimal site for the implantation of a neurotrophic electrode that picks up and converts neuronal activation into digital signals.^[26] Functional magnetic resonance imaging combined with an imaginary finger-tapping task was able to find an activated area in the motor area of a patient who was locked-in because of a brainstem stroke. The implantation of neurotrophic electrodes at the location identified by the fMRI exam (Fig. 4) established the direct interface between the patient’s brain and a device that was used to assist the patient in communication.

Monitoring Functional Changes Related to Diseases and Treatments

Another application of fMRI is to monitor functional recovery, disease progression, treatment efficacy, and the response to medication.^[27,28] For example, fMRI has been used to map the short- and long-term cortical reorganization after a spinal cord injury (SCI). Significant reorganization of the motor cortex was found in completed SCI patients over the time after the injury, revealing the characteristics of brain plasticity of SCI (Fig. 5). This type of information is not previously available, but can be important to the design of rehabilitation therapy. In investigating the recovery of motor ability after brain injury, such as stroke, fMRI is also found to be useful in studying the important underlying mechanism and in developing rehabilitation intervention to improve the recovery of patients. Functional magnetic resonance imaging was applied to monitor the changes of activation pattern that may represent the response of the constraint-induced therapy for motor recovery after stroke.^[29] Applications of

Fig. 5 Functional reorganization of the left motor area was observed in the patients with short-term and long-term SCI. (A) Control; (B) 2 yr after SCI; and (C) more than 10 yr after SCI.

fMRI to study neurological impairments that are not associated with structural abnormalities, such as learning problems, dyslexia, and motor neuron diseases, are currently in progress.

There is a growing interest to look for the brain activation pattern as a possible “marker” for the diagnosis of neurodegenerative diseases, such as Alzheimer’s disease, dementia, as well as mild traumatic brain injuries. As other functional imaging modalities, fMRI provides a promising approach to identify the specific activation pattern or disruption of the normal activation pattern that is associated to the disease and the severity of the disease.

Measuring the Neurological Response to Pharmacological Effects

There is an emerging application of fMRI in studying pharmacological problems in recent years. The ability of fMRI to detect brain activation in vivo can be also applied to investigate the neurological and physiological changes associated to the pharmacological effect of drugs, for instance, the changes evoked by the treatment of the psychotropic drug.^[30,31] Several studies have demonstrated the feasibility and potential of using fMRI to assess the drug effect on the brain function and the specific brain region. Using fMRI, significant BOLD changes in the medial geniculate nucleus, mediodorsal thalamic nucleus, mesencephalic trigeminal nucleus, and parietal cortex can be observed in rats administered with dizocilpine MK-801, an *N*-methyl-d-aspartate receptor antagonist that is a neuroprotective compound with well-documented effects on CBF and metabolism.^[32] Although pharmacological fMRI is largely used in the study of animal models at this time, such application in human is proven to be feasible. However, one of the major challenges of pharmacological applications of fMRI is to quantify the pharmacological effect of drugs. There is a significant limitation in using BOLD fMRI because of the complicated source of the BOLD signal. It is expected that the development of quantitative fMRI methods, such as perfusion fMRI, will facilitate the applications of pharmacological fMRI in the future.

FUTURE DEVELOPMENT OF fMRI APPLICATIONS

Very High-Field MRI Scanner

Both MR signal intensity and BOLD contrast increase as a function of the field strength. With increased signal-to-noise and T_2^* weighting, functional imaging can be performed at higher temporal resolution and sensitivity.

Although the majority of fMRI studies have been done using 1.5 T MRI scanner, it has been demonstrated that both functional and anatomic information can be obtained at high spatial and temporal resolution with high-field magnets (3.0 T). This promoted the rapid development of 3.0 T clinical scanners in recent years. Using 3.0 T scanners, which are currently available from all major manufacturers, anatomical images can be obtained with submillimeter resolution. With the endless effort of developing MRI engineering and technologies, 7.0 T whole-body MRI scanners are becoming available from major MRI scanner manufactures at the end of 2005. This will further enhance the ability of fMRI applications to perform reliable functional studies on individual patients and improve the efficiency of fMRI exams. Once available, such very high-magnetic field systems are capable of performing high-resolution fMRI, which can be used for mapping functional brain organization ranging from large cortical networks to small nuclei, and even to cellular layers.

Quantitative fMRI

Perhaps, the biggest challenge to BOLD fMRI is its limited ability to quantify the BOLD signal itself. However, quantitative fMRI is particularly important to clinical fMRI if it is to assess disease, prognosis, and treatment. A method with great potential for quantitative fMRI is the ASL technique. This is a type of dynamic MRI that can measure the rCBF change associated with brain activation noninvasively. Several technical developments, including the correct measurement of transit and trailing times, improvements in temporal resolution, and data processing, remain to be done. In any case, ASL perfusion MRI is expected to provide a quantitative measurement of activation-induced physiological changes, and can be extremely useful in the applications that study the severity of diseases or disorders, treatment efficacy, and pharmacological effect. Another promising method that provides quantitative measurement of rCBF is dynamic perfusion imaging with bolus injection of exogenous contrast agents, such as gadolinium chelate or superparamagnetic iron oxide nanoparticles. These agents can greatly expand the capability of fMRI and provide accurate measurement of task-induced rCBF change. Applications of susceptibility contrast physics and standard “bolus-tracking” kinetic principles allow the calculation of relative CBV maps and mean transit time parameters, which are related directly to the hemodynamic response.

Integrated fMRI

There are increasing needs in high spatial and temporal resolution to study cognitive functions, functional

connectivity, and neuronal network. This has led efforts to integrate fMRI with other imaging technologies or modalities.

As fMRI can only indirectly measure the neuronal activity via physiological response, its temporal resolution is slower than the time scale of actual neuronal activity. To improve the temporal resolution, approaches of combining MRI and fMRI with EEG or MEG have been developed.^[32] Because electrophysiology recording allows true real-time measurements of the neuronal activity evoked by a stimulus, the combination of event-related fMRI and electromagnetic recording of event-related potential (ERP) may offer the millimeter spatial resolution and the millisecond temporal resolution when used for studying cognitive processes. Furthermore, functional connectivity can be also addressed with the help of diffusion tensor imaging and diffusion tensor-derived white matter tractography, which allow delineating the structural connection between different brain regions that are activated in the network of functional processes.^[33] It is expected that these developments will enhance capability of fMRI and expand its applications, and will particularly benefit the diagnosis and treatment of brain diseases.

CONCLUSIONS

Functional magnetic resonance imaging provides a noninvasive and widely applicable method for functional brain mapping. With excellent spatial and temporal resolution, it allows neuroscientists to study the various functions and their organization of human brain. Development of fMRI applications not only advanced our knowledge and understanding of brain functions in great deal, but also provided clinical neuroimaging tools for improving our understanding, diagnosis, and treatment of brain diseases and disorders. As neuroscience research and fMRI technology continue to progress, it is expected that the applications of fMRI will continue to grow in the future.

Gait Analysis

Richard Baker

Hugh Williamson Gait Laboratory, Royal Children's Hospital, Melbourne, Victoria, Australia

INTRODUCTION

Gait analysis is the study of walking. In a biomedical context it is now assumed to refer to the instrumented measurement of walking and the interpretation of such data. There is now a broad consensus on how clinical gait analysis is conducted and is this that is outlined in this article. After a brief historical review there is a description of the different sorts of data used and of how these are measured and processed. This is followed by an overview of the process of clinical gait analysis. The final section reviews some recent developments.

HISTORY

Scientific interest in walking was first documented by Aristotle (384–322 B.C.^[1]), although it was not until 1680 that the first experimental data were reported by Giovanni Borelli (1608–1679^[2]). In the nineteenth century, Eduard (1795–1874) and Wilhelm (1804–1901) Weber^[3], Etienne Jules Marey (1830–1904^[4]), Edward Muybridge (1830–1904^[5]), and Willhem Braune (1831–1892) and Otto Fischer (1861–1917^[6]) all had a role in developing techniques to document walking and made progressive steps in describing the process of walking. A team headed by Verne Inman (1905–1980) and Howard Eberhart (1906–1993) at the Biomechanics Laboratory of the University of California at Berkeley shortly after the Second World War advanced experimental techniques and theoretical understanding about as far as possible before the advent of modern computers made the processing and study of data from individual patients a realistic undertaking.^[7]

Modern clinical gait analysis involves instrumented data capture and biomechanical modelling and interpretation of these data to assist the clinical management of the subject. Although various centers had a role in developing these elements of analysis during the mid-twentieth century, they were first brought fully together at Newington Children's Hospital (Hartford, CT)^[8] in the early 1980s under the direction of orthopedic surgeon Jim Gage.

The last two decades have seen some stability in the operation of clinical gait analysis based broadly on the

protocols and systems developed at Newington. These techniques were developed to analyze the walking of children with cerebral palsy, and clinical use of these techniques is still most widespread among this patient group. Use with other pathologies is increasing but the same general approach to capture, processing, presentation, and interpretation of data is used. This approach can now justifiably be referred to as conventional clinical gait analysis. In describing methodologies below the implementation of the Newington model will be focused on.

DATA USED IN GAIT ANALYSIS

Conventional clinical gait analysis is based on the collection of four core types of data: clinical examination, basic temporal-spatial data, joint kinematics, and joint kinetics. The clinical examination of the patient includes assessments of joint range of motion, muscle strength and tone, and skeletal abnormalities. This is the realm of the physiotherapist or orthopedic surgeon and will not be discussed further here. Many laboratories also conduct electromyography (EMG) tests and/or oxygen consumption measurements, but these separate subjects are not discussed in this article.

Basic Terminology

Walking is a cyclic process and is broken down into gait cycles for analysis. Specific phases and events within each cycle can be identified. Various systems for subdividing the gait cycle have been suggested; Perry's^[9] is described here (see Fig. 1). In able-bodied walking, the heel is the first part of the foot to strike the ground. This is not necessarily the case for people with pathology, and the term initial contact is preferred. Conventionally, the gait cycle starts with initial contact on one side and continues until the next initial contact on the same side. This is also referred to as a stride. A step starts with initial contact on one side and continues until initial contact on the other side. Two steps thus constitute a stride.

For each limb, the gait cycle can be divided into two phases: the stance phase, when the foot is in contact

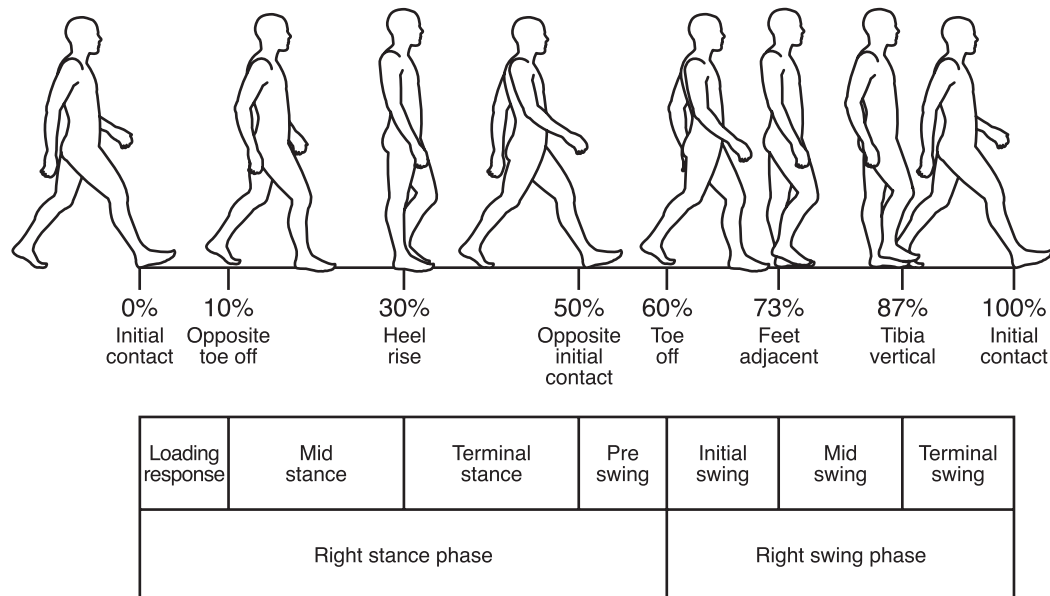

Fig. 1 Terminology to describe the events of the gait cycle.

with the ground, and the swing phase, when it is not. In able-bodied subjects, the stance phase lasts for around 60% of the gait cycle and the swing phase lasts for about 40% of the cycle. It is almost always the toe that is the last part of the foot to leave the ground. This is generally referred to as toe off, although foot off is preferable.

The cycle can be further subdivided by considering what is happening to the other limb. Opposite toe off occurs at around 10% of the gait cycle for able-bodied walking and opposite initial contact occurs at 50% of the cycle. Further divisions of the cycle are depicted in Fig. 1.

Temporal-Spatial Parameters

Definitions

These are the basic time and distance measurements that describe walking. Cadence is the number of steps taken in a given time, generally per minute (occasionally it is reported as strides per minute, which is obviously half the number of steps). Stride length is the distance between the position of any point on the body at the start of the gait cycle and that at the end; by definition this lies in the direction of progression. The base of support (or stride width) is a measure perpendicular to the direction of progression of the separation between the stance phase position of one foot and that of the other. There is no consensus on a precise definition of this. Stride time is that required to complete a gait cycle. The ratio of stride length to stride time is the walking speed; the ratio of

speed to stride length is the cadence. These five parameters are defined for the whole gait cycle and are independent of the side considered.

Step length is the distance between the point of initial contact for one leg and that of subsequent initial contact for the other leg. The component of this along the direction of progression is generally quoted, but occasionally the total distance is used. Step time is that from initial contact to opposite initial contact. Stance time is that between initial contact and toe off; swing time is the time between toe off and initial contact. Double support is the time during which both feet are in contact with the ground, and occurs twice during the gait cycle. If the gait pattern is asymmetric, then the foregoing terms will be different for left and right steps.

Measurement

Temporal-spatial parameters can be directly measured by various methods, but in most conventional gait analysis they are derived from measurements of trajectories of markers used for kinematic analysis. Typically, the position of a marker on the foot will be taken as the reference for stride and step length, and stride width. Detecting the precise instant of initial contact and toe off does not greatly affect measurement of the distance parameters, but can affect measures of the temporal parameters. Force plate data are the most accurate means of detecting these instants if they are available. Autocorrelation techniques on marker trajectories can be used to estimate positions of these events for subsequent gait cycles once they have been identified for any single cycle if the trajectory is

repeatable. Manual identification of the events is required if force plate data are not available or if the walking pattern is not repeatable.

Processing

Little processing is required for temporal-spatial data, although reliability is increased by averaging data, from several strides. Normalization of data is an issue not yet resolved. Both temporal and spatial parameters vary with growth. Dividing lengths by body height or leg length is common but may not fully normalize data.^[10] There is no consensus on the normalization of temporal data. A common approach is to report data with reference to normative data by age cohort, but this makes it difficult to interpret data for a particularly tall or short person within the cohort.

Kinematics

Definitions

Kinematics is the study of movement. Conventional gait analysis focuses on movement at each joint throughout the gait cycle. The most commonly used models in gait analysis,^[8,11,12] all of which are based on the model first fully developed at Newington, assume three degrees of rotational movement at each joint but allow for no translation. Joint movements in three planes are considered, and are the components of a Cardan decomposition of the three-dimensional orientation of the distal with respect to the proximal segment (mathematics more fully described by Wu).^[13]

Cardan angles are sequence-dependent, and for the joints of the extremities, the flexion–adduction–internal rotation sequence is universally applied. It is necessary to describe the orientation of one segment with respect to another, as well as to describe the orientation of at least one segment with respect to the laboratory reference system. The pelvis is used for this. Although the Cardan sequence equivalent for the extremities (tilt–obliquity–rotation) has conventionally been used for the pelvis, it has recently been suggested that the opposite sequence (rotation–obliquity–tilt) gives measurements that are closer to the clinical definition of these terms.^[14]

Measurement

Most contemporary gait analysis systems detect the position of markers placed on the subject. The most widespread systems are based on video camera technology.^[15] Measurement volume is illuminated with a strobed light source in either the visible or infrared

spectrum. The markers are covered in retroreflective tape that reflects light back to the camera. Using pulses of very brief duration, very high-intensity light can be used without risk of damaging eyesight. High-intensity light can eliminate any blurring caused by movement of the markers during capture of the image. Because of the brightness of the reflection from the markers, threshold detection can separate the image of the markers from any background detail. Modern systems generally use some form of pattern recognition in this process to pick up only circular reflections and determine their centroids. Capture rates of 50–120 Hz are fairly common in modern systems and much higher rates are possible for specific applications.

Detection generally occurs in a firmware coordinate generator, the output of which is the two-dimensional coordinates of each of a number of markers in the image plane of the camera. Most systems now incorporate some form of correction factor for non-linear optical or electronic systems within the camera. If more than one camera sees a given marker and the cameras' position, orientations, and magnification factors (focal lengths) are known, then the three-dimensional coordinates can be reconstructed. A calibration procedure to determine these parameters is generally conducted before each test session.

To determine joint angles it is first necessary to define a number of segments on each of which a minimum of three points are defined. The Newington model was developed at a time when system resolutions were low and processing time critical. It is thus based on the minimum number of markers required to define seven segments of the lower limbs (two feet, two legs, two thighs, and one pelvis). The model is hierarchical in that the definition of distal segments depends on the prior definition of the proximal segments. Although modern systems are capable of dealing with many more markers, more complex models have not yet been accepted into widespread routine use.

In order to define joint angles it is first necessary to define a meaningful coordinate system (CS) for each segment. This is referred to as the anatomical CS. To place markers accurately, their position must be defined with reference to bony landmarks, and they must be placed in positions that are visible to the cameras and not likely to be knocked off by the impingement of other body segments. It is thus rarely possible to place markers in positions that allow direct determination of the anatomical CS. It is more common for a technical CS to be defined directly from marker positions. A transformation is then applied to the technical CS to obtain the anatomical CS. This transformation can be determined on the basis of assumptions about the anatomy, anthropometric measurements, or data collected during a static calibration trial.

Processing

The data provided by the coordinate generator are a series of two-dimensional marker coordinates in the image plane of each camera. The first stage in reconstructing the three-dimensional marker positions is to decide which of the images in which of the cameras have been created by which of the markers. Once this has been determined, the data from camera calibration can be used to determine the three-dimensional coordinates. It is then necessary to link each of the detected markers with one of the markers on the subject. This process is now either semi- or fully-automated.

Markers on a given segment are then used to determine a technical CS with a defined origin (generally one of the markers) and axis system (generally using a Gram-Schmidt orthogonalization procedure). This technical CS is then transformed to determine the anatomical reference system for the segment.

In the Newington model,^[8] (Fig. 2), the anatomical CS for the pelvis has its origin at the midpoint of the anterior superior iliac spines (ASIS) of the pelvis, its medial-lateral axis from the right ASIS to the left ASIS, the anterior-posterior axis perpendicular to this and in the plane containing it and the midpoint of the posterior superior iliac spines (PSIS). The proximal-distal axis is orthogonal to the other two axes. Markers

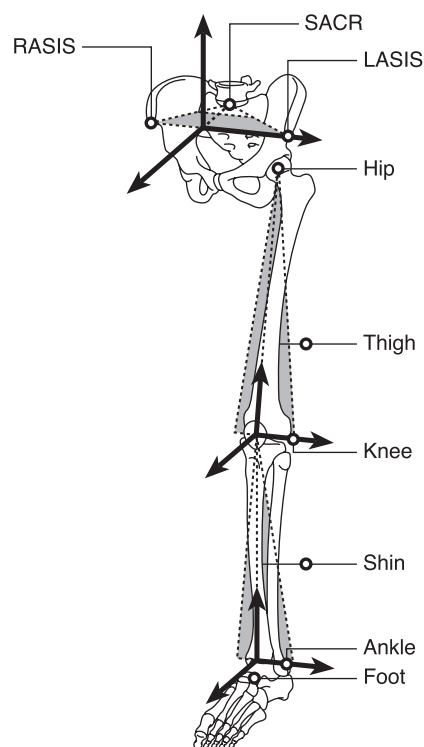

Fig. 2 Definition of Co-ordinate Systems in the Newington model (see text for full description).

(LASIS, RASIS, and SACR) are placed over each ASIS and the mid-point of the PSIS. The only transformation required to obtain the anatomical CS from the technical CS is thus to correct for the marker centers' distance from the bony landmarks.

Locating markers on bony landmarks on the femur is problematic. There is significant skin movement over the greater trochanter (particularly during transverse plane rotations of the hip), and the medial epicondyle is subject to being knocked off by the opposite limb. The only useful landmark is the lateral epicondyle (Knee). Another point of the femur is obtained by recognizing that the center of the femoral head is coincident with the center of the acetabulum in most people. The center of the acetabulum can be estimated on the basis of regression equations relating it to the origin of the pelvis in the anatomical pelvic CS. The third marker is generally on a short wand strapped to the lateral aspect of the thigh.

The anatomical axis system for the femur has its origin at the knee joint center (approximated by the midpoint of the medial and lateral femoral epicondyles). Its proximal-distal axis is from the knee joint to the hip joint center, and its medial-lateral axis is perpendicular to this and in a plane containing the knee axis (approximated by the line from medial to lateral epicondyle). The anterior-posterior axis is orthogonal to both. The transformation from the technical frame to the anatomical frame requires a rotation and translation. Two approaches to quantifying the transverse plane component of the rotation are used. The first is to place the thigh marker (Thigh) accurately so that the coronal plane of the femur's technical CS is coplanar with the anatomical CS in which no rotation is required. The second is to place additional markers to mark the knee axis during a static calibration and to use the data from this to calculate the appropriate degree of rotation.

Although the tibia does have more reliable bony landmarks than the femur, the method for defining it is analogous to the method for the femur. One marker is placed on the lateral malleolus (Ankle); another on a wand on the lateral aspect of the lower leg (Shin); and the knee joint centre, as defined in the femoral CS, is taken as the third point. The ankle joint axis is assumed to pass from the medial to the lateral malleolus, and the joint center is the midpoint of these. This joint center is the origin of the tibial CS, and the axes are then defined as for the femur. Again, either exact placement of the lower leg marker can be used to ensure that the technical and anatomical tibial coronal planes are aligned, or a rotation offset between the two can be calculated during the static test. This is calculated to ensure that knee rotation is zero after a clinical measurement of tibial torsion has been taken into account.

At the time the Newington model was devised, system resolution and the minimum marker size required for detection were such that only one marker on the forefoot could be detected. The Newington model thus allows only the long axis of the foot to be defined, and does not define rotations about this. The line between a forefoot marker (Foot) and the ankle joint center as defined in the tibial CS provides the technical reference for this. Both sagittal and transverse plane offsets are calculated during a static calibration file to quantify the transformation to the anatomical equivalent.

When the anatomical CS for each of the segments has been determined, then the joint angles must be determined. The Cardan angle decomposition is the sequence of rotations about orthogonal axes fixed in an imagined moving segment, starting aligned with the proximal segment and ending aligned with the distal segment. This can also be visualized as the moving segment being rotated about an axis fixed in the proximal segment, an axis mutually perpendicular to this and an axis fixed in the distal segment, and then about that axis in the distal segment. This is the Grood and Suntay^[16] representation, which is often viewed as different from the Cardan representation. It should be noted that the two are simply different ways of visualizing the same underlying mathematical quantities.^[17]

The Cardan angles are derived from the direction cosine matrix, expressing the relative orientation of the anatomical CS for the segment distal to the joint with respect to the segment proximal to it. There are generally two solutions to the resulting equations, and the one with the middle rotation lying in the range -90° to $+90^\circ$ is chosen. At the point at which the middle angle is equal to 90° there is a singularity with the equations, giving an infinite number of solutions. Close to this point, the three angles that result from the Cardan decomposition are increasingly sensitive to small perturbations in orientation, and a clinical interpretation of the results is not meaningful. This is called gimbal lock and is analogous to the ambiguity in defining the directions north, south, east, and west as one gets very close to one of the poles. The effect can be ignored if the middle angle lies in the range -75° to $+75^\circ$ (which is almost always the case in gait analysis). The gimbal lock effect, is however, a major concern in representing movement at other joints, particularly the shoulder.

Kinetics

Definitions

Kinetics is the study of the forces and moments that bring about movement. In clinical gait analysis,

the moments that muscles generate about joint centers are assumed to be the cause of movements of the joints, and hence of body segments. Determining the forces and moments generated by specific internal structures (e.g., tendons, ligaments, joint surfaces) is an indeterminate problem. Although various optimization approaches have been used to estimate these forces and moments, conventional gait analysis tends to be based on the external moments developed about the joints that can be determined uniquely. These moments are generally described as the three components about the axes of the orthogonal CS aligned with the anatomical CS of the segment distal to the joint but with its origin at the joint center. Note that the components of joint kinematics and kinetics are defined about different axes systems; care is needed in correlating features between them.

There is no consensus on whether moments should be described as internal (the moment applied by the muscles to the joints) or external (the moment arising as a consequence of the ground reaction). The magnitude of the moments is completely unaffected by the choice of internal vs. external, and valid arguments exist for each. One convention should be adopted and used consistently, and this should be clearly documented whenever data are presented.

It is also common to see joint powers presented. These are the scalar product of joint angular velocity and joint moment. Although joint angles are defined about nonorthogonal axes, angular velocity is defined as the change in angular position with time in the limit as the time interval approaches zero. As this limit is approached, the components of the change in angular position approach orthogonality, thus angular velocity is a vector quantity and its components are about the same axes as the joint moment. Some systems present three components of joint power, which have no physical significance (power being a scalar variable), but which can be interpreted as having some clinical significance.

Measurement

The principal requirement for determining joint kinetics is measures of the force system applied by the floor on the foot (which is equal and opposite to that applied by the foot on the floor). The full six components of the force system must be recorded. These are probably most easily visualized as the three components of the ground reaction force, the moment about the vertical axis, and the coordinates of the center of pressure (the point on the force plate's surface at which the ground reaction can be considered to be acting). Most force plates designed to make such measurements are based on either piezoelectric

or strain-gauged technology. These plates must be designed so the minimum resonant frequency is considerably higher than the maximum frequency components of the ground reaction, which are generally assumed to be of the order of 10–20 Hz.

Processing

Two steps are required to calculate joint moments from force plate data. The first is to describe the ground reaction in relevant CS; the second is to take into account the gravitational and inertial effects on the segments distal to the joint being considered. This is known as inverse dynamics and requires calculation of the acceleration of these segments and an estimation of their inertial parameters (mass, position of center of mass, and radii of gyration about the principal axes). The acceleration of the segments is calculated from the kinematic analysis. The inertial parameters are taken from tables scaled to body weight and segment length. Early U.S. military data^[18–20] are most commonly used, despite concerns over their relevance. (The data are drawn from elderly cadavers, not from the typical subjects of most clinical gait analyses).^[21–24]

THE PROCESS OF GAIT ANALYSIS

Conduct of Tests

The measurement volume of most clinical gait analysis systems is a few meters in length and around two meters in width and height. It is important to record the cyclic part of walking after initiation and before the process of stopping commences. There is little hard evidence as to how many steps are involved, but most labs allow subjects a minimum of four steps before entering and after leaving the measurement volume.

The conditions of the analysis (i.e., use of footwear, splints, walking aids) will depend on the reason for the analysis. Assessments of functional performance require the subject to be walking under conditions most similar to those of everyday life. An analysis to plan surgery, however, may focus on the intrinsic capabilities of the patient, in which case walking in bare feet with minimal aids is likely to be most useful.

The inverse dynamic calculations of joint moments will not be valid if the foot has only partially hit the force plate or if anything else (e.g., the other foot or a walking aid) makes contact with the force plate at the same time. The calculation will be valid if a walking aid is used, provided it does not make contact with the force plate, and care is taken in interpretation of the data. Subjects are generally not told about the force plates, because their walking pattern may be affected

by targeting the plates. Data are only used from those walks on which clean force plate contact is made (although this itself may lead to some bias in the data analyzed). It is most common to ask subjects to walk at a comfortable walking speed, although there is some evidence that the speed selected may not be representative of the speed they use to walk in other situations.

Presentation of Data

All gait variables (i.e., those that vary with time through the gait cycle) are conventionally presented in the same graphical format (see Fig. 3). Time is plotted along the horizontal axis as a percentage of the gait cycle, starting at foot contact on one side and ending at foot contact on the same side. The gait variable is plotted on the vertical axis. Plot areas often have an aspect ratio of close to 3:4. Keeping a fixed aspect ratio makes interpretation of gait data more intuitive. Gait events are also often plotted. A vertical line across the full height of the plot is often used to mark toe off and therefore distinguish the stance phase (to the left) and swing phase (to the right). Opposite toe off and opposite initial contact are often represented as tick marks along the top or bottom of the plot area.

Data representing measurements of a particular gait variable recorded for able-bodied subjects are generally plotted on graphs to enable comparison with data

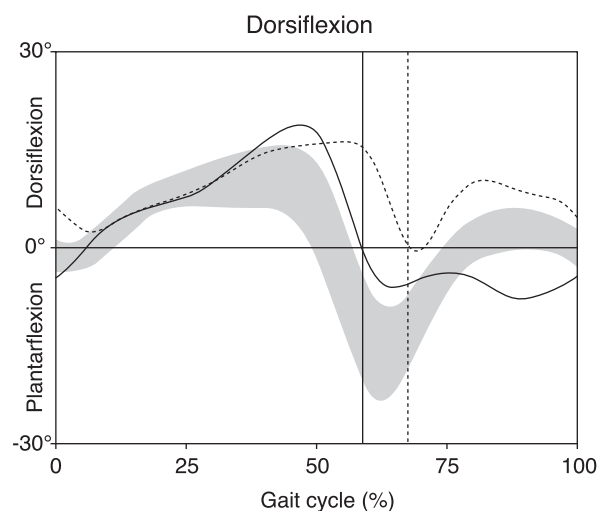

Fig. 3 Graph format for all gait variables. Time is plotted along the x-axis from initial contact to the next initial contact for the same foot. Units are % of gait cycle. The variable is plotted on the y-axis using the relevant units. The left trace is plotted as a solid line and the right unit dashed. Toe off for both sides is marked by the vertical line across the whole graph. The ± 1 standard deviation range about the ensemble average for a cohort of able-bodied comparisons is plotted in light grey. Graphs are all plotted using the same aspect ratio (0.75 in this case).

from a patient. They are often represented as a band representing the ensemble average of data for a number of subjects and a range of a specified number of standard deviations.

Data for the left and right sides are generally plotted on the same axes using different colors. Because the gait cycles for left and right sides start at different times, a point on the graph representing a specific instant during the left-gait cycle represents a different instant in time than does the same point on the graph for the right side. It is particularly important to understand this in relation to pelvic angles because there is only one pelvis, and any differences between the traces for the right and left sides are a consequence of the fact that the same point on the horizontal axis of

the graphs represents the orientation at different times for the left trace and the right trace. It is important to understand the repeatability of a subject's gait pattern, often accomplished by plotting data from several walking trials on the same axes.

Figure 4 shows graphs of individual gait variables, presented as an array on the page. This allows comparison of variables in the same plane for different joints and also of different planes for the same joint. A common arrangement is for the different joints to be represented by different rows (say, pelvis, hip, knee, and for ankle going down the page) and for the different components of the Cardan angle decomposition to be represented by different columns (say, sagittal, coronal, and transverse).

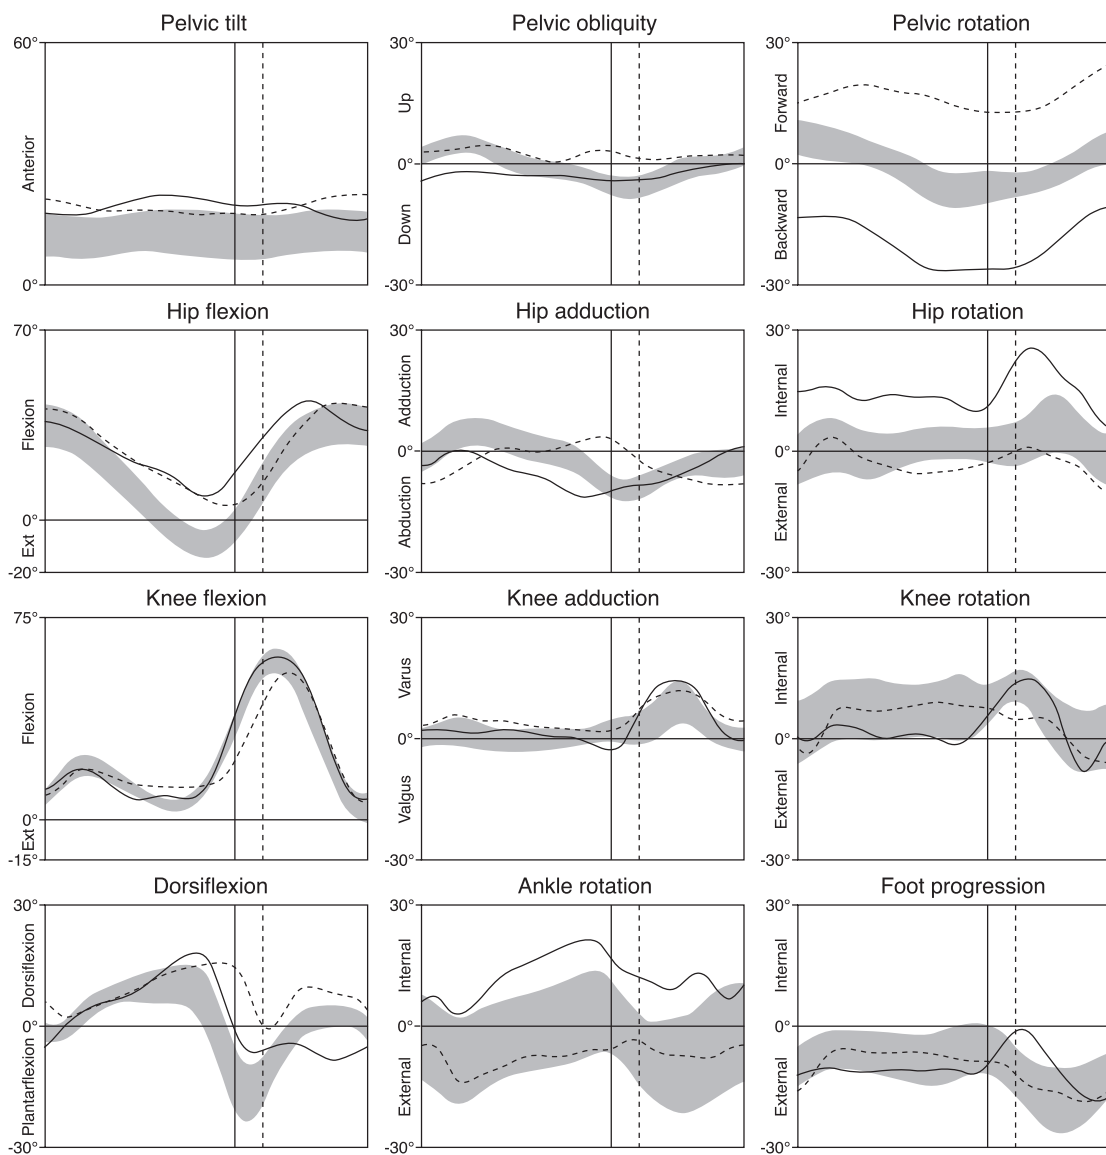

Fig. 4 Layout of graphs for kinematic data. Rows represent different joints (pelvis, hip, knee, ankle in descending order). Columns represent the different planes (sagittal, coronal, and transverse from left to right).

Interpretation of Data

Temporal-spatial data are most often interpreted in comparison to normative data to give an overall assessment of performance. Comparison with subjects' performance at earlier analyses can also provide useful information, but the effects of the subjects' growth on these parameters must always be taken into account. Sometimes comparison of cadence and stride length can give some indication of what is limiting walking speed. Comparison of data for left and right sides can give some indication of gait asymmetry. Subjects will generally spend less time on the weaker or more painful side and will have a shorter step length. Various symmetry indices have been proposed to quantify this.

Detailed interpretation of kinematic and kinetic data is dependent on the diagnosis of the patient, their own functional abilities, and the specific question that the analysis is conducted to address. Although this is beyond the scope of this article, some general guidelines can be given. Interpretation should be carried out following a structured plan. The exact order in which the data are examined is not greatly important, but interpretation should cover at least the issues discussed in the next section.

The first stage of any data interpretation must be an assessment of how reliable the data are. Comparison of data from different trials is required to establish how consistent a subject's gait pattern is. Gait analysis depends on examining a small number of walking trials, assuming that these data are representative of the patient's overall pattern of walking. Evidence of marked variability from walk to walk invalidates the entire approach.

It is also important to be critical of how valid the data are. Certain features intrinsic to the kinematic data can be considered. For example, are there discontinuities in the traces (very rare in human walking)? Is there evidence of cross talk between the knee sagittal and coronal plane kinematics? Is there an appreciable ankle moment in the swing phase? It is also important to ensure that the data is consistent with observation of the patient walking either directly or using video recordings. Gait analysis gives more data than video recordings. The data may explain what is seen but it should never contradict it. For example a coronal plane video recording may clearly show that the knee is being brought across the midline. This may be a result of hip adduction or a combination of pelvic rotation and hip flexion. Gait analysis can be used to determine which of these is happening but must be invalid if it records that the knee is being taken away from the midline. Certain gait data are plotted with respect to the laboratory axis system (pelvic angles and foot progression); these can be straightforwardly compared with video recordings.

If some traces are deemed to be invalid then other traces will necessarily be invalid also. For example, cross talk between knee sagittal and coronal kinematics indicates unreliable transverse plane hip rotations. A swing phase ankle moment almost always indicates invalid moment and power data for other levels. This may be restricted to the swing phase or apply to the entire gait cycle.

The next stage of interpretation is to identify which features of the gait pattern are abnormal. A gait trace can be abnormal in having a more or less fixed offset from the mean trace for able-bodied norms. A gait trace may have the same pattern but exaggerated or diminished features. Finally, the trace may show features that are not present at all in the able-bodied gait. Although the identification of abnormal features may appear to be an objective process, some judgment is required in deciding how large a feature must be to be deemed to be real. Some purists claim that a divergence from the able-bodied mean of at least 2 standard deviations (SD) is required. It must be remembered, however, that much of the variability in the comparative able-bodied data is a consequence of measurement error; rigorously applying the 2-SD rule will mean that some abnormalities are passed over. It must also be appreciated that a trace may be abnormal if the pattern is abnormal, even if it lies entirely within the able-bodied range. Gait traces should be analyzed systematically to identify these abnormalities.

The next stage is to link the identified abnormalities into patterns, where possible. Links can be between different levels; across planes; and between kinetic, kinematic, and EMG data. Flexed hips, knees, and dorsiflexed ankles, for example, represent crouch gait. This almost always results in increased internal knee extensor moments. Any explanation of the abnormalities should concentrate on explaining the overall pattern rather than the individual features.

Once abnormalities have been identified and linked, an attempt must be made to explain them in terms of the patient's pathology. A key factor here is the incorporation of data from the physical examination and EMG studies. Restricted joint movement is often a result of fixed contractures or may be caused by under- or overactivity in specific muscles. Such explanations are rarely either completely objective or completely certain; some indication of the degree of both objectivity and certainty should be recorded, most commonly by the words chosen to describe the features in the report.

It can be argued that this biomechanical explanation of observations ends formal gait analysis, and that decisions as to how the patient should be managed are the realm of the clinician to whom any report is made. It is, common however, for referring clinicians to seek an expert clinical opinion at the time of the

referral. In this case the biomechanical explanation and the clinical recommendations should be clearly distinguished. It is also important that the personnel performing the analysis give clinical recommendations only if they are fully qualified to do so.

RECENT DEVELOPMENTS

Conventional gait analysis has now been in use for around 20 years. In addition to employing these procedures, many centers have done considerable work incorporating other developments into their testing. The most important of these are described in the following section, although none has yet been accepted into widespread clinical practice.

Optimization Techniques in Modeling Gait Data

Perhaps the greatest challenge to clinical gait analysis is obtaining valid basic data. For example, the Newington model^[8] can be very sensitive to small errors in marker placement; the skin on which markers are mounted may move with respect to underlying bone; there is some intersubject variability of the bony anatomy; and the validity of some of the underlying assumptions of clinical gait analysis can be challenged.

The most promising responses to these challenges are optimization approaches that relate marker positions to the underlying anatomy. There have been several attempts to apply such techniques to individual joints,^[25–29] but recent global optimization models applied to the whole body and throughout the measurement period are now proving successful, and are being incorporated into commercially available systems.^[30]

Foot and upper body modeling

For some pathologies the movement of the upper body is an important constituent of gait. For others the assumption that the foot acts as a single segment is invalid. Many detailed models of the trunk^[31–45] and feet^[46–50] have been developed, but none has achieved widespread acceptance. Foot models generally require the placement of additional markers close together on the foot, and are only becoming clinically applicable as measurement technology improves.

Muscle length modeling

In many pathologies for which gait analysis is used, the underlying problem is how the muscles are functioning. Kinematic traces for individual joints offer considerable

insight into how uni-articular muscles contract and elongate, but making inferences about multijoint muscles is much more difficult. By modeling the anatomy of the musculoskeletal system and driving this model by joint kinematics it is possible to estimate the lengths of multijoint muscles, thus giving insight into how they function. Muscle length modeling is probably the most widely used of the techniques discussed here.^[51–57]

Moment arm modeling

The moment that a particular muscle can develop is proportional to its moment arm at a particular joint. In some patients this is critical to the functioning of muscles, and is described by the term, lever arm disease. In two dimensions the moment arm is the perpendicular distance from the joint to the line of action of the muscle. This does not extend to three dimensions, in which case the most common definition is the partial derivative of muscle length with respect to joint angle (component of Cardan angle decomposition). This can be obtained by modeling the path of muscles as a function of the musculoskeletal anatomy and joint angle.^[52,5358–68]

Modelling internal loads

Conventional gait analysis is restricted to consideration of external joint loads. In specific patients, knowledge of internal loads is essential; for example, in determining disease processes in osteoarthritic patients. Based on assumptions about joint anatomy, muscle physiology, and an optimization approach, it is now possible to estimate internal joint loads in certain structures. Duda has established such an approach for the hip,^[69] which has since been validated by measurements from an instrumented hip prosthesis.^[70,71] Similar approaches have been developed for the knee.^[72–74]

Customizing models to individual patients

The Newington model makes various assumptions about the subject. More complex models require more assumptions to be made, and are generally more sensitive to variability between subjects. Various imaging techniques—principally, magnetic resonance imaging (MRI) and computer assisted tomography (CAT scans)—offer the potential to customize models to individual patients. Although considerable research in these areas is ongoing, the cost of obtaining MRI, and CAT scans will probably prevent their widespread clinical use in the immediate future.^[51,60]

Center-of-mass modeling

There has been a long history of interest in how the center of mass moves during walking. Although the insight that center-of-mass modeling gives into the interpretation of gait analysis data has probably been overestimated, there are certain cases where a knowledge of its trajectory does help explain the gait pattern. Models tend to be based on kinematic models involving estimations of the mass and center-of-mass position of each segment of the body. Some studies have validated these models by comparing them with the second integral of the total ground reaction.^[75–81]

Forward simulation

There has been considerable debate (which stimulated the Weber brothers as long ago as 1835) over whether the swing phase of gait is passive or requires muscle action. It is now clear that muscle activity is required, but the balance between initial conditions and ongoing muscle activation in controlling the swing phase is often a key issue in relation to pathological gait. Forward simulation of swing phase motion allows these two to be separated and allows better informed interpretation of gait data.^[82–93]

Induced acceleration analysis

Because the external joint moments act within either an open- or closed-chain structure, there is not a simple relationship between these and joint angular velocities. Methods have recently been established to determine how much of the angular acceleration observed at a particular joint can be attributed to either the external moment generated at that on another joint or, to the tension generated in a specific muscle. Although there are specific technical problems, particularly in modelling contact of the foot with the ground, these methods are perhaps the most exciting recent advances in this field.^[87,94–97]

CONCLUSION

Clinical gait analysis is an increasingly important part of the management of patients with musculoskeletal disorders affecting the lower limbs. The procedures established in Newington in the early 1980s have become widely implemented and can now appropriately be referred to as conventional clinical gait analysis. Many other techniques are now being developed, but none has so far had widespread clinical acceptance. Many of these techniques will make a considerable impact on the interpretation of data for specific

patients, and it is hoped that the next decade will see them implemented in routine clinical practice.

Gene-Activated Matrix

Neil Davies

Cardiovascular Research Unit, University of Cape Town, Cape Town, South Africa

INTRODUCTION

The gene-activated matrix (GAM), a system in which a gene delivery vector is contained within a biodegradable scaffold (Fig. 1),^[1,2] is one of those fertile regions in science in which the paths of two major disciplines, namely gene therapy and tissue engineering, cross. Gene therapy has until recently been considered a treatment whereby genetic diseases could be cured through the introduction of normal genes into the patient to supersede the effects of their malfunctioning counterparts. This understanding of gene therapy resulted in the first human clinical trials in 1990 for the treatment of patients with severe combined immunodeficiency resulting from an adenosine deaminase deficiency.^[3] However, there is another sphere in which gene therapy may prove useful, one that does not specifically require the replacement of a defective gene but rather the production of a desired protein within a specific tissue or disease site. Thus, the gene is delivered by a suitable vector to the defective site resulting in the localized production of a therapeutic protein.

This latter mode of gene therapy is particularly pertinent to the field of tissue engineering. Tissue engineering is principally concerned with the replacement of tissue that has lost function due to injury or disease. In one approach toward this goal, cells are cultured *in vitro* on biodegradable polymeric scaffolds to form neoorgans that are then implanted into the body at the necessary anatomical site. This strategy has great potential and has already resulted in the generation of a clinically approved tissue-engineered human skin equivalent, Apligraf (Organogenesis Inc.; Canton, MA). This bilayering of allogeneic keratinocytes and fibroblasts, respectively on and within a bovine collagen I lattice, has been approved in the United States and been used effectively in the treatment of surgical wounds and venous ulcers.^[4] However, keratinocytes and fibroblasts do not produce an allogeneic T-cell response, enabling this product to sidestep a major hurdle in the use of living cells, the patient's immune response.^[5] Additionally, the need for several weeks of *ex-vivo* culture of the neo organ, the difficulties in preservation of the neo organ, and the sheer number of replacements that are needed (e.g., 570,000 aortocoronary bypass procedures per annum,^[6]

suggest that in the short- to medium-term, other approaches must be explored. The implantation of acellular scaffolds to enhance an organ's ability to spontaneously regenerate is one such tactic. A central component of *in-vivo* tissue regeneration is the supply of proteins, which are involved in driving the process of regeneration (e.g., growth factors) to the required site. It is for this purpose that the GAM was developed.

In this article, the need for gene-activated matrices will be presented, as well as brief overviews of the necessary central tenets: the requirement of a wound bed, gene delivery vectors, and biodegradable polymers. Finally, the advances that have been made in this new field will be summarized.

THE NEED FOR GENE-ACTIVATED MATRICES

Cytokines and growth factors are proteins secreted by cells to induce target cells to carry out specific actions such as migration or proliferation. Many growth factors have been shown to play pivotal roles in the regeneration of tissue, for example, bone morphogenetic proteins (BMP) in bone regrowth, vascular endothelial growth factor (VEGF) in the growth of new blood vessels, and platelet-derived growth factor BB (PDGF-BB) in the healing of skin wounds. Therefore, they are clear targets for exploitation in the pursuit of engineered tissue regeneration.

However, several issues have impeded progress in the use of recombinant growth factors in the repair of damaged tissue. The delicate nature of the complex 3-D structures of the proteins results in very short half-lives in the body as demonstrated by VEGF having a clearance half-life of less than 1 hour after injection.^[7] This phenomenon essentially precludes the systemic delivery of growth factors due to the large doses that would be required. Such doses are naturally associated with the potential for toxicity and have indeed limited the amount of basic fibroblast growth factor (bFGF) and VEGF that could be administered in phase 1 clinical trials due to their potential to induce severe hypotension.^[7] A logical alternative would be the use of a system that allows controlled and sustained delivery of the growth factor. Though this strategy is being actively pursued, it too is hampered by the

Fig. 1 The central components of a GAM—a biodegradable matrix containing gene-delivery vectors—is positioned within a wound. The matrix retains the gene vectors within the wound while the wound is invaded by wound repair cells. The localized concentration of vector promotes gene delivery to the invading cells and the cells that do take up the gene then generate a sustained and focused production of the encoded bioactive product.

fragility of the polypeptide, as the generally available processes to manufacture controlled-release systems expose the growth factor to solvents and/or sonication.^[2] Therefore, this approach still requires fairly high dosages and again raises the issue of toxicity. Pertinent to all of the above is the not-inconsiderable cost involved in the manufacture of recombinant growth factors.

A clear avenue through which the above problems can possibly be circumvented would be, as indicated above, to utilize the tools of gene therapy and deliver the gene encoding for a growth factor directly to the site requiring tissue regeneration. The cells that take up the gene would then serve as in-vivo bioreactors producing the required growth factor. In an indirect manner termed ex-vivo gene therapy, cells are harvested from the patient, the gene delivered in vitro, and the cells transplanted back into the defective site. This is technically demanding due to the need to harvest cells, and simpler approaches involving the direct delivery of the gene would be desirable. Systemic delivery of a gene vector through injection into the blood system, though potentially suitable for the treatment of metastatic diseases such as cancer, clearly would not be useful for tissue regeneration due to the elevated risks associated with delivery of the gene to cells throughout the body. A more directed approach where the VEGF gene in an aqueous vehicle was directly injected into muscle tissue has been shown to be effective in generating the growth of new blood vessels in an ischemic hindlimb of a rabbit.^[8] Indeed, in a phase 1 clinical trial, the same gene was safely delivered via injection into the ischemic myocardium of five patients with some indication of increased reperfusion.^[9] However, where tissue regeneration into an anatomical space is

required, it would be desirable to retain the gene within the actual defective site, thus preferentially targeting ingrowing cells. This would allow for the production of the growth factor within the defective site, generating chemotactic gradients to attract desired cell types into the site. A gene delivered in an aqueous vehicle into the site would probably be poorly retained and evidence indicating this will be detailed below. The provision of a biodegradable scaffold that retains the gene delivery vector but allows the invasion of cells, thereby bringing these cells in direct contact with the gene vector, is the core of the GAM concept.^[10] Though several biodegradable scaffolds and gene delivery vectors have been employed in GAMs, a fundamental component is the harnessing of the cells involved in the wound healing response.

WOUND HEALING

It is difficult to envisage a situation where tissue regeneration is required that will not involve the formation of a wound. The wound will have either been caused by injury or will almost certainly have resulted from surgical intervention. Even intramuscular injections cause sufficient tissue damage to generate a wound repair response.^[11] The wound healing program is highly conserved and follows a very similar pattern in traumatic injury, pathology-induced injury, and injury caused by surgery.^[10] The sequence of events have been most closely studied for cutaneous wound healing and found to consist of three temporally overlapping phases: inflammation, granulation tissue formation, and tissue remodeling.^[12] The inevitable leakage of blood into the wound site results in the formation of a clot that is composed mainly of fibrin and contains many activated platelets. The degranulation of the activated platelets releases a large variety of growth factors that form chemotactic gradients for the inflammatory response neutrophils and monocytes. Neutrophils cleanse the wound area of foreign particles and are rapidly removed by activated macrophages within the first three–four days of the wound healing response. Fibroblasts start to migrate into the wound after three–four days along with the invasion of blood vessels, resulting in the formation of granulation tissue. After laying down a collagen-rich matrix, fibroblasts begin to convert to a contractile myofibroblast phenotype that is believed to be necessary for wound contraction. During tissue remodeling, the cells within the wound undergo apoptosis, leaving behind a relatively acellular scar.

It is the aforementioned cell types that will come into contact with the gene delivery vector contained in the implanted scaffold.

GENE DELIVERY VECTORS

In brief, gene delivery vectors can be viewed as falling into three classes: naked DNA, complexed DNA, and viral vectors. Naked DNA essentially refers to plasmid DNA expression vectors, which are circular DNA constructs consisting of the DNA sequence for the gene of interest and other necessary sequences that include transcriptional promoters and regions that impart stability to the transcribed mRNA. Plasmid DNA is the simplest vector to produce and probably has the optimal safety profile of presently available vectors, but is also the least effective. This is not surprising as eukaryotic cells are well protected against the uptake of foreign nucleic acids by a number of cellular barriers. These compose the plasma membrane, which is negatively charged (repellent to the large negatively charged plasmid molecules), the sequestration of plasmids away from the nucleus through internalization within endosomes, and the nuclear membrane, which does not allow passive diffusion of particles of a greater molecular weight than 60 kDa.^[13]

Therefore, intensive research has been directed toward overcoming these obstacles in order to increase the efficiency of transfection, the process whereby eukaryotic cells take up foreign DNA.^[13] Plasmid DNA has been complexed with a variety of reagents (lipids, polymers, and peptides). The most widely employed complexing agents are cationic liposomes and condensing reagents such as poly(ethyleneimine) and poly(L-lysine), which respectively form lipoplexes and polyplexes with the DNA. Both facilitate interaction of the negatively charged DNA with the negatively charged plasma membrane. They are also presumed to improve transmembrane transport through diffusion of the lipoplexes and via reduction in the size of the DNA molecule in the polyplexes. The complexing reagents also permit the coupling of cell receptor ligands (e.g., epidermal growth factor) that not only enhance the binding of the complex and its subsequent uptake by endosomes but also allow for the potential of cell-specific targeting. In addition, peptides that disrupt the endosome (e.g., bacterial protein toxins) and nuclear localization signals can be bound to lipoplexes and polyplexes.

GAMs that carry plasmid DNA are therefore a subset of the class of complexed DNA vectors. In part, plasmid DNA was utilized in the initial design of GAMs due to its simplicity of production and good safety profile^[1] but also due to the desire to increase the efficiency of plasmid DNA, as a gene therapy vector was central to the development of GAMs. There is a subtle difference in the rationale behind the GAM approach to improved gene delivery from that of other complexed DNA strategies, thus placing GAMs in a distinct subset. The emphasis is on the retention of the gene within a specific locale to await the arrival of

target cells rather than the active delivery of genes to these target cells. Thus, it has been hypothesized that the GAM not only allows for delivery of the therapeutic gene to the desired site in tissue engineering but also that the elevated local concentration and sustained persistence of the gene would enhance uptake.^[14] In a canine tibia defect model, plasmid DNA complexed within a collagen sponge was retained at the site of implantation for at least six weeks as determined by the polymerase chain reaction (PCR).^[1] Similar results were found for a collagen-based GAM implanted into transections in rat optic nerves.^[15] In both cases, expression of the delivered plasmid DNA was also found to persist for at least six weeks as evidenced by the detection of delivered gene-specific mRNA by reverse transcriptase PCR. The high level of invading cells transfected by a reporter gene, β -galactosidase, in the above canine tibia defect model strongly indicates that there is elevated efficiency of delivery by GAM. The exact mechanisms that resulted in 20–50% of the invasive cells taking up the reporter gene are unknown, but it has been speculated that the high mitotic index of cells involved in the wound healing response could have contributed,^[2] with the breakdown of the nuclear membrane during cell division possibly facilitating the plasmid DNA reaching the nucleus.

Viral vectors have been driven by evolution to become highly efficient at bypassing the previously mentioned cellular barriers toward foreign DNA ingress. It is therefore not surprising that the majority of clinical gene-therapy trials have employed them as the vector of choice. The retrovirus, the herpes simplex virus, the adenovirus, and the adeno-associated virus (AAV) are the most commonly used viral vectors.^[16] All of these have been engineered to render them replication-deficient, permitting the initial infection of the target cell but preventing escape of the virus from the target to other cells.

The retroviruses are single-stranded RNA viruses, the majority of which are based on the Moloney murine leukemia virus. These viruses are able to infect only actively dividing cells, limiting their usefulness in gene therapy. However, due to their low immunogenicity resulting from the complete removal of viral proteins, they are the most widely used vectors in clinical trials. Retroviruses can semirandomly insert themselves into the host genome, which results in greater persistence of expression but also raises the risk of insertional mutations. This can potentially occur when the insertion activates a protooncogene or disables a tumor suppressor gene. More recently, vector systems based on the lentivirus genus (which includes the human immunodeficiency virus) of the retroviruses have been developed. These vectors are able to infect dividing and nondividing cells, but their use is still complicated by their pathogenicity.

The herpes simplex virus is a double-stranded DNA virus that is able to take up to 30 kilo bases (kb) of foreign DNA. This complex virus is also able to infect dividing and nondividing cells, but research has been hampered by the vector's cytotoxicity.

The original adenovirus vector was based on the virus that causes the common cold in humans. The recombinant replication-deficient double-stranded DNA virus is able to infect a wide variety of cells, both dividing and nondividing, with excellent efficiency, and the virus is easily produced to high titres (1×10^{13} viral particles/ml). This form of vector does not result in persistent expression, as it does not integrate into the host genome. The first generation versions have been plagued by cytotoxicity and immunogenicity problems related to the expression of viral proteins that remain in the vector backbone. Thus, much research has been directed towards overcoming this problem, resulting in the gutless vectors from which all adenovirus genes have been removed, leaving only the sequences necessary for replication and packaging of the genome. This has, however, complicated the manufacture of recombinant virus due to the need for a helper virus.

AAVs are single-stranded DNA viruses that are nonpathogenic for humans. In their wild-type form they specifically integrate into chromosome 19, but this specificity has been lost in recombinant viruses. Therefore, though recombinant AAVs still have the potential for persistent expression, they are also capable of insertional mutagenesis. These viruses are able to infect both dividing and nondividing cells and are substantially less immunogenic than the adenovirus (though the generation of neutralizing antibodies may restrict readministration). Until recently, their use has been somewhat curtailed by manufacturing difficulties and their limited ability to carry foreign DNA (<5 kb). The former drawback has been surmounted by the development of helper-free systems and a single-step purification methodology that allows for the generation of titres of 1×10^{12} viral particles/ml that are free of replicative virus. Recent exploitation of the need of AAV to form concatemers during their infection of a cell has effectively doubled their payload of foreign DNA.^[16]

So far, adenoviruses are the only viral vectors that have been employed in GAMs. This is probably due in part to their ease of production and high efficiency. In addition, the transient expression of the therapeutic protein that results from adenoviral infection might be sufficient and indeed desirable for the regeneration of tissue.^[17] Conceptually, the GAM would serve a similar role for viral vectors as for naked plasmid DNA, that is, the delivery of the vector to a desired anatomical site with the consequent generation of bioeffectors in the invading wound repair tissue. However, another consideration more pertinent to viral vectors is

the retention of the virus at the site of delivery, thereby increasing the safety profile by reducing infections at distal sites.^[18] In-vitro release studies found 20% of loaded adenoviruses were released from 0.15% collagen GAMs over 48 hours and that this release could be reduced to 10% by increasing the collagen content to 2.6%.^[17,19] When adenoviruses were reacted with biotinylated antibodies specific to the hexon protein of the virus and subsequently polymerized into 0.21% collagen gels containing biotin-binding avidin, the release was reduced to 5% at 48 hours.^[18] However, in a direct comparison between adenoviruses injected either directly or as an antibody-complexed GAM into porcine right ventricles, the biodistribution was found to be identical. For each delivery method, adenovirus was found in the lungs of seven out of eight animals. No evidence for distribution was determined in the liver, kidneys, or left ventricles. The GAM preparation did show significantly more efficient delivery of a reporter gene, green fluorescent protein, to the target tissue of the right ventricle than the aqueous solution. Though the biodistribution results were not significantly different for the antibody-complexed GAM compared to aqueous delivery, this approach holds significant promise, as relatively simple modifications such as a higher-specificity antibody or covalent binding of the avidin to the GAM polymer should greatly improve in-vivo retention.^[18] This aspect in the development of GAMs will become increasingly critical with the employment of viral vectors with the potential for persistent gene expression and hence an increased need for accurate delivery to their target cells. With reference to these persistent expression-type viral vectors, the very small AAV (25-nm diameter, compared to the 90-nm diameter adenovirus) may prove particularly difficult to retain within a GAM.

BIODEGRADABLE SCAFFOLDS

Several biodegradable scaffolds such as collagen, gelatin, carboxymethylcellulose, and poly(lactide-co-glycolide) have been utilized for GAMs. Collagen, a triple helix polypeptide that is the major component of mammalian connective tissue, can be conveniently gelled by elevating the pH to neutral and the temperature to 37°C. In addition, it has been clinically approved for use in a tissue-engineering application (bovine collagen: see the discussion of Appligraf in the Introduction). These considerations have probably resulted in this biopolymer being most commonly employed in GAMs, and it has been used in lyophile sponge, paste, and gel formulations.^[2] Fibrin, another biologically derived polymer, is a potentially interesting candidate that has not yet been reported on in the GAM literature. This polymer, which is the major

constituent of the clot present in the early stages of wound healing, has been found to allow substantially more rapid ingrowth of wound repair cells than collagen,^[20] and human-derived fibrin has been clinically approved.

Biologically derived biopolymers are compromised by their potential to transmit copurified pathogens, batch variation, and their limited ability to be tailored to fit specific requirements. For these reasons, biodegradable synthetic polymers are being intensively investigated.^[21] Focuses of research into synthetic polymers include temporal control of degradation, mechanical properties, and derivatization of polymers with specific signals such as adhesive peptides and growth factors. A promising approach for future use in GAMs is the development of gels that are polymerized with oligopeptides that are substrates for degradative enzymes (e.g., plasmin, collagenase), thus rendering the synthetic matrix degradable by cell-based enzymatic activity.^[22] The synthetic linear aliphatic polyester poly(lactide-co-glycolide) has been used in a GAM-based strategy to deliver a plasmid encoding for platelet-derived growth factor B (PDGF-B) in a rat subcutaneous model.^[14] This approach should perhaps be more strictly classified as a sustained release preparation, as no cells were observed actually to invade the poly(lactide-co-glycolide) sponge and take up a plasmid encoding for the reporter gene β -galactosidase contained within the gel. However, high levels of β -galactosidase expression were observed in the wound repair tissue peripheral to the implant and poly(lactide-co-glycolide)-complexed PDGF-B plasmid significantly enhanced the formation of granulation tissue in the subcutaneous pocket relative to that detected for directly injected PDGF-B plasmid.

TISSUE REGENERATION

GAMs have been used in facilitating the regeneration of several different tissues types, as detailed in the following sections.

Hard Tissue

Bone has the ability to regenerate itself but only if the defect is under a critical size and complex fractures with large voids are therefore at risk of nonunion. Regeneration of bone in critical defects introduced into rat femurs was the first study to assess the viability of GAMs in guiding tissue growth.^[23] Fang and colleagues implanted lyophilic collagen sponges into the defects that delivered 0.5–1.0 mg plasmid DNA encoding for either a secreted form of parathyroid hormone (hPTH 1-34), bone morphogenetic protein-4

(BMP-4), or a combination of these plasmids. The single-plasmid GAMs resulted in bone growth and a functional union across a 5-mm defect within nine weeks where fibrous scarring would have normally occurred. Bridging of the gap was observed at four weeks after delivery of the combination of hPTH 1-34 and BMP-4, these two proteins being known to interact in a synergistic manner. In a follow-up study in a larger animal model (canine tibia critical defect), the exact mechanics of therapeutic protein delivery were examined in greater detail.^[1] As described above, plasmid DNA and RNA transcription persisted for six weeks and 20–50% of the invading cells were transfected. These cells were identified as fibroblasts on the basis of their morphology. At two weeks there was a local content of approximately 2.9 pg hPTH 1-34 in gaps that had received 1.0 mg of hPTH 1-34-encoding plasmid, pMAT-1. Bone growth in a 2.0-cm critical defect in the tibia began when 40.0 mg of pMAT-1 DNA was delivered. This amount allowed for only 25% healing within four weeks and it required 100.0 mg pMAT-1 DNA to generate a 60–75% filling by six weeks. Complete gap filling was not observed in this size defect. It is intriguing that these very high dosages of plasmid were needed to generate a therapeutic effect, as the lower dosage (1 mg) resulted in transfection of a significant percentage of the invading cells. With the maximal loading of plasmid, 1.6-cm gaps were completely bridged in 18 weeks and 1.0-cm gaps in eight weeks. Most strikingly, no bone growth was observed for control sponge implants for either of these two different size defects.

In a preliminary study into lumbar interbody fusions, a lyophilic collagen sponge delivering hPTH 1-34 plasmid DNA was also found to stimulate bone growth above that of control sponges.^[24] These results further substantiate the conclusion from the two aforementioned studies that the production of bone growth factors by wound repair cells present within a defect can induce substantial growth of new bone.

Soft Tissue

Skin

Cutaneous wounds in adults essentially heal as reepithelialized scar tissue due to the respectively potent and feeble regenerative capabilities of the epidermis and underlying dermis.^[25] Venous stasis, pressure, and diabetes mellitus can result in chronic ulcers where even the migration of the epidermis is derailed. The large numbers of these chronic wounds (2 million annually (U.S.A.)^[4]) and the resultant high financial costs have driven research in this area. Growth factors applied as proteins have met with limited success and this

has been ascribed in part to the protease-rich environment of the wound bed.^[26] Therefore, the potential of the GAM for sustained, localized production of a therapeutic protein has made it an interesting candidate in this instance.

Approval of PDGF-BB protein by the U.S. Food and Drug Administration as a treatment for improving the healing of diabetic foot ulcers naturally resulted in this growth factor being the initial candidate for GAM delivery. The effect of the delivery of the gene as a plasmid from lyophilic collagen sponges on wound healing was studied in an ischemic rabbit dermal ulcer model.^[19,27] This model mimics an important component of the human diabetic ulcer, the reduced supply of oxygen and other nutrients resulting from peripheral vascular disease. When 1.0-mg PDGF-B plasmid DNA in lyophilized collagen was placed within 6-mm wounds in ischemic rabbit ears, a five-fold increase in granulation tissue formation and a two-fold increase in epithelialization relative to collagen alone were observed after 10 days. Similar results were found for the delivery of PDGF-A plasmid DNA, a closely related growth factor that forms both homodimers and PDGF-B heterodimers.

GAM-based delivery of PDGF-B gene has also been considered in the context of a highly efficient adenoviral vector, replication-deficient adenovirus serotype 5.^[17,19] Initial investigations into the efficacy of this system in aiding wound healing were carried out in a rodent subcutaneous polyvinyl alcohol (PVA) sponge implant model. Adenoviral vectors in a 0.15% collagen gel were directly injected into PVA sponges four days after their subcutaneous implantation, and the sponges were explanted up to 12 days after viral/collagen injection. PDGF-BB expression, as determined by immunohistochemistry, continued for up to eight days. Six days after treatment, granulation tissue content was increased three- to four-fold by the administration of 2×10^{10} PDGF-B encoding adenoviruses relative to collagen gel alone. Interestingly, a single dose of 100- μ g PDGF-BB protein resulted in significantly less granulation tissue formation even though explanted sponges that had received the above loading of adenovirus contained only 54-ng PDGF-BB protein upon explant. Three sequential doses (alternate days) of 10- μ g protein were needed to generate a similar amount of tissue and this suggests that it is indeed the persistent expression of PDGF-B that is responsible for the effectiveness of the GAM. The efficiency of the adenovirus was demonstrated, as the majority of cells (leucocytes and fibroblasts) at one day after delivery contained virus and expressed PDGF-B mRNA. The PVA sponge model was further utilized to assess the effect of conjugating bFGF to the adenoviral vector.^[26] The targeting of adenoviruses to fibroblast-growth-factor receptor-expressing cells had been

previously shown to increase the potency of the viral vector. Similarly, in a combination of GAM technology and viral targeting, the injection of a 0.15% collagen solution containing 2×10^9 bFGF-conjugated adenoviruses encoding for PDGF-B generated granulation tissue formation equivalent to that obtained with 2×10^{10} nonconjugated adenoviruses. The enhanced tissue formation was not due to any direct actions of bFGF.

In application of PDGF-B gene-encoding adenoviruses in collagen gels or lyophilic sponges to dermal wounds in normoxic pigs and ischemic rabbits, similar improvements in wound healing were observed to those reported in the aforementioned study.^[17,19] Significantly, when an equivalent dosage (2×10^{10} viral particles) was delivered in an aqueous buffer to a wound in the rabbit model, no increase in tissue formation above that of controls was observed. The seepage of the vector from the delivery site was evidenced by fibroblast proliferation and PDGF-BB production in the underlying dermis.

Arterioles

Ischemia caused by vascular disturbances is a devastatingly prevalent condition and can result in, for example, lower limb loss, coronary heart disease, and peripheral neuropathy. It is little wonder, therefore, that growth factor-driven therapeutic neovascularization has received such great attention.

The potency of GAMs in stimulating arteriolization was investigated in a rat model where 3×5 -mm plugs were removed from the rectus femoris.^[17] The defects were filled with collagen-gelatin (1% each) mixtures containing either adenovirus or plasmid DNA encoding for bFGF, FGF6, and PDGF-B. After excision at 21 days, 5×10^9 bFGF-encoding adenoviruses resulted in a six-fold increase in arterioles growing into the wound space relative to matrix alone. Similar results were observed for 1.0-mg loadings of bFGF and FGF6 plasmid DNA, but again no response was observed for 60- μ g bFGF protein. PDGF-B plasmid DNA stimulated the growth of capillaries but did not result in any significant arteriolization, a somewhat puzzling result, as PDGF-BB is a potent chemoattractant for smooth muscle cells.^[28] As evidence of the pleiotropic nature of the FGF proteins, increased muscle regeneration was apparent with an approximately twenty-fold increase in density of a marker for myotube proliferation observed for GAMs carrying either bFGF or FGF6 plasmid DNA.

In a subsequent study, the utility of the aforementioned findings for bFGF in the treatment of ischemic myocardium was determined.^[29] This study was particularly pertinent, as the stimulation of

arteriogenesis rather than capillary growth is considered the preferred form of neovascularization for restoring myocardial perfusion.^[7] Ischemia in the myocardium of pigs was produced by surgically restricting the flow in the left circumflex artery. A GAM of collagen-gelatin (1% each) with an adenovirus encoding for bFGF was injected into the ischemic area (20 injections of 5×10^{10} particles each, one injection/cm²), and the contractility of the region was determined at six weeks by echocardiography analysis and magnetic resonance imaging. Contractility was significantly improved compared to that found in mock-injected ischemic regions and correlated with a five-fold increase in arteriolization.

Nerve

Central nervous system tissues almost always show limited healing and a major cause is the inability of adult neurons to proliferate. Berry and colleagues investigated the efficacy of GAMs in promoting nerve healing in surgically severed rat optic nerves.^[15] The placement of a collagen paste containing a reporter gene encoded on plasmid DNA between the proximal and distal ends resulted in retrograde transport of transfected DNA to the nerve cell body in the retina. A GAM containing a cocktail of plasmids encoding for several neurotrophic growth factors significantly increased the number of surviving active retinal ganglion cells to 2.25% relative to the 0.37% for a GAM containing a reporter gene-encoding plasmid.

CONCLUSION

GAMs have been shown to be capable of promoting growth in a wide variety of tissues. In several instances, the presentation of growth factor genes embedded in a matrix was demonstrably more efficient than the delivery of the gene in an aqueous vehicle or the growth factor protein itself. Therefore, the central premise that invading wound healing cells would be able to serve as bioreactors for sustained production of a therapeutic protein is a sound one.^[30]

The future of the GAM will of course incorporate an increasing range of growth factors and combinations thereof. The delivery of other entities such as antisense DNA and intracellular signaling proteins will become increasingly more common. Recently, an antisense plasmid against thrombospondin 2 was employed in a collagen coating for biomaterials resulting in alterations in the foreign body reaction.^[31] The utilization of improvements in transfection such as endosomal disruption as they become more established would be appropriate, particularly in the nonviral

GAMs. Greater persistence of gene expression may be desirable in certain instances such as particularly large defects in bone. This would be best achieved by the use of vectors with a long-term effect such as AAV or retroviruses. The direct targeting of longer-lived wound repair cells such as fibroblasts through the use of receptor-mediated targeting or cell-specific promoters may also prove useful. Long-term expression would most likely necessitate the combination of a regulatable gene expression system with the GAM.^[2] The use of these systems that employ oral uptake of drugs such as tetracycline or rapamycin to control chimeric transcriptional activators^[32] would also allow for temporal control so that pulsatile delivery of a therapeutic protein could be achieved if required. When the physiological sequences in which different growth factors are supplied during tissue regeneration become more clearly understood, it could be envisaged that the required order of delivery of two or more growth factors might be matched by regulating their genes with distinct drugs.

The challenging arena of human clinical trials still awaits GAMs as many other gene therapies that have shown great promise in animal models have failed at this critical stage. The biodistribution and biotransformation of the genes and their products will of necessity require greater attention. Although these are formidable obstacles, the significant progress made thus far holds great promise for the GAM.

INTRODUCTION

The term “therapy” has been described as treatment of illness or disability. However, gene therapy promises far more than traditional medical therapy. As opposed to treating a condition, gene therapy offers to cure it by correcting, at the genetic level, a congenital deficiency or alteration of some critical function. The first gene replacement therapy clinical trial occurred in 1990 involving Ashanthi DeSilva, who suffered from ADA-SCID, or adenosine deaminase severe combined immunodeficiency. Since the 1990 ADA-SCID trial, patients have enrolled in 918 gene therapy protocols, with the vast majority taking place in the United States.

Gene therapy has a straightforward goal: to introduce genetic information into a host to replace or correct a biological function. Important components of gene therapy include the nature of the vector, the nature of the therapeutic gene, the target cell or tissue (host), and the pathophysiology of the disease process. These factors interact to achieve a biologic effect that can be characterized by a time course (transient v permanent), by a measure of efficacy often directly correlated with efficiency of transduction, and by toxicity. An important feature of the pathophysiology is whether the disease process is functionally a cell-autonomous or non-cell-autonomous one. If correction in one cell can functionally correct a phenotype by complementing the function of neighboring cells, then it may be viewed as non-cell-autonomous process. However, if a phenotypic deficiency cannot be cross-corrected in this way, then it may be viewed as cell-autonomous. This is not always a clear distinction. A simple example of a non-cell-autonomous pathophysiology is a deficiency of a secreted protein such as in hemophilia. In this case, correction of a small number of target cells to overexpress the missing plasma protein may be sufficient to correct the clinical phenotype.

THE DISEASE

Gene therapy can be broadly divided into therapy for three different disease domains. They include gene

replacement therapy of genetic deficiencies, gene therapy for cancer, and gene therapy for infectious diseases. Gene therapy for infectious disease has focused on genetic vaccination. Like a traditional vaccine, genetic vaccination seeks to introduce or stimulate the host immune response by expressing a pathogenic epitope. Genetic vaccination generally initiates a specific host immune response against a single antigenic peptide of a pathogen, obviating exposure to the pathogen in its entirety. The de novo expression of antigenic peptide in a target cell may influence the type of host immune response (Th1 v Th2) and determine whether a cellular or an antibody response is mounted. Th1 (T-helper cell type 1) is characterized by a proinflammatory predominantly cellular response. Th2 responses are partially antagonistic to Th1 and are predominantly humoral (antibody-mediated). This approach may also be applied to the domain of cancer. In this case, cancers often express unique tumor-associated antigens (TAA) and the host immune response could be primed to respond to such antigens by genetic vaccination. Cancers often arise from loss of function of tumor suppressor genes, and gene replacement therapy can target replacement of such a gene in an effort to restore growth control.

Another approach draws upon pharmacological manipulations to convert a systemically delivered nontoxic prodrug into its toxic counterpart by prodrug-converting enzymes that are delivered to tumor cells by gene therapy. The transduced cancer cells expressing the enzyme will subsequently convert the prodrug into a lethal compound in a cell-specific manner and thus achieve a cancer-specific suicide gene therapy. Another approach of gene therapy relevant for cancer as well as infectious disease is immunotherapy, which resembles genetic vaccination because it also primes the immune system. In this case, the goal is to introduce genes that encode cytokines or signaling molecules that facilitate autocrine and/or paracrine signaling. Numerous cytokines have differential properties associated with cell maturation, cell proliferation and apoptosis, transcriptional repression or

enhancement, recruitment of inflammatory cells, etc.; thus, the immunomodulatory cytokine gene(s) is chosen in a context-dependent fashion.

In contrast to cancer and infectious disease gene therapy, where the patient immune system is an ally, gene replacement therapy for genetic disease must often overcome the host immune system to achieve long-term correction without toxicity. In this situation, the goal is to replace a missing protein in a sufficient number of target cells, at the same time avoiding immune clearance of the vector or the transgene. This contrasts with cancer and infectious disease therapy, in which the goal is to stimulate clearance of a pathogenic target by directly transducing either the pathogenic cell or a host cell to facilitate the clearance.

THE VECTOR

Vectors, or delivery systems, are an integral part of gene therapy in that the vector is the vehicle that achieves gene transfer into target cells or tissues. Depending on the disease, the vector may be delivered systemically or locally to tissues. Depending on the disease pathophysiology, different vectors are chosen to satisfy specific requirements relating to: 1) vector tropism for target tissue; 2) cloning capacity; 3) persistence in target cells (episomal v integrating vectors); 4) production yields; 5) immunogenicity/toxicity; and 6) cost (Table 1). The disease pathophysiology will dictate the qualities required for a vector system. This implies that there is no general vector system that will satisfy all disease processes. Instead, the features of each vector system will be suited for a particular group of conditions. Vectors can be broadly classified as nonviral v viral vectors. In the latter, the natural life cycle of the virus is co-opted and engineered to generate replication deficient versions that will express a therapeutic transgene.

Nonviral Vectors

Naked DNA

One of the simplest methods of gene transfer is the administration of a plasmid containing the gene of interest. Purified plasmid can be introduced *in vivo* by injection into tissue, or by delivery into a vein (which often favors hepatocyte transduction).^[1] Kou-Gi et al.^[2] found that injection of plasmids encoding human VEGF (vascular endothelial growth factor) or HIF-1 (hypoxia-inducible factor 1) into rat heart resulted in detectable tissue-specific expression of the transgene for up to 14 days. This study, like many others, relied upon commercially available plasmid

constructs and plasmid purification kits. Thus, production is both simple and affordable. The transduction efficiency can be enhanced by precipitation of the DNA with calcium phosphate before delivery; this process has been widely found to increase entry of DNA and RNA into cells.^[3] With regard to genetic deficiencies, gene transfer holds a distinct advantage over recombinant protein administration, because the efficacious yield of recombinant protein may be artificially reduced *in vivo* due to intra- and extracellular enzymes and proteases.^[4] The Wolff and Kay labs^[5] have also validated, in mice, the concept of “hydrodynamic” tail vein injections toward enhanced naked DNA transfection (especially of the liver). These large-volume, high-speed, high-pressure injections of plasmid have been found to dramatically enhance hepatocyte transduction (maximum of 40%), with consistent but transient acute toxicities. The proposed mechanism involves the accumulation of fluid from the overloaded heart back to the liver.

Although one study found high-level expression of rat erythropoietin for up to 12 weeks in the liver following rat tail-vein injection of an erythropoietin-expressing plasmid,^[1] the majority of naked DNA gene therapy applications are complicated by low-level transduction as well as transient expression.^[6] A possible reason may be that naked DNA must contend with extra- and intracellular nucleases in the recipient tissue.^[7] Successful transfection is further complicated by the necessity of several concurrent events: nucleic acid entry into the cell, followed by unimpeded transport into the nucleus, as well as recruitment of transcription machinery to the transgene. Even if these conditions are met, the percentage of transduced cells is halved following each round of cell division, unless the DNA has integrated into the host genome. Furthermore, transfection with plasmids encoding noncytotoxic transgenes was found to induce Fas-mediated apoptotic cell death in a murine cell line.^[8] In this Fas study, apoptosis of transfected cells may logically account for short-term transgene expression. Although transfection efficiency is low, naked DNA transfer may still be adequate for genetic vaccination, in which transient expression may generate sufficient priming of the immune system.^[6,7] A major advantage of naked DNA delivery is absence of a robust immune response, although unmethylated CpG sequences (cytosine-guanine dinucleotides that are a hallmark of foreign bacterial DNA) can sometimes stimulate a host response.

Gene gun delivery

A variation on naked DNA transfection is ballistic or “gene gun” delivery. In this system, the DNA is

Table 1 Characteristics of viral vectors

Recombinant viral vector	Genome	Duration of expression	Advantages	Disadvantages	Applications
Adeno-associated virus (AAV)	Single-stranded DNA (+ and - polarity)	Persistent	Low immunogenicity; integrates into genome; different serotypes offer different cell tropisms	Low production yields; lower transduction than efficiency than adenovirus; smaller packaging capacity; potential integration risk	Infects actively dividing and quiescent cells, epithelial cells, and hepatocytes
Retrovirus	Two (+) sense RNA molecules	Persistent	Integrates into genome; low immunogenicity	Nonspecific integration; transduces only actively dividing cells; production yields low; lower transgene capacity	Hematopoietic cell transduction; cancer gene therapy
Lentivirus	Two (+) sense RNA molecules	Persistent	Transduces both dividing and nondividing cells	Potentially higher risks due to HIV genome; nonspecific integration	Immunotherapy of T cells; genetic vaccination against HIV; CNS transduction
Herpesvirus	Double-stranded DNA	Persistent	Tropism for neurons; large transgene capacity; infection may be asymptomatic; persists episomally in neuronal nuclei	Substantial safety risks	Neurodegenerative disease (Parkinson's)
Adenovirus	Double-stranded DNA	Transient; can be longer term	Large transgene capacity; high production yields; multiple cell-type transduction, especially high-level hepatocyte transduction; non-integrating	Immunogenic; acute toxicity; short-term expression	Transduction of hepatocyte, muscle, endothelium, etc.

precipitated onto chemical particles (usually gold), which are then loaded onto a pressurized gun. The gun propels the particles into tissue at high speed via release of pressurized gas. Although gene guns have shown success at introducing DNA and chemicals into cells, it has the drawback of limited penetration, i.e., the particles do not embed into deeper layers of tissue. Hence, regarding *in vivo* applications, the gene gun currently is somewhat limited to transduction of superficial tissue layers. Transgene expression may be additionally restricted to cells with gold particles lodged specifically in the nucleus as opposed to cytoplasm.^[9]

Electroporation

Electroporation is historic practice of using pulses of electricity to temporarily disrupt cell membranes. The application of an electric field generates a voltage potential across the cell membrane. Normally, the membrane acts as an electrical insulator between the cytoplasm and extracellular space. However, when the insulating capacity of the membrane is exceeded, it is reversibly permeabilized. During this period, negatively charged nucleotides can travel across the membrane. One mouse muscle study found up to a 70-fold increase in reporter luciferase expression by plasmid injection followed by electroporation, as compared to plasmid injection alone.^[10] However, this same study found substantial development of muscle injury resulting from the combination of plasmid injection plus electroporation, as well as a characteristic necrosis of fiber cells and infiltration of muscle by inflammatory cells. Whereas many naked DNA-electroporation applications target muscle, a recent study found that injection of naked DNA into mouse melanoma followed by electroporation led to high reporter gene expression coupled to drastic tumor regression. The antitumor activity of naked DNA (which in this study encoded a reporter, but no therapeutic transgene) was rationalized by citing a possible innate immune response against cells harboring bacterially-derived unmethylated plasmid DNA (especially CpG sequences, mentioned previously).^[8,11] Such results suggest that the naked DNA/electroporation treatment combination might be more relevant to cancer tissues where injury and stimulation of host immune response are less problematic, because enhanced transgene expression coupled to destruction of transduced cells (“suicide” gene therapy) may be desirable in a tumor application. It should be kept in mind that electroporation requires an unbroken membrane to hold an electric potential.^[12] Therefore, cell membranes and organelle membranes are amenable to electroporation, but nuclear pores prevent a potential from forming

across the membrane of the nucleus. Thus, electroporation can enhance entry of exogenous DNA via the cell’s outer membrane, but offers no enhancement of actual DNA import into the nucleus.

Liposomes

Liposomes have been shown to enhance nucleic acid incorporation into cells and help mask the nucleic acids from extracellular nucleases. Liposomes are rounded structures composed of lipid bilayers, whose hydrophilic interior contains the nucleic acid of interest. The DNA is integrated into enclosed liposomes via sonication of the lipids.^[13] The bilayer structure allows fusion with the target cell’s outer membrane, followed by subsequent entry into endosomes. Endosomal uptake, however, leads to lysosome-mediated degradation of the endosomal contents; lysosome-disrupting peptides have been shown to reduce this degradation.^[14] The efficacy of liposome-mediated gene transfer has been noted in several studies. In a growth-enhancement application, keratinocyte growth factor (KGF)-encoding liposomes were found to stimulate epidermal growth and neo-angiogenesis *in vivo*, in rat models of thermal skin injury.^[4] In a growth-suppressive application, alternatively, liposomes containing a plasmid encoding human interferon-beta were reported to have initiated tumor regression in human esophageal cancer cell lines.^[15] This growth suppression correlated to that seen upon addition of exogenous interferon-beta cytokine. Enhanced cell specificity of liposomes, and even for naked DNA, can be achieved by attaching targeting peptide ligands. This approach was utilized to generate a liposome whose membrane incorporated integrin-targeting peptides.^[16]

Synthetics

One approach that has been aggressively pursued is the application of synthetic molecular networks for the containment and controlled release of naked DNA. These occur in various forms including capsules, beads, magnetized particles, and gels. One murine intramuscular transfection experiment found enhanced transgene expression when injection of plasmid DNA, entrapped in a proprietary polymeric network, was coupled to electroporation.^[17] Whereas some synthetic vectors have demonstrated cell-type specificity,^[18] others are designed for controlled release of DNA from a matrix.^[19]

In general, nonviral methods are characterized by relatively low transduction efficiencies, but minimal host immune response and toxicity from the delivery vehicle. They have been shown to be especially

efficacious in genetic vaccination strategies for cancer and infectious disease gene therapy, and for gene replacement therapy of non-cell-autonomous processes to generate highly bioactive molecules that are needed in small concentrations.

Viral Vectors

Viral vectors take advantage of millions of years of evolution that have optimized wild-type viruses' ability to infect host cells, co-opt the cellular machinery, and produce new virions. Because of this, viral gene therapy vectors are often superior to nonviral vectors for efficiency of transduction and gene expression. This is not unexpected, given the evolutionary history of viruses. They have been under constant pressure to successfully maintain and propagate their life cycle in the face of ever-evolving host immune mechanisms. As a result, viral gene therapy researchers have an ample variety of vectors, each with particular characteristics that make them attractive reagents: often high levels of transgene expression, varied range of host cell tropism, and ease of vector production in cell systems. However, major modifications must be made to prevent them from becoming pathogenic to the host. This involves making them conditionally replication-defective. The virus must be able to replicate in a producer system or cell line, but not when delivered into the host. Conditional replication is generally achieved by deleting essential viral genes necessary for replication or packaging of the virus. Hence, these viral vectors should be able to facilitate transgene expression but be unable to autonomously replicate within a host organism. To be able to generate such vectors *in vitro*, producer cell lines are designed to efficiently complement the missing essential factors of the virus life cycle *in trans*. This can be done transiently or stably in the producer cells. This is most simply done by transfecting DNA plasmids expressing the essential genes into the producer cell lines. As of now, the most widely used viral vectors are based on oncoretrovirus and adenovirus. However, other viruses such as herpesvirus are increasingly being studied.

Adeno-associated virus (AAV)

Adeno-associated viruses do not cause known disease in humans. Categorized within the parvoviridae family, adeno-associated virus offers at least three advantageous features for gene therapy: integration into the mammalian genome, absence of associated pathogenicity in humans, and wide range of cellular tropism. However, these viruses are among the smallest and are subsequently constrained by one of the lowest transgene packaging limits. Furthermore,

AAVs' tropism for the relatively widespread heparan sulfate proteoglycan (HSPG) receptor complicates attempts at achieving cell-specific transduction.^[20]

Single-stranded DNA genome molecules of either polarity are found in an AAV capsid. Both ends of the molecule comprise palindromic sequences that form base-paired hairpin structures, essential for priming replication and packaging. The conditional replication of wild type AAV is possible only via coinfection by either adenovirus or herpesvirus (helper viruses) or by UV irradiation,^[21] all of which likely stimulate cellular components necessary for viral replication initiation in the host cell.^[22] In the absence of these costimulators, the AAV genome integrates into the host genome, also via the hairpin-shaped DNA ends. This establishes a period of latency that is reversible by exposure to helper virus.^[23] There are two AAV genes that code for Rep (replication, transcription, and integration) and Cap (capsid protein) proteins.^[23] By deleting these genes, transgenes up to 5 kb in size can be inserted. To generate the viral vectors, the Rep and Cap genes are often provided *in trans* by cotransfection of plasmids, along with helper adenovirus infection. As an alternative to adenovirus infection, the early genes of adenovirus may be provided on a plasmid via transfection. One limitation of the recombinant AAV production system is the often mediocre yield when compared to adenovirus and the possibility of helper adenovirus contamination.^[22] Although wild-type AAV has been shown to exhibit site specificity for integration into a locus on human chromosome 19, a study on engineered AAV vectors found that genomic integration was nonhomologous and random.^[24] This introduces a rare but tangible possibility of AAV integration into a locus whose disruption may lead to oncogenesis. Adeno-Associated Virus preferentially transduces dividing cells, and has been used in several gene transfer approaches, such as epithelial^[25] and hepatocyte transductions. The hepatocyte transduction experiments were particularly significant because they employed a single administration of recombinant AAV vector to achieve sustained and therapeutic levels of human Factor IX in mice.^[26]

Non-cell-autonomous diseases such as hemophilia B (or factor IX deficiency) are well suited for use of AAV because transduction of a small percentage of target cells (for example, 5% of hepatocytes) may be sufficient for a clinically relevant effect. Importantly, AAV transduction may be optimized by using a serotype that offers stronger infection (and potentially less toxicity) to a desired cell type. For example, data from Chao et al.^[27] suggest that AAV serotype 1 expresses Factor IX in mouse muscle in quantities that are several logs higher in magnitude than the more often used serotype 2. Wilson's group^[28] found that of serotypes 1–8, AAV serotype 8 demonstrates optimal

hepatocyte gene transfer capacity in murine models of hemophilia B. Whereas AAV is less efficient at transducing tissues such as liver, it does hold the advantage of sustained expression as well as transduction of both dividing and non-dividing cells. Significantly, its cytotoxic effect upon transduced cells is substantially less than with many other viral vectors.^[25]

Retrovirus

Retroviruses have been correlated with several human inflammatory diseases, such as rheumatoid arthritis,^[29] as well as leukemia and AIDS. Retroviruses, whose genome consists of two positive-sense RNA single strand molecules,^[6] are integrated into the host genome following error-prone reverse transcription of the RNA molecule into double-stranded DNA. Integration is found to be nonspecific *in vivo*.^[30] Although retroviruses are relatively large, the transgene insertional capacity of retroviruses is only about 7.5 kb. The retroviral genome encodes three genes: gag (core proteins), pol (reverse transcriptase and integrase enzymes), and env (envelope proteins). These genes can all be deleted and replaced by a therapeutic transgene. As with AAV, these deleted genes must be provided in trans, often by cotransfection of different plasmids. Retroviral expression is contingent upon integration into actively dividing cells, placing a limitation on *in vivo* applications. However, this preference for active cell division may be an advantage in cancer gene therapy,^[22] in which targeting cells of high mitotic index would be desirable. Although genomic integration should in principle facilitate persistent transgene expression, retroviral transgene expression is often transient. This is due in part to vector inactivation by circulating complement proteins^[22] and by the suppression of retroviral gene expression, at the post-transcriptional level, by host interferon cytokines.^[31] Retroviral vectors are the most often used viral vector type in gene therapy trials focusing on hematopoietic cells because they have a particular tropism for this tissue. In fact retroviral vectors were used in the first gene transfer marking trials in the late 1980s.

The majority of retroviral constructs are based on the Moloney murine leukemia virus, or MMLV, virulent in both mouse and human tissue.^[22] The retroviridae family also includes lentiviruses. These are the most recently discovered members of the family, which include the human and simian immunodeficiency viruses (HIV, SIV). Unlike other retroviruses, lentiviruses transduce both dividing and nondividing cells. The natural tropism of lentiviruses for CD4+T cells makes them attractive for immunotherapy research. Importantly, lentiviral vectors may potentially serve as a preventive therapeutic agent against virulent HIV.^[6]

Like that of AAV, the random integration of retroviruses into a host genome raises the possibility of oncogenesis via tumor suppressor gene disruption, or by activation of a protooncogene. This risk may be higher than in AAV because of the presence of transcriptionally active long terminal repeat (LTR) sequences that may act as local enhancers of transcription. This risk of insertional oncogenesis has been realized. Two French patients enrolled in a gene therapy trial for X-SCID recently developed leukemialike symptoms. This adverse event likely arose because of insertion of the retrovirus within the LMO-2 gene, which is responsible for blood cell replication.

Herpes virus

Oral and genital herpes are untreatable conditions in the human population, caused by two herpes simplex viruses, HSV-1 and HSV-2. Although the herpesvirus may lay dormant in the person's neurons, outbreaks of sores do occur with various periodicity. These sores are the manifestation of "viral shedding" from infected skin cells. Importantly, a person does not have to be in the midst of a herpes outbreak to be potentially transmissible.^[72]

Herpesvirus (HSV) double-stranded DNA genomes can reach 235 kb, although the herpes simplex viral genome is 152 kb. The genomic sequence is characterized by two large unique regions flanked by short repeats. About half of the approximately 81 total genes can be removed from engineered HSV vectors, allowing massive transgene inserts up to 50 kb.^[22] In addition to their large size relative to other viral vectors, HSV particles follow a more complicated physical packaging arrangement: The DNA is wound upon a scaffold in the core, which is surrounded by an icosahedral capsid. Another protein-rich layer, named tegument, surrounds the capsid and is in turn encapsulated by the outer envelope. In the HSV life cycle, transcription occurs in a temporal pattern, and the following transcriptional units have been assigned: alpha (immediate early), beta (delayed early), and gamma (late).^[22] Herpes simplex virus vectors have been designed along two related paths: plasmid amplicons, and attenuated recombinant virus.^[22] The amplicons are circular DNA molecules, not actual virus, and resemble generic plasmids: an origin of replication, promoter, transgene, and a selectable marker. The key differences are that the replication origin derives from HSV, not bacteria, and an HSV packaging signal must also be included. Vector production consists of cell transfection with the amplicon in the presence of a helper virus that provides, in trans, all missing HSV components. Recent studies have confirmed high levels of transgene expression in cancer

cell lines from HSV amplicons.^[32,33] Recombinant HSV viral vectors, like the other engineered viral vectors, are attenuated via deletion of genes essential for viral replication, i.e., immediate early (alpha) genes.^[22] For vector production, missing factors are provided in trans via packaging cell lines. Viral gene removal alleviates vector-induced toxicity.

HSV is infective in multiple types but leads to degradation of both host and viral mRNA in nonneuronal cell types. This degradation is facilitated by HSV's virion host shutoff (Vhs) protein, which was recently found to have active nuclease activity.^[34] Neurons, then, are the only true HSV latency-permissive cells. Although HSV latency is restricted to nondividing neurons, HSV's lytic function has a fortuitous preference for dividing cells expressing activated Ras.^[35] This makes HSV vectors well suited for cancer suicide gene therapy. The HSV thymidine kinase (TK) enzyme has been widely employed in suicide therapy (in non-HSV and in nonviral vector applications) via enzymatic conversion of the prodrug gancyclovir (or its related compounds). The HSV-TK enzyme converts the prodrug into a toxic metabolite in HSV-TK-transduced cancer cells, but also kills neighboring cells to some degree via the "bystander effect."^[36] Herpes simplex virus-1 vectors offer a unique combination of large transgenic carrying capacity, neuronal specificity, and persistent latency in the recipient (potentially obviating the need for repeat vector administration). Consequently, HSV vectors have been developed for gene therapy in Parkinson's disease to express tyrosine hydroxylase and neurotrophic factors that have therapeutic potential in this setting.^[22,23] Similarly, in a rat study, nerve growth factor (NGF) was delivered via HSV vector to a superior cervical ganglion that then underwent axotomy. Herpes simplex virus-mediated expression of NGF was found to abrogate the tyrosine hydroxylase deactivation normally associated with axotomy. Indeed, the HSV-transduced ganglion had higher levels of tyrosine hydroxylase than control ganglia 10 days after the axotomy.^[37]

Adenovirus

Adenoviral vectors have been among the most flexible of gene transfer vectors. Wild-type adenovirus is pathogenic and can cause upper respiratory tract symptoms, such as those associated with the common cold. However, it can also cause more serious disease including conjunctivitis, pharyngitis, and hepatitis.^[22] Of more than 40 human serotypes, Ad2 and Ad5 have found the most applications in gene transfer. These serotypes have not been associated with human oncogenesis. Applications for adenoviruses are second only to retroviruses in human gene therapy settings.^[38] The

36-kb linear genome of adenovirus is composed of double-stranded DNA with each 5' end bound by a 55 kD terminal protein (TP). Terminal protein primes viral replication and also functions in packaging signal (ψ)-mediated insertion of viral genomes into capsids.^[39] Packaging constraints limit the size of an engineered genome to 105% of a wild-type genome's size.^[22] The genome is flanked by inverted terminal repeats, with the packaging signal at the left end, and is enveloped by an icosahedral capsid composed of hexon and penton peptide bases. From each of the icosahedron's 12 vertices extends a fiber peptide, whose globular end facilitates recognition by host cell receptors, such as CAR (Coxsackie and adenovirus receptor). The fiber's shaft is also implicated in binding to cellular heparan sulfate glycosaminoglycan receptors. The penton bases are involved in host cell entry by adenovirus: They are recognized by integrin receptors on the cell membrane and initiate endocytosis. Furthermore, a toxic function of pentons may facilitate rupturing of adenovirus-containing endocytic vesicles, enhancing migration of intact adenoviral cores from the cytoplasm into the nucleus via the nuclear pore.^[22]

Like herpesvirus, adenoviral transcription occurs in a temporal pattern after the initial infection. E1A, the sole gene referred to as "immediate early" and the first-transcribed protein, is a transcriptional regulatory factor responsible for initiating other early genes' transcription, including E1B and E2 through E4. The E1B gene product binds p53, the cell cycle regulator, and, by preventing p53 activity, renders the infected cell replication-competent. E2 encodes the DNA polymerase, E3 downregulates MHC antigen presentation (and is referred to as the stealth gene), and the E4 protein disrupts the cytoskeletal network, making the infected cell more amenable to lysis and release of virus.^[22]

The final late phase of transcription includes genes for structural proteins. The majority of adenoviral vectors have been rendered replication-deficient by deletion of the E1 gene. For vector production purposes, a packaging cell line (HEK293) has been developed that expresses the adenoviral E1 gene products in trans. The viral E1 deletion prevents replication of the viral genome as well as expression from the early transcriptional units. Nevertheless, leaky transcription still occurs from early and late transcription units, contingent upon multiplicity of infection.^[22] The term "first generation" denotes replication-deficient adenoviral vectors with deletions in E1 or E1/E3. The deletion of E3 increased overall transgene carrying capacity but removes the stealth functions associated with that gene, rendering these vectors more immunogenic than E1-only deletions. Specifically, E3 gene products were shown to downregulate inflammatory chemokines^[25] and reduce Fas-mediated apoptosis among lymphocytes; hence,

recent studies have suggested returning the E3 gene in E1/E3-deleted adenoviral vectors.^[40]

Adenoviruses have a broad host cell range, and can infect hepatocytes especially efficiently. In fact, they are the only vector capable of achieving near complete transduction of the liver with a single intravascular injection. Unfortunately, of all the vectors, they are also the most immunogenic. This can be related to three phases of toxicity. First is an acute toxicity associated with interaction between vector and host cell (endothelial, antigen presenting cells, platelets) and a cytokine burst. This occurs within hours of a systemic injection. It is likely followed by an intermediate toxicity from hours to days of injection that involves augmentation of the systemic inflammatory immune response with a further amplification of cytokines and also dose-related thrombocytopenia. Finally, chronic toxicity can be seen within days to weeks after treatment and is due to a host cell-mediated immune response. Ways to avoid the acute toxicity include limiting the dose and focusing on local tissue delivery.

Substantial immune-mediated cytotoxicity against cells presenting viral antigens has provided the impetus to develop “gutless” or helper-dependent adenoviral vectors devoid of all viral genes. Although the inverted terminal repeats and packaging signal (ψ) remain, the rest of the viral genome is replaced by human genomic “stuffer” DNA.^[6] The issue of viral gene complementation in trans becomes more salient, because the E1-expressing 293 cell line is incapable of propagating gutted adenoviral vectors that are missing all early and late genes. Thus, a helper adenovirus has been engineered to provide all necessary viral genes in trans, hence the application of the “helper-dependent” nomenclature. The helper virus genome has also been engineered with a removable packaging signal, such that recombinant vector genomes are packaged into viral capsids whereas helper virus genomes are not.

Numerous gutless adenoviral vectors have displayed prolonged transgene expression and reduced immunogenicity as compared to their first-generation counterparts.^[41,42] An important caveat is that our understanding of the *in vivo* performance of most vectors has been limited to cell culture and mouse models. How they function *in vivo* in humans may be significantly different. After having addressed the variables of pharmacogenetic variation to any biological therapy in an outbred genetically diverse population, careful risk-benefit considerations should be made in every case of human gene therapy.

HOST RESPONSES TO GENE THERAPY

An aspect common to all gene therapy systems, both viral and nonviral, is their potential to trigger a host

response. For this reason, it has not been uncommon for researchers to develop methods of high level transduction and expression *in vitro* that do not translate to *in vivo* success.

Immune Responses

All organisms currently utilized for gene therapy employ robust, highly evolved systems to respond to foreign material. These response systems consist of at least two pathways: innate immune and adaptive immune responses. The innate immune response employs nonspecific effector molecules and cells to recognize and eliminate the majority of foreign particles that enter the host. The interaction between effector and target can occur literally within minutes, and is sufficient to clear many infections. Pathogens that evade or overwhelm the innate system, however, are subject to elimination by the adaptive immune response. The adaptive system employs specific antigen-targeting cells that undergo clonal expansion. The specification and expansion of these cells requires a latency period of up to several days before an attack by mature targeting cells commences. Although the timing and pathogen-specificity are drastically different between the innate and adaptive responses, several effector components are common to both.

Innate immunity

Some of the earliest responses to foreign material are unassociated with the immune system *per se*. As mentioned earlier, for example, host intra- and extracellular nucleases and proteases may lead to considerable degradation of therapeutic nucleic acids or recombinant proteins, respectively. Innate immunity comprises effectors that act on classes of foreign particles, as opposed to adaptive immunity's recognition of a specific antigenic epitope. Complement proteins, for example, bind to particles and cells circulating within the plasma. “Self” cells express complement control proteins that cleave complement proteins into inactive isoforms. Pathogenic surfaces that fail to express these control proteins are coated by active forms of complement. This active complement is a recruitment factor for circulating macrophages. Macrophages, in addition to responding to active complement on pathogenic surfaces, also display receptors with affinity for general features of bacteria (particularly lipopolysaccharide, a common bacterial cell wall component) and yeast. Additionally, macrophages that ingest foreign particles and present their antigenic epitopes are referred to as APCs, antigen presenting cells. These APCs are a critical link between innate immunity and the transition to antigen-specific

adaptive immune responses. Furthermore, these macrophages initiate cytokine cascades that recruit additional macrophages and initiate inflammatory host responses. The inflammatory response is characterized by a local widening of blood vessels leading to a lower velocity of blood flow, which in turn allows leukocytes and other blood components to aggregate at the infection site. The interferon cytokines are active against viral replication, fulfilling the dual roles of activation of a ribonuclease (RNA degradation) along with increasing major histocompatibility complex (MHC) class I expression. Increased MHC expression increases presentation of viral antigens by infected cells. Natural killer (NK) cells conversely target those cells with abnormally low MHC expression, and employ cytotoxic effector molecules against targets. While innate effector functions are general, not pathogen-specific, they may act instantly against many pathogens and can clear certain infections within a few days or even a few hours.^[43] Importantly, activation of innate immunity and the associated systemic inflammatory immune response can cause significant morbidity and mortality for the host.

Adaptive immunity

Adaptive immunity is composed of T and B lymphocyte cellular responses. T and B lymphocytes derive from the thymus and the bone marrow, respectively. Both are generated in an inactive, or naïve, state. Activation of either is dependent upon the combined interaction with antigen and costimulatory signals. Activation and proliferation of these lymphocytes takes up to several days, highlighting the significance of the early innate immune responses in attenuating pathogenic activity until adaptive responses are mounted.

In the case of T cells, exposure to antigen followed by interaction with an APC (the costimulator), displaying the same antigen, leads to a tighter association between the cells. Mature APCs are found in the lymphoid organs. The association between the two cells leads to clonal expansion of that T cell into a T cell subtype: Th1 and Th2 are helper T cell subtypes involved with macrophage and B-cell stimulation. Another subtype is the cytotoxic or killer T cell. Killer T cells employ lytic enzymes against target cell membranes.

B lymphocytes contribute the humoral or antibody-mediated response. The first step toward activation is also exposure to antigen. The costimulator for a B cell is an already-armed helper T cell, which provides stimulatory signals that induce hyperproliferation of B cells and somatic hypermutation (which maximizes antibody diversity) at their immunoglobulin loci; these

processes occur in germinal centers of secondary lymphoid organs. These primed B cells return to the systemic circulation where they can secrete antibodies that carry out several functions: They inhibit pathogen entry into host cells (neutralization), they may inactivate pathogen-generated toxins, and they coat particles to mark them for phagocytosis (opsonization). Hence, in any gene transfer protocol, acute toxicity of the vector must be considered. Later, toxicity directed at the vector-transduced cells or at the therapeutic transgene (which can itself act as a neoantigen) needs to also be carefully considered.

Clinical Trials in Gene Therapy

There have been numerous early phase clinical trials of gene therapy. The diseases targeted are diverse and include cystic fibrosis, Duchenne muscular dystrophy, severe combined immunodeficiencies, heart failure, cancer, and hemophilia.^[44–50,69]

Cancer

Cancer accounts for the majority of gene therapy clinical trials. Two-thirds of the gene therapy protocols that have been reviewed by the National Institutes of Health Recombinant DNA Advisory Committee (NIH RAC) are for the treatment of cancer.^[51] Two examples of cancer gene therapy approaches are prodrug activation and tumor-suppressor gene replacement. Both modalities have been employed for the treatment of prostate cancer.

In the prodrug approach, a gene is delivered to the prostate via a viral vector that has the ability to convert an inactive nontoxic prodrug into an active toxic metabolite that can destroy prostate cancer cells. Because the active drug is confined to the prostate, the patient is spared the potentially severe side effects that could result if it were delivered systemically. In one such trial, the prodrug used was gancyclovir, which is converted to its active form by the herpes simplex viral gene, thymidine kinase (HSVtk).^[52] This gene was delivered via an adenoviral vector injected into the prostates of 52 patients who were subsequently given two-week courses of systemic gancyclovir. Prostate-specific antigen (PSA) was measured as an endpoint. PSA levels rise with progression of prostate cancer and fall when therapy has been effective. Side effects were mild and nearly half of the patients had a decline in PSA.^[53,54]

p53 is a tumor suppressor gene; mutations in this gene have been associated with more severe disease in patients with prostate cancer.^[55] In vitro studies demonstrated that prostate cancer cells that are transfected with an adenoviral vector encoding normal

p53 undergo programmed cell death (apoptosis).^[56] Thirty patients with prostate cancer were given intraprostatic injections of the adenoviral vector encoding p53 and followed over time. Analysis of preinjection prostate biopsies demonstrated minimal p53 expression at baseline in the cancer cells. After injection, biopsies showed p53 expression and evidence of apoptosis.^[52] Side effects were minimal.

Genetic Disease

Several coagulation factors circulate within the bloodstream, and comprise catalytic enzymes or inactive protein precursors necessary for proper blood coagulation. Hemophilia A and B are disorders of coagulation that result from a deficiency or abnormality in the plasma coagulation factors VIII and IX, respectively.^[57] There are three ongoing gene therapy trials for hemophilia. Two are directed at hemophilia A and one at hemophilia B. All use different modes of gene delivery.

A muscle-directed approach was employed in a clinical trial of adeno-associated virus delivering factor IX for the treatment of hemophilia B.^[58,59] Three adults with severe hemophilia B were treated. Safety analysis revealed no germline transmission of vector and no development of inhibitory antibodies to factor IX. Analysis of muscle biopsies by PCR and Southern blot found the presence of vector sequences, and immunohistochemistry revealed evidence of FIX (factor IX) expression. However, only modest improvements in the clinical endpoints of circulating FIX and frequency of exogenous factor IX infusions required were noted.

Another study used a retroviral vector to deliver factor VIII to patients with hemophilia A. Retroviral vectors require cells to be dividing for effective transduction. Preclinical studies using this vector to deliver transgene to FVIII-(factor VIII)-deficient mice demonstrated detectable FVIII production in 6 of 13 treated animals with inhibitor antibody development in the other seven.^[60] Expressing animals maintained FVIII production for over 14 months. It should be noted that neonatal mice were used in these experiments. At this age there is rapid proliferation of liver cells leading to effective retroviral transduction. The clinical trial underway will determine if these results can be translated to adult patients.^[61]

An *ex vivo* approach has been used to deliver transfected autologous fibroblasts to six patients with severe hemophilia A.^[62] In this design a skin biopsy was taken from each patient and transfected with plasmids encoding FVIII. Cells producing FVIII were identified and propagated *in vitro* by clonal expansion. These cells were then surgically implanted into the

omentum of the patients. No serious adverse events were reported and inhibitors to FVIII were not detected. In four of six patients, FVIII levels in the serum rose slightly. This rise was correlated with a decrease in episodes of bleeding and exogenous factor requirements.

Whereas none of these studies resulted in production of sufficient factor to cure affected patients, they all demonstrate that effective gene transfer for this disease is possible. Moreover, the therapies were well tolerated without significant toxicity.

To date, the only trial that has unambiguously achieved a clinical cure involves an inherited immunodeficiency. Unfortunately, the therapy was also associated with significant toxicity directly attributable to the gene transfer. X-linked severe combined immunodeficiency (X-SCID) is an inherited disorder characterized by severe infections which usually presents in males early in life.^[63] It is caused by dysfunction of T and NK lymphocytes resulting from abnormal cytokine receptors required for the differentiation of these cells.^[64] Traditionally, the only treatment option available to patients with this deadly disease was allogeneic bone marrow transplantation (BMT). However, BMT may only partially restore immune function and can lead to serious complications.^[47] For this reason, a gene therapy clinical trial was initiated in France.

Bone marrow cells from five boys with X-SCID were harvested and transfected *ex vivo* with a retroviral vector carrying the normal form of the receptor gene. The cells were then expanded in culture and transplanted back into the boys. The patients were then followed for 2.5 years. The patients had few immediate side effects and a restoration of immunity sufficient to allow for a normal life.^[65] Six more patients eventually entered the trial and 9 of 11 were effectively cured. This was the first real clinical success for gene therapy and proved that the technique could cure a life-threatening disease.

However, long-term complications became evident when one of the boys developed a leukemia-like illness in which one type of his immune cells began to proliferate uncontrollably.^[66] The reason appears to be secondary to insertional mutagenesis in one clone from the treated cells. When an integrating virus such as a retrovirus is used in a stem cell population, the point of integration cannot be controlled. If the virus integrates into a gene that is involved in cell growth, uncontrolled growth can result. This is what happened in this case. Several months later a second boy developed a similar illness.^[67] In both cases, the retrovirus integrated into or near the LMO-2 gene, a gene known to be involved in lymphoproliferation.^[68] When gene therapy is applied to genetic disease, the long-term follow-up may differ from cancer trials where the baseline

comorbidity and mortality may obscure cumulative toxicity attributable to gene therapy. At the same time, the underlying disease pathophysiology may confound the evaluation of toxicity. The SCID phenotype has a negative survival impact on noncorrected cells; hence, there is a selective pressure for corrected cell clones that have a proliferative advantage. It may not be surprising that, over time, those cells with activated growth signals such as in the LMO-2 integrants will appear.

While the clinical application of gene therapy has had setbacks, significant milestones have been achieved. Each trial serves to incrementally expand our knowledge base. Continued efforts to increase our understanding of the complex mechanisms involved are ongoing. The long-term goal is the development of a system or systems that can safely deliver therapeutic genes to patients who need them.

Glucose-Responsive Hydrogels

Nicholas A. Peppas

*Departments of Chemical and Biomedical Engineering and Division of Pharmaceutics,
University of Texas at Austin, Austin, Texas, U.S.A.*

INTRODUCTION

Hydrogels are hydrophilic polymer networks that can absorb large amounts of water, but remain insoluble because of the presence of cross-links, entanglements, or crystalline regions.^[1] Hydrogels often exhibit good biocompatibility, because of their high water content. They have been used in various biomedical applications including biosensors, contact lenses, and drug delivery systems because of these characteristics.^[2] Hydrogels can also be sensitive to the conditions of the external environment, because of the presence of certain functional groups along the polymer chains. The swelling behavior of these materials may be dependent on pH, temperature, ionic strength, or even glucose concentration. In particular, there has been increased research interest in the development of glucose-sensitive polymeric systems that deliver appropriate amounts of insulin in response^[2,3,24] to changing glucose levels, so as to mimic the natural response of the body. This could lead to better control of blood glucose levels in diabetic patients. This approach involves an enzyme–substrate reaction that results in a pH change and a pH-sensitive polymer that responds to the change. Glucose reacts with glucose oxidase (GOD) forming gluconic acid (GlucA) and, thus decreasing the pH of the environment. With the change in pH, the gel swells or collapses depending on the characteristics of the particular polymer of the system. Insulin is released from this system with the change in the size of the pores of the polymer.^[3]

In the last few years, extensive work has been carried out with poly(methacrylic acid) (PMAA), poly(ethylene glycol) (PEG), poly(diethylamino ethyl methacrylate) as well as more complex structures including complexation hydrogels of poly(methacrylic acid-g-ethylene glycol) [P(MAA-g-EG)]. Interpolymer complexes are formed in these hydrogels because of hydrogen bonding between the hydrogens of the carboxylic group of the PMAA and the oxygens on the ether groups of the PEG chains. At low pH values, there is sufficient protonation of the carboxylic acid groups causing complexes to form. This results in a collapse of the gel because of the increased hydrophobicity in the polymer network. At high pH values, complexes break as the carboxylic groups

become ionized. This results in an expansion of the gel as electrostatic repulsion is produced within the network. In our specific hydrogel systems, the two species involved in the complexation are bound together in the same polymer. This allows for the reversible formation of complexes at appropriate conditions. Therefore, these materials allow for pH-sensitive solute permeation, a property that is important for drug release.^[4] When incorporating P(MAA-g-EG) with GOD, a “squeezing gel” is formed. At high concentrations of glucose, the GOD-catalyzed reaction of glucose produces GlucA, resulting in a decrease in the pH of the environment around the gel. Glucose-sensitive hydrogels collapse in response to the decrease in pH. Thus, insulin could be squeezed out of the network.

There are several important parameters controlling the behavior of glucose-responsive hydrogel system. The equilibrium and dynamic degrees of swelling are important parameters for calculating network mesh size and molecular weight between cross-links under different experimental conditions. The permeability characteristics of the gels are also important when considering the system for insulin release.

HYDROGELS AS DRUG CARRIERS

Hydrogels

Hydrogels can be described as materials that have the ability to swell in water and retain a significant amount of water within its structure. These materials are capable of absorbing water because of the presence of hydrophilic functional groups^[5] such as $-\text{OH}$, $-\text{COOH}$, $-\text{CONH}_2$, $-\text{CONH}$, and $-\text{SO}_3\text{H}$.

Hydrogels can be classified as neutral or ionic in nature. The swelling of neutral hydrogels is governed by the water–polymer thermodynamic mixing contribution to the overall free energy as well as an elastic polymer contribution. Equilibrium swelling is reached when these two forces are equal.^[1]

In ionic hydrogels, the swelling is governed by thermodynamic mixing, elastic–retractive forces, and ionic interactions between charged polymer and free ions. The swelling behavior is affected by an osmotic

G

force that develops as the charged groups on the polymer are neutralized by mobile counterions. Electrostatic repulsion is also produced between fixed charges and mobile ions inside the gel, affecting the swelling of ionic gels.^[6] The equilibrium swelling ratios of ionic hydrogels are often an order of magnitude higher than those of neutral gels, because of the presence of intermolecular interactions including coulombic, hydrogen bonding, and polar forces.^[7]

Polyelectrolytes have ionized macromolecular chains with more than one ionizable group in their backbone. Upon cross-linking, polyelectrolytes form three-dimensional networks that exhibit high degrees of swelling because of ionization and ion hydration. In these gels, ionization of the fixed charges of the backbone contributes to swelling. Polymer chains uncoil^[8] as electrostatic repulsion is produced between adjacent fixed charges.

Properties Affecting the Swelling of Ionic Hydrogels

There are many properties of ionic hydrogels, which contribute to the swelling of the network. Peppas and Khare^[9] have presented some of these properties, including the ionic content, ionization equilibrium considerations, nature of counterions, and the nature of the polymer.

An increase in the ionic content of the gel increases the hydrophilicity leading to faster swelling and a higher equilibrium degree of swelling. Anionic hydrogels, which contain carboxylic groups, swell at a pH higher than the gel pK_a , because of ionization within the network. At a pH lower than the pK_a , the gel is in a unionized state and does not swell to a high extent. The opposite behavior occurs for cationic gels that contain amine groups. In an ampholyte, the gel contains both acidic and basic groups. In this case, the isoelectric pH determines the transitional pH of swelling of the gel. A polyampholyte is highly swollen at high alkaline pH and low acidic pH because of ionization. However, near the isoelectric pH, the gel swells only to a moderate degree.

Ionization equilibrium considerations also affect the swelling behavior of ionic hydrogels. Fixed charges in the network lead to the formation of an electric double layer of fixed charges and counterions in the gel. According to Donnan equilibrium, the chemical potential of the ions inside the gel is equal to that of the ions outside the gel in the swelling medium. Donnan exclusion prevents the sorption of coions, because of electroneutrality resulting in a higher concentration of counterions in the gel phase than in the external swelling agent. The efficiency of coion exclusion, or an increase in the Donnan potential, increases with

decreasing solution concentration. Increasing ionic content of the gel also increases the efficiency of coion exclusion.

The nature of counterions also impacts the swelling of ionic hydrogels. Polyelectrolyte gels generally prefer counterions of higher valence. The counterion of higher charge is more strongly attracted to the gel, as the concentration inside the gel decreases. Therefore, the preference for higher valence counterions increases with dilution and for ionic gels with high internal molality. Polyelectrolyte gels also prefer counterions with smaller solvated equivalent volume.

The degree of swelling may be affected by the nature of the polymer. An increase in the hydrophobicity of the network can sharpen the transition pH of swelling. This leads to a decrease in the pH range over which the transition swelling behavior occurs. At constant pH, an increase in the ionic strength causes a decrease in the Donnan potential and water uptake resulting in a reduction of swelling.

ENVIRONMENTALLY RESPONSIVE HYDROGELS

There has recently been increased research in the preparation and characterization of materials responsive to changing environmental conditions. Some of the environmental conditions that can affect hydrogel swelling include pH, ionic strength, temperature, and glucose concentration.

In cross-linked networks that contain weakly acidic (anionic) and/or basic (cationic) pendant groups, water sorption can result in the ionization of these pendant groups, depending on the solution pH and ionic composition. The gel then acts as a semipermeable membrane to the counterions.^[10] This influences the osmotic balance between the hydrogel and the external solution through ion exchange, depending on the degree of ionization and ion-ion interactions. For ionic gels containing weakly acidic pendant groups, the equilibrium degree of swelling increases as the pH of the external solution increases,^[11] while the degree of swelling increases as the pH decreases for gels containing weakly basic pendant groups.^[12]

Some hydrogels undergo volume phase transition with a change in the temperature of the environmental conditions. The reversible volume change at the transition depends on the degree of ionization and the components of the polymer chains. There is usually a negligible or small positive enthalpy of mixing, which opposes the process. However, there is also a large gain in the entropy, which drives the process. The opposite behavior is observed in aqueous polymer solutions. This type of behavior is related to polymer phase separation, as the temperature is raised to a critical value

known as the lower critical miscibility or solution temperature (LCST).^[2] Tanaka^[13] investigated the effect of temperature on polyacrylamide gels. Networks showing lower critical miscibility temperature tend to shrink or collapse, as the temperature is increased above the LCST. The gels were found to swell upon lowering the temperature below the LCST.

Environmentally sensitive hydrogels have been studied as possible controlled insulin release systems for the treatment of diabetes. Controlling insulin release with respect to the amount of glucose in the bloodstream is of great importance for an effective insulin delivery device.^[14] An approach to producing materials that are sensitive to glucose involves the incorporation of a pH-sensitive hydrogel with immobilized GOD. GOD acts as a glucose sensor, as it produces GlucA by an enzymatic reaction with glucose. The GlucA produced lowers the pH of the medium, resulting in a change in the degree of swelling of the gel because of its pH sensitivity.^[15] This type of system will be discussed in greater detail later in the entry.

Controlled release systems are capable of delivering a drug at a specific rate over a desirable time period. Some of the advantages of controlled release over conventional drug therapies include maintenance of the drug in a desirable therapeutic range, localized drug delivery to a particular site of the body, protection of drugs that are rapidly destroyed by the body, better patient compliance, and increased comfort. Controlled release systems based on polymers or polymeric materials release drugs by diffusion, chemical reaction, or solvent activation.^[16]

Diffusion-controlled release systems can be classified as reservoir (membrane) and matrix (monolithic) systems. In a reservoir device, a polymeric membrane surrounds a core of drug. Drug release is controlled by the drug diffusion through the surrounding polymer membrane. A constant concentration gradient of drug can be maintained in the device if there is a saturated concentration of the drug inside the reservoir.

In a matrix system, the drug is uniformly dissolved or dispersed throughout the polymer matrix. Matrix systems exhibit a continuously decreasing release rate over time, because of a decrease in the concentration gradient at the polymer surface while the drug is released. It is therefore difficult to achieve zero-order release with matrix systems with conventional geometric shapes such as films, spheres, and cylinders. However, zero-order release can be obtained, however, by careful design of a matrix system. Increase of the surface area can compensate for lowering of the concentration gradient. This results in a suppression of the decrease in release rate with time. Near constant release has been achieved by releasing drug from the center pole of a hemispherical matrix that was coated with a non-permeable membrane.^[17]

Some examples of chemically controlled systems include bioerodible and biodegradable systems and pendent chain systems. In certain biodegradable systems, the polymer undergoes a decrease in molecular weight and eventually disintegrates or dissolves in the dissolution medium. As the polymer dissolves, drug can be released into the medium. Degradation is often hydrolytic and no enzymes are involved for polymers and copolymers of lactic, glycolic, and hydroxybutyric acids. Natural polymers including starch and cellulose are also biodegradable, but require enzymes for degradation. In erodible systems, the release of the active substance is controlled by surface or bulk erosion of the matrix.^[18] In pendent chain systems or prodrugs, the drug molecule is chemically bonded to a polymer backbone and is released through hydrolytic or enzymatic cleavage. The rate of hydrolysis controls the rate of drug release. An advantage of this type of drug release is the ability to target a drug to a particular cell type or tissue. But a disadvantage is the inability to hydrolyze exactly. Natural polymers, including polysaccharides, and synthetic polymers such as polylysine and copolymers of 2-hydroxypropylamide have been investigated for use as drug carriers in such systems. By modifying the structure of these polymers with the incorporation of sugar residues or sulfonyl units, a specific affinity can be obtained.^[9]

Solvent-activated systems include osmotic-controlled and swelling-controlled release systems. Osmotic systems contain a dry core and a semipermeable membrane that controls the permeation of water. The overall rate of drug release is controlled by the rate of water influx and remains constant provided the drug concentration across the membrane is constant. Advantages of osmotic-controlled systems include the capability of providing extended time-independent release and higher delivery rates that can be achieved by solution-diffusion systems. In swelling-controlled systems, the drug that is dispersed in the polymer diffuses out as water uptake occurs and the polymer swells. The drug release rate is dependent on both water diffusion into the polymer and chain relaxation. Continued swelling of this system results in the drug diffusing out at a faster rate. The rate of swelling of the network controls the overall drug release rate. The time dependence of the rate of drug release can be determined depending on the rate of water diffusion and chain relaxation.^[9]

SELF-REGULATED INSULIN DELIVERY DEVICES

Self-Regulation

Current methods of insulin delivery provide inadequate control of blood glucose levels in diabetic patients. This

has motivated research for the development of novel self-regulated devices that deliver insulin as a result of a triggering process because of high glucose concentration.

Diabetes mellitus is a disease that affects approximately 14 million people in U.S.A. It is characterized by the body's inability to completely and continuously metabolize glucose, resulting in poor regulation of blood sugar levels in the body. This poor control is attributed to a decrease in insulin secretion from the β -cells of the pancreas. In Type I (insulin-dependent) diabetes, this decrease in insulin secretion arises from a loss of β -cells. In Type II (non-insulin-dependent) diabetes, the decrease in insulin secretion is attributed to a defective response of the β -cells to glucose.^[19] Insulin is a hormone that accelerates glucose transport into most cells of the body, causing an increase in the rate of glucose metabolism, a decrease in blood glucose concentrations, and an increase in glycogen stored in tissues.^[20]

Control of blood glucose levels in diabetics is important in preventing health problems that could occur from hyperglycemia (high blood glucose levels) and hypoglycemia (low blood glucose levels). Normal blood glucose levels range from 70 to 120 mg/dl. During prolonged hyperglycemia, there is an increase in the oxidation of fats causing the accumulation of ketone substances, the by-product of fat metabolism, in the blood and urine. One breakdown product of the ketone substances, acetoacetic acid, is toxic and can cause diabetic coma in extreme untreated cases.^[21] Hypoglycemic conditions can also be dangerous. It is important to maintain blood glucose levels sufficiently high to provide the nutrition that is required by certain tissues and organs that depend on glucose as their sole source of energy, including the brain, retina, and germinal epithelium.^[20]

In a normal patient, blood glucose levels remain relatively constant at their basal value. High glucose levels signal the β -cells of the pancreas to increase insulin secretion and the α -cells to decrease glucagon secretion. The opposite occurs with low glucose levels. Insulin increases glucose uptake in fat and muscle tissues and suppresses the production of glucose from the liver, while glucagon stimulates the production of glucose. Glucose uptake in the brain is not insulin dependent.^[22]

In a diabetic patient, the β -cells of the pancreas do not produce sufficient insulin to provide for good control. Therefore, it is necessary for a diabetic to take insulin in some form to maintain glucose levels within the normal range. It is also important that diabetics control their diets and their activities.^[20]

The need for better control of blood glucose levels in diabetics has led to increased research in the development of controlled release devices that deliver appropriate amounts of insulin in response^[23,24] to changing

glucose levels, so as to mimic the body's natural response. Insulin release systems have been proposed, which consist of a pH-sensitive hydrogel with GOD and an enclosed insulin solution. Glucose diffuses into the hydrogel, where GOD catalyzes its conversion to GlucA, thereby decreasing the pH of the environment. Then the membrane permeability changes in response to the decrease in pH. It is owing to this change in permeability that insulin release varies with changing glucose concentrations.^[25]

Horbett et al.^[26] prepared a self-regulated, closed loop, feedback-controlled insulin delivery system based on an amine-containing hydrogel. In alkali solutions, the pendent NR_2 groups remained neutral, yielding a membrane that was unswollen and impermeable. In an acidic solution, however, the $-\text{NR}_2$ groups were protonated to $-\text{NR}_2\text{H}^+$, causing the hydrogel to swell and become insulin permeable. The pH change that created the acidic environment was produced by incorporating GOD in the membrane. The resulting pH in the membrane depended on the glucose concentration in the fluid that permeated the hydrogel. However, this system produced only an increase in permeability of a factor of 1.5 with glucose concentrations ranging from 50 to 500 mg/dl. This change was too small to be useful for an insulin delivery device.

Ito et al.^[27] produced a system with increased insulin permeability. In this work, poly(acrylic acid) chains were grafted on a porous cellulose membrane yielding a pH-sensitive membrane. GOD was immobilized onto the membrane. In the absence of glucose and at a neutral pH, electrostatic repulsion of the carboxyl groups resulted in poly(acrylic acid) grafts that were fully extended. The extended chains blocked the pores of the membrane. In the presence of glucose, GlucA was produced, protonating the PAA grafts. This resulted in coiling of the graft chains, because of decreased electrostatic repulsion. The permeability of insulin increased 1.7 times in the presence of glucose with a pH difference of only -0.4 pH units.

Goldraich and Kost^[25] investigated hydrogel matrices that were prepared by chemical polymerization of solutions containing 2-hydroxyethyl methacrylate, *N,N*-dimethyl-aminoethyl methacrylate, tetraethylene glycol dimethacrylate (TEGDMA), ethylene glycol, and water solutions of GOD or insulin. They found that hydrogels with high amine content and low cross-linking agent concentrations were the most sensitive to pH. As the pH decreased, the number of protonated amines on the gel increased. A higher charge density was possible with higher amine content on the polymer chain. The charges localized counterions in the vicinity of the gel. Thus, an increase in the osmotic pressure and swelling of the gel occurred with this high concentration of counterions. They also observed that hydrogels with immobilized GOD displayed faster and higher swelling and release

rates at higher glucose concentrations. Swelling and release kinetics were also responsive to step changes in glucose concentrations. Swelling and release rates increased after a step in glucose concentration from 0 to 500 mg% glucose. Some problems encountered with this system included slow release response to changes in glucose concentration, possible encapsulation after implantation, and low physiological concentrations of oxygen.

Heller et al.^[28] studied the development of a bioerodible insulin delivery device that releases insulin in response to the concentration of external glucose. The release of insulin from this device was modulated by pH changes resulting from the glucose–GOD reaction. They prepared a bioerodible polymer that could reversibly change erosion rates in response to small changes in the pH of the environment by incorporating tertiary amine groups into a linear poly(ortho ester). The incorporation of the tertiary amine groups in the polymer backbone led to increased polymer hydrophilicity and swelling because of repulsion of charged groups. Therefore, water penetration into the matrix was facilitated resulting in accelerated insulin release and polymer erosion. They found excellent control over release when insulin was homogeneously dispersed in the polymer. The polymer was observed to respond almost instantaneously to a decrease in pH, and insulin release was stopped as the pH increased. Their results suggested that a device could be designed to allow for extended, repetitive release before exhaustion as only a small fraction of available insulin was released in response to moderate pH pulses.

Ishihara, Kobayashi, and Shionohara^[29] investigated a glucose-responsive polymeric membrane that was composed of two polymeric membranes. One was a polyacrylamide membrane containing GOD, which acted as a sensor of glucose, forming hydrogen peroxide by an enzymatic reaction. The second membrane was a redox polymer with a nicotinamide moiety that served as a regulator of the insulin permeation rate through an oxidation reaction with the hydrogen peroxide. In the presence of glucose, the permeation rate of insulin was found to increase immediately. Problems with controlling the permeation rate of insulin reversibly were encountered with this system.

A self-regulating insulin delivery system based on the competitive and complementary binding behavior of concavalin A with glucose and glycosylated insulin was examined by Jeong and Kim.^[30] They developed an implant consisting of a regenerated cellulose membrane with the necessary diffusional properties for the exchange of glucose and glycosylated insulin. They found this type of system could approximate the functional response of the intact pancreas. Problems they encountered included inadequate insulin delivery to peripheral and portal blood supplies.

Of particular interest have been pH-sensitive graft copolymers of P(MAA-g-EG). These systems exhibit interpolymer complexation because of hydrogen bonding. Incorporation of these pH-sensitive materials with immobilized GOD yields a glucose-sensitive hydrogel that can be investigated for insulin-release applications.

The hydrogels of interest are graft copolymers of PMAA and PEG. In this system, interpolymer complexes form between PMAA chains and PEG grafts. The complexation occurs because of hydrogen bonding between hydrogens on the carboxylic acid groups of PMAA and the oxygens of the ether groups of the PEG chains. This complexation only forms at a pH low enough to allow for sufficient protonation of the carboxylic acid groups. When complexes form, the polymer is in a collapsed state because of the increased hydrophobicity in the polymer network. At high enough pH values, hydrogen bonds break as the carboxylic acid groups become ionized. As a result, the polymer swells to a high degree as electrostatic repulsion is produced within the network.^[4]

This hydrogel system is unique in that the two species that are involved in the complexation are bound together in the same polymer. This allows for the reversible formation of complexes at appropriate conditions. It is with this complexation behavior that these materials allow for pH-sensitive permeation of solutes, which is of great importance for the release of drugs.

Previous work based on the interpolymer complexation between PMAA and PEG was carried out by Osada and Takeuchi^[31] in which they examined the effects of treating PMAA with PEG. They observed dilations and contractions of the system owing to reversible complexation of PMAA with PEG. In the presence of a small amount of PEG, a PMAA membrane could contract and dilate many times to over 90% of its length. They found PMAA membranes to exhibit an increase in water permeation and flow rate when treated with PEG. When the membrane was rinsed with an alkali solution, the complex dissociated, PEG was removed, and the membrane recovered its initial low water permeability. Flow tests conducted with hemoglobin and albumin solutions showed that these proteins were capable of permeating the membrane without decreasing the water permeability or clogging the membrane. These problems were encountered with untreated PMAA membranes.

The effect of the PEG chain length used to treat PMAA membranes was investigated by Osada.^[32] It was found that PEGs with low molecular weight of 600 and 1000 produced rapid but small contractions and easily attained equilibrium. PEG of molecular weight 2000 yielded a rapid and pronounced contraction. PEGs of molecular weight greater than 2000 showed considerable contractions over a long period of time. This work indicated that the membrane contraction

was closely related to the chemical structure of the polymer and their chain length.

Klier, Scranton, and Peppas^[33] investigated the preparation and characterization of P(MAA-g-EG) networks. Self-associating networks were prepared by the copolymerization of methacrylic acid with poly(ethylene glycol) monomethacrylate (PEGMA) in the presence of the cross-linking agent and TEGDMA. They found the swelling of the networks to depend on swelling solution pH, swelling temperature, copolymer composition, and network structure. Nuclear Overhauser enhancement measurements indicated that graft copolymers of methacrylic acid and PEG formed complexes for a wider range of concentration and PEG molecular weights than the two ungrafted homopolymers. Copolymer networks were also found to swell to a lower extent than homopolymer networks owing to complex formation between PEG and PMAA segments.

Swelling Behavior of P(MAA-g-EG) Hydrogels

Previous work with P(MAA-g-EG) hydrogels has been carried out to characterize their swelling behavior as a function of pH. Bell and Peppas^[4] have done extensive work to characterize this swelling behavior by performing equilibrium swelling studies as a function of pH and oscillatory swelling studies as a function of time and pH.

Equilibrium studies indicated that at low pH values, the polymer network was collapsed and the swelling ratio was low. This behavior was observed up to about pH 4. In the region above pH 4 to about pH 8, the swelling ratio of the gels increased with increasing pH. In this range, the complexes broke, and the carboxylic acid groups of the PMAA were ionized. Network chains were driven apart by electrostatic repulsion and swelling resulted. However, above pH 8, the gels collapsed to an extent. This was because of the acid groups becoming neutralized by cations resulting in diminished electrostatic repulsion. From these equilibrium swelling studies, mesh sizes of the network were calculated as a function of pH. At low pH, the mesh sizes of the various samples were small, between 3 and 9 Å, whereas at high pH in the uncomplexed or expanded state, they were in the range of 240–350 Å. The mesh sizes between the complexed and uncomplexed states for all samples increased by 96–99%. These results showed that this material could possibly be used in controlled drug delivery and membrane separations.

In the oscillatory swelling studies, the swelling ratio of the gels was monitored as a function of time, as the pH of the surrounding solution was changed from acidic to basic over several cycles. In a basic solution, the gel swelled in a linear manner and did not approach equilibrium over the timescale of the experiment. When

transferred to an acidic solution, the gel collapsed abruptly. This swelling/collapsing behavior was repeated over four cycles. Mesh sizes of the networks were also calculated under oscillatory conditions. The mesh sizes responded rapidly to pH changes. Maximum mesh sizes in the expanded states ranged from 11 to 27 Å, whereas in the collapsed states they ranged from 4 to 9 Å.

The relaxation times of the polymer chains were also determined from the oscillatory studies. Average relaxation times were significantly greater during decomplexation in pH 10 than during complexation in pH 2. Relaxation times during the collapse of the gels owing to complexation were between five and eight times faster than those of expansion of the network because of decomplexation.

The permeability of these materials was also determined. It was found that the permeability of membranes of P(MAA-g-EG) was higher in the uncomplexed state than in the complexed state as the expanded, uncomplexed membranes contained larger mesh sizes available for solute permeation. The permeability of the membranes in the uncomplexed states was lower in membranes that contained longer PEG grafts. This was attributed to PEG grafts that were free to dangle in the mesh space of the polymer network in the uncomplexed state. The longer grafts interfered with solute diffusion through the network more than shorter grafts.^[4]

Glucose-Sensitive P(MAA-g-EG) Hydrogels

P(MAA-g-EG) hydrogels are of particular interest in this research because of their pH sensitivity. As described previously, glucose-sensitive hydrogels can be produced by the incorporation of a pH-sensitive hydrogel with immobilized GOD. A “squeezing gel” is expected when incorporating P(MAA-g-EG) with GOD, as shown in Fig. 1. At high concentrations of glucose, the GOD–glucose reaction produces GlucA, resulting in a decrease in the pH of the environment. The hydrogels are expected to collapse abruptly with the decrease in pH. It is with this collapse that insulin could be “squeezed out” as shown in Fig. 2. As the glucose concentration decreases by the action of the released insulin, less GlucA is produced, resulting in an increase in pH of the environment. The hydrogel is expected to swell with this pH change. Owing to the swelling/collapsing behavior of this system, insulin could be released in a pulsatile manner. A basal dose could be released from the gel in the swollen state at normal glucose concentrations, whereas an increased dose could be released as the gel collapses at high glucose concentrations. This mechanism of insulin release is a hypothesis to be tested in this research.

Fig. 1 Mechanism of action of glucose-sensitive P(MAA-g-EG) with GOD, glucose (G), and GlucA. (A) In the absence of glucose, at physiological pH, the hydrogel is in the swollen state. (B) In the presence of glucose, the GOD–glucose reaction produces GlucA causing a decrease in the pH. (C) The hydrogel collapses in response to the decrease in pH.

In previous work,^[34] graft copolymers of pH-sensitive P(MAA-g-EG) were investigated for use in such a hydrogel system. P(MAA-g-EG) hydrogels were synthesized and then characterized at a small physiological pH range. Complexation in this polymer network occurred by hydrogen bonding between the hydrogens of the carboxylic group of PMAA and the oxygens of the PEG chains. The collapse (complexation) of the hydrogels at pH 4.0 occurred much faster than the expansion (decomplexation) at pH 6.6. Glucose-sensitive hydrogels of P(MAA-g-EG) were synthesized by immobilizing GOD onto the polymer network. This was accomplished by first activating the enzyme, and then polymerizing P(MAA-g-EG) in the presence of the activated enzyme. It was determined that the GOD in the glucose-sensitive P(MAA-g-EG) hydrogels remained active throughout the activation and polymerization steps. The swelling behavior of the glucose-sensitive hydrogels was characterized as a function of time, pH, and glucose concentration. The glucose-sensitive hydrogels were shown to exhibit swelling and collapsing behavior for conditions varying by 1 pH unit, indicating that the hydrogel system has the capability of responding to small changes in glucose concentration. Swelling and collapsing behavior of glucose-sensitive P(MAA-g-EG) did not occur with varying glucose concentrations of 50 and 100 mg/dl, because the transition pH of the hydrogel was too high. Equilibrium swelling studies were carried out, and the transition pH was determined to occur between pH 4.3 and 4.9. However, by modifying some of the parameters of the P(MAA-g-EG) hydrogels, this transition pH could be shifted to a value that would yield desirable glucose-responsive behavior.

The specific goals of many of these newer devices are the development of new regimens for the treatment of diabetes in two specific cases:

1. A closed-loop feedback system that responds to changes in blood glucose concentration, the latter being based upon an implantable glucose sensor and permits adjustment of the rate of insulin release provided by the pump.

2. A Feedback system that responds to changes in blood glucose concentration and pH, leading to abrupt *swelling* and *deswelling* of a controlled drug delivery device based on a glucose- and pH-sensitive hydrogel that releases insulin at triggered intervals.

We have developed^[35–44] a series of novel self-regulated, glucose- and pH-sensitive gels for insulin delivery. In preparation for these systems, we have experimented with novel hydrogels in which the swelling ratio and the resulting mesh size change reversibly as a function of environmental parameters such as pH or temperature. These reversible changes allow for the release of drugs or the permeation of solutes depending on surrounding environmental conditions. PMAA exhibits interpolymer complexation with PEG, as the protons of the carboxylic acid groups on PMAA form hydrogen bonds with the ether groups on the PEG chain. This complexation forms only at a pH low enough to insure substantial protonation of the carboxylic acid groups. Complexation of free chains of PMAA with PEG in solution has been studied. We have also shown that poly(dimethyl aminoethyl methacrylate) (PDMAEM) and PEG [henceforth designated as P(DMAEM-g-EG) and shown in Fig. 2] exhibit the same type of hydrogen bonding, except that the pH dependence is such that the

Fig. 2 Mechanism of insulin release from glucose-sensitive P(MAA-g-EG). With increased glucose concentration, complexation occurs resulting in a decrease in the mesh size and a “squeezing out” of insulin from the network.

systems decomplex at low pH and complex at high pH values.

In our early research, Doyle et al.^[45] have studied GOD-immobilized P(MAA-g-EG) hydrogels for pH sensitivity. In the hydrogels mentioned so far, insulin is released by diffusion. In this study, however, the hydrogels are expected to release insulin by a rapid squeezing effect. Oscillatory pH-swelling studies show a promising rapid collapse that can be expected to release insulin by squeezing. Also, a model-based design procedure has been suggested to obtain a hydrogel having the most desirable release characteristics. In another paper,^[34] the authors have characterized the equilibrium and the dynamic swelling behavior of these anionic-grafted hydrogels. The characteristic swelling behavior has been attributed to the formation of reversible complexes within the matrix.

Graft P(MAA-g-EG) and poly(dimethyl aminoethyl methacrylate-g-ethylene glycol) (P(DMEAEM-g-EG)) copolymers were synthesized by free-radical solution polymerization of MAA and dimethyl aminoethyl methacrylate (DMEAEM) purified by vacuum distillation, and PEGMA. TEGDMA was added as a cross-linking agent in the amount of 2 wt% monomer. The reaction mixture was diluted with a 50:50 ethanol:water mixture and a 50:50 mixture of ammonium persulfate, and sodium metabisulfite was used as a redox initiator in the amount of 0.025 wt% monomer. The reaction was carried out in polypropylene vials under nitrogen for 24 hr at 37°C. The cylindrical-shaped polymer samples were dried in air and cut into 0.5 mm thick disks using a diamond blade rotary saw. All disks were washed in distilled/deionized water for a week and dried in air. In addition, we have been able to carry out the same reaction under ultraviolet (UV) irradiation conditions at room temperature, using 0.5% dimethylphenyl acetophenone as a photoinitiator. The latter provides free radicals for the reaction, is partially incorporated in the growing chains but does not affect the swelling behavior, and is known to be a non-toxic initiator.^[34,40,41,46]

Hydrogels of the previous comonomers containing GOD have been prepared. GOD was first functionalized. The ensuing monomer was reacted with diethyl aminoethyl methacrylate (DMEAEM) and PEGMA under the same conditions as above. In the preliminary studies, we have concentrated only on copolymers consisting of 1:1 ratio of DEAEM and PEG monomethacrylate. Upon polymerization, such systems exhibit cationic behavior with hydrogen-bonding characteristics similar to those of P(MAA-g-EG), albeit with a reversal in behavior. Swelling studies were performed in 50 ml of constant pH solution at 37°C; the pH was adjusted by adding sodium hydroxide, hydrochloric acid, or sodium acetate.^[35,47,48] Dynamic and equilibrium swelling was determined gravimetrically

until an equilibrium value was reached. The swelling response of the gels under varying pH conditions was obtained by equilibrating samples in an acidic solution at 37°C and then placing them into a basic solution (still at 37°C) for 45 min following weight changes gravimetrically. The cycle was repeated several times.

To examine the pH sensitivity, the equilibrium swelling behavior of P(MAA-g-EG), P(DEAEM-g-EG), and GOD-containing hydrogels were investigated as a function of pH. The presence of hydrogen bonding in the complexes caused the network to be less hydrophilic because the carboxylic acid groups on the PMAA main chains were used in the complexes. P(MAA-g-EG) gels expand in acidic environment, but collapse at pH values higher than about 6.8. This swelling ratio changes from q of 1.2 (17% water) at pH = 7.2 to $q = 17.5$ at pH = 4.2 (95% water) indicates a change of the insulin diffusion coefficient by about two orders of magnitude. This means that the associated flux will be about 100 times higher at the pH values where GlucA is produced. On the other side P(DEAEM-g-EG) gels exhibit the opposite behavior, as shown in Figs. 3 and 4. Fig. 3 shows the shrinking behavior of glucose-oxidase-bound networks based on P(DEAEM-g-EG) as a function of pH. Clearly, as the pH decreases, because of the enzymatic reaction, there is a drastic swelling of the networks, allowing the release of the incorporated insulin. While this pH dependence is clearly a function of the pH of the ionizable unit (here DEAEM), the level of cross-linking, as defined by the nominal cross-linking ratio X (in moles of cross-linking agent per moles of all reactants) has also a significant effect on the swelling, as shown in Fig. 4. It

Fig. 3 Typical equilibrium-swelling characteristic obtained from poly(diethylaminoethyl methacrylate-g-ethylene glycol) hydrogels immobilized with GOD and catalase. The arrow indicated the location of the transition pH. This characteristic curve is specifically for a hydrogel sample containing $X = 0.015$, 50 mol% DEAEM to PEGMA 200 and 5.413×10^{-4} g of GOD/g of polymer.

Fig. 4 Variation of equilibrium swelling characteristics based on the cross-linking ratio used in the formation of the network. The graphs shown are for $X=0.005$ (●), 0.01 (■), 0.02 (◆), and 0.04 (▲).

is also interesting to note that the mesh size of such hydrogels changes significantly as they expand or collapse at different pH values as shown in Fig. 5. When analyzing the behavior of glucose-sensitive hydrogels for their response to varying glucose concentrations,^[49–53] the GOD of the hydrogel reacts with glucose to produce GlucA. At high concentrations of glucose, the pH of the glucose solution may be decreased at about 3.0. But even with low concentrations of glucose, enough GlucA is produced to decrease the pH of the glucose solution to 3.0.

The glucose-sensitive hydrogels synthesized were tested to determine if the GOD remained active with the synthesis techniques used.^[54] In a disk of 3-mm thickness, a drop of 3 pH units was caused when placed in a 100-mg/dl solution of glucose for 15 min. Over this 15-min interval, the GOD of the polymer reacted with

Fig. 5 Mesh sizes of P(DEAEM-g-EG) gel discs under varying pH conditions at 37°C are calculated.

Fig. 6 Pulsatile swelling studies on P(DEAEM-g-EG) microparticles for changes in glucose concentrations in the swelling medium. The results have been shown for different nominal cross-linking ratio of the polymer, namely, $X=0.02$ (●), $X=0.03$ (■), and $X=0.04$ (◆).

the glucose in the surrounding solution to produce GlucA. Thus, GOD remained active throughout the activation of the enzyme and polymerization procedures. Typical results of this effect are shown in Fig. 6, which shows the effect of glucose concentration on the swelling and release.

We have shown that P(MAA-g-EG) and P(DEAEM-g-EG) hydrogels exhibited pH-sensitive swelling behavior owing to the formation and dissociation of complexes. This interpolymer complexation was because of hydrogen bonding between the hydrogels on the carboxylic acid groups of the MAA or the amino groups of DEAEM and the etheric groups on the PEG chains and resulted in pH-sensitive swelling behavior.

CONCLUSIONS

Glucose-sensitive systems based on glucose-responsive hydrogels have a series of unique characteristics that make them exceptional candidates for insulin delivery:

1. They respond fast and abruptly to glucose concentration.
2. They expand and contract abruptly because of pH changes.
3. They are mechanically strong.
4. They can be prepared in simple ways using UV polymerization and can contain large amounts of insulin dispersed uniformly in the gels.

Recent research has shown that these systems are excellent candidates for new glucose sensors, although they will require further studies for proof of

reproducibility of glucose response over hundreds and thousands of cycles, and ability of the carriers to release the same amount of insulin even under decreasing insulin concentration gradients.

Such promising systems provide also an excellent starting point for the study of a large generation of enzyme-sensitive sensors based on hydrogels.

Glucose Sensors

INTRODUCTION

Proper function of an implantable glucose sensor requires fundamental understanding and control of the biological processes that occur at the sensor-tissue interface.^[1] Scientists have only recently begun to unravel the complex biological interactions that occur between the biomaterial surface and the tissues.^[2,3] Systematic studies are currently underway to optimize sensor size, geometry, surface structure, surface biochemistry, method of transduction, and method of implantation for a specific sensor in a specific location of implantation. Each type of invasive and minimally invasive glucose sensor requires a unique set of physical and biochemical properties to withstand the rigors of the *in vivo* environment. This article will summarize the design and biomaterial issues most important for optimal function of the following glucose sensors.

1. Needle-type, enzyme-based electrochemical sensor (biocatalytic): for short-term implantation in the dermis or subcutaneous tissue.
2. Dialysis catheter ISF glucose monitoring system with an external glucose sensor (electrochemical with enzyme, pressure/viscosity): for short-term implantation in the subcutaneous tissue.
3. Enzyme-based electrochemical sensor (biocatalytic) with telemetry: for long-term implantation in the subcutaneous tissue.
4. Affinity chemical/optical sensor (using concavalin A): for long-term implantation in the subcutaneous tissue.
5. Enzyme-based electrochemical/oxygen sensor: for long-term implantation in the bloodstream (intravascular catheter).
6. Near-infrared absorption spectroscopy sensor: for long-term implantation around a vascular tissue (perivascular sensor head).

CLINICAL SIGNIFICANCE

Diabetic patients treated with intensive insulin therapy and near-normal blood glucose (BG) control live

longer and healthier lives. Long-term tight BG control is achieved in only a select group of patients that modify their insulin doses according to meal size, meal composition, and six or more finger-stick BG measurements per day. Unfortunately, the great majority of diabetics using insulin do not self-monitor frequently enough to achieve tight BG control, without significantly increasing their risk for hypoglycemia.^[4] Confusion, seizure, coma, and death can occur when there is a mismatch between the delivered dose of insulin and the immediate metabolic needs of the patient.

Safe diabetes management demands that the sensor output signal be an accurate estimate of the actual glucose level in the blood or interstitial fluid (ISF). Implantable sensors have the potential to measure glucose on a near-continuous basis (1440 measurements per day). Real-time analysis of glucose data can provide the patient with key information, such as the rate of glucose rise or fall in relation to meals, exercise, sleep, and illness (Fig. 1). Trend analysis can provide an early warning of hypoglycemia, well before the onset of clinical symptoms. Patients are able to more precisely titrate the appropriate dose of insulin using frequent glucose data. Complications due to chronic hyperglycemia will be prevented. Glucose sensors must be accurate, robust, easy to calibrate, and patient-friendly to be useful in the clinical setting. An array of sensors can be used to improve accuracy and reliability.

The current goal of sensor research is the clinical application of an automated device that can measure and display glucose values in real time, with alarms for hypoglycemia. The ultimate goal of sensor research is an automated device often called the artificial pancreas (AP) that integrates a glucose sensor, an insulin pump, and a computer controller (Fig. 2). Insulin delivery can be adjusted on a minute-by-minute basis according to the immediate metabolic needs of the diabetic patient. Blood and ISF glucose AP monitoring systems are able to precisely control the delivery of intravenous or subcutaneous tissue insulin (CSII: continuous subcutaneous insulin infusion therapy), with improved short-term BG control.^[5] The feasibility of continuous glucose monitoring with closed-loop insulin delivery has been demonstrated in ambulatory and hospitalized humans.

Fig. 1 Real-time display of frequent BG data (mg/dl), demonstrating the rate of glucose rise and fall in relation to meals and exercise, measured using the Metracor VIA-GLU enzyme-based electrochemical sensor.

**INTERSTITIAL FLUID (ISF)
GLUCOSE SENSORS**

Needle-Type, Enzyme-Based Electrochemical Sensor (Biocatalytic) for Short-Term Implantation in the Dermis or Subcutaneous Tissue

The glucose concentration within the ISF of the dermis and subcutaneous tissue generally parallels the glucose concentration within the blood.^[6] The most advanced needle-type sensors use an enzyme, selective membranes, and electrodes to measure glucose in the ISF.^[7] The patient can easily self-insert the sensing device through the skin with minimal discomfort. Depending upon the length of the sensor, the distal tip resides within either the dermis, the loose connective tissue just below the dermis, or the adipose tissue. The sensor's proximal portion is connected to a power source and electronics module with telemetry. The absolute glucose value and the glucose value trends can be visualized on a wristwatch or belt-worn display (Fig. 3).

Needle-type sensors have functioned well within the subcutaneous tissue for weeks to months. The Food and Drug Administration (FDA), however, requires

that percutaneous sensors be removed every three days, to minimize the risk of infection. More than 100 sensors are therefore required in order to provide continuous ISF glucose monitoring for a period of one year.

Fig. 2 The artificial pancreas (AP) combines a glucose sensor, an insulin infusion pump, and a computer controller to precisely control the delivery of insulin, based upon the absolute glucose concentration and the rate of rise and fall over time.

Fig. 3 Needle-type glucose sensor with arterioles, capillaries, and venules of subcutaneous tissue. The pictured sensor is manufactured by Medtronic-MiniMed as the Continuous Glucose Monitoring System-CGMS. (Used with permission from Medtronic-MiniMed Corporation, www.medtronic-minimed.com.)

Typical needle-type sensors use semipermeable membranes and an enzyme (glucose oxidase or glucose dehydrogenase) to provide specificity and selectivity in the detection and measurement of β -D-glucose. Sensors tested *in vitro* with glucose solutions demonstrate high sensitivity (change in current per change in glucose concentration), linearity over the physiological range (40 to 600 mg/dl), specificity for glucose, and stability over time. When implanted in the body, however, there is an immediate loss of stability characterized by a significant loss of sensitivity, followed by a period of relative stability, followed by further loss of sensitivity.^[8]

Tissues react to the trauma of sensor implantation and the presence of foreign biomaterial surfaces by activating the coagulation and immune systems.^[9] Platelets, red blood cells, fibrous proteins, and tissue fluids coat the surface and fill the pore structure of the implanted sensor's outer membrane. Neutrophils and macrophages engulf bacteria, injured cells, damaged ECM, and sensor debris. Fibroblasts and macrophages manufacture new ECM in response to the healing wound and the chemical/physical characteristics of the adjacent biomaterial surface.^[10] A foreign body capsule (FBC) develops, initially as a thin layer of fibrous protein (10 to 50 microns) that can severely slow the inward diffusion of glucose. The thin layer of exudative fluid, commonly located between the FBC and the sensor surface, contains dead cells, white blood cells, and numerous products of inflammation. Sensor function requires that glucose molecules be able to freely diffuse from capillary blood through the ISF, though the FBC, through the inflammatory exudate, and through one or more porous membranes to interact with the sensor's transducer.^[11] Biological changes within the membrane pore structure are collectively known as biofouling.^[1]

Percutaneous insertion of a needle-type sensor damages cells, blood vessels, and ECM. Red blood

cells, platelets, plasma proteins, and cellular debris mix with tissue fluid and ECM proteins to form the environment of the fresh wound.^[12] Cells and proteins (fibrinogen, albumin, vitronectin, and fibronectin) adhere to the surface of the sensor's outer membrane, eventually filling the voids of the interconnecting pore structure. Activated platelets release cytokines and growth factors that are chemotactic for neutrophils and macrophages. Neutrophils arrive by the thousands to remove bacteria and cellular debris. Activated monocytes enter the wound and change phenotype to migratory tissue macrophages—cells that are programmed to remove cellular/ECM debris (by phagocytosis and proteolysis) and produce/secrete new ECM. Macrophages release cytokines and growth factors that promote the inward migration and growth of new vascular tissue, containing functional arterials, capillaries, and venules.^[13]

The process of angiogenesis starts immediately with activation of the coagulation and immune systems. The new wound develops a functional vascular system over three to six days.^[14] Prior to new vessel ingrowth, the environment immediately adjacent to the sensor may lack essential nutrients (oxygen, glucose, amino acids, fatty acids, co-enzymes), and may have an excess amount of cellular waste products (hydrogen ions, lactic acid, urea nitrogen, water). Neutrophils leave the region, and by day three the wound is filled with macrophages, fibroblasts, organizing ECM, and the start of a vascular network. The new tissue has a high metabolic rate due to the large number of dividing, growing, moving, synthesizing, secreting, and digesting cells. Control of this complex process depends upon the regulation of cell membrane receptors (RGD and similar ligands) and the chemical composition of the newly formed ECM, recently secreted by the macrophages and fibroblasts. The new ECM develops into a three-dimensional scaffold or gel—consisting of collagen, fibronectin, vitronectin, and other compounds and optimized by cytokines, growth factors, and cell-to-cell communication—for the regeneration of new healthy tissue, rather than the formation of fibrous scar.^[10,12] Even the most biocompatible materials develop a thin layer of fibrous tissue (5 to 10 microns) within 24 hours of implantation.^[15] Sensor movement promotes fibrous protein layer thickening.^[16] The fibrous connective tissue of the developing FBC hinders glucose diffusion to the sensing region, altering sensitivity and prolonging time constants.

Figure 4 illustrates a typical needle-type glucose sensor with an outer membrane, an enzyme layer, an inner membrane, an electrolyte solution, and insulated metal electrodes. The sensor's outer membrane is designed for three functions: 1) to interface with the fluid, cells, and ECM of the interstitial tissue; 2) to slow the diffusion of glucose into the underlying enzyme layer

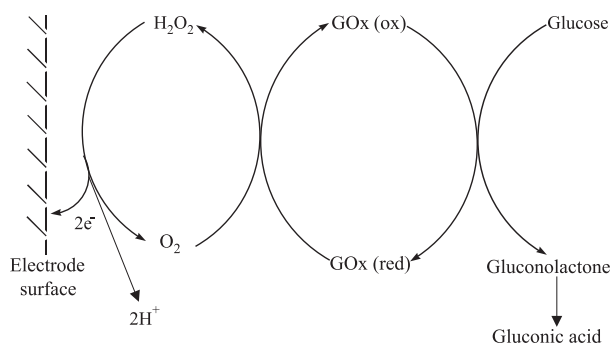

Fig. 4 Typical enzyme-based electrochemical glucose sensor with an outer membrane, an enzyme layer, an inner membrane, an electrolyte solution, and insulated metal electrodes. The basic design applies to all types of sensors that use an enzyme. (Original drawing by Brian Hipszer.)

to a rate much slower than the rate of the enzyme-catalyzed reaction, ensuring that oxygen will always reach the enzyme in excess of glucose (minimizing the effect of tissue hypoxia); and 3) to protect the underlying glucose oxidase enzyme from leaching, degradation, and fouling.

Glucose molecules diffuse through the outer membrane into the gel-like enzyme layer, to bind with the active site of the glucose oxidase enzyme. The following series of redox reactions occur within the enzyme layer: 1) oxidation of β -D-glucose by glucose oxidase to form gluconolactone; 2) reduction of gluconolactone to gluconic acid; 3) reduction of glucose oxidase enzyme; and 4) reoxidation of glucose oxidase by the reduction of oxygen to hydrogen peroxide:

Hydrogen peroxide and oxygen exit the enzyme layer through an inner membrane, to reach the platinum and silver/silver-chloride electrodes. The inner membrane is designed for two functions: 1) to protect the underlying electrodes from fouling and degradation; and 2) to inhibit the inward diffusion of chemical analytes other than hydrogen peroxide (ascorbic acid, uric acid, acetaminophen, and glutathione) that may be oxidized at the platinum electrode. Small-pore membranes made from cellulose acetate, PTFE, silicone, or polyethylene perform well for these functions. Hydrogen peroxide is oxidized at the platinum electrode, which is biased at +700 mV relative to the silver/silver-chloride reference electrode: producing electrons, protons, and oxygen. Two electrons are formed for each molecule of hydrogen peroxide oxidized. An electronic circuit is used to measure a current or voltage. Electrons reaching the reference electrode combine with oxygen and protons to produce water.^[11] The sensor's output signal is converted to a glucose value by correlating the current or voltage to one or more reference BG measurements.^[9]

Alternate embodiments of the needle-type sensors use a mediator such as ferrocene, or a ferrocene derivative, to transfer electrons directly to the working electrode, eliminating the need for oxygen as an electron acceptor.^[17] Catalase has been added to the enzyme layer to prevent the toxic accumulation of hydrogen peroxide.^[18]

Prior to *in vivo* testing, sensors should be rugged enough to function long-term in physiologic solutions at body temperature. Hardware issues leading to premature sensor failure include outer membrane delamination, loss of hermetic seal with corrosion (short-circuit), lead detachment, and enzyme degradation following sterilization.^[11] Biologic issues leading to sensor malfunction and failure include membrane fouling/degradation, enzyme fouling/degradation, and electrode fouling (passivation).^[1]

Outer membranes manufactured from porous polyurethane, cellulose acetate, Nafion, PHEMA (hydrogel), albumin, collagen, fibronectin, silicone, polyethylene, PTFE, ePTFE, Dacron, epoxy, alginate/polylysine, and Parylene demonstrate adequate biocompatibility, but do poorly at providing a hermetic or biologic seal.^[11] Enzyme fouling can be caused by toxic molecules such as oxygen radicals, activated complement, protein degradation products, heavy metals, and hydrogen peroxide. Membrane and enzyme biofouling are reversible. Explanted sensors regain near-normal function when soaked in saline. Macrophages have the capacity to secrete more than a dozen different compounds capable of damaging the glucose oxidase enzyme. For example, macrophages are known to release potent oxidative species from the enzyme myeloperoxidase, which produces hypochlorite (bleach) that can

destroy the glucose oxidase enzyme activity and cause rapid sensor failure. Electrode fouling (passivation) occurs when small molecules and ions pass through the inner membrane to coat the electrode's metal surface.

The biological response to sensor implantation is often complex and variable. Drift in sensitivity requires periodic recalibration of the sensor's output signal to a reference BG measurement.^[8] Very frequent recalibration provides a close correlation of the sensor signal with BG measurements. The clinical success of any sensor, however, requires a low frequency of recalibration, estimated to be four finger-stick blood samples or fewer in 24 hours. This type of recalibration is feasible if sensor drift occurs slowly and consistently. Unpredictable *in vivo* sensor performance cannot be compensated for with intermittent blood samples and recalibration.^[11]

Unique biomaterials are being developed to improve sensor stability and longevity. The wound surrounding traditional membranes develops a classic inflammatory reaction that leads to FBC formation. Sensors typically fail 14 to 30 days after implantation when vascularized granulation tissue is replaced with fibrous connective tissue. Methods to prevent inflammation and FBC formation have been explored. Membranes with an interconnecting pore structure provide a large surface area (scaffold) for cell and ECM adhesion. Pore size and porosity may greatly influence blood vessel density, the location of vessels within the three-dimensional scaffold, and long-term stability of the vascular network. Large-pore scaffolds (greater than 8 microns) permit deep penetration of capillaries and supporting ECM. Membranes with 1 to 3 micron pore size tend to develop a FBC that is thinner, less dense, and more vascular compared to capsules surrounding smooth membranes.^[19] Implanted membranes with greater than 0.8 micron pore size have remained vascular for more than one year in the subcutaneous tissues of rodents.^[20]

Although studies reveal that thinner fibrous capsules allow faster diffusion of small analytes, capsules as thin as 10 microns have been shown to significantly slow the diffusion of glucose.^[15] Membranes made from soft hydrophilic hydrogel polymers (such as PHEMA) produce the least inflammation and thinnest FBC. Scaffolds can be functionalized with receptor ligands (RGD and others) to enhance cell and ECM adhesion.^[21] Steroid and nonsteroidal compounds (dexamethasone, indocine, and cyclosporin) that suppress white blood cell (immune) function have been delivered directly to the sensor-tissue interface in an attempt to improve sensor stability.^[22] Drugs that inhibit the ability of macrophages and fibroblasts to synthesize and secrete collagen have great potential to prevent FBC formation. Growth factors that promote angiogenesis have been incorporated into membranes to promote and maintain a high capillary

density. Degradable microspheres have been developed that release anti-inflammatory drugs and growth factors into the porous membrane at the appropriate time interval (controlled release) following implantation.^[22] This area of research is exciting and clinically relevant.

Dialysis Catheter ISF Glucose Monitoring System with External Glucose Sensor

Microdialysis catheters (probes) can be inserted into the subcutaneous tissue to obtain continuous samples of dialysate containing ISF glucose. A glucose-free physiologic solution (dialysate) is pumped from an external reservoir into the dialysis probe. Glucose molecules pass from the adjacent tissue fluids, through the dialysis membrane pores, into the glucose-free dialysate. If pressure gradients are well balanced at the catheter-tissue interface, glucose will move into (and out of) the porous catheter by simple diffusion. Microdialysis techniques do not measure glucose directly in the ISF environment, in contrast to needle-type sensors. The concentration of glucose in the dialysate and ISF will be identical when complete equilibrium across the dialysis membrane has been reached. Dialysate is continuously pumped into (and/or suctioned out of) the dialysis probe through tubing, to an external (flow-through) glucose sensor. Dialysate waste is stored in an external reservoir (Fig. 5). Three highly sensitive and novel glucose-sensing mechanisms have been developed.^[23]

1. Small volumes of dialysate are continuously delivered to an external enzyme-based electrochemical sensor with a flow-through sample reservoir. Issues related to membrane/enzyme biofouling and degradation are minimized, because the dialysate fluid contains only small molecules and does not contain white blood cells, degraded ECM, and many of the toxic compounds of inflammation. As a result, continuous glucose sensors based upon microdialysis remain relatively stable over a 24-hour period. Sensor drift does occur due to ongoing inflammation and wound healing at the catheter-tissue interface, and to biofouling of the glucose sensor's outer membrane, enzyme, and electrodes. Water-soluble compounds with molecules as small as those of glucose, lactate, glycerol, and amino acids can easily pass through the 20 kDa pore size dialysis membrane to reach the glucose sensor. Toxic products of inflammation (oxygen radicals, ions, complement) can still reach the sensor to adversely affect membrane and enzyme performance. This type of sensor is being developed by A. Menarini Diagnostics (Florence, Italy, <http://www.menarini.com>).

Fig. 5 Dialysis catheter ISF glucose monitoring system with an external enzyme-based electrochemical glucose sensor, designed for short-term implantation in the subcutaneous tissue. Note percutaneous insertion and the large size of the dialysis catheter and monitoring system. (Used with permission of Disetronic Medical, www.disetronic.com.)

2. The preceding system can be modified to continuously infuse a solution of glucose oxidase (GO) enzyme into the outflow channel of the dialysis probe. The external glucose sensor does not require an enzyme layer because the incoming dialysate has already been exposed to the enzyme's active site. This technique improves sensor stability by always supplying an excess amount of fresh GO enzyme. The biocompatibility issues and limitations discussed for the preceding system apply. This type of sensor is being developed by Roche Diagnostics GmbH (Mannheim, Germany, <http://www.roche.com>).
3. This microdialysis-based system uses a novel dialysate solution containing a mixture of high-molecular-weight dextran and concavalin A, an affinity receptor with specificity for β -D-glucose. Molecules of ISF glucose diffuse through the porous membrane to interact with the dialysate solution. The viscosity of this solution can rapidly increase or decrease in direct response to a change in the glucose concentration. Glucose-sensitive dialysate is continuously pumped into (and out of) the dialysis probe at a very slow rate (5 μ l/min) to allow complete equilibrium with ISF glucose. Pressure sensors are located at the inflow and outflow channels to continuously measure the pressure differential across the dialysis probe. The change in viscosity can be strongly correlated to a change in the glucose concentration of ISF fluid. Although this type of system provides superior stability and rapid response, there is a risk that dextran and concavalin A will leach out of the

dialysis probe to contaminate the subcutaneous tissue. Both compounds can initiate an allergic reaction, and concavalin A is considered a carcinogen. This type of sensor is being developed by Disetronic Medical (Burgdorf, Switzerland, <http://www.disetronic.com> or <http://www.adicol.org>).

Incomplete equilibrium occurs when the dialysate does not have sufficient time to equilibrate fully with ISF glucose. This may occur when membrane biofouling and FBC formation slow the rate of glucose diffusion into the dialysate. Microliter volumes of dialysate are pumped into and out of the catheter at specific flow rates (0.3–10 μ l/min). Slow rates of perfusion increase the relative recovery of ISF glucose, defined as the concentration of glucose in the outgoing dialysate compared to the concentration of glucose in the fluid surrounding the probe. Relative recovery from ISF is constant, independent of changes in ISF glucose concentration, as long as the perfusion conditions remain unchanged.^[23] Fortunately, many of the factors that influence *in vivo* glucose recovery (membrane surface area/volume, pore size, pore density, surface chemistry, ECM chemistry, dialysate chemistry, flow rate of dialysate, pressure gradients, temperature) remain relatively stable over short periods of time.

Subcutaneous tissue reacts to insertion of the dialysis probe with acute inflammation, wound repair, and FBC formation: similar to that found at the membrane-tissue interface of needle-type sensors.^[2] A break-in or waiting period, ranging from 2 to 12 hours, is required before initial sensor calibration and the onset of clinical monitoring. This break-in period is characterized by variable glucose recovery, most probably due to biofouling of the probe's pore structure with platelets, red blood cells, and fibrin. Remarkably, the processes of acute inflammation, wound healing, and FBC formation at the catheter-tissue interface affect short-term sensor stability only slightly. Studies have reported that calibration to a reference BG measurement is typically required no more often than once every 24 hours.^[23]

Dialysis catheter ISF glucose monitoring systems are limited by the following factors: 1) medical personnel are required for dialysis probe insertion; 2) the physical lag time is long (approximately 31 minutes); 3) the dialysis probe is large and painful to insert; 4) dialysis probes implanted percutaneously must be removed every three to four days to prevent infection (FDA requirement); 5) 90 to 100 dialysis probes are needed to continuously monitor ISF glucose levels for one year; 6) probes and sensors are expensive; 7) the belt-worn sensor/pump/electronics module is large and heavy; 8) the risk of infection, allergic reaction, and cancer may be increased; 9) progressive biofouling of

the dialysis membrane and GO enzyme leads to sensor instability; and 10) sensors eventually fail when the vascular granulation tissue that surrounds the probe is replaced with avascular fibrous tissue (scar).

Enzyme-Based Electrochemical Sensor (Biocatalytic) with Telemetry for Long-Term Implantation in the Subcutaneous Tissue

The ISF glucose sensor under development by Dexcon Corporation (San Diego, California, <http://www.dexcominc.com>) has been given long-term testing in ambulatory patients with type I diabetes. The sensor has been miniaturized into the shape of a rounded cylinder with an enzyme-based electrochemical sensor at the sensing region. The small, implantable package contains the enzyme sensor, electronic circuitry, power source, antennae, and telemetry. A belt-worn electronics module receives and displays sensor data in real time. Key to the clinical success of this long-term implantable sensor is a precisely engineered sensor-tissue interface that remains highly vascular for the life of the sensor. The vascular FBC has been able to provide ISF to the enzyme surface for more than 11 months with rapid kinetics (5–10 minute delay) and stable sensitivity, after an initial time period for capsule formation (15–30 days). After formation of a stable vascular FBC, external calibration can be extended to monthly intervals. The miniature sensor has been designed with sufficient enzyme capacity and low power requirements to function longer than 24 months *in vivo*. Below the angiogenic scaffold is a bioprotective membrane layer, designed to keep macrophages and their corrosive compounds away from the underlying urethane membrane and enzyme. The membrane's thickness and pore size have been designed to supply oxygen in excess of glucose (30:1 ratio of oxygen to glucose molecules) to the underlying glucose oxidase enzyme.^[24]

The challenge for scientists is to maintain functional capillaries for the long term in the region adjacent to the sensor's outer membrane. This sensor is subject to the same immune and wound-healing response following subcutaneous tissue implantation as other sensor technologies. Under the leadership of Jim Brauker, Ph.D., Dexcon Corporation has optimized membrane structure and chemistry (pore size, pore density, pore connectivity; membrane surface area, thickness, texture, and chemistry) to produce a FBC that maintains long-term vascularity. Studies in animals have shown that following subcutaneous tissue implantation, vascular granulation tissue completely fills the pore structure of large-pore membranes, including the boundary region between laminated large- and small-pore membranes. Porous membranes tested

in animals have maintained a functional capillary network for more than one year.^[20] Sensors constructed with an outer covering of Dacron velour (90-micron pore size) develop a well-vascularized FBC that can supply adequate glucose and oxygen to the sensing region for many months. The sensor can provide linear glucose tracking over the 35- to 800-mg/dl range.^[24] Some scientists hypothesize that an ongoing inflammatory process is required to maintain a long-term vascular FBC. Dacron is known to induce chronic inflammation, characterized by a persistent population of macrophages and the formation of multinucleated giant cells. Human trials to evaluate the safety and efficacy of the implantable glucose sensor are under way. The fact that the sensor-tissue interface of diabetic patients with poor glycemic control may heal differently than that of nondiabetics, or of diabetics with good BG control, complicates the process of sensor development.^[5] Sensors eventually fail when the vascular granulation tissue that surrounds the sensing region is replaced with avascular fibrous tissue.

Affinity Chemical/Optical Sensor for Long-Term Implantation in Subcutaneous Tissue

A novel ISF glucose sensor has been developed by BioHybrid Technologies (Shrewsbury, Massachusetts, <http://www.bio.org/memberProfile/biohybrid.html>) that is based on changing fluorescence within a hydrogel bead (1.5 × 4 mm) implanted chronically in the subcutaneous tissue. Glucose is able to diffuse from ISF into the bead, to compete for glucose binding sites on donor-labeled glycosylated substrate and acceptor-labeled glucose binding ligand. Glucose competes for the glucose binding sites and alters the nonradiative fluorescence resonance energy transfer (FRET) efficiency. An external hand-held laser is used to illuminate the subcutaneous sensor (hydrogel bead) with visible light. Energy reflected from the implanted sensor is detected with a CCD array and analyzed to determine the degree of energy transfer. The sensor has been able to track changes in ISF glucose for more than two months. The long-term biological issues discussed for the enzyme-based sensors apply to this technology as well. Although the PHEMA hydrogel bead causes minimal inflammation at the sensor-tissue interface, biofouling and FBC formation can lead to premature sensor failure. Slowed glucose diffusion into the hydrogel further worsens the time delay due to slow glucose binding/unbinding within the hydrogel.^[25] There is an additional risk of contaminating the subcutaneous tissue with toxic compounds, such as concavalin A, if there is loss of capsule integrity (degradation or breakage due to mechanical factors or macrophage actions).

BLOOD GLUCOSE (BG) SENSORS

Enzyme-Based Electrochemical/Oxygen Sensor for Long-Term Implantation in the Bloodstream (Intravascular Sensor)

Intravascular (IV) sensors for chronic implantation resemble a modern pacemaker, except that the distal end of the flexible lead (sensing region) remains free-floating in the superior vena cava (Fig. 6). The sensor lead is connected to an implanted electronics module that contains a microprocessor, power source, antennae, and telemetry. Data are transmitted to an external data manager with a flat-panel display.

Key to the IV sensor's long-term stability and function is the ability of blood flow to keep the sensor surface clean of platelets, cells, plasma proteins, and blood clot. Allowing the sensor to move freely in the vena cava blood flow optimizes the shear forces generated along the sensor's outer surface. This mechanism prevents significant accumulation of platelets, cells, and protein on or within the sensor's outer porous membrane. Clots that do form may be dissolved by fibrinolysis, or they may break loose to become lodged within the arterioles and capillaries of the lungs. Fortunately, small emboli are rapidly dissolved by fibrinolysis.^[26] The long-term clinical success of implanted pacemaker leads and drug delivery catheters in the superior vena cava provides a strong basis for the safety of this location for the IV glucose sensor. Catheter tips that stay mobile within the central portion of the vena cava remain relatively free of adhered proteins and cells for the life of the sensor.

Tips that contact the endothelium can become mechanically attached to the vena cava wall by an overgrowth of fibrous tissue. On the proximal end, the sensor lead travels from the subcutaneous tissue

Fig. 6 Enzyme-based electrochemical/oxygen sensor for long-term implantation with the tip of the flexible lead (sensing region) free-floating in the superior vena cava. Intravenous (IV) sensor developed by Medtronic-MiniMed Corporation. (Used with permission from Medtronic-MiniMed Corporation, www.medtronic-minimed.com.)

through the wall of the subclavian vein to enter the bloodstream. A layer of fibrous tissue (with or without endothelial cells) extends 3 to 5 cm from the vessel wall to encase the sensor lead.^[18] Removal of a sensor lead from the vena cava is therefore associated with significant surgical risk, due to vessel wall adhesion at two locations. Methods must be developed to remove chronically implanted leads safely, because more than 12 sensors will be required to provide continuous BG monitoring over the lifetime of a young type I diabetic (assuming 5-year sensor function).

University of California (San Diego) scientists Gough, Lucisano, Armour, McKean, and others developed an intravascular BG sensor that can function long-term in the ambulatory setting. The tip of the sensor contains immobilized enzymes glucose oxidase and catalase, layered over a potentiostatic oxygen sensor. Oxygen not consumed by the enzyme reactions is electrochemically reduced at the oxygen sensor to produce a current that is proportional to the glucose concentration. The implanted system requires a second sensor, similar to the glucose sensor but without enzymes, to simultaneously measure the concentration of oxygen in venous blood. The difference between the two sensor output signals provides an accurate estimate of the BG concentration.

The novel mechanical design guarantees that oxygen diffusion to the enzyme layer far exceeds the diffusion of glucose. An outer membrane of porous cross-linked albumin is used to cover the distal end of the enzyme layer, enhancing hemocompatibility and limiting the inward diffusion of glucose (relative to oxygen). The sides of the enzyme layer are surrounded by silicone rubber that is permeable to oxygen, but impermeable to glucose. Oxygen is therefore supplied to the enzyme region in sufficient quantity to avoid stoichiometric oxygen limitation. Glucose oxidase is loaded in excess of the amount calculated for long-term function, and catalase is coimmobilized in excess to prevent hydrogen peroxide-mediated enzyme inactivation. The pore-free hydrophobic membrane placed between the enzyme layer and the electrodes permits the free inward diffusion of oxygen, but it inhibits the passage of interfering substances (ascorbate, acetaminophen) and biochemical toxins that may foul the electrode. Each innovation has been designed to enhance glucose sensor performance and extend operational lifetime.^[18]

A similar enzyme-based electrochemical/oxygen IV glucose sensor is being developed by Medtronic-MiniMed (Northridge, California, <http://www.medtronic-minimed.com>). Sensors implanted in the superior vena cava of 10 ambulatory patients with type 1 diabetes functioned well for an average of 287 days (range: 89–431) with satisfactory correlation to reference BG samples. Complications such as thrombosis,

pulmonary embolism, or vena cava injury (during lead removal) did not occur.^[27]

Near-Infrared Absorption Spectroscopy Sensor for Long-Term Implantation Around a Vascular Tissue (Perivascular Sensor Head)

Long-term implantable optical sensors based upon absorption spectroscopy of near-infrared (NIR) light may overcome the diffusion limitations of traditional enzyme-based glucose sensors.^[28–30] NIR light can easily penetrate any layer of cells or proteins that coat the optical windows. It is not necessary for glucose or other analytes to diffuse through one or more membranes to reach an enzyme or electrode surface. The region between the light source and the sample detector defines a gap, or path length, that can be filled with blood, ISF, or a combination of cells, ECM, and ISF (tissue). The molecular bonds of glucose have a unique absorption signature that can be detected in the near-infrared region of the electromagnetic spectrum.^[30] The optical sensor is able to produce high-quality NIR spectra (intensity versus wavelength) using blood, ISF, or tissue as the sample. Numerous spectra are collected over a wide range of blood chemistries to develop a robust library of spectra, which can be mathematically analyzed to produce a calibration model. Subsequent spectra are mathematically compared (at multiple wavelengths) to the calibration data set, to provide an accurate prediction of the glucose concentration. Multivariate statistical methods such as partial least squares regression and filtering techniques can be used to construct the calibration model. The monitoring system must be very sensitive and stable to measure the very subtle optical changes caused by glucose that occur in the NIR spectrum. The optics must be very efficient, because much of the incident light is scattered.^[29] Biological challenges depend upon the tissue fluid being sampled,^[28] as in the following examples.

1. Placing the light source and detector on opposite sides of a vascular membrane provides complex NIR absorption spectra of cells, ECM, and ISF. The membrane between the sensor halves (gap) must remain healthy and vascular for the life of the sensor.
2. Placing the light source and detector opposite one another, on the outside walls of a blood vessel, provides NIR absorption spectra of blood and two blood vessel walls. There is a large body of literature describing successful long-term implantation of flow probes (electromagnetic and ultrasound) around the outside wall of both arteries and veins.^[31–33]

3. Placing the light source and detector within the bloodstream provides NIR absorption spectra of blood. This sample site eliminates many issues related to time lags and correlation with ISF glucose. Blood flow and shear forces are used to prevent thrombosis and maintain a thin and stable protein/cell coating over the optical windows.

The long-term implantable NIR glucose sensor being developed by Animas Corporation (Fraser, Pennsylvania, <http://www.animacorp.com>) contains a miniature optical sensor head, mechanically coupled to a vein, that measures NIR spectra of blood. The implantable system consists of a perivascular sensor head, a flexible lead, and an electronics/optics/telemetry module. An external electronics module (wristwatch) will receive, analyze, and display glucose data in real time.^[28–30]

CONCLUSION

Each of the implantable sensors requires a unique set of physical and biochemical properties to withstand the rigors of the *in vivo* environment. Systematic studies are under way to determine the optimal sensor size, geometry, surface structure, surface biochemistry, method of transduction, and method of implantation for a specific sensor in a specific location of implantation. Future efforts will focus on the development of novel membranes with chemistry and textures that: 1) promote the ingrowth of healthy vascular tissue; 2) prevent the formation of an avascular FBC; and 3) better protect the underlying enzyme and electrodes from fouling. Controlled delivery of anti-inflammatory and angiogenic factors into the outer membrane shows great promise for optimizing *in vivo* sensor performance and preventing sensor malfunction due to biofouling/degradation of membranes, enzymes, and electrodes.

ACKNOWLEDGMENTS

A special thank you to my wife Celia and children Mark and Amanda for providing support and guidance during preparation of this article. As always, Brian Hipszer provided expert and timely review, in addition to using his artistic talents to produce three-dimensional drawings.

Glues

Shojiro Matsuda

INTRODUCTION

Surgical glues are widely used to seal small holes present in diseased soft tissues such as lung (sealants), to stop bleeding from damaged tissues (hemostatic agents), and to bond two separated tissues (surgical adhesives). The biomaterials currently used for these surgical purposes include fibrin glues, α -cyanoacrylates, and GRF (gelatin-resorcinol-formaldehyde) glues. All of them are applied to tissues in the liquid state (sol), followed by gel formation. This sol-gel transition takes place rapidly on the tissues. Fibrin glue, which comprises fibrinogen and thrombin, is clinically used for the purpose of sealing, hemostasis, and bonding, while cyanoacrylate monomers are utilized mostly as tissue adhesives. GRF with higher gel strength and bonding strength than fibrin glue has a unique application, that is, ceasing of bleeding from acute aortic dissection. Although these currently available glues are greatly contributing to surgical operations, they have disadvantages. For instance, fibrin glues have a potential risk of viral infection in spite of careful screening of plasma, because fibrinogen and thrombin are harvested from human plasma. Low bonding strength of the gelled fibrin to tissues is also a weak point. Cyanoacrylates are instantly allowed to polymerize, forming a gel in the presence of moisture under strong adhesion to tissues, but yield toxic formaldehyde as a result of hydrolytic degradation of the polymer main-chain. As formaldehyde is a major component of the GRF glue, attempts have been made to develop new liquid-type biomaterials that are free of virus, prion, and carcinogen, and can transform into a gel having a high potential of strong tissue adhesion in the presence of water. Glues should be absorbed after having fulfilled their task so as not to induce undesirable reactions as a foreign body.

REQUIREMENTS FOR SURGICAL GLUE

Sutures have been the most widely used method for wound closure, but suturing has shortcomings, such as the requirement of highly skillful procedures and a

long time to close wound and the postoperative removal of nonabsorbable suture. It is, therefore, desired to develop surgical glues that can overcome these problems. Various conventional glues are known for home and industrial use, but only three glues, namely, fibrin glues, α -cyanoacrylates, and GRF, are widely available for medical use.

Requirements for these surgical glues are listed in Table 1. As they are applied to the human body, they must be safe, nontoxic, and free from risk of infectious transmission. They should be preferably bioabsorbable and not remain long as a foreign body. Not only must the applying solution and gelled glue be safe, but also the degradation products as well. In addition, they must not hinder the natural healing process.

Most surgical glues are gelled in situ, applicable on rough surfaces, and act as tissue anchors. Appropriate gelling time and mechanical properties of formed gel are important. They should bond rapidly to the surrounding living tissues in the presence of water or aqueous fluids, such as blood, and keep the adhesion strength. Similar to the glue itself, degradation products of the glue must be safe. Besides the chemical nontoxicity, their mechanical properties are also important. If the cured glue is harder than tissue, it may induce undesirable tissue reactions. Good handling (ease of use and gelation speed) is also important.

FIBRIN GLUE

Fibrin glue, which consists of human fibrinogen, thrombin, factor XIII, and bovine aprotinin, has been widely used in Europe, Canada, and Japan for about two decades and available in the United States since 1998. Figure 1 shows the mechanism of gelation of fibrin glue. When fibrinogen solution and thrombin solution are mixed at the site of injury, fibrin gel formation occurs through the physiological coagulation and the tissue adhesion cascade. Thrombin catalyzes partial hydrolysis of fibrinogen to form fibrin monomers if calcium ion is present. Thrombin also activates factor XIII into factor XIIIa in the presence of calcium ions. Factor XIIIa reacts with fibrin monomers to form

Table 1 Requirements for surgical glues

1. In situ curable from liquid-state through polymerization, chemical cross-linking, or solvent evaporation
2. Rapidly curable under wet physiological conditions
3. Strongly bondable to tissues
4. Nontoxic for both agents and their degradation products
5. Tough and pliable as natural tissues
6. Biodegradable

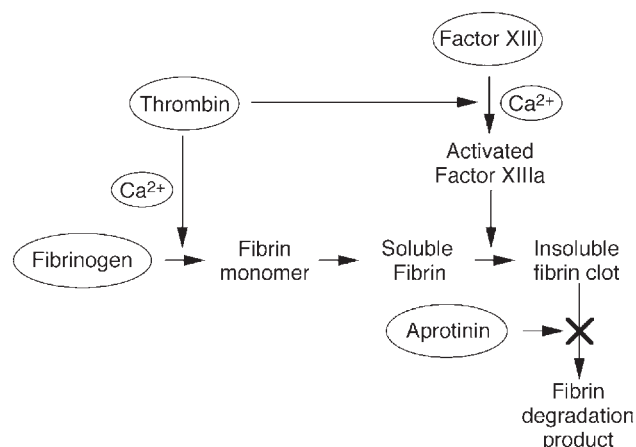

insoluble fibrin clots. Aprotinin inhibits fibrinolysis (degradation of fibrin clot). The fibrin clot will be totally resorbed by fibrinolysis and phagocytosis.

Fibrinogen and thrombin are dissolved separately in medium before surgical operation. Each of two solutions is filled in a separate dual syringe, which is set to Y-connector and applying needle or a spray system.

Application of Fibrin Glue

Surgical fields for fibrin glue and its application purposes are shown in Table 2. Mostly they work as sealants, hemostatic agents, and surgical adhesives. Hemostasis is also effectively carried out by suturing, electrocauterization, infrared coagulation, compression, and tamponade. Very small blood vessels, fragile tissues, and small spaces are difficult to apply with these devices, but liquid-type surgical glues are useful in these cases and also for sealing if they have a proper adhesion strength to tissue, and a proper physical-barrier strength in the presence of water.

The application activity of fibrin glue depends on surgical procedures.^[1] Cardiovascular surgery is the most common among them and its major purpose is hemostasis and suture line sealing. Successful local hemostasis of bleeding after open-heart surgery can reduce blood loss, operative time, and the need for

**Fig. 1** Mechanism of gelation of fibrin glue.**Table 2** Clinical applications of fibrin glue

Cardiovascular surgery	Hemostasis of bleeding from mediastinum and small blood vessels, reinforcement of suture line, sealing of vascular grafts and anastomoses.
Thoracic surgery	Sealing of air leaks from raw lung surface, and pulmonary and bronchial staple lines.
Gastroenterological surgery	Hemostasis and reinforcement of intestinal anastomosis, prevention of bile leakage, and hemostasis of hepatectomy, pancreatic fistula, and gastroduodenal ulcers.
Neurosurgery	Sealing of cerebrospinal fluid leaks, nonsutured peripheral nerve repair.
Gynecologic surgery	Anastomosis of fallopian tube, adhesion of peritoneum.
Plastic surgery	Closure of skin wound, attachment of skin grafts, fixation of tissue flaps.
Orthopaedic surgery	Fixation of bone fragments, hemostasis during total knee arthroplasty.
Urologic surgery	Anastomosis of urinary tube and adhesion of kidney, pelvis renalis, and ureter.

resternotomy in these high-risk patients. Fibrin glue is highly effective as a tissue sealant in diffuse, low-pressure bleeding such as coronary vein, right-ventricle/pulmonary-artery conduits, and right-ventricular patches. Fibrin glue is used routinely whenever suturing is impossible, dangerous, or difficult, and for spontaneous hemostasis to save waiting time. Suture holes, staple line, anastomoses, fistulas, and raw surfaces are effectively treated with fibrin glue, similarly to aortic and coronary suture line. It is also used for sealing vascular grafts. Perfect hemostasis is quite important in pediatric cardiac surgery because of the high incidence of coagulopathy after open-heart procedures and increased risks associated with the use of blood and blood products.

Fibrin glue is also very effective for reoperative procedures, because mediastinal bleeding and excessive non-suturable bleeding from adhesions are highly problematic. The adhesion of tissue induces complications during reoperation, prolonging the operation time and increasing the need for blood transfusion, and hence preventing the formation of adhesion is very important.

In thoracic surgery, fibrin glue is applied to cease hemorrhage and air leaks following pulmonary resection

and decortications. It is also used for the treatment of bronchopleural fistulae and pneumothorax. To reduce air leaks after stapled pulmonary resection, several kinds of predget, such as poly(glycolic acid) (PGA) fabric and bovine pericardium, have been clinically applied. Fibrin glue is also used for this purpose with PGA fabric.

In the treatment of bleeding from highly vascularized parenchymal tissues, such as elective hepatic resection and pancreatic fistula, and from anastomotic sites, such as recurrent bleeding from gastroduodenal ulcers, fibrin glue is effectively applied. Many other applications such as dural closure are known to prevent cerebrospinal-fluid (CSF) leaks, burn bleeding after debridement, and bleeding during the total knee arthroplasty (TKA) procedure, and control artery or aneurysm closure in endovascular surgery.

Future and Improvement of Fibrin Glue

Since fibrin glue is made from human and bovine proteins, potential risk of viral transmission cannot be fully denied, but there have been reported no proven cases of viral transmission associated with the use of commercial fibrin sealant. To circumvent this risk, the development of recombinant thrombin and fibrinogen is currently ongoing. Other sources, well-purified materials, and new synthetics are studied as alternatives to fibrin glue.

For the treatment of acute aortic dissection, fibrin glue does not have sufficient gel strength and bonding strength, and GRF and other glues are superior to fibrin glue. It is also claimed that fibrin glue is readily washed away even by weak bleeding, as no compression is possible on the bleeding area. In this case, collagen sheet is effective for the scaffold of fibrin glue.

Other clinical applications under study include the prevention of postoperative adhesion, endoscopic procedure for minimal invasive surgery, drug and cell delivery vehicle, and scaffolding of cell culture.

Fibrin glue sheet

TachoComb (Nycomed Arzneimittel, Germany) is a ready-to-use hemostatic agent.^[2] As this spongelike sheet is prepared by coating human fibrinogen, bovine thrombin, and bovine aprotinin on the surface of equine collagen fleece, it does not need to solidify, warm, or set to syringe. This dry sheet can be applied directly to traumatized tissues, in contrast to the liquid application of fibrin glue. TachoComb has mechanical stability, can be effectively used for the treatment of diffuse bleeding of the thoracic wall, and is absorbed within a few weeks. Bleeding site in the thoracic apex, especially after lysis of adhesion between lung and parietal pleura, is very difficult to treat with fibrin glue and other conventional methods. By using TachoComb, this bleeding is

effectively hemostased.^[3] Parenchymal leak of the lung after decortication can also be treated with this glue, when the visceral pleura is removed or lacerated. Hemostasis is effective and well tolerated as a secondary procedure in urological, ENT (ear, nose, and throat), hepatic, and vascular surgery when primary hemostatic measures are proved insufficient. TachoComb may be used to control oozing hemorrhage from surgical sites in gynaecological patients effectively and prevent adhesion formation at the application site, thus offering an effective method for preventing adhesion-induced infertility.

Adhesion prevention

Fibrin glue is also expected as an adhesion-prevention material. It is applicable to damaged tissue, fully covering it to avoid contact with another tissue. If the injured tissue comes in contact with another tissue, adhesion formation occurs during wound healing. Since fibrin glue is a kind of hydrogel with a high water content, water-soluble nutrients can pass through this hydrogel without affecting wound healing. The use of fibrin glue results in a significant decrease in postoperative adhesion of a rabbit model compared with the control side in the uterine horns and the ovaries.^[4]

Drug release vehicle

Because fibrin glue can form gel under a physiological condition, it can be easily mixed with drugs under a liquid condition and be applied to any tissue. Local delivery of drug has been carried out to avoid complications of systemic administration. The delivery vehicles for local delivery must stay at the applied place without diffusion into any undesired location. Thus, tissue adhesives are effective for sustained release of drugs. Bioabsorbable materials are applicable for sustained release of water-soluble drugs for a relatively short duration because of their high rate of diffusion. Poorly soluble drugs can be released from hydrogels such as fibrin glue as a result of vehicle degradation. Antibiotics for the treatment of large-area burns, antiproliferative drugs for chemotherapeutics, and growth factors such as bone morphogenetic protein (BMP) and basic fibroblast growth factor (bFGF) for tissue regeneration can be incorporated into fibrin glue for this drug delivery system.^[5]

Applications in tissue engineering

Fibrin monomer can be polymerized into moldable gels to encapsule cells and to provide three-dimensional scaffold of cell culture. Because fibrin glue is bioabsorbable, it is applicable to tissue engineering. When

chondrocytes trapped in fibrin glue gels are transplanted subcutaneously in nude mice, the actively proliferating cells can well form cartilaginous matrix.^[6] Urothelial cells, tracheal epithelial cells, and preadipocytes cultured in vitro were successfully transplanted onto a prefabricated capsule and tubelike structure using fibrin glue as a delivery vehicle and native cell expansion vehicle.^[7-9]

CYANOACRYLATE

When cyanoacrylate monomers come into contact with moisture, they change into a polymer. The detailed mechanism of polymerization of 2-cyanoacrylates is not fully understood, but it seems very probable that they polymerize via an ionic mechanism in which a water molecule acts as coinitiator. The liquid-state monomers polymerize to a solid within a short time period in the presence of water and are stored in one tube as a single component. Very high stiffness of cured glues, low viscosity of monomers, and toxic formaldehyde released during their degradation are drawbacks. However, cyanoacrylates have been used for wound closure, cartilage and bone grafting, coating of corneal ulcers, coating of aphthous ulcers, embolization of gastrointestinal varices, and embolization in neurovascular surgery.

Wound Closure

Surgical glues are preferable to skin sutures owing to good cosmetic outcome and pain reduction, especially in cosmetic surgery and surgery for children. Cyanoacrylate is the only surgical glue that is used for dermal wound closure instead of suturing. Tissue adhesives can save time during wound repair, provide flexible water-resistant protective coating, and eliminate the need for suture removal. Since the 1970s, n-butyl 2-cyanoacrylate (NBCA) with negligible histotoxicity and good bonding strength has been clinically applied and shown to have acceptable cosmetic outcome, but with too high bonding strength and too rapid reaction. Dermabond (Ethicon, Inc., Somerville, New Jersey) is 2-octyl cyanoacrylate that forms a strong bond across wound edges, allowing normal healing. The long-term cosmetic outcome of Dermabond was comparable to that of traditional methods of repair.^[10]

Blood Vessel Embolic Material

Endovascular neurosurgery is one of the strategies for treatments of various neurovascular diseases such as cerebral and spinal arteriovenous malformations (AVMs), dural arteriovenous fistulas, and cerebral aneurysms. A microcatheter is advanced into or close to a lesion and then an embolic material is administered

through it to obliterate the lesion. This less invasive method is accepted as an attractive alternative therapy making up a conventional surgical technique. Requirements for blood vessel embolic materials are shown in Table 3.

Various biomaterials have been used for embolization, but each material has some problems. Polymer solutions have ever been used as liquid-type materials for embolization, including poly(ethylene-co-vinyl alcohol), cellulose acetate, cationic methacrylate copolymer (Eudragit-E), and poly(vinyl acetate) emulsion. When polymer solution is given into a blood vessel, the organic solvent diffuses into the blood and surrounding tissues, thus forming polymeric precipitates and emboli. However, as most of them contain organic solvents, such as dimethyl sulfoxide and ethanol, they exert toxic effects on the surrounding tissues. Cyanoacrylate monomers that instantly polymerize upon contact with blood are used as liquid embolic material. Among the monomers, NBCA has been preferentially used in Europe and North America. NBCA is injected into the diseased part of the blood vessel through a long thin catheter and then quickly becomes solid, blocking blood flow into the diseased part of the blood vessel.

Although NBCA has been successfully used as embolic material, several troubles have been reported. Its instantaneous polymerization and quite low degradation rate are suitable for embolization of diseased lesions, but its exceptionally high adhesive force sometimes causes adhesion between the tip of the microcatheter and the artery. As a result, it becomes impossible to withdraw the microcatheter from the blood vessel and, in addition, the inner space of the microcatheter is occluded with the rapidly polymerized material when intermittently injected. Therefore, intermittent injection should be avoided and the microcatheter should be withdrawn immediately after completion of embolization. The surgeon is required to accumulate many experiences so that she or he can acquire skillful techniques to carry out embolization safely and effectively when NBCA is used.

To overcome these problems, isostearyl 2-cyanoacrylate (ISCA), which carries a long hydrophobic side isostearyl group with lower reactivity than n-butyl

Table 3 Requirements for blood vessel embolic materials

-
1. In situ curable from liquid-state (one liquid) through polymerization or solvent evaporation
 2. Curable in proper time in the presence of blood
 3. Tightly bondable to blood vessel wall tissue and not adhesive to microcatheter
 4. Nontoxic
 5. Tough and pliable as natural tissues
 6. Preferably radiopaque
-

group, was synthesized.^[11] Its adhesive force was low enough not to cause these problems. However, as its polymerization rate was too low to obliterate a vascular lesion with a rapid blood flow, ISCA was mixed with NBCA. The adhesive force of this mixture became extremely low, compared with that of NBCA, and adhesion between the tip of microcatheter and artery was not problematic. The viscosity of the mixture was low enough to use as embolic material. Tissue reactions toward the mixture were milder than those of NBCA and radio-angiography became possible by mixing further with Lipiodol. The evaluation of this new embolic material with a rabbit renal artery showed that the obliteration effect of the mixture from ISCA and NBCA was excellent to allow the use of this embolic material for clinical applications.

GRF GLUE

Gelatin is a widely used bioabsorbable material, especially as surgical glue. This natural polymer is extracted from biological tissues, and has many functional groups. Gelatin is soluble in water at temperatures higher than 35°C, and can form gel by lowering temperature below 25°C or by cross-linking. Gelatin gel is as elastic and soft as natural tissue. Braunwald reported that a gelatin-resorcinol mixture cross-linked with a combination of formaldehyde (GRF) and sometimes glutaraldehyde gave satisfactory bonding strength in hepatic and renal tissues of dogs.^[12] Formaldehyde undergoes condensation with resorcinol to give a three-dimensionally cross-linked water-insoluble resin. GRF is a two-liquid system glue. One component is aqueous solution of gelatin, resorcinol, and calcium chloride, and the other is an aqueous solution of formaldehyde and glutaraldehyde. After warming the polymer solution to 45°C and mixing 1 ml of polymer solution with two or three drops of aldehyde solution, gel is formed within about 1 minute.

GRF has largely been used in Europe to treat acute aortic dissections because of its ability to reinforce the delicate structure of the aortic wall.^[13] Every acute dissection involving the ascending aorta (Stanford type A) should undergo emergency surgical repair. 75% of Type A AAD patients die within two weeks. The surgical techniques vary depending on the clinical status of patients or the anatomical patterns observed. Furthermore, surgery is generally difficult because of very brittle aortic tissues, especially in advance-aged patients. Bachet et al. applied GRF glue for 212 patients with an emergency operation for type A aortic dissection. Their experience extending over more than 23 years proved that GRF glue is extremely useful, making the procedure much easier and safer. GRF is

said to adhere to the false lumen and shows excellent solidity and hemostasis of suture sites.^[14]

Since highly concentrated solutions of formaldehyde and glutaraldehyde are directly applied to an injured tissue, its toxicity is of major concern. Formaldehyde will be released from the cured glue when gelatin undergoes enzymatic hydrolysis and, therefore, surgical application of GRF glue is limited to special cases such as where high bonding strength is imperative.

OTHER SURGICAL GLUES

As mentioned earlier, fibrin glue, cyanoacrylates, and GRF glue show risk of viral infection, toxicity, low-adhesion strength, and long curing time. Thus many studies have been carried out to replace these glues. The curing modality of most surgical glues studied is either in situ cross-linking or in situ polymerization of monomer. Less toxic and bioabsorbable polymers such as gelatin, albumin, hyaluronic acid, chitin, poly(ethylene glycol), and poly(L-glutamic acid) have been studied and glutaraldehyde, formaldehyde, water-soluble carbodiimide, *N*-hydroxysuccinimide, and photoreactive agents have been used as cross-linkers. These agents are mostly multifunctional cross-linkers and are directly used at the application site or immobilized to structural polymers. Several studies will be described below.

Aldehyde System

Aldehyde can react with primary and secondary amines through Schiff's base. Since glutaraldehyde has two aldehyde groups in one molecule, it can react with two amines. If they are from different polymer molecules, glutaraldehyde will produce intermolecular cross-linking. Thus, by mixing the solution of polymer with amines in its side-chain and glutaraldehyde solution, gelation will occur. Natural polypeptides, such as collagen, gelatin, albumin, and enzymes, have amines that are reactive with aldehyde. So, glutaraldehyde is also used as a tissue fixation agent for micrograph observation. As aldehydes with high reactivity show cytotoxicity, too much volume and too high concentration of aldehyde solution may induce untoward tissue reactions.

Aldehyde-polysaccharides and amine-gelatin

Gelatin and polysaccharides were employed to prepare the hemostatic glue, which does not release any low molecular weight substances. To this end, gelatin was modified with ethylenediamine using water-soluble carbodiimide to introduce additional amino groups into the original gelatin, while dextran and hydroxyethyl-starch were oxidized by sodium periodate to convert

1,2-hydroxyl groups into dialdehyde groups.^[15] Upon mixing the two polymer components in aqueous solution, Schiff's base was formed between the amino groups in the modified gelatin and the aldehyde groups in the modified polysaccharides, thus resulting in intermolecular cross-linking and gel formation. The fastest gel formation took place within 2 seconds, and its bonding strength to porcine skin was 225 gf/cm² when 20 wt% of amino-gelatin (55% amine group) and 10 wt% of aldehyde-HES (>84% dialdehyde) aqueous solutions were mixed. In contrast, the gelation time and bonding strength of fibrin glue was 5 seconds and 120 gf/cm², respectively, when the same system was applied for the comparative evaluation.

Albumin glue

Albumin is a natural protein present in blood serum and used as structural polymer for a surgical glue similar to GRF. A glue consisting of 45% bovine serum albumin and 10% glutaraldehyde formed gel within 2 to 3 minutes. Herget et al. reported that this glue was effective as a sealant for bronchial anastomoses and parenchyma lesions in sheep.^[16] Bronchial anastomosis and parenchymal tissue repair could be sealed successfully against air leakage with this adhesive. Healing was not complicated much by foreign body reaction and tissue granulation.

Adhesion of aldehyde-gelatin film

It was reported that a glutaraldehyde (GA)-modified dry gelatin film could adhere to tissues.^[17] As described above, GA has two reactive aldehyde groups in one molecule and hence can act as a cross-linker of collagen, other proteins, and biological soft tissues. In a similar manner, GA can introduce cross-links into gelatin, making it insoluble even in hot water, where the physical cross-link of gelatin is destroyed. It is highly possible that at the gelation reaction with GA, one aldehyde group of a GA molecule will react with an amino group of gelatin, while the other aldehyde of the same GA molecule will not be able to find an appropriate amino group with which to react, thus remaining free. When a gelatin film was treated with 0.5 M GA solution at 60°C, free aldehyde groups were introduced in the film by up to 150 mmol/g. The dried gelatin film could strongly adhere to the porcine skin as strongly as 250 gf/cm², whereas the native gelatin film before GA treatment showed bonding strength of 40 gf/cm². The dried film could probably adsorb and remove the water existing between the GA gelatin film and the biological tissue, thus enabling aldehyde groups on the film and the amino groups on the natural tissue to approach each other and result in Schiff's

base formation. This reaction scheme was supported by the fact that GA-treated films did not demonstrate high bioadhesion when the remaining aldehydes were quenched with glycine or reduced with NaBH₄.

WSC and NHS System

Carbodiimide is a bifunctional cross-linker, similar to GA. 1-Ethyl-3-(3-dimethylaminopropyl) carbodiimide hydrochloride (EDC) and 1-cyclohexyl-3-(2-morpholinoethyl) carbodiimide metho-p-toluenesulfonate (CMC) are available as water-soluble carbodiimide (WSC). WSC is a coupling agent to form an amide bond between amino and carboxyl groups in a short time period in aqueous solution. Therefore, WSC functions as a catalyst to cross-link molecules and no WSC-related fragments are incorporated in the structure of resulting cross-linked molecules. An urea derivative is produced from WSC after the catalytic reaction and is much less toxic than the original WSC.

N-Hydroxysuccinimide (NHS) is a well-known coupling agent that can be immobilized to the carboxyl group of a host polymer through ester bonding. WSC also functions as a catalyst of ester formation. Immobilized NHS-ester can easily react with amines of other molecules through ester-exchange reaction. No NHS-related fragments are incorporated in the reacted molecules as NHS is released after the reaction. Such ester formation is used for the cross-linking of aqueous polymer solution to induce gel formation.

Gelatin, PLGA, and WSC

Gelatin and poly(L-glutamic acid) (PLGA) are natural and synthetic polypeptides, respectively, and are soluble in water and biodegradable. Gelatin is a heat-denatured product of collagen and is obtained commonly by extraction from bovine or porcine bone and skin. This natural polymer contains reactive groups such as –COOH and –NH₂ in the side-chain while PLGA has only –COOH groups. An addition of WSC to aqueous solution containing both of these polymers induces gelation, because the amide bond formation between –COOH of PLGA and –NH₂ of gelatin will form intermolecular cross-linking.^[18] The gelation time decreased with an increase in the WSC concentration to the comparable level of fibrin glue. When applied to the dog spleen injured by needle pricking, the WSC-modified gelatin-PLGA hydrogel exhibited superior hemostatic capability to fibrin glue. The WSC-modified gelatin-PLGA hydrogel strongly adhered to the surface of the dog spleen, whereas the fibrin hydrogel was easily detached from the spleen surface.

NHS-PLGA and gelatin

WSC is as cytotoxic as glutaraldehyde and the urea, a byproduct of this glue, also has slight toxicity. To circumvent the toxicity of WSC and urea, a new gelatin-PLGA glue that does not use WSC was designed.^[19] NHS-ester yields stable products upon reaction with primary or secondary amines and the coupling reaction proceeds efficiently at the physiological pH. An attempt was made to synthesize a new NHS derivative of PLGA, that will induce prompt gelation when mixed with aqueous solution of gelatin. NHS-esters can also react with amines of natural protein, resulting in tissue adhesion. The gelation scheme between gelatin and this PLGA derivative is shown in Fig. 2. Esterification of PLGA with NHS was performed by adding WSC to the reaction mixture. After 20 h at an ambient temperature, the whole reaction mixture was poured into dehydrated acetone to precipitate the resulting NHS ester of PLGA (NHS-PLGA). The NHS-PLGA could be synthesized at high yields and was found to be stable for an extended time without losing the ability to cross-link with gelatin when stored under a dry-cold condition. This NHS-PLGA could spontaneously form a gel with gelatin in aqueous solution within a short time, comparable to fibrin glue, when gelation was allowed to proceed at pH 8.3. The bonding strength of NHS-PLGA-gelatin glues to natural tissues was higher than that of fibrin glue. With the increase of NHS-ester introduced to PLGA, the gelation time became shorter and the bonding strength increased.

NHS-PEG and SH-PEG

Poly(ethylene glycol) (PEG) is a highly hydrophilic synthetic polymer and has found wide applications in medicine. A new rapidly synthetic tissue sealant can be synthesized from tetra-succinimidyl and tetra-thiol-derivatized PEG. Wallace et al. studied the *in vitro* and

in vivo efficacy of this glue by dissolving the two reagents in aqueous buffer and subsequently spraying it on a tissue surface.^[20] This glue exhibited good adhesion to collagen membrane, PTFE graft, and carotid artery *in vitro*. The gel maintained fluid pressure of 125 mmHg, which is fivefold greater than the capillary blood pressure and one-half that observed in hypertension. Bleeding in rabbit arteries was stopped immediately in five out of six trials. A significant reduction was observed for the time until to hemostasis and blood loss, compared to the control. Carotid artery and subcutaneous implant data in rabbits showed that the formulation was compatible with biological tissues.

NHS-PEG and albumin

Kobayashi et al. reported the ability of an albumin-based hydrogel sealant (ABHS) to prevent air leakage through a suture line after pulmonary surgery.^[21] This glue is a hybrid of synthetic and natural products and has two basic components: PEG disuccinimidylsuccinate (cross-linker) and human serum albumin. The terminal reactive ester of the PEG-derived cross-linker and the free amine groups in albumin react to form a gel. When the rat lung was used as an air-leak model, the average burst pressure of the ABHS-treated group was higher than that of fibrin glue throughout the observation period. Histological examination of the incision at day 14 revealed that no sealant was visible at the incision site, without any evidence of adverse tissue reaction.

Photocurable System

With the use of a photosensitizer, UV and visible light can initiate radical polymerization. If dye, azide, and acrylic macromer are used at a suitable combination, polymerization is initiated under a mild condition,

Fig. 2 Gelation scheme between gelatin and NHS-PLGA.

enabling its application as surgical glue. Water-soluble macromers, such as PEG diacrylate, become insoluble upon light irradiation through polymerization. Optical fiber or other devices are used for light irradiation. UV irradiation should be avoided because of its toxic reaction.

PEG diacrylate

Hubbell et al. reported the photoinitiated polymerization of a biodegradable tissue adhesive in 1993.^[22] This is made from the macromer that consists of a copolymer of water-soluble PEG with the two terminals capped with biodegradable oligomer such as glycolide and lactide oligomers. The two terminals of this macromer are further capped by acrylates to provide an unsaturated hydrocarbon required for photoinitiation by UV or visible light in the presence of eosin Y, triethanolamine, and 1-vinyl 2-pyrrolidinone. Depending on the type and molecular weight of the capped oligomer and the molecular weight of PEG, the resulting sealant has a wide range of biodegradation kinetics ranging from 1 day to 6 months.

Tanaka et al. evaluated the efficacy of this glue using a canine acute descending aortic dissection model.^[23] When the glue was applied to the false cavity for reinforcing and fusing the dissected layers and also to the suture line under a wet condition, hemostasis was easily achieved during surgery. All false cavities were perfectly thrombosed, causing no deleterious effects related to the glue, indicating that this glue can be used easily and effectively for the treatment of acute aortic dissection.

Photoreactive-gelatin and PEG-diacrylate

Nakayama et al. reported on a photocurable glue composed of gelatins partially derivatized with photoreactive xanthene dyes (fluorescein, eosin, and rose bengal) and a hydrophilic difunctional PEG macromer.^[24] When a dye-derivatized gelatin (20 wt%), a PEG diacrylate (10 wt%), and ascorbic acid (0.3 wt%) were dissolved in saline solution and irradiated with visible light, a swollen gel was formed within a few tenths of a second due to dye-sensitized photo-cross-linking and photograft polymerization. When a rat liver injured on laparotomy was coated with this hemostatic glue and irradiated with visible light through an optical fiber, the coated viscous solution was immediately converted to a swollen gel and hemostasis was completed. According to a histologic examination at the 7th day after surgery, little gelatin remained in the injured region, scarring with little necrosis occurred, and inflammatory cell infiltration from the surrounding tissue and tissue regeneration proceeded well.

Hyaluronic acid and albumin indocyanine

A photocurable tissue sealant composed of hyaluronic acid, albumin, and indocyanine was studied. For instance, 0.4 ml of hyaluronic acid, 0.2 ml of albumin, and three drops of indocyanine green dye gave a sealant with a peak absorbance of 805 nm, which matches the wavelength (808 nm) of a small, hand-held diode laser. Because tissues do not absorb any light of this wavelength, laser energy is focused in the sealant, minimizing collateral thermal damage. Auteri et al. reported the efficacy of this glue using a canine model of esophageal closure.^[25] The tissue sealant was applied to the edges of a hand-sewn closure, and then exposed to diode laser. The end-point was visible shrinking and desiccation of the sealant, which required about 2 minutes. At all time points, closures with this glue had significantly higher bursting pressure than the control closures. Histologic study revealed trace thermal injury with regeneration of intact mucosal lining by 7 days.

Azide chitosan lactose

Ono et al. studied the efficacy of a photo-cross-linkable chitosan glue, to which both azide and lactose moieties were introduced (Az-CH-LA).^[26] Introduction of the lactose moieties yielded a much more water-soluble chitosan at the neutral pH. UV irradiation to Az-CH-LA produced an insoluble hydrogel within 60 s. This hydrogel firmly bonded two pieces of sliced ham with each other at appropriate Az-CH-LA concentrations. The bonding strength of the chitosan hydrogel prepared from 30–50 mg/mL of Az-CH-LA was similar to that of fibrin glue. Compared to the fibrin glue, the chitosan hydrogel more effectively sealed air leakage from pinholes on an isolated small intestine and aorta and from incisions on an isolated trachea. Neither Az-CH-LA nor its hydrogel showed any cytotoxicity. Furthermore, all mice studied survived for at least 1 month after implantation of 200 μ L of photo-cross-linked chitosan gel and intraperitoneal administration of 1 mL of 30 mg/mL Az-CH-LA solution.

CONCLUSION

Although numerous studies have been carried out to develop surgical glues, as described in the preceding discussion, no perfect glue has been developed yet. Several surgical glues such as fibrin glue, cyanoacrylate, and GRF glue are clinically used, but they have limitations. Requirements for surgical glues such as viscosity, gelation time, adhesion strength, and duration time (biodegradation time), are different depending on the application site and purpose. Handling

of glue is also important for the clinical application. Warming and light irradiation may be hazardous and the toxicity of agents should be taken into consideration. Reactive chemicals have some risks of toxicity and natural biomaterials have a risk of virus infection.

Surgical glues were studied first to replace sutures, but they are mostly used also for hemostasis and sealing. In the future, they may be applicable to less invasive surgery and tissue engineering. However, intimate collaboration between material scientists, clinicians, and industries is needed for the development of new good glues.

G

INTRODUCTION

Glycosaminoglycans (GAGs) are polysaccharides that are present on cell surfaces or in the extracellular matrix as free molecules or proteoglycans (PGs). GAGs are especially abundant in articular cartilage. Hyaluronan (hyaluronic acid; HA), chondroitin 4- and 6- sulfates, keratan sulfates (KSs) I and II, heparin, heparan sulfate, and dermatan sulfate are the most physiologically significant GAGs known. GAGs are involved in many biological functions such as embryonic development (e.g., synovial joints), wound healing, cell signaling, growth factor regulation, protein trafficking, etc. GAGs such as heparin (anticoagulant) and HA (orthopedic, ophthalmology, and cosmetic use) are also widely used clinically, and chondroitin sulfate (CS) is commonly used as a dietary supplement. Mutations in genes involved in the biosynthesis and degradation pathways of GAGs result in a number of hereditary disorders. In addition, GAGs have been implicated in diseases such as cancer, metastasis, viral infections, and amyloid diseases such as Alzheimer's disease.^[1] The main focus of this review will be on the role of GAGs and PGs in synovial joints and articular cartilage specifically.

A complex milieu that includes collagens, GAGs, PGs, proteases, cytokines, growth factors, and mechanical stimuli directs the development, function, and maintenance of synovial joints and articular cartilage. Articular cartilage is the smooth glistening white and remarkably durable hyaline tissue that covers the bone in our joints and supports the movement of joints by greatly reducing friction between bones. In articular cartilage, a sparsely distributed population of specialized cells (chondrocytes) synthesize different matrix components and assemble and organize them into a highly ordered macromolecular framework consisting largely of Type II collagen and the PG aggrecan. The unique properties of free and protein-bound GAGs provide the shock-absorbing and lubricating properties necessary for the high demands placed on joints.

GLYCOSAMINOGLYCAN STRUCTURE

GAGs are long unbranched polysaccharides with repeating disaccharide units containing uronic acid (glucuronic or iduronic) or hexose (galactose) and hexosamine (galactosamine or glucosamine). GAGs form long chains of negative charges owing to disaccharide units that contain negatively charged carboxylate or sulfate groups. The majority of GAGs are covalently bound to protein cores to form PGs. GAGs extend perpendicularly from the core protein attachments in a brush-like manner. HA is unique among the GAGs in that it does not contain a sulfate group and does not appear to covalently bind to protein. HA is composed of repeating units of *N*-acetylglucosamine and glucuronic acid. Although it is not covalently linked to protein cores, it is an essential backbone for aggregating PGs such as aggrecan.

Chondroitin-, heparan-, and dermatan sulfates are predominantly linked to serines of the protein core via tetrasaccharide. CS contains a series of 30–50 repeating disaccharides of *N*-acetylgalactosamine and glucuronic acid in β 1-3 linkage, either unsulfated or sulfated in 4 or 6 position of the galactosamine residue. Dermatan sulfate is a variation through iduronic acid instead of glucuronic acid by epimerization of C5 carboxylic group and sulfation at C2 position of glucuronic acid. Heparan sulfate can consist of glucosamine and either glucuronic or iduronic acid including *N*-sulfated *N*-acetylglucosamine acetyl groups. Compared to heparin, heparan sulfate contains more *N*-acetyl groups and fewer *N*-sulfate or *O*-sulfate groups. KS is composed of *N*-acetylglucosamine and galactose instead of uronic acid in β 1-4 linkage. This GAG binds covalently to protein cores, either *N*-linked to asparagines or *O*-linked to serine or threonine. In addition to mannose, fucose and, sialic acid, KS's sulfate content may vary and occurs in both galactose and hexosamine. Interestingly, evidence suggests that GAGs contain information in the form of a "sulfation code," which may specify protein function and location.^[2]

PGS

Articular cartilage PGs are a group of complex and fascinating molecules with functional and structural diversity (Fig. 1). Originally named owing to their GAG content, they can be categorized as a protein core-encoding molecule family. Generally, they are composed of a central protein core, oligosaccharides, and GAG chains. Although articular cartilage PGs provide a broad combinatorial potency and functional specificity, they can be categorized in two major groups: large aggregating PGs such as aggrecans (Figs. 1 and 2) and versican, and small, leucine-rich repeat PGs (SLRPs) such as decorin, biglycan, fibromodulin, and lumican. Additional PGs relevant to cartilage include among others perlecan and superficial zone protein (SZP)/lubricin.

PGs play either structural roles or may be involved in cell regulation, and contribute 25–35% of the dry weight of healthy articular cartilage. They fulfill a variety of biological functions such as matrix organization, cell adhesion, lubrication, ionic filtration, and growth and growth factor modulation. Many of them differ between their deposition and structure in

anatomical site, age, or biomechanical stress. Differences in composition, organization, and function can be found among the cartilage layers and cell-related matrix compartments. PGs resist compression (Fig. 2): negatively charged GAG chains of aggrecan in particular contribute more than 50% of the equilibrium compressive stiffness of articular cartilage.^[3,4] Moreover, they are crucial for molecule passing/rate and tissue fluid. Negative charges repel other negatively charged chains and attract ions, which maintain the fluid within the matrix and regulate electrolyte concentrations related to the Donnan osmotic pressure.

Importantly, the extracellular matrix protects chondrocytes from mechanical stress and preserves phenotype. In this context, habitually loaded cartilage regions may show high aggrecan deposition, whereas dynamic loading and mobilization further increase aggrecan concentration combined with restitution of biomechanical properties.^[3] Physical stimulation alters both matrix production and quality and function of newly synthesized PGs.

It is important to note that zonal organization of articular cartilage has functional significance (Fig. 3 a₂ and b₁).^[3] Besides the PG-rich pericellular matrix

Fig. 1 Schematic overview of articular cartilage PGs. Aggrecan macromolecules bind non-covalently with HA molecules to assemble into large aggregates. HA forms a backbone with multiple palisading aggrecan molecules. Binding of HA to cell surface receptor CD44 provides pericellular matrix homeostasis. Moreover, abundance of SLRPs are present in the articular cartilage matrix. Decorin and fibromodulin are considered to play a role in organizing and stabilizing the collagen meshwork, whereas biglycan can be found in the pericellular matrix. Perlecan and its protein core are characterized by five distinct domains. Perlecan is enriched in the pericellular matrix. SZP is specifically synthesized by superficial chondrocytes and synoviocytes.

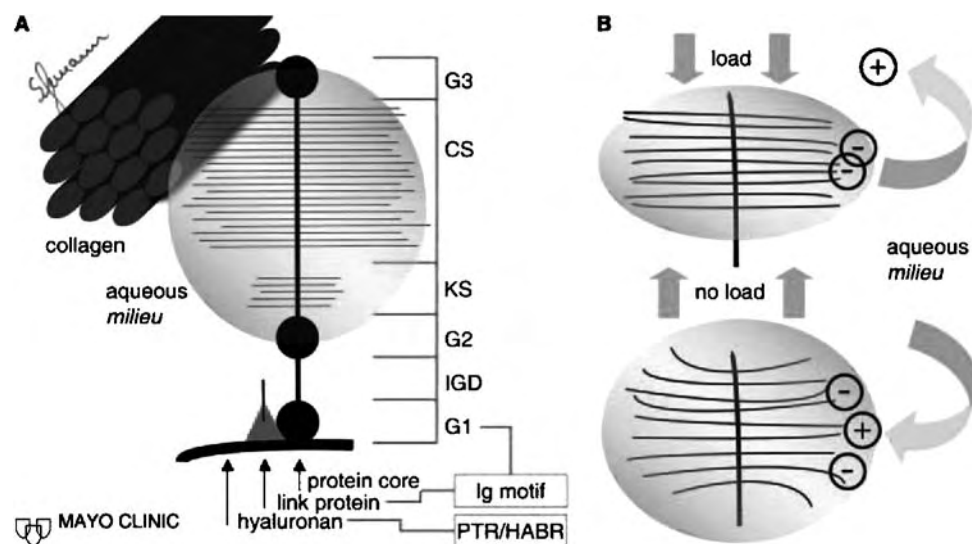

Fig. 2 (A) Schematic structure of the multimodular macromolecule aggrecan characterized by its protein core consisting of three distinct globular domains (G1–3) and related interglobular domains. The complex G1 domain is responsible for non-covalent interactions with HA [PG tandem repeat (PTR)/HA binding region (HABR)] and link protein [immunoglobulin (Ig) motif], which stabilizes the connection between aggrecan monomers and HA. KS and CS attachment domains are located between G2 and G3. GAGs are posttranslationally, covalently linked to the protein core filament and extend perpendicularly in a brush-like manner. Aggrecans can contain up to 60 KS chains and 100 CS chains. CS side chains bind to collagen fibrils allowing for cross-linked matrix meshwork. (B) GAG chains are negatively charged. Hence electrostatic repulsion between chains provides fully extended conformation and compressive stiffness as well as molecule passing/rate and tissue fluid equilibrium.

(Fig. 3a₃ and b₃), low PG concentration is apparent in the superficial zone (Fig. 3a₂ and b₂). Presumably, superficial cells degrade PGs more rapidly and synthesize less matrix compared to the deeper zones where higher PG concentrations can be found.^[3] However, the clarity of the zonal differences in PG content depends on the histological methods used (compare Fig. 3a₂ and b₁). It is also important to note that interaction of all components acting in concert is pivotal for the viscoelastic properties of articular cartilage, which allow it to withstand forces.

Aggregating PGs

Among the large aggregating PGs, the prototypical multimodular macromolecule aggrecan has been extensively studied owing to its abundance in articular cartilage, major contribution to compressive resistance, and degradation in cartilage disorders. Aggrecan (2×10^3 kDa) is the major PG in cartilage. It fills most of the interfibrillar space contributing to about 90% of the total matrix PGs mass. Aggrecans bind non-covalently with HA molecules on the protein core via link proteins and form large, multimolecular aggregates (Fig. 1). The aggrecan protein core (~ 230 kDa) consists of three globular domains (G1–3), with distinct motifs and folded structures and related interglobular domains in between (Fig. 2). The N-terminal globular domain G1

is responsible for interactions with HA. It contains an Ig motif and two PTR units. The Ig motif mediates the interaction between aggrecan and link protein, and the two PTRs formed of disulfide bonding structures provide functional sites of the aggrecan-HA binding within the HABR.^[5,6] The short, relatively stiff and inflexible interglobular domain IGD is located between G1 and G2. It contains proteolytic cleavage sites to a variety of proteinases.^[4] The G2 domain is unique to aggrecan. Although tandem repeats similar to G1 could be found, no binding capacity to other macromolecules has been observed. The C-terminal globular, multifunctional domain G3 is produced by alternative splicing of exons during posttranscriptional processing and contains three modules with homology to epidermal growth factor, complement reactive protein, and C-type lectin.^[6] Presumably, G3 facilitates endoplasmic reticulum (ER)-Golgi complex trafficking and GAG chain binding and enhances product secretion.^[4,6] Its lectin-like properties may explain extracellular matrix interactions and intracellular synthesis regulation.^[6,7] G2 and G3 domains are separated by an extended carbohydrate-rich domain that includes KS and CS attachment domains.^[8,9] The KS domain is not the only site for KS chain attachment in the protein core. The CS attachment domain is the largest domain of aggrecan and notably encoded by a single exon. Aggrecan can contain up to 60 KS chains (5–15 kDa each) and up to 100 CS chains (~ 20 kDa each), which are posttranslationally,

Fig. 3 Safranin O/fast green stained histology obtained from femoral condyles of skeletally immature New Zealand white rabbits using (a) standard paraffin sections, (b) and (c) the Exakt™ system. Series (a) and (b) show articular cartilage while series (c) shows undeveloped growth plate before fusion that is highly enriched with PGs. Articular cartilage shows a characteristic zonal morphology through subchondral, trabecular bone (a₁ and b₁). Low PG content can be found in the superficial zone (a₂ and b₂; black arrows) compared to higher amounts in deeper zones (white arrows). In particular, the pericellular matrix is highly stained for PGs (a₃ and b₃). Notice different Safranin O intensities while comparing histology processed either with the Exakt™ system or with standard protocols: decalcified paraffin sections (a₂) depict highest Safranin O intensities within the extracellular matrix of the deep and calcified zone (white arrow). In contrast, this could not be seen in non-decalcified sections (b₁) using the Exakt™ system (white arrow). Moreover, histological processing via the Exakt™ system leads to less shrinking artifacts and higher structural preservation.

covalently linked to the protein core filament. The CS side chains in aggrecan bind to collagen fibrils (namely Type II in cartilage) to form a cross-linked matrix. Both CS and KS are negatively charged; hence, electrostatic repulsion between chains and along chains allows for PGs to achieve a fully extended conformation.

Link proteins are small non-collagenous glycoproteins, which are highly homologous to the N-terminus of aggrecan. They stabilize the connection between aggrecan monomers and HA,^[10] which forms a backbone with palisading aggrecan molecules. Link proteins seem to play a role in directing aggregates assembling within the extracellular matrix, whereas HA can bind to the cell surface receptor CD44 providing pericellular matrix homeostasis.^[5] Length of the central HA can vary from several hundred to more than 10,000 nm.^[3] Spatial aggregation enables PG anchorage within the matrix, which prevents displacement and provides an organized and stabilized connection and entrapment to the collagenous meshwork.

Versican, a large CS PG, is also expressed in articular cartilage, but at a much lower level than aggrecan. It has been shown that versican represents a splice variant of the larger PG-M.^[11] Versican with its G1 and G3 domains shares this general structure with aggrecan and other members of the HA binding PG or hyalactan family including also neurocan and brevican. Versican contains cysteine-rich regions at both N- and C-termini and a long potential GAG attachment region in between. It may function as a cell adhesion-mediating molecule during initiation of matrix assembly and is no longer expressed after the deposition of aggrecan in the developing cartilage anlagen.^[5]

Small Proteoglycans

SLRPs are characterized by a central leucine-rich repeat domain and can eventually be subdivided into dermatan/CS and KS-substituted SLRPs. Their variety

provides a broad combinatorial potency and functional specificity.

Biglycan contains two dermatan or CS chains, and decorin contains one dermatan or CS chain. Both have short N-terminal propeptides and contain smaller protein cores than aggrecans.^[3,5] Two potential articular cartilage KS SLRPs are lumican and fibromodulin, which contain up to four KS chains.^[5] Decorin is the most abundant SLRP and is increased during degeneration or senescence, along with fibromodulin and lumican. Like dermatan sulfate SLRPs, fibromodulin is present in articular cartilage throughout life. Fibromodulin contains KS just during chondrogenesis, whereas it is present as a glycoprotein in adults.^[12] On the contrary, lumican is only present in adults, predominantly as a glycoprotein.^[13]

Although these molecules contribute little-to-overall PG mass, tissue volume, or mechanical properties, there may be an equal or greater number of SLRP molecules present compared to large PGs. SLRPs do interact with other macromolecules such as Type II collagen and influence cell function. Decorin, present in the interterritorial matrix and enriched in the superficial zone, and fibromodulin are considered to play a role in organizing and stabilizing the collagen meshwork,^[5] whereas biglycan can be found in the pericellular matrix and may interact with Type VI collagen. One of the most important functions of SLRPs is the ability to bind growth factors and cytokines such as decorin and biglycan to transforming growth factor- β (TGF- β).^[9,14]

Restricted expression of the dermatan sulfate PG epiphygan can be noticed during cartilage maturation.^[5] Owing to its single CS chain on the 2 α chain (NC3 domain), Type IX collagen is also considered to be a PG. Other small PGs remain to be discussed.

Other Proteoglycans

Perlecan is a large heparan/CS hybrid PG present in all basement membranes.^[15] Although cartilage is devoid of basement membranes, perlecan is also present in cartilage and enriched mainly in the pericellular matrix suggesting a role in chondrocyte-matrix attachment.^[16] Its protein core seems to be involved in the control of important biological functions such as cell adhesion, maintenance of the extracellular matrix, and binding to growth factors. The perlecan gene encodes a protein core (~467 kDa) consisting of five distinct domains with multiple functions and a single N-terminal GAG attachment domain. The N-terminal domain is unique to perlecan and may play a role in chondrocyte differentiation and cartilage development,^[17] whereas the other domains share sequence similarities with other

cell surface and extracellular matrix proteins.^[5] Domain 1 contains three potential GAG attachment sites.

The SZP, a ~345 kDa PG, is specifically synthesized by superficial chondrocytes and synoviocytes. It has one CS chain attachment domain and is identical to megakaryocyte stimulating factor.^[8] Similarities or homology to lubricin, which is responsible for joint lubrication and frictionless motion have been described.^[18,19] Moreover, potential growth promoting, cytoprotective, and matrix binding properties associated with certain domains as well as influence on synovial cell proliferation have been suggested.^[8,19]

GLYCOSAMINOGLYCAN AND PROTEOGLYCAN BIOSYNTHESIS

PG biosynthesis is a complex process, with multiple steps including numerous posttranslational modifications that are context dependent. The synthesis of aggrecan, for example, presumably involves more than 30 enzymes,^[5] and is still being explored. Intracellular regulatory systems monitor the concerted synthesis of protein core domains, domain folding, and GAG composition and length. CS can serve as a prototype for the GAG synthesis owing to similarities in sugar sequences, which link to the protein core.

Xylosyltransferase recognizes GAG chain consensus sites on the protein core and catalyzes GAG chain initiation that begins in the late ER and continues into the Golgi complex by addition of xylose to serine residues embedded in a specific peptide sequence. Elongation of the linkage region is catalyzed by three different and specific glycosyltransferases forming a glycosidic bond by transferring sugar residues from a donor nucleotide sugar to the non-reducing end of the accepting sugar. The subsequent repeating polymer is catalyzed by both *N*-acetylgalactosaminyltransferase and glucuronosyltransferase.^[9] Synthesis of heparan sulfate requires additional modifying enzymes such as *N*-deacetylase/*N*-sulfotransferase, glucuronic acid C5 epimerase, iduronic acid 2-O-sulfotransferase, and glucosamine 6-O- and 3-O-sulfotransferases.^[9]

During GAG chain elongation, nascent protein core substrates are traversing intracellular secretory pathways. Cotranslational routing and translocon targeting and passing are complex processes. N-linked mannose-rich oligosaccharides are added cotranslationally to the initial unfolded nascent protein core, which is released into the ER lumen.^[6] Molecular chaperones survey folding and advancing to distal compartments. Until a fully glycosylated and sulfated aggrecan molecule is synthesized, xylosylated precursor protein cores are translocated and undergo further modifications and

trimming in various Golgi compartments where both mono- and oligosaccharides are added.

Sulfation of GAG chains in either 4 or 6 hexosamine position concomitant with or shortly following GAG polymerization completes the complex synthesis of a mature aggrecan molecule.^[6] Finally, motifs are properly folded, certain domains are decorated with GAG chains, and hence aggrecans are exported to the extracellular matrix into unique macromolecular arrays.

HA occurs as a free molecule or as the backbone of PG aggregates. Three different HA synthases (HAS) have been characterized with respect to chromosomal location and amino acid sequence.^[20–23] Mice deficient for HAS2 die early in embryogenesis owing to multiple, most prominently cardiac defects that are compatible with key functions of HAS for epitheliomesenchymal transformations.^[24] HAS proteins are thought to be located largely interior to the cell membrane and have been shown to produce HA chains of different molecular masses.^[25] To date, all three HAS isoforms were found, HAS2 being the most, HAS3 the least abundant mRNA in articular chondrocytes, and HAS1 being highly expressed in synovial cells.^[26] Increased numbers of HAS expressing cells have also been detected in neocartilage following cartilage repair techniques.^[27]

CARTILAGE PROTEOGLYCAN DEGRADATION AND AGING

Biomechanical properties of articular cartilage are inseparably dependent on matrix integrity. Throughout life, cartilage undergoes internal remodeling. Chondrocytes sense matrix alterations, degradation, and mechanical demands, as they are able to respond limitedly by synthesizing and reorganizing appropriate types and amounts of matrix components. Senescence, degenerative diseases, altered joint activity, and post-traumatic disorders decisively alter matrix morphology and chondrocyte function, and remarkably the capacity to maintain and replenish regular PGs and amounts of GAGs.

Decreased staining of PGs in superficial cartilage layers are, among others, the first microscopically detectable changes of degeneration.^[28] In the beginning, the inert macromolecular framework is altered at molecular level.^[3] Simultaneous to collagenous alterations, aggrecan aggregation decreases owing to reduced binding capacity of PTR and HABR to HA molecules.^[4] Aberrant integrity or uncoupling of CD44, HA, and aggrecan deteriorates pericellular matrix homeostasis, matrix turnover, and PG retention, and can even initiate chondrocytic chondrolysis.^[5] GAG chains alter in length and charge density or even lose their connection to the protein

core. This break down can cause swelling, increased permeability, and further vulnerability. Non-aggregated PGs, unbound to HA, and tissue softening are the direct correlates of (early) osteoarthritis. Cs-Szabo et al.^[29] summarized the changes found in osteoarthritic and rheumatoid cartilage. Regular PGs remain in diseased cartilage; however, KS and chondroitin-6-sulfate epitopes of aggrecan were missing and in their place was an increased concentration of chondroitin 4-sulfate and fetal epitopes. Subsequently, molecular pattern is disordered owing to elevated proteolytic activity and impaired PG turnover. Biochemical changes are accompanied by chondrocyte hypertrophy and upregulation of Type X collagen and alkaline phosphatase. Altered biomechanical properties make cartilage even more susceptible to further damage. Anabolic repair, namely matrix neosynthesis associated with cell proliferation and cell clusters can temporarily provide satisfactory stages. Yet, catabolic processes of a variety of proteinases result finally in decline of chondrocytic repair response and destructive progression.^[3]

The detailed mechanisms of degeneration and pathogenesis and the impact of different factors in aging are not yet completely understood and cannot generally be equated with osteoarthritis. Moreover, a broad range of causes for degradation such as genetic predisposition, inflammation and hormonal and metabolic disorders should be taken into account.

Proinflammatory Cytokines

Release of nitric oxide and other proinflammatory cytokines such as interleukin -1 and -6 (IL-1, IL-6), and tumor necrosis factor- α (TNF- α) upregulates expression of several matrix metalloproteinases (MMPs), and inhibits synthesis of their inhibitors namely tissue inhibitors of metalloproteinases (TIMPs) and of PGs such as aggrecans and the SZP.^[30] IL-1 plays one of the crucial roles in this cascade by suppressing matrix synthesis in low concentrations and by stimulating production of proteolytic enzymes in high concentrations.^[31] Thereby, the matrix turnover balance, which is also regulated by bone morphogenetic proteins (BMPs), is shifted from anabolism to catabolism. This may also be owing to decorin, which accumulates during degeneration and can bind anabolic cytokines.^[3]

Recently, work by Poole^[32] includes IL-1 and TNF- α antagonists as a useful therapeutic approach to the management of osteoarthritis. Decreased response to catabolic factors, increased rate of PG turnover and synthesis, and a greater inherent amount of PG explain why some joints are less predisposed to osteoarthritis.^[31,33]

Owing to polymorphisms in the region encoding aggrecan's CS1 domain, individuals with short alleles have low CS content aggrecans and may be more susceptible to degradation.^[34] Moreover, aging is characterized by an increased amount of aggrecan monomers that lack the G3 domain probably owing to proteolytic processing, by declined cell response to anabolic cytokines and the synthesis of smaller aggrecans, fewer functional link proteins and thus irregular PG aggregates.^[11,35]

Proteoglycan Cleavage

Besides MMPs' physiological role in matrix turnover controlled, e.g., by cathepsin B or TIMPs, their over-expression enhances matrix degradation and destabilization of the macromolecular framework. MMPs such as MMP-3 (stromelysin), and aggrecanase, a member of the ADAMTS protein family (a disintegrin and metalloproteinase with thrombospondin motifs), are known to cleave aggrecan at the IGD, KS and CS attachment domains, and even at the carboxyl tail.^[36] How far other PGs are degraded remain unresolved.^[11] Two major aggrecan cleavage sites are located between Asn341-Phe342 and Glu373-Ala374 of the IGD.^[4] Cleavage results in a separation of the G1 domain from the whole GAG attachment region generating specific fragments, which could hence be found in both cartilage and synovial fluid to be useful as markers for tissue destruction.^[4] MMPs additionally affect other matrix molecules resulting in, e.g., fibronectin fragments that are shown to modulate PG synthesis and degradation as well.^[31]

In this context, severe impact or overload may trigger deregulation of MMPs and can cause degradation.^[30] It was shown that static compression can reversibly inhibit synthesis and downregulate gene expression of among other aggrecan core protein and link protein.^[3,31] Immobilization or reduced loading can result in decreased matrix synthesis too.

Additionally, it is believed that other mechanisms, proteolytic and non-proteolytic, cleaving HA renders portions likely contribute to PG fragment release with concomitant fragmentation and release of link protein, smaller HA or irregular molecule complexes. This might be owing to HA depolymerization, reactive oxygen, hyaluronidase, or IL-1 β interactions, which are still questionable.^[7]

SLRPs and Degradation

It was shown that discoordinated mRNA expression and imbalanced matrix accumulation of SLRPs and eventually other aggregating PGs may contribute to osteoarthritic degeneration,^[11,37] even though SLRPs'

role in degeneration is unclear. They show disease- and age-related proteolytic processing resulting in SLRPs increase and accumulation of, e.g., non-glycanated fragments. N-terminal propeptides of decorin and biglycan can potentially be removed by procollagen-C proteinase, however, they appear relatively resistant to cytokine-induced proteolytic modifications.^[8,38]

MEASUREMENT OF GAG CONTENT

GAG assays are useful in the clinical setting to quantify the amount of GAGs synthesized within biological samples. As GAGs are found ubiquitously in the body, GAG assays are also used for cancer (tumor samples), cardiovascular disease (artery samples), Rhesus compatibility, renal (urine), and metabolic disease (urine samples) studies.^[39,40] With respect to orthopedic and cartilage research, GAG assays allow for the determination of efficacy of tissue regeneration techniques by providing a quantifiable measure of cartilage matrix. These assays are proving to be of value in the detection, study, and treatment of osteoarthritis, especially with respect to improved understanding of the pathology of the disease and how it can best be detected and managed.

Histological staining methods are commonly used to demonstrate the presence of GAGs in histological sections. These include viz. Thionin, Safranin O (Fig. 3), Toluidine Blue O, Dimethylmethylene Blue (DMMB), Cuproline Blue, Cupromeronic Blue, and *N,N'*-Diethylpseudoisocyanine. Cartilage is largely made up of water. Just as water molecules are attracted to the negative charges of the sulfate and carboxyl groups of GAGs, these same charges also attract dye molecules, which are usually cations. The different extent of staining or dye uptake is correlated with the amount of GAG present in a tissue sample. As PGs are usually found concentrated around chondrocytes within the extracellular matrix, staining is hence most intense in this region (Fig. 3a₃ and b₃).

Some dyes like Toluidine Blue are metachromic. This is a process of color change induced by the negative charges in GAGs, causing aggregation of dye molecules and subsequent change in dye absorption. Toluidine blue stains nucleic acids blue (the orthochromatic color), but sulfated polysaccharides purple (the metachromatic color).

Using these histological stains, indirect quantification of GAGs in cartilage samples can be estimated. Kiraly et al.^[41] found Thionin and Safranin O to be excellent cationic dyes for the histochemical quantification of cartilage matrix PGs using semiquantitative estimations by microspectrophotometry in sections of articular cartilage. Other groups like O'Driscoll et al.^[42] and Martin et al.^[43] developed their own

in-house computer-based techniques for quantitative analysis of Safranin O stained histological sections, using low magnification light microscopy images. Burkhardt, Hwa, and Ghosh^[44] developed a method for the quantitation of GAG content in 6 μm histological sections that involved direct biochemical analysis of GAGs of unstained sections, which were then compared against a standard scanned image of the same section. This method could be applied when specific information about GAG content of different zones in a joint or body is required. It also allows for subtle changes in PG distribution in different cartilage zones to be detected more readily.

These methods have been developed based on the changes in dye absorption spectrum. Dyes commonly used are Alcian Blue, Toluidine Blue, Azure A, B,^[45] and 1, 9-DMMB. Early methods using these dyes have usually been laborious and complicated. However, modifications have been made over the years to make these processes simpler and easier to use. The main dyes used in GAG assays today usually involve DMMB.

Farndale, Sayers, and Barrett^[46] reported a method using DMMB for rapid estimation of sulfated GAGs in cartilage samples. Cartilage samples are digested with papain and mixed with the dye to allow dye complex formation with sulfated GAGs present in the tissue sample. Absorbance at 535 nm is then measured by spectrophotometer, and the values compared to a standard curve prepared using whale chondroitin 4-sulfate. This general method was later modified to obtain better specificity for sulfated GAG detection.^[47,48] Commercial kits are now available (Blyscan by Biocolor Ltd), which allow for quick and easy estimation of GAGs in tissue samples based on Farndale's technique that had unreliable results at levels of GAG less than 5 $\mu\text{g}/\text{ml}$. Recent studies by Barbosa et al.^[49] have improved this and other assay methods to detect submicrogram quantities of GAGs in samples. This modified method is inexpensive, quick, and specific.

Current biochemical methods also incorporate electrophoretic techniques for improved detection of GAGs in cartilage cultures as described below.^[50,51]

Horner^[52] was the first to describe a use for agarose gel electrophoresis for GAG quantification in 1967. This was adapted to achieve the separation of the major sulfated GAGs produced by cells in culture by Funderburgh and Chandler^[53] in 1978. Volpi and Maccari^[50] subsequently improved the detection of GAGs on agarose gels to the submicrogram level. Their work has included immunodetection using the antichondroitin-6-sulfate antibody that specifically recognizes intact chondroitin-6-sulfate, sequential staining with Toluidine Blue and Stains-All to obtain more sensitive visualization of GAGs with a detection

limit at submicrogram level greater than other conventional procedures.^[51,54] Electrophoresis procedures are generally used for pharmaceutical quality control to detect contaminations of polysaccharides species present in GAG preparations such as heparin.

IMAGING OF GAGs WITH MAGNETIC RESONANCE IMAGING

The use of magnetic resonance imaging (MRI) is a well-established technique for the monitoring of cartilage diseases in clinical routine. However, imaging and evaluation of particular cartilage matrix components was not possible for a long time. The introduction of delayed gadolinium enhanced MRI of cartilage (dGEMRIC) in the 1990s offered a revolutionary, non-invasive technique to monitor the maturation of neocartilage matrix following reconstructive surgery such as autologous chondrocyte implantation/transplantation (ACI/ACT).^[55-57]

GAGs form a dense negatively charged entity within the cartilage matrix. An injected negatively charged MRI contrast agent called gadopentetate dimeglumine [$\text{Gd}(\text{DTPA})^{2-}$] will therefore distribute in areas of GAG depletion (Fig. 4). It penetrates into cartilage from both the joint cavity through the synovial fluid and the subchondral bone. It then shows a distinct concentration-dependent effect on the T1 parameter of MRI. Measurement of T1 serves as an index for the concentration of [$\text{Gd}(\text{DTPA})^{2-}$] and therefore inversely allows for GAG concentration estimation within the cartilage matrix. "Delayed" refers to the fact that it takes time for the contrast agent to penetrate into articular cartilage.^[58-61]

GLYCOSAMINOGLYCAN DISORDERS

GAG disorders cause serious abnormalities in a wide variety of organs as they are ubiquitously present in the body. The majority of these disorders are caused by faulty degradation of PGs such as mucopolysaccharidoses (MPS).^[62] However, some defects in PG biosynthesis also exist. Studies involving experimental animals have shown impaired processing of cartilage PG core protein in nanomelic chickens.^[63] Defective PG biosynthesis in humans is responsible for diseases like macular corneal dystrophy and a variant of spondyloepiphyseal dysplasia.^[64] A Progeroid variant of Ehler Danlos Syndrome has also been described as being owing to defective biosynthesis of dermatan sulfate or decorin.^[65,66] These patients suffer from an aged appearance, short stature, osteopenia, and possess Ehler Danlos syndrome characteristics such as joint hypermobility and muscle hypotonia. Quentin

Fig. 4 dGEMRIC. Images postprocessing (usually >1 hr) with contrast distribution map are based on T1 values and allow for quantitative assessments of GAG deposition. Image (a) reflects normal structural GAG distribution in different cartilage zones of the patella. Notice high GAGs/PG concentrations in the middle and deep zone (blue/green) compared to low densities in the superficial zone (yellow/red). In contrast, degenerative diseases such as hip dysplasia (**b₁** and **b₂**) lead gradually to loss of GAG content (yellow/red) and zonal organization.

et al.^[67] found the genetic defect, which results in a deficiency in galactosyltransferase I, which is involved in the synthesis of PG linkage regions.

Lysosomal storage diseases describe a heritable group of heterogeneous human disorders characterized by the accumulation of undigested macromolecules intralysosomally, resulting in an increase in the size and number of these organelles and ultimately in cellular dysfunction and clinical abnormalities. Lysosomes are subcellular organelles responsible for the physiologic turnover of cell constituents containing catabolic enzymes requiring a low optimum pH to function. Lysosomal storage diseases are generally classified by the accumulated substrate and they include sphingolipidoses, glycoproteinases, mucopolisidoses, MPSs, and others.

MPSs result from abnormal degradation of GAGs resulting in organ accumulation and eventual dysfunction. Because GAGs are normal components of the cornea, cartilage, bone, connective tissues, and the reticuloendothelial system, these organs are also targets for excessive GAG storage. Ten known enzyme deficiencies give rise to six distinct MPSs (Table 1). All of these disorders, excepting Hunter's syndrome, are inherited in an autosomal recessive manner.

A major feature of the MPS disorders is abnormal skeletal development leading to short stature, dysostosis multiplex, and degenerative joint disease. Ultrastructurally, the cytoplasm of MPS-affected chondrocytes is filled with membrane-bound vacuoles containing undegraded GAGs. Clusters of hypertrophic chondrocytes form in these disorders, leading to the disruption of the normal cartilage organization. A variety of mutations are described, and correlation of genotype with disease severity is beginning to emerge from mutation analysis.

Simonaro et al.^[68] examined primary cultured chondrocytes and articular cartilage from cats and rats with MPS Type VI (Maroteaux–Lamy disease) and found markedly increased numbers of apoptotic chondrocytes in the MPS animals as compared to age-matched controls. The prevalence of apoptotic cells

was correlated with increased levels of nitrite and TNF- α . Marked PG depletion also was observed in the MPS epiphyses and there was also presence of excess of Type II collagen.

In general, MPS are progressive disorders, characterized by involvement of multiple organs including brain, liver, spleen, heart, and blood vessels, and many are associated with coarse facial features, clouding of the cornea, and mental retardation. Diagnosis can often be made by examination of urine, which reveals increased concentration of GAG fragments.

Enzyme replacement therapies exist for some forms of MPS with the exceptions of MPS III (though trials are ongoing to evaluate efficacy of central nervous system administration of enzyme), MPS IV, and MPS VII. Aldurazyme (Laronidase) is an approved once weekly treatment for the non-neurological symptoms of MPS I after studies demonstrated its efficacy and safety in 2004.^[69] Phase III trials using human enzyme replacement I2S have been completed with good outcomes for MPS II (Hunter's). The drug is currently awaiting Food and Drug Approval (FDA) approval in

Table 1 Summary of known enzyme deficiencies giving rise to six distinct MPS groups

MPS I	Hurler syndrome Schele syndrome Hurler–Schele syndrome
MPS II	Hunter syndrome (mild or severe forms)
MPS III	San Filippo syndrome (A, B, C or D)
MPS IV	Morquio syndrome (A or B)
MPS VI	Maroteaux–Lamy syndrome (mild, intermediate or classic severe)
MPS VII	Sly syndrome

Diseases lead to abnormal degradation of GAGs and become apparent by accumulation in organs, and can result in dysfunction and eventually failure. GAGs are ubiquitous components within the body; therefore, various tissues and organs are targets for excessive GAG storage owing to MPS. All of these disorders, except Hunter's syndrome, are inherited in an autosomal recessive manner.

U.S.A. Naglazyme has recent FDA approval for use in the treatment of MPS VI (Maroteaux–Lamy).

CLINICAL EFFICACY OF CS, GLUCOSAMINE, AND HYALURONAN IN THE TREATMENT OF OSTEOARTHRITIS

As explained in detail previously, GAGs are key components of extracellular articular cartilage matrix. They undergo constant degradation, removal, and replenishing.

In the disease process of osteoarthritis, the equilibrium of GAG degradation and resynthesis are heavily disturbed. Insufficient GAG synthesis (either of lower quality or insufficient quantity) ultimately causes overall cartilage degradation owing to altered matrix composition.^[70]

Glucosamine plays an important role in the synthesis of two of the most abundant GAGs, namely CS and HA. Therefore, glucosamine as well as CS and HA has been used in the past as dietary supplements for the treatment of “cartilage diseases.” This “new way to treat osteoarthritis” was initiated based on the theory that loss or insufficient synthesis of these key molecules in cartilage could simply be corrected by oral supplementation or even intra-articular injections.^[71,72] These nutraceuticals are commonly extracted from animal tissues, namely beef trachea.^[70]

Over time, many concerns from researchers in the field of orthopedics and rheumatology arose, questioning the efficacy of these new “drugs.” Many industry-funded studies, which were published in questionable journals stated highly positive effects and even postulated the potency to restore damaged articular cartilage and stop the disease process early on. A book entitled “The Arthritis Cure” finally provoked the initiation of serious studies in the field for the evaluation of the supplements efficacy.^[73–75]

Whereas in some European countries, these nutraceuticals have already achieved approval by the drug administration authorities, FDA approval has not been issued yet for any of these dietary supplements which are readily available “over-the-counter.”^[70,72]

The bioavailability and pharmacokinetics of glucosamine and CS were among the initial concerns raised by researchers over the use of these supplements. Various studies have investigated serum levels of glucosamine and CS after oral ingestion. Results to date are still controversial and published pharmacokinetic information appears to be incomplete. Oral daily intake of 1500 mg glucosamine seems to be absorbed to up to 87%. A single daily dose is recommended.^[76] Almost 40% of the unaltered molecule seems to be excreted through the urinary system. Additionally, a high first pass metabolism in the liver is apparent.

Nevertheless, radiolabeled glucosamine has been detected in all joint tissues following oral administration.^[70,77–82]

CS’s gastrointestinal absorption rate appears to be very much lower compared to glucosamine’s. However, with only 10–15% absorption after oral administration it can still be detected in human joint tissues. The recommended oral daily intake shall be 1500–2000 mg, based on recent bioavailability studies.^[70,78,81,83]

Because these nutraceuticals are not regulated in U.S.A., the quality of the products appears to be highly variable. The European market offers few products approved by drug administration agencies. The actual content of chondroitin and glucosamine sulfate in nutraceuticals may be significantly different from what product labels claim. According to a study of Adebowale et al.,^[84] deviations from label specifications ranged from 0–115%. These results again underline the need for a quality control and regulation of these products.

Glucosamine has been reported to inhibit disease progressing mediators such as IL-1, which are known to increase aggrecanase activity. It could also be shown that it increases synthesis of PGs in chondrocyte monolayer cultures.^[70]

Numerous studies on clinical improvement of symptoms after oral administration of glucosamine/CS in patients suffering from osteoarthritis have been published within the last decade. Almost all of the early studies until 2000 have shown positive results.^[70,73] A meta-analysis published in 2000 analyzed these studies and reported that the majority of these studies were of low or even unacceptable quality. Higher and high-quality studies showed lower significance levels and more recent, independent studies even null or negative effects.^[70,73,74,85] McAlindon et al. reported that the manufacturer supported most of the studies reporting positive effects. Reviewing these studies, different authors came to the conclusion that oral supplementation of CS and glucosamine should be part of the standard non-surgical armamentarium of an orthopedic surgeon for the symptomatic treatment of osteoarthritis.^[86–88] Skepticism arose especially from experts in the field and they called for more rigorous trials.^[70,73]

In fact, research in the field did greatly intensify within the last few years: Richy^[89] evaluated 500 publications from 1980 to the current which investigated the morphological and symptomatic efficacy of glucosamine and CS with 15 of them matching his quality criteria for randomized, double-blind, placebo-controlled studies. He found both significant morphological and symptomatic efficacy for glucosamine compared to placebo. CS instead showed only significant symptomatic efficacy. Both oral supplements were

tolerated with almost no major adverse effects, demonstrating the safety of these drugs.

McAlindon et al.^[74] performed an internet study among 205 individuals with osteoarthritis. They concluded that glucosamine has no more clinical efficacy than placebo for the treatment of osteoarthritis.

A discontinuation trial performed by Cibere et al. studied the effects of discontinuation of glucosamine in osteoarthritis patients who were already taking these supplements. The design was placebo-controlled, randomized, and double-blind over 6 mo and included four centers with 137 patients. No significant differences were found in disease flare between the placebo and glucosamine group.^[90] They also studied the effect of glucosamine discontinuation on serum and urine Type II collagen degradation fragments in the same patient group. Again, statistically no significant effect was found.^[91]

Another highly interesting recent study investigated the effect of CS on the inhibition of joint space narrowing on osteoarthritis patients. Three hundred patients were recruited and were given a daily oral dose of 800 mg of CS over 2 yr. Loss of joint space as well as pain and function measures was recorded. Again, no symptomatic or inhibitory efficacy could be revealed.^[92]

Conclusively, it still remains to be shown whether or not these nutraceuticals should have a place in the symptomatic, non-surgical treatment of osteoarthritis. In fact, results from a large multicenter trial are awaited shortly.

The term “viscosupplementation” describes the intra-articular injection of HA, a technique that has been performed since the 1970s.^[93] This treatment option for osteoarthritis reached FDA approval and has also been recommended by the American College of Rheumatology as an alternative for pain relief in osteoarthritis. Currently, two preparations are available and approved for the treatment of pain associated with knee osteoarthritis in U.S.A.: Hylan G-F20 (Synvisc[®]) and sodium hyaluronate (Hyalgan[®] and Supartz[™]). They differ greatly in molecular weights and concentrations.

The mechanisms by which intra-articular HA unfolds its effects still remain cryptic. HA half-life within the joint cavity is known to be short (15–36 hr); however, its effects seem to last much longer.^[72]

Commercial preparations are not identical with the body's own HA but chemically altered to improve viscoelastic properties and extend the molecules' half-life within the joint. In fact, different preparations with various molecular weights were compared to placebo or corticosteroid injections and efficacy could be shown for all of the different molecular weights.^[72,94,95]

Still, some studies do not support the opinion that HA injections truly resemble a worthy treatment

option.^[96] It could be demonstrated that this treatment has no measurable effects.^[97] However, Lo et al. found that intra-articular HA injections have a small effect with respect to pain relief when compared to placebo. They also concluded that high and highest molecular weight HA preparations may be more efficacious than low molecular weight HA.^[98] Additional studies suggest that intra-articular application of HA may inhibit or decelerate structural degradation of articular cartilage. Jubb et al. found a slower disease progression in patients with a radiologically milder disease at baseline. However, overall treatment effect after one year could not be observed.^[99]

In addition, the long-term effectiveness of HA is still unknown, and there is a great need for studies revealing prolonged effects and possible side effects.^[72] So far, no reports about significant adverse effects have been reported. Nevertheless, intra-articular injections always bear the risk of causing joint cavity empyemas.

Overall, viscosupplementation seems to be an alternative treatment with beneficial effects for patients suffering from therapy-resistant knee pain owing to osteoarthritic changes. However, contradictory results have been reported, and structural, disease progress inhibiting effects have not been shown to date.

CONCLUSIONS

GAGs are a very diverse family of molecules with multiple physiological functions. Variations in structure and modifications to the backbone such as sulfation add to the complexity of GAGs and may serve to regulate cell fate and function. It is not surprising, therefore, that GAGs are implicated in many diseases and targets of therapeutic approaches. GAGs are especially important for normal joint development and homeostasis. Because GAGs are abundant in articular cartilage, they are commonly used as indicators of cartilage integrity and chondrocyte activity. CS and glucosamine have become very popular nutritional supplements for joint health, although the scientific evidence regarding the efficacy of these supplements remains controversial. In addition, GAGs have been employed in a number of cartilage repair and tissue-engineering techniques. Although there is an abundance of information accumulating about GAGs, there is clearly much more to learn about the role of GAGs in normal tissue and disease and to develop their clinical potential.

ACKNOWLEDGMENTS

We would like to thank Dr. M. Yaszemski and collaborators from the Bone Histomorphometry

Laboratory (D. Jewison, J. Burgess, and L. Peterson) for histological contributions and for using the Exakt™ system, and to J. Fitzsimmons for technical and histological support. Fig. 4 was kindly donated by Drs. D. Burstein and K. Amrami from the Department of Radiology (Mayo Clinic College of Medicine, Rochester, Minnesota, U.S.A.).

INTRODUCTION

Over the last three decades, the importance of biomaterials has been recognized in the biomedical market and thus several specialized biomaterials were provided as commercial grades to the medical market in several countries. The biomaterials have ranged from synthesized materials of metals, ceramics, and polymers to those including biological materials. The newest definition of biomaterials is “either naturally occurring materials in living organisms or materials designed to repair humans.”^[1]

Although the biomaterials may have excellent bulk properties such as strength and elasticity, they may show relatively poor surface properties, e.g., poor wear resistance and limited biocompatibility. It may be necessary to make a compromise between the bulk and surface properties to fulfill biocompatibility. The properties of the biomaterial surface, such as wettability (hydrophilicity/hydrophobicity), chemistry, charge, and roughness, have been shown to be critical for biocompatibility.

Some groups have studied the interactions of different types of biological species with various solid substrates (mainly polymer) with different wettabilities to correlate the relationship between surface wettability and compatibility of biological species. The interactions with biological species mainly concern phenomena like protein adsorption,^[2] cellular adhesion and spreading,^[3] and inflammatory reactions^[4] that may take place under biological circumstances.

The modification of biomaterials by various surface treatment methods has been focused for decades as an interesting topic in the field of surface engineering. Large numbers of research groups have extensively studied the effect of the surface wettability on the interactions of biological species with solid substrates. The popularly used solid substrates with different

wettabilities are listed in Table 1. The water contact angle is an indicator of wettability of material surfaces, which is usually measured using a goniometer (static method) or the Wilhelmy plate apparatus (dynamic method).^[13]

Among various solid substrates, the importance of polymer surface wettability for cell adhesion was reported by Weiss in 1960,^[14] and was later confirmed in many other studies. Kaelble and Moacanin studied bioadhesion in relation to surface energy.^[15] Baier et al.^[16] and Van der Valk et al.^[17] showed some relationships between surface free energy and cell adhesion: Materials with low surface energies showed low cell attachment. Grinnell demonstrated that surface wettability influences the adhesion and proliferation of different types of mammalian cells.^[18] Cell adhesion occurred preferentially on water-wettable substrates.

Schakenraad et al.^[5] and Absolom, Hawthorn, and Chang^[19] reported that human fibroblasts or endothelial cells are spread poorly on hydrophobic substrates and more extensively on more hydrophilic substrates. Tamada and Ikada found that the maximal adhesion of fibroblasts occurs on surfaces having moderate water wettability and the adhesion decreases on surfaces with both higher and lower water wettabilities.^[6,20] van Wachem et al. also found that human endothelial cells adhere optimally on moderately wettable polymers.^[7] Jansen, van der Waerden, and de Groot observed that human fibroblasts are sensitive to surface wettability, whereas epithelial cells may not be.^[21] van Kooten et al. determined the strength of adhesion and detachment of fibroblasts from substrates with different wettability.^[22] Ease of detachment seemed to decrease with increasing wettability.

Much attention has also been paid to the interactions of blood proteins with various polymers having different wettabilities. Uyen et al. studied the

adsorption of albumin to substrates with a broad range of wettabilities.^[23] They showed that the amount of adsorbed protein is the highest on the most hydrophobic material and decreases with increasing wettability of the substrates. Lu and Park studied the extent of conformational changes of fibrinogen adsorbed on substrates with different wettabilities.^[8] They showed that the amount of adsorbed protein increases as the surface becomes more hydrophobic and the adsorbed protein undergoes a larger degree of conformational changes as the surface hydrophobicity increases.

One main problem derived from the studies using different kinds of substrates is that the surfaces are heterogeneous both chemically and physically (different surface chemistry, charge, roughness, rigidity, crystallinity, etc.), which may result in considerable variation. Another methodological problem is that such studies are often tedious because a large number of samples must be prepared to cover the range of the desired wettability. They may also involve the strong possibility of methodological error because the experiment for each sample is carried out separately.

Many studies have recently been focused on the preparation of surfaces with properties that change gradually along the material length. Such a “gradient surface” is of particular interest for basic studies of the interactions between biological species and surfaces because the effect of a selected property like wettability can be examined in a single experiment on one surface.^[24] Many papers have been published about the preparation of wettability gradient surfaces and their uses in studying the interaction phenomena of biological species like proteins, cells, or enzymes. Moreover, several techniques for preparing chemical composition gradients on various substrates have been developed, and such gradients have been used for further experiments and applications such as biomolecular interactions,^[25] cell-motility studies,^[26] or diagnostics.^[27]

In the forthcoming sections, brief summaries on the preparation methods of wettability gradient surfaces, introduction of biofunctional groups on gradient surfaces, characterizations, and applications of gradient surface in the biomedical fields will be given.

PREPARATION OF WETTABILITY GRADIENT SURFACES

The preparation of wettability gradient surfaces^[28–42] has been described by several groups, as reviewed in detail below.

Gas or Solvent Diffusion

The gas diffusion technique is based on exposing silicon wafers to the vapor of a volatile silane with the vapor concentration being diffusion controlled. A water contact angle hysteresis between 6° and 8°^[43] is typical for gas diffusion gradients, which is low compared to the hysteresis encountered on solvent diffusion gradients. Unfortunately, the wettability steepness cannot be easily controlled.^[43,44]

Meanwhile, the solvent diffusion technique usually uses silane dissolved in a solvent such as xylene, and the silane solution diffuses to the xylene region.^[30]

Fig. 1 Schematic diagram showing the diffusion method used to prepare surface gradients of methyl groups. (From Ref. [30].)

Silane is simultaneously bound to a silicon wafer or glass surface and subsequently is coupled to the surface (Fig. 1). The experiment is stopped by removing the solution through the drain. Thus a gradient of coupled silane is formed along the length of the silicon wafer. The gradient of these functional groups can be used as a template for a second reaction step to introduce other biomolecules or even biomaterial grafts.^[45] Liedberg et al. also prepared molecular gradients with various alkanethiols on gold particles using the solvent diffusion technique to design model surfaces for fundamental studies of protein adsorption and immobilization phenomena.^[46,47]

The main advantage of the diffusion technique is that this technique is easily utilized and gives exactly parallel and continuously varying chemical composition profiles on a single substrate surface along the sample length, while the disadvantage is that this technique can only be applied to hydrophilic inorganic substrates like silicon, silica, quartz, or glass.^[36]

Radio-Frequency Plasma Discharge

Various gases such as oxygen and nitrogen are used for the plasma treatments of various substrates. An increased surface energy of substrates results from the plasma treatment. A method for preparing wettability gradients on various polymer surfaces via radio-frequency plasma discharge (RFPD) treatment was developed by Pitt,^[48] Golander and Pitt,^[49] and our group.^[12,50–52]

The wettability gradients were produced by moving a cover over the polymer surface during exposure to RFPD (Fig. 2). As the exposure time to the plasma on the polymer surface gradually increases along its length, a gradient surface is produced. The technique can be applied to any polymer such as PE, PP, PET,

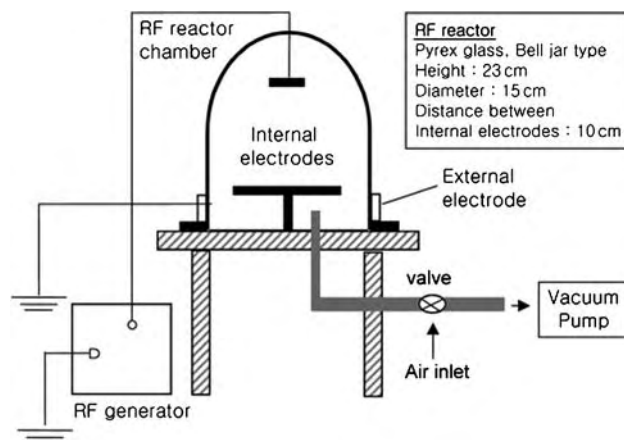

Fig. 2 Schematic diagram showing RFPD apparatus. (From Ref. [50].)

PMMA, and PS. It also allows a wide choice of different gases including water vapor^[50] or oxygen.^[51,52] By this treatment, the polymer surfaces are oxidized gradually along the sample length with increasing plasma exposure time, and thus the wettability gradients are created. The polymer surfaces prepared by the plasma treatment showed a wettability gradient with the water contact angle ranging from 80–90° to 35–50°, depending on the treatment conditions (Fig. 3).^[50–52]

Fig. 4 shows the possible mechanism by which the oxidation that occurs on a polymer surface like PE or PS is affected by the plasma treatment. The plasma discharge treatment on the polymer surface may produce carbon radicals from the hydrocarbon backbone, followed by the formation of unstable hydroperoxides through rapid binding with oxygen in the reactor chamber. The unstable hydroperoxides are easily

Fig. 3 Water contact angles of gradient surfaces as a function of water vapor plasma treatment (plasma exposure time, up to 10 sec). (From Ref. [50].)

Fig. 4 Plausible mechanism of the formation of oxygen-based functionalities on a polymer surface by oxygen plasma discharge treatment. (From Ref. [50].)

decomposed to produce various oxygen-based polar functionalities (hydroxyl group, ester, ketone, aldehyde, carboxylic acid, carboxylic ester, etc.) by reaction with additional oxygen in the reactor chamber or air.^[53–58] It seems that the oxygen-based functional groups produced on the polymer surface increase with increase in the plasma exposure time, resulting in the formation of wettability gradient on the surface. The main disadvantage of the plasma treatment method is that it is usually carried out in vacuum and may also yield anomalous surface chemistries that are, in addition, not always stable over time.^[59,60]

Corona Discharge

A new method for preparing wettability gradients on polymer surfaces using the corona discharge treatment was developed by our group (Fig. 5).^[60,61] A radio frequency (RF) corona discharge apparatus was used for the preparation of wettability gradient surfaces.^[60] The corona discharge apparatus consists of two key parts that produce the wettability gradient on polymer surfaces: a knife-type electrode onto the sample with

increasing power (from 10 to 35 W at 100 kHz) and a movable sample bed (usually 1.0 cm/sec). By this treatment, the sample surface is continuously exposed to the corona with increasing power. Thus, the surface is oxidized gradually along the sample length, resulting in the wettability gradient with various functional groups (Fig. 4). Corona discharge has also been used to prepare gradients by biomaterial grafts.^[62–64] This method is easier to apply as it can be done under atmospheric conditions.

INTRODUCTION OF BIOFUNCTIONAL GROUPS ON GRADIENT SURFACES

Introduction of various biofunctional groups on biomaterial surfaces may be important to improve biocompatibility or induce an appropriate response in biological systems. The introduction can be performed by employing physical or chemical immobilization of bioactive molecules on various gradient substrates, as reported by several groups.

Hydroxy Groups on Gradient Surface

Various polymer surfaces, including PE, PP, PS, PET, and PMMA, were modified by water vapor plasma discharge treatment. It was observed that by the water vapor plasma treatment, the wettability of the polymer surfaces increases largely and almost all functional groups produced on the surfaces are hydroxyl groups. The changes in chemical structure on the polymer surfaces by water vapor plasma treatment were investigated using the measurement of water contact angles and electron spectroscopy for chemical analysis (ESCA). Among the polymers, PE showed the highest hydroxyl group density on the surface (Table 2).

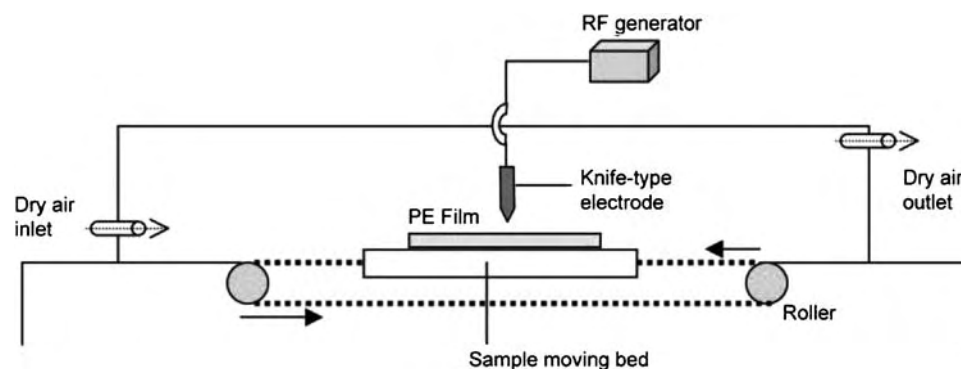

Fig. 5 Schematic diagram showing the corona discharge apparatus for the preparation of a wettability gradient on polymer surfaces by the corona discharge treatment. (From Ref. [60].)

Table 2 ESCA analysis of H₂O plasma-treated polymer surfaces

Substrate	Oxygen content (%)	C-OH/C-C (%)
PE	19.2	13.0
PP	10.3	5.4
PS	17.1	7.8
PET	37.5	7.1
PMMA	34.8	6.6

(From Ref. [50].)

Water vapor plasma treatment seems a simple and effective method to produce hydroxyl groups on the polymer surfaces.^[12,50]

Ionic Functional Groups on Gradient Surface

The gradient surfaces with ionic functional groups were prepared by the graft copolymerization of ionic vinyl monomers such as acrylic acid (AA), sodium *p*-styrene sulfonate (NaSS), and *N,N*-dimethyl amino-propyl acrylamide (DMAPAA) after the corona discharge treatment (Fig. 6).^[65-67] The peroxides produced on the corona-treated PE surface act as

**Fig. 6** Chemical structures of chargeable monomers. (From Ref. [65].)

an initiator for graft copolymerization. Ionic vinyl monomers were graft-copolymerized through the peroxides on the corona-treated PE surface. Acrylic acid was graft-copolymerized on the PE surface (PE-COOH) in aqueous solution at 70°C without any additives. Hydroxyl group-grafted (PE-CH₂OH) and amide group-grafted (PE-CONH₂) surfaces were prepared by substituting the -COOH groups grafted on the PE surface to -CH₂OH and -CHNH₂ groups, respectively, via -COCl groups (Fig. 7). The amine groups grafted on the surface (PE-CH₂NH₂) were induced from amide group-grafted surface. PE-COOH or PE-NaSS is negatively chargeable and PE-CONH₂ or PE-DMAPAA is positively chargeable in

**Fig. 7** Schematic diagram showing the formation of functional group-grafted PE surfaces by corona discharge treatment followed by graft copolymerization and subsequent reactions. (From Ref. [66].)

Table 3 Comparison of water contact angles of functional group-grafted PE surfaces

Surface	Contact angle (°)
PE-COOH	22.8
PE-CH ₂ OH	34.8
PE-CONH ₂	23.2
PE-CH ₂ NH ₂	28.4
PE-NaSS	35.6
PE-DMAPAA	36.8

(From Ref. [67].)

phosphate-buffered saline or plasma solution at pH 7.3–7.4. The gradient surfaces with ionic groups were characterized by the measurement of water contact angles, ESCA, and Fourier-transform infrared spectroscopy in the attenuated total reflectance mode (FTIR-ATR). All these measurements indicated that the ionic groups were grafted on the PE surfaces with gradually increasing density. However, the wettability of the different ionic group-grafted surfaces was not much changed by the kind of functional groups grafted (Table 3).

Polyethylenimines (PEIs) that have long spacers can be used for the immobilization of the surface, and consequently allow flexible and multifunctional sites on the surface in the biological environment. In addition, PEI in water is cationic owing to protonation. Thus chemical modification of the surface using PEI was performed.^[68,69] The carboxylic groups on the corona-treated gradient PE surface were activated by the *N*-ethyl-*N'*-(3-dimethylaminopropyl) carbodiimide, followed by the reaction with PEI. The peak assignable to C=O functional groups on the corona-treated PE surface disappeared at 1735/cm while a new peak was observed at around 1586/cm after reaction with PEI. In ESCA, the gradual increase in height of the carbon 1s peak owing to the attribution of C-N species within the PEI was observed along PE length. In addition, nitrogen 1s peak was observed in the survey scan spectrum and the intensity also gradually increased along PE length, indicating nitrogen content increase on the PE surface. Thus PEI was gradually modified on the gradient PE surface.

Polyethylene Oxide on Gradient Surface

Particularly effective polymers for “protein-resistant” (or “blood-compatible”) surfaces appear to be polyethylene oxide (PEO) owing to its minimum interfacial free energy with water, hydrophilicity, high surface mobility and steric stabilization effects, and unique solution properties and molecular conformation in water.^[70,71] Comb-like PEO gradient surfaces were

**Fig. 8** Schematic diagram showing a comb-like PEO gradient produced on polymer surfaces. (From Ref. [64].)

prepared by graft copolymerization of poly(ethylene glycol) monomethacrylate macromers (PEO-MA) on PE surface (Fig. 8).^[64,72] The macromers with different PEO repeat units, 1, 5, and 10, were used. The comb-like PEO chain density was changed gradually along the sample lengths by the corona discharge treatment with gradually increasing power (Fig. 9). The grafted amount of PEO-MA increased as the PEO chain length in the PEO-MA decreased owing to the steric interference of longer PEO side chains in PEO-MA macromers. The prepared comb-like PEO gradient surfaces were characterized by the measurement of water contact angles and FTIR-ATR (Fig. 10), and ESCA (Fig. 11). All these measurements indicated that the PEO chains are grafted on the PE surface with gradually increasing density of PEO.

Phospholipid Polymer on Gradient Surface

Ishihara et al. reported the synthesis of 2-methacryloyloxyethyl phosphoryl choline (MPC) polymers with

**Fig. 9** Relative amount of PEO-MA grafted on PE surfaces. (From Ref. [72].)

Fig. 10 FTIR-ATR spectra of PEG10-MA grafted PE surface along the sample length. Numbers labeled on the spectra (0.5–4.5) represent the positions from the untreated end of the gradient surface. (From Ref. [64].)

excellent blood compatibility and applied them to biomedical fields.^[73,74] They also prepared the gradient PE surface, grafted gradually with the poly [ω -methacryloyloxyalkyl phosphorylcholine (MAPC)] by corona discharge treatment to examine the surface characteristics, i.e., density, mobility, and orientation of the poly(MAPC) (Fig. 12). The P/C ratio of the PE surface grafted with poly(MAPC) gradually increased along the sample length (Fig. 13). The orientation and mobility of the poly(MAPC) grafted on the PE surface was evaluated using 1,6-diphenyl-1,3,5-hexatriene. The orientation of poly[6-methacryloyloxyhexyl phosphorylcholine (MHPC)], which has six methylene chains between the phospholipid polar group and the backbone, was higher than that of other poly (MAPC)s. The mobility of the poly(MAPC) decreased with an increase in the methylene chain length in the MAPC unit.

CHARACTERIZATION OF GRADIENT SURFACES

Water Contact Angle

Chemical gradient surfaces are nearly always characterized by their wettability using contact angle methods, especially because the measurement of contact angles is one of the most sensitive techniques to study a surface with a depth of information within a few atomic layers.^[75,76] Contact angles can be measured by a variety of methods,^[77,78] however, not all are suitable to measure wettabilities as a function of position. Sessile drop technique can be used in case of gradients with a long extension (Fig. 14)^[12,59,80,81] and involves placing microliter droplets over the length of the

Fig. 11 ESCA carbon 1s core-level spectra of PEG10-MA grafted PE surface along the sample length. (From Ref. [64].)

gradient surface and the measurement of the contact angle of the droplet with the surface by simple goniometry. However, variations in position-bound wettability may occur over the dimensions of the droplet, which makes the sessile drop method less suitable for application on steep gradients.

Fig. 12 Chemical structures of MAPC. (From Ref. [74].)

Fig. 13 Changes in P/C ratio of the gradient PE surface grafted with poly(MAPC) along the sample distance: (●) poly(MPC); (■) poly(MHPC); (▲) poly(MDPC). (From Ref. [74].)

Pitt^[48] and Golander and Pitt^[49] also prepared the wettability gradients on various polymer surfaces (PE, PS, PDMS, and PTFE) via RFPD treatment by exposing the polymer sheets continuously to oxygen, ammonia, or sulfur dioxide plasma. They demonstrated that the water contact angles on the plasma-treated polymer surface decrease monotonically as the plasma exposure time increases. They showed that a wide range in wettability is produced by manipulating

Fig. 14 Contact angle of gradient PE surface measured by sessile drop method. (From Ref. [79].)

the RF power, the gas species, and the duration of plasma exposure.

Ellipsometry

Ellipsometry measures the change in polarization of light upon reflection against a surface, which can subsequently be employed to calculate, for example, the thickness of adsorbed films on a surface.^[82] Thus, ellipsometry was employed as the main technique for monitoring the gradient thickness as a function of distance of the samples.

Recently, the spatial resolution of ellipsometry could be observed even at nanometer scales required to determine the variation in density of functional compounds over the length of a gradient surface. Liedberg et al., for instance, by using ellipsometry and infrared (IR), measured steadily increasing thicknesses of adsorbed alkanethiol with different chain lengths of ethylene oxide on gradient surfaces (Fig. 15).^[47] The thickness of the nanometer scale obtained from the gradient is in good agreement with the thickness of the corresponding single component. In addition, ellipsometry is frequently applied to determine the mean position-bound thickness of proteins adsorbed to the gradient surfaces.^[30,32–36]

ESCA

The ESCA, also called x-ray photoelectron spectroscopy (XPS), is useful for the characterization of surface properties although it has a relatively low spatial resolution of about several square millimeters up to 1–2 μm^2 for small spot, scanning XPS instruments and is not always adequate to detect adsorbed monomolecular layers. The depth of their information is

Fig. 15 Ellipsometry thickness of oligo(ethylene glycol)-terminated alkanethiols (Eg4 and Eg6 represent the ethylene oxide unit) on gradient surface. (From Ref. [47].)

within the nanometer range, which is better than that of IR spectroscopy but worse than that of ellipsometry.

As many gradients are prepared using polymer materials, carbon contamination of gradient surfaces, which is almost unavoidable in ESCA, poses a severe complicating factor in the ESCA characterization of gradient surfaces. Although ESCA does not provide absolute quantification, it is very sensitive to the small changes in the surface composition.^[83]

The changes in chemical structure of polymer surfaces by RFPD treatment were investigated by ESCA.^[50,79] Fig. 16 shows ESCA carbon 1s core-level scan spectra of the corona-treated PE surface. The hydrophobic side of the gradient (position, 0.5 cm) showed an alkyl carbon ($-C-C-$) peak at a binding energy, ~ 285 eV. The positions with increasing corona power showed new peaks at higher binding energies, indicating the formation of carbon-oxygen functionalities. The peaks of the high binding energy region correspond to $-C-O-$ at ~ 286.6 eV (e.g., hydroxyl or ether groups), $-C=O$ at ~ 287.9 eV (e.g., ketone or aldehyde groups), and $O=C-O-$ at ~ 289.1 eV (e.g., carboxylic acid or ester groups). The oxygen-based functional groups increased with increasing corona power. In addition, the survey scan spectrum provides information about the elemental composition of surfaces for all elements present (except hydrogen and

Fig. 16 ESCA carbon 1s core-level spectra of a corona-treated PE surface along the sample length. Numbers labeled on the spectra (0.5–4.5) represent the positions from the untreated end of the gradient surface. (From Ref. [79].)

Table 4 ESCA analysis of a corona-treated PE surface along the sample length

Position from untreated end (cm)	Atomic (%)				O/C ratio
	$-C-C-$ (~ 285.0) ^a	$-C-O-$ (~ 286.6) ^a	$-C=O-$ (~ 288.0) ^a	$-O=C-O-$ (~ 289.1) ^a	
0.5	100	0	0	0	0.00
1.5	92	5	2	1	0.09
2.5	88	8	2	2	0.13
3.5	86	8	3	3	0.16
4.5	80	11	4	5	0.25

^aBinding energy, eV.
(From Ref. [79].)

helium). The elements are identified from their binding energies, which are unique for each element. In the case of corona treatment, hydroxyl or ether groups ($-C-O-$) were produced more largely on the surface than other functional groups, as seen in Table 4.

Infrared Spectroscopy

IR spectroscopy in the attenuated total reflection (ATR) mode is sometimes used to characterize gradient surfaces although the surface sensitivity of IR spectroscopy is within the micrometer range, which is often too deep to detect the adsorbed monomolecular layers on gradient surfaces. For all that, microscopic IR spectroscopy in the ATR mode is technically feasible, like for ellipsometry.

We^[50,60–67,70–74,79] prepared oxygen-rich gradients on PE surface by a corona-discharge treatment and subsequently determined the position-bound infrared spectra by FTIR-ATR. Regions of the gradient that had been exposed longer to the corona discharge had stronger C=O absorption bands, indicating the gradually increasing peak intensity (Fig. 17). Thus, IR spectroscopy in general is a suitable technique to characterize gradient surfaces.

Atomic Force Microscopy

Atomic force microscopy (AFM) has been established as a technique for high-resolution surface imaging. The ability to map the forces between the scanning tip and a surface within nanometer resolution makes it a unique tool to analyze properties of molecules on a surface, although the dangers of creating artifacts by the scanning tip are huge.^[84] The AFM studies to characterize gradient surfaces have been done by our group.^[74] As shown in Fig. 18, AFM measurements showed the corona-treated PE surface increased in

Fig. 17 FTIR-ATR spectra along the PE length after corona treatment. (From Ref. [79].)

roughness, from 10 nm at position 0.5 cm to 100 nm at position 4.5 cm, after corona treatment, indicating that the PE surface changes in roughness after corona treatment, as the corona power increased along the PE length. Thus, AFM can be employed as the unique technique for gradient surface imaging.

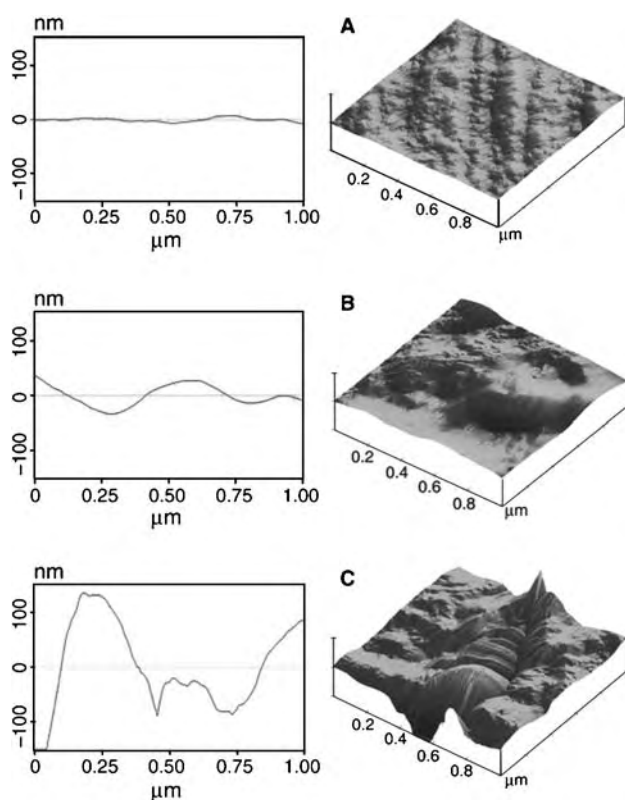

Fig. 18 AFM images at the position (A) 0.5 cm, (B) 2.5 cm, and (C) 4.5 cm of gradient PE surface. (From Ref. [69].)

Other Methods

Characterization of the gradient surfaces was carried out with total internal reflection fluorescence (TIRF) spectroscopy in the presence of 1-anilinonaphthalene-8-sulfonate (ANS) as a surface probe.^[38,85] Strong enhancement of ANS fluorescence is found at the hydrophobic side of the gradient and no fluorescence enhancement at the hydrophilic side. Thus TIRF can be used to characterize the wettability of the gradient silica or glass surface.

Time-of-flight secondary ion mass spectrometry (TOF-SIMS) is a surface analytical technique that is capable of detecting elemental and molecular species with a spatial resolution of $<1 \mu\text{m}$. Because of these characteristics and the imaging capabilities of TOF-SIMS, the technique is ideal for compositional analysis on surface. Roberson et al. reported the analysis of functional groups present on the gradient surface by using TOF-SIMS.^[86] Fig. 19 shows the positive secondary ion trends observed for the silane monolayer gradient surface. The signals for the oxidized species, SiOH^+ and Si_2O^+ , increase with the increasing gradient nature of the surface.

INTERACTIONS OF GRADIENT SURFACES WITH BIOLOGICAL SPECIES

Recent developments in the design of biocompatible materials have focused on biomimetic materials that are able to recognize biomolecules originating from the extracellular matrix or specific cell responses. Gradient modification of biocompatible materials is one of the simplest methods to make biomimetic materials that possess biomolecule-recognizing properties. Thus

gradient surfaces can offer great potential to examine behaviors and biological interactions of biological species such as proteins and cells. It was observed that the adhesion of biological species to the gradient surfaces decreases gradually with the increasing surface density of functional groups. It seems that surface functional groups and their charge character, as well as wettability, play important roles for the adhesion of biological species. This may be related to the relationship between hydrophilicity and hydrophobicity of the surfaces. Thus, the study for the rapid and accurate recognition of binding behavior of biological species at a specific location on biocompatible materials *in vivo* or *in vitro* presents a challenging target. An overview will be given of protein adsorption and cell adhesion studies on gradient surfaces.

Interaction with Proteins

Elwing et al. studied the surface energy dependence of the adsorption or exchange of single proteins like fibrinogen (molecular weight, 340,000 Da) and

γ -globulin (molecular weight, 160,000 Da) on the solid substrates using the wettability gradient surfaces.^[30,31] The protein adsorption or exchange reactions were quantified along the gradient using ellipsometry or corresponding antibodies. From the study of exchange reactions between fibrinogen and γ -globulin on the fibrinogen-preadsorbed gradient surface, they found that fibrinogen is partially exchanged by γ -globulin only on the hydrophilic side of the gradient, whereas on the hydrophobic side, there appears to be no exchange at all. They also observed that fibrinogen adsorbs in a larger amount on the hydrophobic side of the gradient. The binding energy of fibrinogen was much larger on the hydrophobic side of the gradient; thus exchange reactions were more difficult there. They have also used the wettability gradients to study the surface hydrophilicity-induced conformational changes of adsorbed proteins.^[33] The adsorption of protein and its subsequent interaction with antibodies were measured using enzyme-linked immunosorbent assay and ellipsometry. The interaction force between the hydrophobic surface and the protein molecule gives it an extended structure, covering a relatively large area of the surface. On a hydrophilic surface, however, the forces acting between the surface and the protein molecule may be smaller and, because the conformational change will be smaller, a large repulsive force will act between the protein molecules. Therefore, the packing of adsorbed protein molecules will be less than on a hydrophobic surface and a smaller number of adsorbed proteins will be found on the hydrophilic surface.

We examined binding properties of the human albumin as a model protein adsorbed onto corona-treated PE gradient surfaces.^[61] Albumin also has big hydrophobic patches on its surface. The albumin-adsorbed gradient surface was analyzed by ESCA. The nitrogen signal from the surface was used as an indicator of the protein adsorption because it was observed that little nitrogen is incorporated onto the surface by corona treatment in air. It is mainly derived from peptide bonds of the adsorbed protein. Fig. 20 shows that the nitrogen peaks (binding energy, ~ 399 eV) from ESCA survey scan spectra decreased gradually along the wettability gradient, indicating that the albumin adsorption increased gradually with the increasing hydrophobicity of the surface. This is owing to the increased hydrophobic interactions of the protein molecules with the hydrophobic sections of the gradient surface, as discussed above. The nitrogen content determined by ESCA on the hydrophobic section (water contact angle, 98°) was about 9.3%, which is nearly the value of the monolayer coverage of albumin.^[87] The albumin-adsorbed surfaces were also analyzed by FTIR-ATR. It was observed that the amide II (1500–1600/cm) absorption bands from the

Fig. 20 ESCA survey scan spectra of corona-treated PE surface along the gradient after albumin adsorption (one hour adsorption in 1 mg/ml albumin solution). Numbers labeled on the spectra (1–5) represent the positions from the untreated hydrophobic end of the gradient surface at 0.5, 1.5, 2.5, 3.5, and 4.5 cm, respectively. (From Ref. [61].)

protein adsorbed on the surface also decrease gradually along the wettability gradient. For the desorption study, the albumin-adsorbed PE gradient surfaces were exposed to a nonionic polymeric surfactant, Tetric 1504, which contains starlike 4 PEO (ethylene glycol unit, 26)/polypropylene glycol (propylene glycol unit, 29) blocks in its structure. The exposure of the albumin-adsorbed gradient surface to the surfactant solution resulted in partial displacement of the protein (Fig. 21). This displacement was much greater on the hydrophobic sections of the gradient surface than on the hydrophilic ones. The results of increasing protein adsorption and desorption toward the hydrophobic sections of the corona-treated PE gradient surface agree with those in the works of others, even though the functional groups introduced on the substrates are different.^[30,31,34,39]

The relative amount of proteins adsorbed onto comb-like PEO-grafted PE surfaces was also evaluated.^[64,72] The proteins adsorbed on the control PE surface was much higher than those on PEO-MA-grafted surfaces, indicating the larger amount of

Fig. 21 Adsorption and desorption behavior of albumin on corona-treated PE gradient surface. Nitrogen atomic percent represents the amount of the protein adsorbed (for adsorption) and remaining (for desorption) on the surface (one hour adsorption in 1 mg/ml albumin solution; 30 min desorption in 1 mg/ml Tetric 1504 solution after one hour adsorption in 1 mg/ml albumin solution; $n = 3$). (From Ref. [61].)

protein adsorption on the control surface. This is also owing to the hydrophobic interaction of the protein molecules with the hydrophobic PE surface. Fig. 22 compares the relative adsorbed amount of proteins on the PEO-MA-grafted PE surfaces. It was

Fig. 22 Relative adsorbed amount of proteins on PEO-MA-grafted PE surfaces ($N = 3$). (From Ref. [72].)

determined as follows: Relative adsorbed amount of proteins = $(N\% \text{ of PEO-MA-grafted surface}) / (N\% \text{ of control surface})$. The surfaces grafted with PEO-MA having longer PEO chains showed less protein adsorption. PEO10-MA-grafted surface at position 4.5 cm was very effective in the prevention of protein adsorption. In the case of PEO10-MA-grafted surface, the amount of adsorbed proteins was reduced more than 90% as compared with the control surface while the PEO1-MA-grafted surface showed about a 50% reduction.

We also reported the gradient PE surface displaying fluorescein intensity of proteins on a gradient surface.^[68,69] Among several binding systems, the binding affinity of the avidin–biotin interaction ($K_D \sim 10^{-15} \text{ M}$) is one of the highest to occur in nature as a non-covalent bond.^[88] Thus, the biotinylated gradient PE surface was prepared by the reaction of PEI and biotin after corona treatment with increasing power along the PE length. The gradient biotinylated PE surface was incubated in a solution of streptavidin–fluorescein isothiocyanate (FITC). The binding of the streptavidin–FITC to the gradient biotinylated PE surfaces was characterized by fluorescence microscopy. The fluorescence microscope image, which corresponds to a binding of FITC with streptavidin on gradient biotinylated PE surfaces, is shown in Fig. 23. The luminosity of fluorescence increased gradually on the surface when corona power for the surface increased along the sample length. Plotting of the length treated by corona vs. the fluorescence intensity of the streptavidin–FITC reveals a gradient as shown in Fig. 24. The longer the length treated by corona, the smaller the water contact angle value and the stronger the fluorescence intensity, which could well explain the gradient PE surface.

Cellular Interactions

The studies on cellular interactions with gradient surfaces were carried out, while distinguishing between numbers of adhering cells, their spread areas, and growth rates. Carter, in 1965,^[89] was probably the first to study the directional migration of mouse fibroblasts on steep palladium gradients, referred to at that time as “adhesion gradients.”

Recently, we reported the property of Chinese hamster ovary (CHO) cells, fibroblasts, and endothelial cells (ECs) cultured on the wettability gradient PE surfaces.^[79] Fig. 25 shows the cell adhesion (after one day) behavior on the wettability gradient surfaces. The CHO cells are recognized as highly surface adhesive and showed large amount of cell attachment compared to fibroblasts and EC. As the surface wettability increased along the sample length, the cells

Fig. 23 Change of fluorescence images on gradient PE surface from 0 to 5 cm after binding of streptavidin–FITC. (From Ref. [69].)

adhered on the surface increased and then decreased, regardless of the cell types used. The cells were adhered more on the positions with moderate hydrophilicity of the wettability gradient surface than on more

Fig. 24 Plot of (A) water contact angle vs. length treated by corona and (B) fluorescence intensity vs. length treated by corona. (From Ref. [69].)

Fig. 25 Different types of cell adhesion on wettability gradient PE surface after a one-day culture (number of seeded cells, $4 \times 10^4/\text{cm}^2$; $n=3$). (From Ref. [79].)

hydrophobic or hydrophilic positions. The maximum adhesion of the cells appeared at around position 2.5 cm (water contact angle, 57° ; Fig. 24). The cell morphology was also changed along the wettability gradient, as observed by SEM. The cells, regardless of the cell types used, were spread and flattened more on the positions with moderate hydrophilicity of the wettability gradient surface than on more hydrophobic or even hydrophilic ones after a one-day culture (Fig. 26). The cells after a two-day culture were almost flattened on all positions of the gradient except the hydrophobic one (position, 0.5 cm). When the number of cells attached on the wettability gradient surfaces were compared after a one- and two-day culture, the cell growth behavior on the surfaces after a two-day culture was almost similar to that of cell adhesion after one day—more attachment of the cells on the positions with moderate hydrophilicity of the wettability gradient surface than on the more hydrophobic or hydrophilic positions. For CHO cells, the large number of attached cells on the surface after a two-day culture was owing to the large amount of cell adhesion after one day compared to other cells. The growth rate of the cells up to two days was in the order of fibroblasts, CHO cells, and ECs. The fact that cells are more adhered, spread, and grown on the moderately hydrophilic surfaces was also observed by other research groups^[6,7,20,22] as they cultured ECs, HeLa S3, or fibroblasts onto various polymer substrates with different surface wettabilities.

The adhesive strength of ECs attached on polymer surfaces with different hydrophilicity was also

Fig. 26 SEM pictures of different types of cells adhered on wettability gradient PE surfaces after a one-day culture (original magnification, $\times 400$). C.A. means water contact angle ($^\circ$). (From Ref. [79].)

investigated using wettability gradient PE surfaces prepared by corona discharge treatment.^[90] The EC-attached wettability gradient surfaces were mounted on parallel plate flow chambers in a flow system prepared for cell adhesiveness test. Three different shear stresses (150, 200, and 250 dyne/cm^2) were applied to the flow chambers and each shear stress was maintained for 120 minutes to investigate the effect of shear stress and surface hydrophilicity on the EC adhesion strength (Fig. 27). It was observed that the ECs were adhered more onto the positions with moderate hydrophilicity of the wettability gradient surface than onto the more hydrophobic or hydrophilic positions. The maximum adhesion of the cells appeared at around water contact angles of 55° . The EC adhesion strength was higher on the hydrophilic positions than on the hydrophobic ones. However, the maximum adhesion strength of the cells also appeared at around water contact angles of 55° . More than 90% of the adhered cells remained on that position after applying the shear stress— 250 dyne/cm^2 for two hours—whereas the cells were completely detached on the hydrophobic position (water contact angle, about 86°) within 10 minutes after applying the same shear stress. Fig. 28 shows a series of sequential images of ECs adhered on hydrophobic (0.5 cm) and hydrophilic (2.5 cm) positions of the wettability gradient surface at shear stress, 250 dyne/cm^2 . We can see that almost all cells were detached from the hydrophobic position during

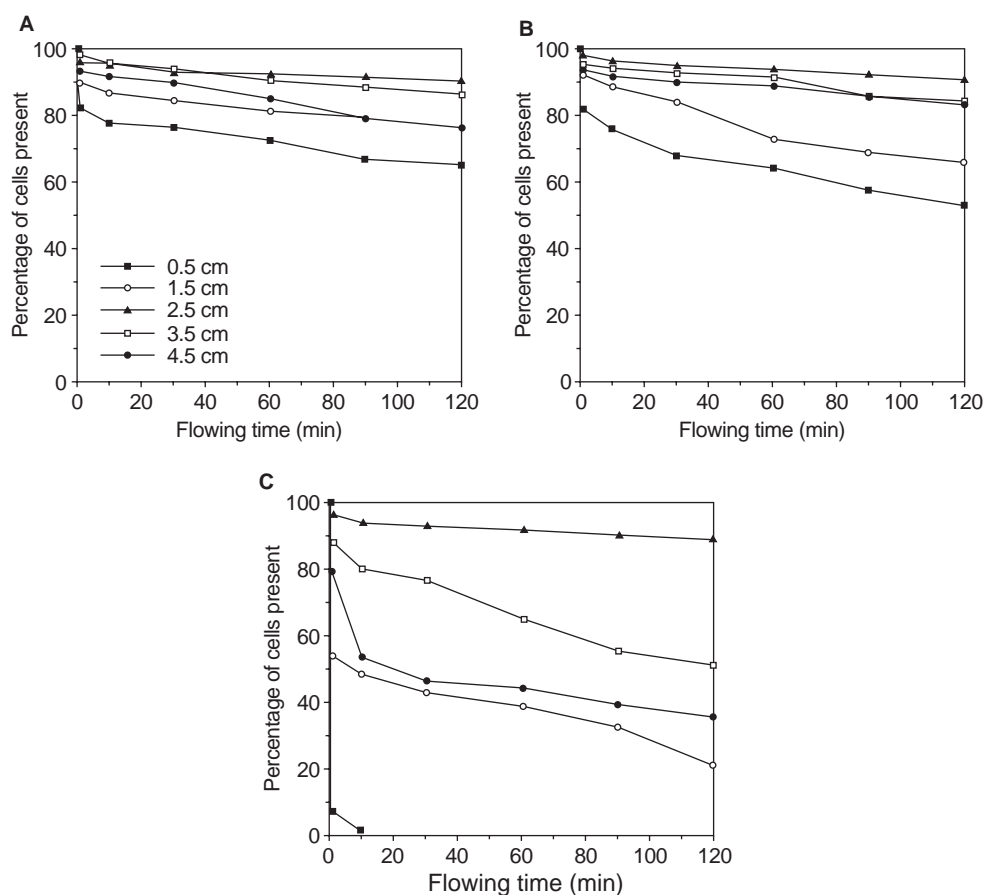

Fig. 27 The percentage of cells present on the positions of wettability gradient PE surfaces as a function of flowing time for different shear stresses: (A) 150 dyne/cm²; (B) 200 dyne/cm²; and (C) 250 dyne/cm². (From Ref. [90].)

the first one minute after applying the shear stress. It seems that surface hydrophilicity plays a very important role for cell adhesion strength.

The human normal diploid fibroblasts (WI-38 cells) were cultured on the gradient PE sheet grafted with poly(MAPC) (Fig. 12). The adhesion behavior of the WI-38 cells was different depending on the concentration of the seeded WI-38 cells.^[73,74] Fig. 29 shows SEM pictures of the gradient PE surface grafted with poly(MAPC) after 24 hr contact with WI-38. A number of adherent cells on the gradient PE surface grafted with poly(MPC) and poly(MDPC) were observed similar to the original PE surface. On the other hand, the gradient PE surface grafted with poly(MHPC) effectively reduced WI-38 cell adhesion. The number of adherent WI-38 cells on the gradient PE surface grafted with poly(MAPC) is summarized in Fig. 30.

By increasing the concentration of the seeded WI-38 cells, the number of adherent WI-38 cells on the gradient PE surface grafted with the poly(MAPC) was increased. In a comparison among the poly(MAPC)s, the poly(MHPC) most effectively reduced

cell adhesion. On every PE surface grafted with the poly(MAPC), the number of adherent cells increased with an increase in the concentration of the seeded cells. On the gradient PE surface grafted with

poly(MHPC), adhesion of the WI-38 cells was reduced even when the concentration of the seeded WI-38 cells was high. The cell adhesion can be nonspecifically reduced by modification with a highly oriented phosphorylcholine group.

CONCLUSIONS

The interactions of different types of proteins or cells with various solid substrates depend mainly on surface characteristics such as wettability (hydrophilicity/hydrophobicity or surface free energy), chemistry, charge, roughness, and rigidity. We focused on the surface wettability (particularly on wettability gradient surfaces) in this review. The wettability gradient surfaces have been prepared to study the interactions of proteins or cells since 1987, by many research groups. They were prepared onto silicon or glass substrates by the diffusion method and onto various polymer substrates by plasma discharge treatment and by corona discharge treatment. In most studies, a region of the gradient could be identified where the number of adhering proteins and cells, and their corresponding spread areas were maximal, usually at water contact angles with a specific hydrophilic point.

The major advantage of the use of wettability gradient surfaces as a tool to study protein adsorption/desorption and cell adhesion/proliferation on solid substrates is that several wettabilities are effectively compared at the same time and on the same surface. This is convenient and time saving. The wettability gradient can be used to systematically investigate the interactions of the different types of biological species in terms of the surface wettability of solid substrates. Other specific functional groups or charge gradient surfaces can be produced using plasma or corona discharge treatment and the following graft reactions, which give us useful information on the interaction

behaviors of biological or other species continuously related to the surface chemistry, positive or negative charge, and density of solid substrates. We believe that this method will be useful in study of the analysis of functional biological species on the gradient surface through one experiment because the designed gradient PE surface is experimentally simpler than using a series of single surfaces.

Hard Tissue: Biomaterial Interactions

Feza Korkusuz

Medical Center and Department of Physical Education and Sports, Middle East Technical University, Ankara, Turkey

Petek Korkusuz

Department of Histology and Embryology, Hacettepe University, Sıhhiye, Ankara, Turkey

INTRODUCTION

Bone and cartilage are vulnerable to injury and replacement of these tissues by biomaterials, synthetic and treated natural materials used to replace and/or regenerate functioning tissues, has been successfully used for years. Recent advancements in science elaborated the Tissue Engineering concept where regeneration of injured tissues is intended by the combined application of: a) biomaterial-based scaffolds; b) cells grown in culture; c) systemic and/or local hormones/mediators; and recently d) genetic modulators. Tissue engineering products and basically biomaterials of various shapes and forms have been widely used in musculoskeletal diseases and disorders for decades. Metals of steel, cobalt–chrome, and titanium in pure and/or alloy form, ceramics of hydroxyapatite (HA) and calcium phosphate, and polymers such as polymethyl-methacrylate are currently used in bone, cartilage, and joint replacement. Biocompatibility of biomaterials is simply defined as the *in vivo* functioning of the implant without causing local and/or systemic intolerable responses. Implants used for hard tissue replacement should also possess appropriate mechanical properties as load bearing of bone and lubrication in joints are among the basic physiological functions of these tissues. Research to improve the biocompatibility of biomaterials and tissue engineering products is still going on as bone and cartilage will, nevertheless, cause a response even when “inert” materials are implanted.^[1] Local and systemic responses elaborated by biomaterials depend on various factors including surface topography, heterogeneity, and chemical and physical properties. The tissue–implant interface is, therefore, the hot spot of research for the better understanding of the response to biomaterials and tissue engineering products. Industry has also focused on improving biomaterial surfaces, the front line of tissue–implant interactions.

Eleven million patients in the U.S.A. receive at least one implant each year. These implants can be classified as: a) artificial joints; b) fracture fixation devices; c) artificial heart valves; d) intraocular lenses; e) internal heart stimulators/defibrillators; f) ventilation tubes; g) infusion pumps; h) dental implants; i) silicon

implants; and j) artificial blood vessels. Fracture fixation devices and artificial joints cover almost 50% of these implants and its impact on the implant applied individual and society, excluding its impact on quality of life, productivity, sociology, and psychology, is very high.^[2] Furthermore, it is well appreciated that the demand for fracture fixation and joint replacement devices is expected to increase within the next few decades because of aging population.

As a basic concept, a time, type, and dose-dependent systemic and/or cellular response will be elaborated by any biomaterial when implanted into living tissues.

METALS

Metals and their alloys are widely used as fracture fixation and joint replacement devices. Biocompatibility of metals depends on their: a) type; b) producer and production technique; c) composition; d) mechanical properties; e) structure; and f) geometry. Low carbon concentration in stainless steel is essential for its biocompatibility. Chromium in the microstructure of stainless steel provides corrosion resistance by forming a passive layer on the surface of the implant. Passive layer of titanium oxide on titanium implants provides a significantly better corrosion resistance than stainless steel and cobalt–chromium implants. Titanium alloys have a lower elastic modulus that improves the structural stiffness of the implant compared to steel and cobalt alloys.^[3] One structural disadvantage of titanium alloys is its vanadium content that can be toxic when released, and recent studies^[4] focus on replacing vanadium with niobium to improve their biocompatibility.

Interaction of the implant and the host mainly occurs through its surface, and a) structure and b) coating of the surface are major determinants of biocompatibility. Theoretically, smoother the implant’s surface, lesser the response to it. In recent years, ion implantation techniques were developed and used to obtain smoother surfaces on metallic surfaces. In contrast, various surface modification techniques are developed to obtain a larger surface area with the aim of tissue integration into the implant. Chemical methods are

used to macroscopically and microscopically modify the surface of metallic implants. For example, surface modified titanium implants using phosphoric acid were presented to increase covalent bonding with biological molecules.^[5] One recent *in vitro* study^[6] presented significantly better interaction between coarse-blasted, acid-etched titanium surfaces and osteoblasts. Other methods include: a) sphere;^[7] b) wire mesh; and c) porous surface coatings for surface expansion of metals with the aim of better tissue integration. An optimal pore size of implants for osteoblast but not fibroblast in-growth is assumed to be between 150 and 450 μm . Interconnected pores are preferred for better tissue integration. Other method that enhances tissue integration^[8] and biocompatibility^[9,10] in cementless implant application is HA coating. The thickness and the method of HA coating are important in preventing delamination.^[11] In artificial hip replacement immersion techniques for HA coating of the acetabular component are preferred to overcome the delamination problem. Furthermore, HA coating of the femoral side prevents wear particle migration into the bone-implant interface and avoids early implant failure.^[12,13] Other study, however, revealed that ceramic particles detached from the coating may immigrate into the artificial joint space and can cause wear debris from the polymer.^[14] It is assumed that novel methods such as calcium ion implantation^[15,16] may replace conventional methods in the near future to overcome these problems.

Coating of titanium implants with bioactive molecules other than ceramics for better tissue integration is getting popular. Studies using fibronectin^[17] or type 1 collagen^[18] confirmed the improved osteointegration and cellular attachment. One recent study^[19] regarding dental implants presented the importance of epithelial cells in implant integration. In that study, polarization of cells was superior on the titanium surface while the number of cells was higher when the implant was coated with HA. When evaluated in details, serum extracellular matrix deposition on the substrate is followed by cellular attachment. This event in implant-bone integration can be called "Osteoblast-Substrate Adhesion."^[19] Cellular attachment to implants is modulated by integrin-mediated (extracellular matrix receptor) signal transduction.^[20] Once when cells are attached to the implant they start to spread their focal contact area. Fibronectin and/or laminin play important roles at this stage of cell attachment. Basically fibronectin promotes cell adhesion and reorganization of actin microfilaments within osteoblasts. Surface chemistry of the material^[19] will keep influencing cytoskeletal molecules including vinculin, actin, and focal adhesion kinase following cellular attachment. Cellular attachment is followed by migration and secretion of cytokines and extracellular matrix elements. At

this stage, surface roughness promotes osteogenic differentiation of less mature cells. The optimal rate and shape of surface roughness however is not determined. It is well noted that increasing surface area will improve osteogenic differentiation. One recent study^[21] using scanning electron microscopy and double immune labeling of vinculin and actin presented marked synergistic effect of micro- and nanoscale topography on cell proliferation. On the other hand, this may increase the incidence of particle detachment from the surface. The so-called "Particle Disease" may lead to implant loosening and other severe disorders defined in the literature.^[22-25] Optimization studies of surface area and roughness in the benefit of osteoblast attachment and differentiation and particle detachment should be therefore taken into consideration. Adhesion molecules lead to polarization and colony formation of cells in *in vitro* conditions. *In vitro* conditions may not necessarily simulate *in vivo* conditions as agonist and antagonist factors of cellular adhesion and colony formation may differ when a material is implanted into the tissue.

Maintaining vascularity of the implant applied bone site during surgery is as important as material and surface characteristics of the implant for integration. Tissue damage will initiate a cascade of apoptosis, osteoclastic activity, bone resorption (osteolysis), and implant failure. Furthermore, an ill-vascularized bone is prone to infection. A well-vascularized bone, on the other hand, may establish strong bonds with the implant through adhesion molecules such as fibronectin, laminin, fibrinogen, and vitronectin owing to the establishment of a metabolically active tissue.

Microscopical and molecular interaction between the implant and the hosting bone is broadly evaluated in material science and dental surgery.^[26] Microparticles produced or migrating into the bone-implant interface initiate a cascade of inflammatory reaction according to their type, size, and amount.^[27] As a general rule, when the components of the implant (i.e., metal, polymer, and ceramic) increase, the incidence of wear debris will also increase. Particles from metals are detached by corrosion, abrasion, adhesion, and/or delamination. Interfaces such as the implant-bone, implant-cement, and cement-bone are the sites of wear production. Initial response to the debris is elicited and mediated by osteoclasts.^[28] Release of large amounts of osteolytic factors such as interleukin-1 (IL-1),^[29] interleukin-6 (IL-6), and tumor necrosis factors alpha and beta (TNF- α and - β) from macrophages in response to wear debris will eventually lead to chronic inflammation and implant failure.^[30] Cell types in periprosthetic membranes surrounding failed hip arthroplasties of 10 patients were macrophages and fibroblasts.^[31] These fibroblasts differentiated peripheral blood mononuclear cells into mature osteoclasts. Inhibition of inflammatory

cytokines^[31] and/or type 1 IL-1 receptors^[29] are proposed to control periprosthetic osteolysis.

Metals and basically cobalt–chrome alloys may also discharge ions which could mediate cytokine release and hypersensitivity reaction.^[32] A hypersensitivity test before metal implantation is therefore recommended when available. One other cellular response to metals implanted into bone is apoptosis that is significantly higher in failed ones than in stable ones.^[33]

BIOCERAMICS

Bioceramics are basically divided into a) fast resorbing; b) slow resorbing; and c) injectable ceramics.^[34] High temperature sintered (>1000°C) HA is a slow resorbing bioceramic with a 1–3% degradation rate per year. Calcium phosphates' degradation rate, on the other hand, is 35–40% per year. These ceramics alone or as a composition are used as scaffolds or void fillers in non-weight bearing sites for osteoconduction. Apart from osteoconduction, these ceramics were effectively used as antibiotic^[35] or as anticancer drug^[36] carriers in bone sites. One recent study^[37] focused on the improvement of mechanical determinants of HA–calcium phosphate

ceramics that may enable their usage in load bearing sites.

Ceramics have also been used in hip joint replacement as the femoral head and acetabular cup. Their gliding properties are superior to metals and polymers. Load bearing is balanced as long as they do not present microfractures. They obviously last longer than any other material and do not cause wear debris.

Ceramics that are implanted as porous scaffolds to bone without cells and growth factors are involved in a cascade of events similar to the molecular and cellular events seen in fracture healing. This cascade includes: a) hematoma; b) inflammation; c) neovascularization; d) osteoclastic resorption; and e) new bone formation. Osteoclastic resorption and new bone formation are coupled with the integration process. First line of cells to get in touch with the ceramics is assumed to be monocytes that stimulate IL-1, IL-6, and TNF- α secretion. In dental ceramic implants, endothelial cells are also involved in this process. Endothelin is effective in neovascularization and enhances ceramic integration and bone healing. It was observed that when 1 μ g of endothelin was applied to bone together with HA and calcium phosphate composite (60/40) lamellar bone formation was obtained (Figs. 1A and 1B). Bioceramics

Fig. 1 (A) ET-1 antagonist bositentan loaded HA/tricalcium phosphate (60/40) composite implanted into rabbit critical size segmental tibial defect; six weeks. 250 \times , Masson trichrome staining and (B) HA/tricalcium phosphate (60/40) composite implanted into rabbit critical size segmental tibia defect without active molecule; six weeks. BT: new bone trabecules; HA: hydroxyapatite; 250 \times , hematoxylin and eosin staining.

are defined as bioactive materials. They cause no or minimal tissue reaction when implanted into bone, and chronic inflammation is almost never observed. Giant cells and macrophages are seldom seen around ceramic implants. New bone formation begins from the outer surface and proceeds to the center of the ceramic. The presence of free calcium ions on the surface of HA ceramic, but not carbonate, sulfate, and sodium ions, significantly enhances protein binding in a dose-dependent manner.^[38] Proteoglycans and glycosaminoglycans of bone were proposed to have important roles in the mineralization process.^[39] Bone sialoprotein and osteopontin were also presented^[40] to bind to HA ceramics for the regulation of bone mineralization.

POLYMERS

Polymers are promising materials to be used in bone^[41] and cartilage^[42,43] engineering. They can effectively be used in controlled delivery of cells and mediators to the injury site and can aid in regeneration. Polylactides, polyglycolides, and polyhydroxybutyrates (PHBV) are effectively used for these reasons. Macrophages increase in number in about 12 weeks of polymer application into the bone.^[44] Advancements in bone morphogenic protein (BMP)-2 (Fig. 2) and -7^[41,45] delivery and chondrocyte^[43] transfer using polymers were experimentally achieved in the last few years.

Scaffolds for tissue engineering, whether ceramic or polymer in nature, should be: a) biocompatible;

Fig. 2 One microgram BMP-2 loaded PHBV implanted rat tibial cortical defect. Note that a partial cortical defect was established to prevent the migration of cells and mediators from the bone marrow; three weeks. BT: new bone trabeculae; P: polymer; CB: cortical bone; 200 \times , hematoxylin and eosin staining.

b) porous; c) cell and mediator friendly; d) resorbable; e) mechanically suitable; f) inexpensive; and g) surgically easy applicable. Characterization of these implants before experimental or clinical application is essential, i.e., a) scanning electron microscopy; b) electron diffraction spectroscopy; c) porosimetry; d) pore size distribution; e) internal void volume assessment; and f) degradation profile are usually assessed.

The sources of osteoblasts and chondrocytes are many. Bone marrow is the source of stem cells and therefore widely used to obtain osteoblast precursors. The cambium layer of the periosteum has the potential to contain osteoblast and chondrocyte precursors. Cartilage tissue itself is also a major source for chondrocytes. Adipocytes have also attracted attention recently as they can be induced into osteoblast-like cells *in vitro* under appropriate stimulus.

Local mediators, except for common features, may vary from tissue to tissue. These features include: a) time and dose-dependent action; b) possible side and adverse effects even when applied locally; and c) triggering antagonistic mechanisms and losing activity after local application. Various mediators may have different effects at different stages of bone and cartilage regeneration. For example, one mediator that is effective at the proliferation stage may lose its effect at the differentiation stage. Besides local mediators and cells, controlled mechanical stimulation for musculoskeletal tissue healing and regeneration is additionally essential.

Factors that influence bone regeneration are complex (Fig. 3). Among the factors are: a) mechanical and physical forces; b) systemic hormones; and c) neuro-mediators. All these three factors control bone cell proliferation and differentiation through local mediators. Local mediators stimulate osteoblasts and/or osteoclast formation/activity/neogenesis; the former causing bone formation and the latter mediating bone resorption. In normal bone, osteoblastic and osteoclastic activity is coupled and balanced. The balance between osteoblastic formation and osteoclastic resorption is controlled, among other factors, by osteoprotegerin and its ligand.^[46] When applied to bone externally the type, time, and dose of local mediators should be well defined.

Cartilage is a highly differentiated tissue, and tissue engineering is recently used for the repair of its defects.^[47] Polymers alone^[43] or in combination with ceramics^[47] are preferred for cartilage replacement; the former is used as chondrocyte carrier for the replacement of the cartilage layer and the latter for the replacement of subchondral bone. Some biomaterials were further used to transfer transforming growth factor beta and mesenchymal stem cells for cartilage repair.^[48] Such implants were also used in clinical practice in limited cases to replace the injured cartilage.^[49,50]

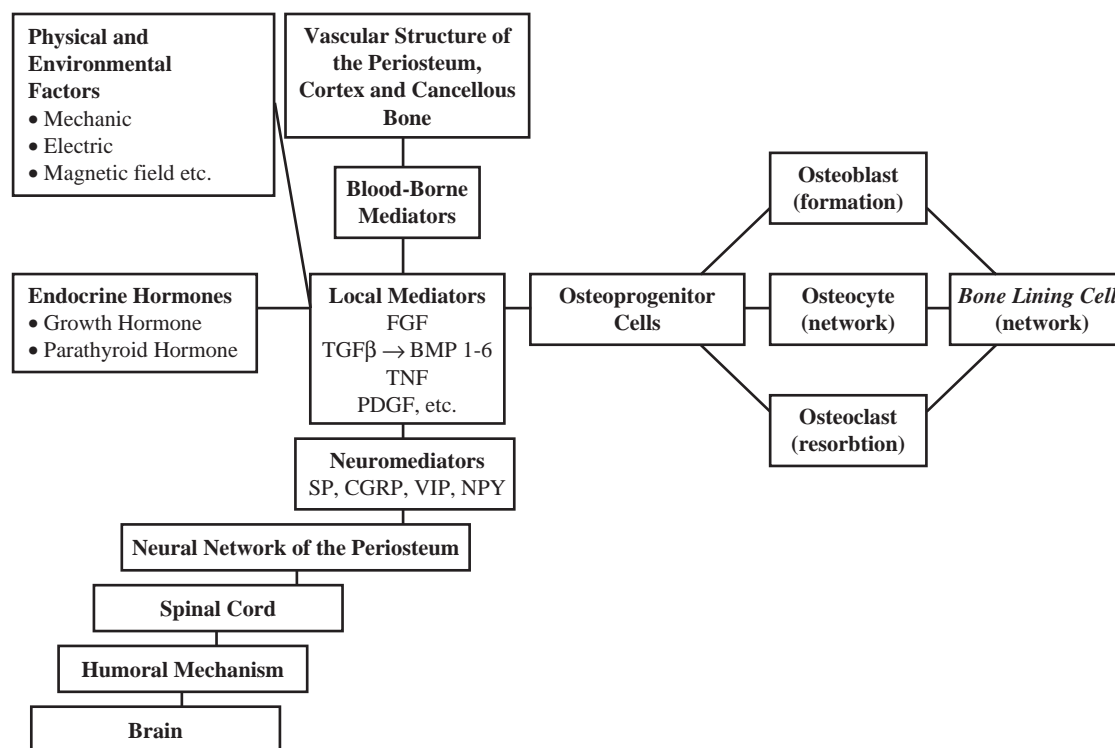

Fig. 3 Systems that control bone repair and regeneration.

CONCLUSIONS

As a conclusion, biomaterials are frequently and widely used in bone and cartilage tissue. Metals are the most common used biomaterials in bone, and extensive research is focused on surface coating or engineering of metals. Advanced techniques in surface coating are assumed to decrease particle release from metal implants and increase biocompatibility. Another approach with metal implants is to decrease their profile and contact area with bone. Ceramic and polymer based implants are likely to be more frequently used as tissue engineering products leading to complete regeneration of bone and cartilage tissue, and such products are already used in clinical applications.

Hard Tissue Elastic Properties

J. Lawrence Katz

*Co-Director, Center for Research on Interfacial Structure and Properties,
University of Missouri–Kansas City, Kansas City, Missouri, U.S.A.*

INTRODUCTION

The principal protein of bone is type 1 collagen, which along with other proteins, glycoproteins, and protein-polysaccharides, comprises about 50% of bone's volume.^[1,2] The other major constituent of bone is a calcium phosphate in the form of a crystalline carbonateapatite.^[3] Bone is an anisotropic, heterogeneous, inhomogeneous, non-linear, thermorheologically complex viscoelastic material, making it one of the most interesting materials known in terms of structure–property relationships. In addition, bone exhibits electromechanical effects, presumed to be because of streaming potentials, both in vivo and in vitro when wet.^[4]

Currey^[5] states unequivocally that he thinks, “the most important feature of bone material is its stiffness.” This statement constitutes the rationale that it is only the elastic and viscoelastic properties of compact cortical bone as well as the elastic properties of trabecular bone that will be covered in this article. Although bone is such a complex material, we will take advantage of some simplification by modeling its behavior as a linear elastic material with additional indication, at the end of this article, of how to take into account its viscoelastic properties.

STRUCTURE/COMPOSITION OF BONE

To understand the structure–property relationships in bone, it is necessary to consider it as a complex hierarchical structural material.^[6] An artist's sketch of this hierarchical arrangement for compact cortical femoral bone is shown in Fig. 1. It is convenient to categorize the structure on four levels: molecular, ultrastructural (nanostructural), microstructural, and macrostructural (whole bone). Fig. 2 further illustrates the hierarchical subdivisions within mammalian bone. At the molecular structural level, we have the tropocollagen molecule and apatitic mineralites (Ap). The tropocollagen molecule is $\sim 1.5 \times 280$ nm and is made up of three individual left-handed helical polypeptide (alpha) chains coiled into a right-handed helix.^[2] The mineralites have been found to be carbonate-substituted hydroxyapatite, generally thought to be

non-stoichiometric.^[3] Atomic force microscopy (AFM) measurements have shown them in mature bovine bone to be about $0.61 \times 10 \times 12$ nm in size,^[9] while those isolated from young bovine bone are about $2.0 \times 6.0 \times 9.0$ nm in size.^[10] At the ultrastructural level, the collagen and Ap are closely associated and formed into a microfibrillar composite that is then assembled into fibers that range from approximately 3 to 5 μ m thick. At the microstructural level, these fibers are either randomly arranged (woven bone) or organized into concentric lamellar groups (secondary osteons or haversian systems) or linear lamellae (plexiform bone).^[5,11] This generally is the tissue level of structure that is used when making measurements of elastic moduli either by mechanical testing or ultrasonic wave propagation techniques. Bone, at this level, is found in two different architectural structures—dense and porous.^[5] Dense bone is found, for example, in the shafts of long bone and is usually termed “compact or cortical bone.” The porous, or spongy type of bone is found, for example, in the articulating ends of long bones, and is called cancellous bone. It is important to note that both cortical and cancellous bone comprise the same basic materials in essentially the same hierarchical arrangements. The macroscopic or whole bone comprises the tissue level components organized into both the cortical shell around the medullary canal and the cancellous bone in the articulating regions.^[5] The mechanical properties of the whole bone results from the contribution of each of these hierarchical levels.^[6]

The composition of bone can vary depending upon a large number of factors: species; type of bone, e.g., woven and cancellous; location; age; sex; etc. Some data for overall composition of both human and bovine cortical bone by weight is given in Table 1.

ELASTIC PROPERTIES

As indicated above in the Introduction, for the purposes of this article, it is reasonable, as a first approximation, to model bone as an anisotropic, linear elastic solid with Hooke's law as the appropriate constitutive equation. Although bone is a viscoelastic material, at the quasistatic strain rates used in

Fig. 1 Hierarchical levels of structure of human bone. (From Ref. [7], permission sought from CRC Press, Boca Raton, FL.)

mechanical testing and the near zero strain rate ultrasonic frequencies used experimentally, linear elasticity is a reasonable approximation. It must be kept in mind that this holds if the range of frequency (time) studied is relatively small. If, for example, one were to compare the results of the quasistatic mechanical tests with the ultrasonic tests, dispersion (variation of modulus with frequency) associated with viscoelasticity becomes evident, as seen in Table 2. Standard international units are used throughout this article. In tensor notation, Hooke's law is written as

$$\sigma_{ij} = C_{ijkl} \varepsilon_{kl} \tag{1}$$

where σ_{ij} and ε_{kl} are the second rank stress and infinitesimal second rank strain tensors, respectively, and C_{ijkl} is the fourth rank elasticity tensor. Using a reduced notation, where: 11 → 1, 22 → 2, 33 → 3, 23 → 4, 31 → 5, and 12 → 6 in Eq. (1), we can rewrite Eq. (1) as

$$\sigma_i = C_{ij} \varepsilon_j \quad i, j = 1 - 6 \tag{2}$$

where the C_{ij} are the stiffness coefficients (elastic constants), and the S_{ij} are known as the compliance coefficients.

Lang,^[18] Katz and Ukraincik,^[19] and Yoon and Katz,^[20,21] based on their ultrasonic wave propagation measurements, assumed cortical bone to be transversely isotropic with the bone axis of symmetry (the 3 direction) as the unique axis of symmetry; this requires five independent C_{ij} (or S_{ij}) to fully describe its anisotropic elastic properties. The matrix form of Eq. (2) for transverse isotropy is given in Eq. (3), while the corresponding matrix form for the compliances is given in Eq. (4).

$$\begin{Bmatrix} \sigma_{xx} \\ \sigma_{yy} \\ \sigma_{zz} \\ \sigma_{yz} \\ \sigma_{zx} \\ \sigma_{xy} \end{Bmatrix} = \begin{bmatrix} C_{11} & C_{12} & C_{13} & 0 & 0 & 0 \\ C_{12} & C_{11} & C_{13} & 0 & 0 & 0 \\ C_{13} & C_{13} & C_{33} & 0 & 0 & 0 \\ 0 & 0 & 0 & C_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & C_{44} & 0 \\ 0 & 0 & 0 & 0 & 0 & (C_{11} - C_{12})/2 \end{bmatrix} \times \begin{Bmatrix} \varepsilon_{xx} \\ \varepsilon_{yy} \\ \varepsilon_{zz} \\ \varepsilon_{yz} \\ \varepsilon_{zx} \\ \varepsilon_{xy} \end{Bmatrix} \tag{3}$$

$$\begin{Bmatrix} \varepsilon_{xx} \\ \varepsilon_{yy} \\ \varepsilon_{zz} \\ \varepsilon_{yz} \\ \varepsilon_{zx} \\ \varepsilon_{xy} \end{Bmatrix} = \begin{bmatrix} S_{11} & S_{12} & S_{13} & 0 & 0 & 0 \\ S_{12} & S_{11} & S_{13} & 0 & 0 & 0 \\ S_{13} & S_{13} & S_{33} & 0 & 0 & 0 \\ 0 & 0 & 0 & S_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & S_{44} & 0 \\ 0 & 0 & 0 & 0 & 0 & 2(S_{11} - S_{12}) \end{bmatrix} \times \begin{Bmatrix} \sigma_{xx} \\ \sigma_{yy} \\ \sigma_{zz} \\ \sigma_{yz} \\ \sigma_{zx} \\ \sigma_{xy} \end{Bmatrix} \tag{4}$$

Fig. 2 Diagram showing mammalian bone at different levels. Diagram showing the structure of mammalian bone at different levels. Bone at the same level is drawn at the same magnification. The arrows show what types may contribute to structures at higher levels: (A) collagen fibril with associated mineral crystals; (B) woven bone, the collagen fibrils are arranged more or less randomly. Osteocytes are not shown; (C) lamellar bone, there are separate lamellae, and the collagen fibrils are arranged in "domains" of preferred fibrillar orientation in each lamella. Osteocytes are not shown; (D) woven bone, blood channels are shown as large black spots. At this level woven bone is indicated by light dotting; (E) primary lamellar bone, at this level lamellar bone is indicated by fine dashes; (F) haversian bone, a collection of Haversian systems, each with concentric lamellae round a central blood channel. The large black area represents the cavity formed as a cylinder of bone is eroded away. It will be filled in with concentric lamellae and will form a new Haversian system; (G) laminar bone, two blood channel networks are exposed. Note how layers of woven and lamellar bone alternate; (H) compact bone of the types shown at the lower levels; and (I) cancellous bone. (From Ref. [8], permission sought from Princeton University Press.)

On the other hand, Van Buskirk and Ashman^[16] assumed cortical bone to have orthotropic symmetry based on their ultrasonic measurements that showed small differences in the elastic properties between the

radial (1 direction) and transverse (2 direction) axes; this requires nine independent C_{ij} (or S_{ij}) to fully describe its anisotropic elastic properties. Yoon and Katz^[20,21] deemed that this was essentially because of

Table 1 Composition of adult human and bovine cortical bone

Species	%H ₂ O	Ap%	Dry weight collagen	GAG ^a	References
Bovine	9.1	76.4	21.5	ND ^b	[12]
			Human	7.3	67.2
21.2	0.34	[13,14]			

^aGlycosaminoglycan.^bNot determined.

the apparent gradient in porosity from the periosteal to the endosteal sides of bone, and therefore, that this defect did not alter the basic transverse isotropic symmetry, so that there was a saving in modeling to need only five instead of nine constants in any calculations. While plexiform (young) bovine bone is widely accepted to be orthotropic, in both human and mature bovine haversian bone, any deviations from transverse isotropy is small and is generally neglected in modeling calculations. The matrix for the transverse isotropic C_{ij} is as presented in Eq. (3).

The corresponding matrix can be written for the compliance coefficients, S_{ij} , based on Eq. (4) following

$$\varepsilon_i = S_{ij}\sigma_j \quad i, j = 1 - 6 \quad (5)$$

where the S_{ij} th compliance is obtained by dividing the $[C_{ij}]$ stiffness matrix, minus the i th row and j th column, by the full $[C_{ij}]$ matrix and vice versa to obtain the C_{ij} in terms of the S_{ij} . It is important to recognize that, although Young's modulus in the bone axis, 3, direction, $E_{33} = 1/S_{33}$, where $E_{33} \neq C_{33}$, because C_{33} and S_{33} are not reciprocals. In general, C_{ij} and S_{ij} are not simple reciprocals for either transverse isotropy or orthotropic symmetry, or even for the isotropic case.

Ultrasonic wave propagation techniques provide a non-destructive means for in vitro measurements of bone tissues' elastic anisotropy;^[16,18,20,21] they are measurements done near the limit of zero strain at a high strain rate. However, rate is not the best measure in

the linear domain because at a given frequency doubling the amplitude entails doubling the rate. In the linear domain, this has no effect in that damping and modulus are independent of amplitude. Also, the mechanical damping is at a minimum near 1 Hz; so in that region the bone is most closely approximated as linear. Thus, non-linearities present in the material are not likely to be easily assessed with this technique, which is one reason why Hooke's law works so well when analyzing ultrasonic measurements. As for Hooke's law in ultrasonic measurements, there is still attenuation; so Hooke's law is extended to complex moduli with ultrasonics as well as with lower frequency cyclic tests. The combination of Hooke's law with Newton's second law results in a wave equation that yields the following relationship involving the stiffness matrix

$$\rho V^2 U_m = C_{mrsn} N_r N_s U_n \quad (6)$$

where ρ is the density of the medium, V is the wave speed, and U and N are unit vectors along the particle displacement and wave propagation directions, respectively, so that U_m , N_r , etc. are direction cosines.

Thus to find the five transverse isotropic elastic constants, at least five independent measurements are required e.g., a dilatational longitudinal wave in the 3 and 1 or 2 directions, a transverse wave in the 13, 23, and 12 planes, etc. Technical moduli can then be calculated from the full set of C_{ij} . Redundant measurements should be made both for transverse isotropic and orthotropic symmetry to ensure good statistics.

There are several major advantages of the ultrasonic measurements technique over mechanical testing: 1) The former can be done with specimens too small for the latter technique; 2) ultrasonic reproducibility of measurements is greater than for mechanical testing; and 3) the full set of either five or nine coefficients can be measured on a smaller number of specimens using ultrasound, than is possible with mechanical testing. Thus, at present, ultrasonic techniques are preferred in studies of elastic anisotropy in both human and other mammalian bones.

Table 2 Elastic stiffness coefficients for various human and bovine bones measured with ultrasound except for Knets mechanical tests

References	Bone type	C_{11}	C_{22}	C_{33}	C_{44}	C_{55}	C_{66}	C_{12}	C_{13}	C_{23}

(From Ref. [15].)

In addition to the bulk wave measurements of individual elastic constants as described above, it is possible to obtain Young's modulus directly. If the wavelength of the sound is larger than the specimen cross section, e.g., low-frequency ultrasound with samples of small cross sections. For this case, an extensional longitudinal (bar) wave of velocity V is propagated yielding Young's modulus, E , directly, Eq. (7)

$$V^2 = E/\rho \quad (7)$$

This is analogous to a uniaxial mechanical test experiment in which the slope of the stress/strain curve yields E .

The precision of the ultrasonic measurement technique provides values of the C_{ij} , confirming the anisotropic property difference between bovine haversian and plexiform (lammelar) bones. These differences in C_{ij} between the two types of bone tissue are hypothesized to be owing essentially to the differences in their microstructural organization (Fig. 3). At this level of structure, the textural symmetry has dimensions comparable to those of the ultrasound wavelengths used in the experiment. In addition, the molecular and ultrastructural levels of organization in both types of tissues are essentially identical. These results reinforce the importance that it is necessary to understand bone as a hierarchical ensemble to model its elastic properties as a material/structural composite system. The human femur data^[16] support this description of bone tissue. The nine individual C_{ij} measured for the human femur treated as an orthotropic material are such that their results are consistent with a near-transverse isotropic symmetry. However, the nine C_{ij} measured for bovine femoral bone clearly show the influence of the orthotropic microtextural symmetry of that tissue's plexiform structure.

Fig. 3 Diagram showing how lamellar (plexiform) bone (A) differs more between radial and tangential directions (R and T) than does haversian bone and (B) the arrows are vectors representing the various directions. (From Ref. [8], permission sought from Princeton University Press.)

The C_{ij} are simply related to "technical" elastic moduli such as Young's modulus, E , shear modulus, G , bulk modulus, K , and others. Thus, it is possible to describe the moduli along any given direction. In place of the full equations for the most general anisotropy, which are too long to present here, given in the following are the simplified equations for the case of transverse isotropy, e.g., Ref. [22]. For this symmetry, Young's modulus is

$$1/E(\gamma_3) = S'_{33} = (1 - \gamma_3^2)2S_{11}/[\gamma_3^4 S_{33}/\gamma_3^2(1 - \gamma_3^2) \times (2S_{13} + S_{44})] \quad (8)$$

where $\gamma_3 = \cos \phi$ and ϕ is the angle made with respect to the 3 (bone) axis.

The shear modulus (rigidity modulus or torsional modulus for a circular cylinder) is

$$1/G(\gamma_3) = 1/2(S'_{44} + S'_{55}) \\ = S_{44} + (S_{11} - S_{22}) - 1/2S_{44}(1 - \gamma_3^2) \\ + 2(S_{11} + S_{33} - 2S_{13} - S_{44})\gamma_3^2(1 - \gamma_3) \quad (9)$$

where, again $\gamma_3 = \cos \phi$.

The bulk modulus (reciprocal of the volume compressibility), independent of ϕ , is

$$1/K = S_{33} + 2(S_{11} + S_{22} + 2S_{13}) \\ = [C_{11} + C_{12} + 2C_{33} - 4C_{13}]/ \\ [C_{33}(C_{11} + C_{12}) - 2C_{13}^2] \quad (10)$$

The S_{ij} in Eqs. (9) and (10) can be converted to the C_{ij} through the following set of transformation equations:

$$S_{11} = (C_{22}C_{33} - C_{23}^2)/\Delta; \\ S_{22} = (C_{33}C_{11} - C_{13}^2)/\Delta; \\ S_{33} = (C_{11}C_{22} - C_{12}^2)/\Delta; \\ S_{12} = (C_{13}C_{23} - C_{12}C_{33})/\Delta; \\ S_{13} = (C_{12}C_{23} - C_{13}C_{22})/\Delta; \\ S_{23} = (C_{12}C_{13} - C_{23}C_{11})/\Delta \\ S_{44} = 1/C_{44}; \quad S_{55} = 1/C_{55}; \quad S_{66} = 1/C_{66} \quad (11)$$

where the determinant, Δ , of the C_{ij} matrix is being taken

$$\Delta = \begin{vmatrix} C_{11} & C_{12} & C_{13} \\ C_{21} & C_{22} & C_{23} \\ C_{31} & C_{32} & C_{33} \end{vmatrix} \\ = C_{11}C_{22}C_{33} + 2C_{12}C_{23}C_{13} \\ - (C_{11}C_{23}^2 + C_{22}C_{13}^2 + C_{33}C_{12}^2) \quad (12)$$

The full equations for general symmetry can be found in Yoon and Katz.^[20] There also is available a considerable amount of data on the mechanical properties of cancellous (trabecular) bone, including measurements of the elastic properties of single trabeculae. Keaveny and Hayes^[23] presented an analysis of 20 years of studies on the mechanical properties of trabecular bone. These earlier studies generally used mechanical testing of bulk specimens of a size reflecting a cellular solid, i.e., of the order of cubic centimeter or larger. In these studies, both the modulus and strength of trabecular bone were strongly correlated to the apparent density, where apparent density, ρ_a , is defined as the product of individual trabeculae density, ρ_t , and the volume fraction of bone in the bulk specimen, V_t , and is given by $\rho_a = \rho_t V_t$.

A wide range of Young's moduli, E , resulted from these measurements, ranging from approximately 10 MPa to the order of 1 GPa depending on the apparent density. Keaveny and Hayes^[23] showed that these results could be correlated to the apparent density in g/cc by a power law relationship, $E = 6.13\rho_a^{1.44}$, with an $r^2 = 0.62$ calculated for 165 specimens.

As early as 1975, Townsend, Rose, and Radin^[24] machined individual trabeculae and measured their moduli in buckling, yielding a modulus of 11.4 GPa (wet) and 14.1 GPa (dry). New techniques of micromechanical measurements of bone allowed the determination of the elastic properties of the individual trabeculae in addition to the measurements of bulk properties. Nanoindentation and ultrasonic techniques such as scanning acoustic microscopy have been used for these studies, as well as by other mechanical testing methods. Ultrasound measurements^[25,26] have yielded values commensurate with the measurements of Townsend, Rose, and Radin (Table 3).^[24] Rho et al.^[29] using nanoindentation obtained average values of Young's modulus ranging from 15.0 to 19.4 GPa depending on orientation. These values were somewhat lower compared to 22.4 GPa for osteons and 25.7 GPa for the interstitial lamellae in cortical bone (Table 3). Turner et al.^[30] compared nanoindentation and acoustic microscopy at 50 MHz on the same specimens of trabecular and cortical bone from a common human donor (Table 3). The anisotropy ratio of longitudinal modulus to transverse modulus for cortical bone was similar for both modes of measurement even though the nanoindentation measurements resulted in Young's moduli greater than those measured by acoustic microscopy by 4–14%; the trabecular values are given in Table 3. Acoustic microscopy at 400 MHz has been used to measure the moduli of both human trabecular and cortical bone,^[25] yielding results comparable to those of Turner et al.^[30] for both types of bone (Table 3).

All moduli in GPa.

Such studies provide the data for micromechanical analyses using material properties measured on the microstructural level. They also indicate that nanoscale measurements such as those provided by AFM is the next step necessary to analyze the mechanics of bone on the smallest unit of structure shown in Fig. 1.

ELASTIC ANISOTROPY

A full set of either five or nine C_{ij} (S_{ij}) does describe the anisotropy of that particular specimen of cortical bone. However, there is no simple way of comparing the relative anisotropy between different measurements on one specimen or on different specimens of the same bone or between different species or even between experimenters' measurements by trying to relate the individual C_{ij} (S_{ij}) between sets of measurements. Katz and Meunier^[32,33] adapted a procedure from crystal physics that provided a method for obtaining two scalar mechanical quantities—the compressive and shear anisotropy for crystals with cubic or hexagonal symmetry—to calculate those quantities for transverse isotropic bone tissue. They then extended the calculation to bone tissues exhibiting orthotropic symmetry.^[34] For both cases, the percentage compressive (Ac^*) and shear (As^*) elastic anisotropy are given, respectively, by

$$Ac^*(\%) = 100(K^V - K_R)/(K^V + K_R)$$

$$As^*(\%) = 100(G^V - G_R)/(G^V + G_R) \quad (13)$$

where K^V and K_R are the Voigt^[35] (uniform strain across an interface) and Reuss^[36] (uniform stress across an interface) bulk moduli, respectively, and G^V and G_R are the Voigt and Reuss shear moduli, respectively. Voigt moduli represent the upper bound values while Reuss moduli represent the lower bound values. The equations for K^V , K_R , G^V , and G_R are provided for both transverse isotropy and orthotropic symmetry in the Appendix.

Haversian bones, whether human or bovine, have both their compressive and shear scalar anisotropy factors considerably lower than the respective values for plexiform bone. Plexiform bone is stiffer than haversian bone; it is also more anisotropic.

MODELING ELASTIC BEHAVIOR

The first attempt to model bone as a composite material composed of a simple linear superposition of collagen and apatite was made by Currey.^[37] He followed this later by taking into account the orientation of the apatite crystallites^[38] using a model proposed by Cox^[39] for fiber-reinforced composites. Katz^[40] and Piekarski^[41] independently using Voigt and Reuss or even Hashin-Shtrikman^[42] composite modeling showed that using such linear combinations of either elastic moduli or elastic compliances failed to provide a realistic description of the behavior of cortical bone as a composite material. The reason for these failures is that they were based on considerations of material properties alone. This is comparable to trying to determine the properties of the Eiffel Tower by simply modeling the composite material properties without considering void spaces and the interconnectivity of the structure.^[43] It is clear for both bone and the Eiffel Tower that, in addition to the material properties, consideration of their hierarchical structural organization must be introduced into the modeling; i.e., these systems are complex structural/material composites.

Based on the realization that the simple linear rule of mixtures could not explain the behavior of bone as a composite material,^[40] Katz^[44] hypothesized that haversian bone should be modeled as a hierarchical/structural material composite. Thus, he adapted a hollow fiber composite model of Hashin and Rosen^[45] for compact cortical bone that he published in a number of papers.^[6,46] Bonfield and Grynpas^[47] reported, in *Nature*, their study of the elastic properties of cortical bone specimens cut at angles of 0°, 5°, 10°, 20°, 30°, 40°, 50°, 70°, 80°, 85°, and 90° with respect to the long bone axis, using extensional (longitudinal) ultrasonic wave propagation in both wet and dry bovine femoral cortical bone specimens. They compared their experimental results for Young's moduli with the

theoretical curve predicted by Currey's^[38] 1969 model; the comparison is shown in Fig. 4. The bump in the ultrasonic measurements between 60° and 80° may be because of the mixing in of stiffer plexiform specimens with the other specimens. The clear lack of agreement between theory and experiment led them to "conclude, therefore that an alternative model is required to account for the dependence of Young's modulus on orientation."^[47] Katz and coworkers^[48–51] applying their hierarchical material-structure composite model were able to explain the data in Fig. 4 by considering different amounts of apatitic crystallites aligned parallel to the long bone axis (Fig. 5). More sophisticated modeling has progressed beyond this initial attempt at hierarchical structural/material micromechanical modeling, e.g., finite element micromechanical computations^[52] or homogenization theory.^[53] Further improvements will require the inclusion of more definitive information on the structural organization of collagen and apatite mineralites at the molecular-ultrastructural level. In addition to obtaining more definitive structural information, it will also be necessary to obtain constitutive mechanical properties at each level of the hierarchy before a complete mechanical model of bone is arrived at. That these concerns have generated a considerable range of research activities during the past several decades can be seen in

Fig. 4 Variation in Young's modulus of bovine femur specimens, E , with the orientation of specimen axis to the long axis of the bone for wet (o) and dry (x) conditions compared with the theoretical curve (—) predicted from a fiber-reinforced composite model. (From Ref. [47], permission sought from Nature.)

Fig. 5 Predictions of Katz's hierarchical structural/material composite model for cortical bone compared with the experimental data of Bonfield and Grympas. Each curve represents a different lamellar configuration within a single osteon, with longitudinal fibers: A, 64%; B, 57%; C, 50%; D, 37%; and the rest of the fibers assumed to be horizontal. (From Refs. [47–51], permission sought from Nature.)

just a few of the examples cited here.^[9,10,54–66] Considerable research in these areas continues at a rapid pace.

VISCOELASTIC PROPERTIES

Although, the emphasis in this article has been on bone as a linear elastic material, it is clear that bone, along with all other biologic tissues, is a viscoelastic material. Thus, Hooke's law for linear elastic materials must be replaced by a constitutive equation that includes the time dependency of the material properties. The behavior of an anisotropic linear viscoelastic material may be described by using the Boltzmann superposition integral as the constitutive equation^[67]

$$\sigma_{ij}(t) = \int_{-\infty}^t C_{ijkl}(t-\tau) \{d\varepsilon_{kl}(\tau)/d\tau\} d\tau \quad (14)$$

where $\sigma_{ij}(t)$ and $\varepsilon_{kl}(\tau)$ are the time-dependent second rank stress and strain tensors, respectively, and $C_{ijkl}(t-\tau)$ is the fourth rank relaxation modulus tensor. This tensor has 36 independent elements for the lowest

symmetry case and 12 non-zero independent elements for an orthotropic solid. As for Hooke's Law in linear elasticity, a reduced notation is used here as well, i.e., 11 → 1, 22 → 2, 33 → 3, 23 → 4, 31 → 5, and 12 → 6. Applying Eq. (14) to the case of an orthotropic material, e.g., plexiform bone, in uniaxial tension (compression) in the 1 direction,^[67] the following set of equations is obtained

$$\begin{aligned} \sigma_1(t) = \int_{-\infty}^t & [C_{11}(t-\tau) \{d\varepsilon_1(\tau)/d\tau\} \\ & + C_{12}(t-\tau) \{d\varepsilon_2(\tau)/d\tau\} \\ & + C_{13}(t-\tau) \{d\varepsilon_3(\tau)/d\tau\}] d\tau \end{aligned} \quad (15)$$

$$\begin{aligned} \sigma_2(t) = \int_{-\infty}^t & [C_{21}(t-\tau) \{d\varepsilon_1(\tau)/d\tau\} \\ & + C_{22}(t-\tau) \{d\varepsilon_2(\tau)/d\tau\} \\ & + C_{23}(t-\tau) \{d\varepsilon_3(\tau)/d\tau\}] d\tau = 0 \end{aligned} \quad (16)$$

$$\begin{aligned} \sigma_3(t) = \int_{-\infty}^t & [C_{31}(t-\tau) \{d\varepsilon_1(\tau)/d\tau\} \\ & + C_{32}(t-\tau) \{d\varepsilon_2(\tau)/d\tau\} \\ & + C_{33}(t-\tau) \{d\varepsilon_3(\tau)/d\tau\}] d\tau = 0 \end{aligned} \quad (17)$$

for all t .

Setting the integrands in both Eqs. (16) and (17) to 0 and solving them simultaneously for $\{d\varepsilon_2(\tau)/d\tau\}$ and $\{d\varepsilon_3(\tau)/d\tau\}$ and substituting these values in Eq. (15) yields

$$\sigma_1(t) = \int_{-\infty}^t E_1(t-\tau) \{d\varepsilon_1(\tau)/d\tau\} d\tau \quad (18)$$

where, for convenience, adopting the notation $C_{ij} \equiv C_{ij}(t-\tau)$, Young's modulus is given by

$$\begin{aligned} E_1(t-\tau) = & C_{11} + C_{12} \{ [C_{31} - (C_{21}C_{33}/C_{23})] / \\ & \{ (C_{21}C_{33}/C_{23}) - C_{32} \} \} \\ & + C_{13} \{ [C_{21} - (C_{31}C_{22}/C_{32})] / \\ & \{ (C_{31}C_{22}/C_{23}) - C_{23} \} \} \end{aligned} \quad (19)$$

For the case of uniaxial tension (compression), only nine independent orthotropic tensor components are involved, the three shear components being equal to zero. If dealing with compliances rather than with moduli, a compliance tensor element can be measured in a tensile creep experiment. Still, this time-dependent Young's modulus is still a rather complex function to calculate. Using the inverse form of the Boltzmann integral would constitute the compliance formulation. It is easier to measure the C_{ij} using ultrasonic wave propagation; it is easier to measure Young's modulus, E , in quasistatic mechanical testing. The modulus and

compliance formulas are equally valid; one does conversions between them if needed.

For bone being driven by a strain at a frequency ω , with a corresponding sinusoidal stress lagging by an angle δ , the complex Young's modulus $E^*(\omega)$ may be expressed as

$$E^*(\omega) = E'(\omega) + iE''(\omega) \quad (20)$$

where $E'(\omega)$, the stress-strain ratio in phase with the strain is known as the storage modulus, and $E''(\omega)$, the stress-strain ratio 90° out of phase with the strain is known as the loss modulus. $\tan \delta$ is equal to the ratio of the loss modulus to the storage modulus. Usually, data are presented by a graph of the storage modulus along with a graph of $\tan \delta$, both against frequency. A clear indication of the frequency (time)-dependent nature of bone is shown in Fig. 6 where values for $\tan \delta$ are plotted over 13 decades of frequency. For a more complete development of viscoelasticity, including some of the biological applications, see Lakes.^[7]

To better understand the response of bone to applied loads, it is important to know its rheologic properties. The viscoelastic properties of various long bones have been studied by a number of investigators, e.g., Sedlin,^[68] Smith and Keiper,^[69] Laird and Kingsbury,^[70] Lugassy and Korostoff,^[71] and Black and Korostoff.^[72] Unfortunately, none of these early measurements were performed over a sufficient range of frequency (or time) to completely define the viscoelastic properties measured. Thus, it is not possible to mathematically transform one property such as creep into another such as stress relaxation, or vice versa, to compare the results of different viscoelastic experiments on different bones.^[67] In the interest of completeness, it would also be appropriate to make

Fig. 6 $\tan \delta$ vs. frequency over 13 decades. (From Ref. [7], permission sought from CRC press, Boca Raton, FL.)

Fig. 7 Comparison of relaxation spectra for wet human bone, specimens 5 and 6, in simple torsion at $T = 37^\circ\text{C}$. First approximation from relaxation and dynamic data. (\bullet) Human tibial bone, specimen 6 and (\blacktriangle) human tibial bone, specimen 5. (From Ref. [77], permission sought from Elsevier.)

some mention of the literature on bulk fluid flow in bone because this is a rapidly growing area of the literature on bone mechanics, see for example Ref. [73].

Lakes and coworkers^[74,75] performed the first viscoelastic measurements of both human and bovine wet bone over an extended frequency range. He measured both the uniaxial and biaxial properties, using both dynamic and stress relaxation techniques, over eight decades of frequency (time).^[74,75] Although, in the normal range of function, bone could be treated as a linear viscoelastic material, the results of these experiments showed that over the eight decades bone, as a material, was both non-linear and thermorheologically complex, i.e., time-temperature superposition could not be used to extend the range of the viscoelastic measurements. A non-linear constitutive equation was developed based on these measurements.^[76] It should be noted that bone has a weak non-linearity at physiological strains, in contrast to tendon and ligament, which are highly non-linear at physiological strains.

Lakes also obtained relaxation spectrums for both human and bovine cortical bone (Fig. 7). Fig. 8 shows the contributions of several mechanisms to the loss tangent of cortical bone; it is interesting that almost all the major loss mechanisms occur at frequencies (times) at or near to those in which there are "bumps" in the relaxation spectrums, indicating possible strain energy dissipation.

Gottesman and Hashin^[78] adapted Katz and coworkers' adaptation^[48-51] of the Hashin-Rosen hollow fiber composite model to perform a viscoelastic calculation using the same major assumptions.

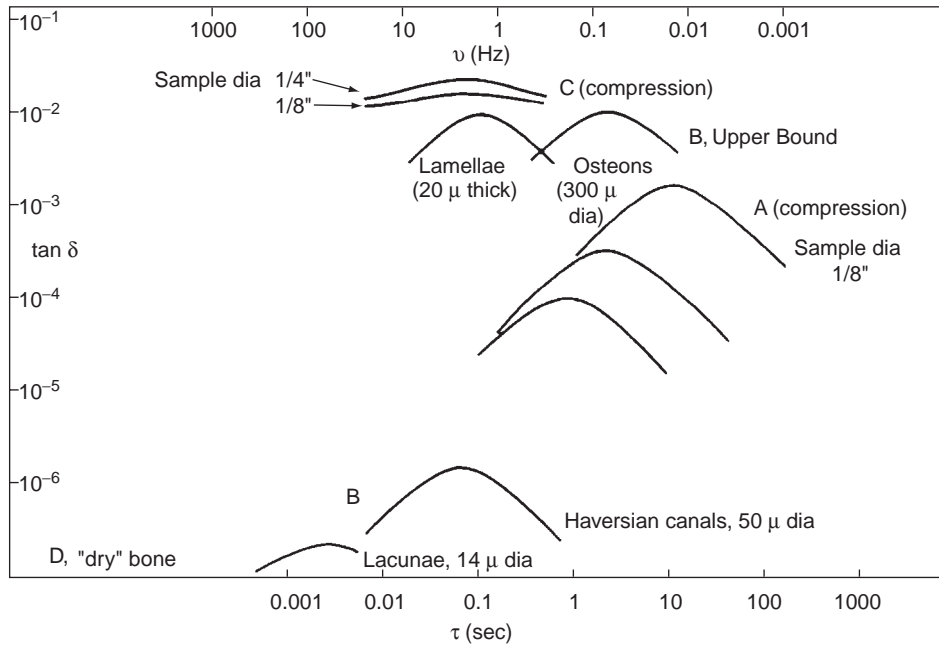

Fig. 8 Contributions of several relaxation mechanisms to the loss tangent of cortical bone. (A) Homogeneous thermoelastic effect; (B) inhomogeneous thermoelastic effect; (C) fluid flow effect; and (D): Piezoelectric effect. (From Ref. [77], permission sought from Elsevier.)

CONCLUSIONS

Although this article is titled, “Hard Tissue Elastic Properties,” it essentially has dealt only with cortical and cancellous (trabecular) bone. There is significant interesting research on other hard tissues, namely dentin and enamel, in the dental area where there are both similarities and considerable differences in structure and properties depending on which level of scale is being examined within these hierarchical structures as well. Indeed, as an example of similarity, the same calculations of scalar shear and compressive anisotropy factors performed for bone as a transverse isotropic material^[33] has been applied to wet and dry dentin^[79] based on resonant ultrasound spectroscopy measurements.^[80] While wet dentin exhibits transverse isotropic symmetry, the calculation shows that dry dentin is isotropic. This may be of clinical significance as there are patients with decreased saliva output, or “dry mouth” syndrome, in which there is an associated drying of tooth structure leading to serious problems. Interestingly, there is a prior small angle x-ray diffraction of human dentin experiment,^[81] which provides independent experimental evidence to support this calculation of isotropy based on the resonant ultrasonic data. Results of this experiment led to the conclusion that the collagen near the pulp appeared to have isotropic symmetry with mild anisotropy in the mid-dentin region.^[81] As the Aps’ orientations are in register with the collagen fiber orientations, this implication supports the above calculation of isotropy for the dry dentin.

Also, this article has not considered other key mechanical properties of bone, such as fracture and fatigue. They have considerable importance both in

basic understanding of bone behavior as well as in clinical practice. A complete understanding of bone formation, resorption, and remodeling clearly requires a comprehensive knowledge of both stiffness and strength and their relationship to fluid flow^[82] and cellular processes.^[83] These are complex problems and are at the cutting edge of present-day hard tissue research.

APPENDIX

The Voigt and Reuss moduli for both transverse isotropic and orthotropic symmetry are given below:

Voigt Transverse Isotropic

$$K^V = [2(C_{11} + C_{12}) + 4(C_{13} + C_{33})]/9 \tag{A1}$$

$$G^V = [C_{11} + C_{12} - 4C_{13} + 2C_{33} + 12(C_{44} + C_{66})]/30 \tag{A2}$$

Reuss Transverse Isotropic

$$K_R = [C_{33}(C_{11} + C_{22}) - 2C_{13}^2]/[C_{11} + C_{22} - 4C_{13} + 2C_{33}] \tag{A3}$$

$$G_R = 5\{C_{33}(C_{11} + C_{12}) - 2C_{13}^2\}C_{44}C_{66}/2\{[C_{33}(C_{11} + C_{12}) - 2C_{13}^2](C_{44} + C_{66}) + [C_{44}C_{66}(2C_{11} + C_{12}) + 4C_{13} + C_{33}]/3\} \tag{A4}$$

Voigt Orthotropic

$$K^V = \{C_{11} + C_{22} + C_{33} + 2(C_{12} + C_{13} + C_{23})\}/9 \quad (\text{A5})$$

$$G^V = \{C_{11} + C_{22} + C_{33} + 3(C_{44} + C_{55} + C_{66}) - (C_{12} + C_{13} + C_{23})\}/15 \quad (\text{A6})$$

Reuss Orthotropic

$$K_R = \{\Delta/(C_{11}C_{22} + C_{22}C_{33} + C_{33}C_{11}) - 2(C_{11}C_{23} + C_{22}C_{13} + C_{33}C_{12}) + 2(C_{12}C_{23} + C_{23}C_{13} + C_{13}C_{12}) - (C_{12}^2 + C_{13}^2 + C_{23}^2)\} \quad (\text{A7})$$

$$G_R = 15/\{4[(C_{11}C_{22} + C_{22}C_{33} + C_{33}C_{11} + C_{11}C_{23} + C_{22}C_{13} + C_{33}C_{12}) - (C_{12}^2 + C_{12}C_{23} + C_{23}^2 + C_{23}C_{13} + C_{13}^2 + C_{13}C_{12})]/\Delta + 3(1/C_{44} + 1/C_{55} + 1/C_{66})\} \quad (\text{A8})$$

where Δ is given in Eq. (13).

INTRODUCTION

Connective tissues (CTs) bind, support, and protect the various structures of the body. Derived from embryonic mesoderm, each tissue has an extensive extracellular matrix (ECM) containing relatively few cells. The ECM gives each tissue its particular character. Examples include ligament, tendon, cartilage, meniscus, fascia, intervertebral disc, bone, dermal layer of skin, adipose, iris, etc. Blood is also classified as a CT but is not included herein. In a broad sense, CTs are composed of tissue specific cells (e.g., osteoblasts and osteoclasts in bone, fibroblasts in ligament and tendon, chondrocytes in cartilage, etc.) and their ECMs, which are composed of collagen fibrils, elastin fibrils, proteoglycans, and other glycoproteins, in varied combinations and proportions (Fig. 1 and Table 1). Collagen provides tensile strength and stiffness, and elastin allows large amounts of stretch and recovery (i.e., elasticity) in certain CTs. Many of the other proteins help hydrate the “ground substance” within the ECM. Hydration is important for transport of nutrition and wastes and for mechanical behavior and function. In addition to these organic components, bone is highly mineralized to provide compressive strength and stiffness. Bone also provides a storage site for minerals and a medium (marrow) for the development and storage of cells and cytokines.

Mechanical stability and proximity of the damaged tissue ends are prerequisites for CT healing. An unstable bony fracture will not mineralize. Ruptured intracapsular ligaments floating in synovial fluid have no opportunity to heal. With stability and proximity satisfied, the biological processes have an opportunity to proceed. This mechanical prerequisite is assumed to be satisfied from this point forward and only the biological processes are considered hereafter.

The potential of CTs to heal varies greatly. Ligaments outside of synovial capsules (e.g., medial and lateral collateral ligaments, MCL, and LCL) heal reasonably well, although typically with scar tissue and

greater joint laxity before bearing load. Tendons typically heal if the ruptured ends remain in stable proximity, but matrix proliferation during healing can produce adhesions that impair function. Some CTs have much lower healing potential. Partial thickness lesions in articular cartilage, for example, typically do not heal. Full thickness lesions can spontaneously heal, but usually with a functionally inferior fibrocartilage. Bone, on the other hand, is quite unique in that it can regenerate itself without scar or functional degradation.

Because of their specific cells, structures and functions, CTs do not heal precisely like other tissues. The CT healing response is directed from chemical signals released from local cells, surrounding ECM, and vasculature. The number and type of cells that infiltrate a wound, and the type of local ECM, greatly influence the quality of the repair. Partial thickness lesions in articular cartilage, for example, have no local blood supply to initiate and support a healing response. When soft CTs heal, they have common wound healing processes and conditions. Bone has additional processes that allow it to regenerate its calcified matrix.

This chapter covers two broad topics: healing requirements as they pertain to soft CTs and healing requirements of bone. Some sub-topics in these sections overlap, showing commonalities that underly all CT healing. Others are tissue specific. Within these topics are concepts of deficient healing. By recognizing these deficiencies, targets become apparent for tissue engineering solutions. The scope of this chapter is very limited. Fortunately, recent literature probes healing of each CT and each CT subgroup considered herein in much greater depth.^[3,15,16]

SOFT CONNECTIVE TISSUE HEALING

A wound or injury disrupts the normal structure and function of these tissues. The wound healing process is

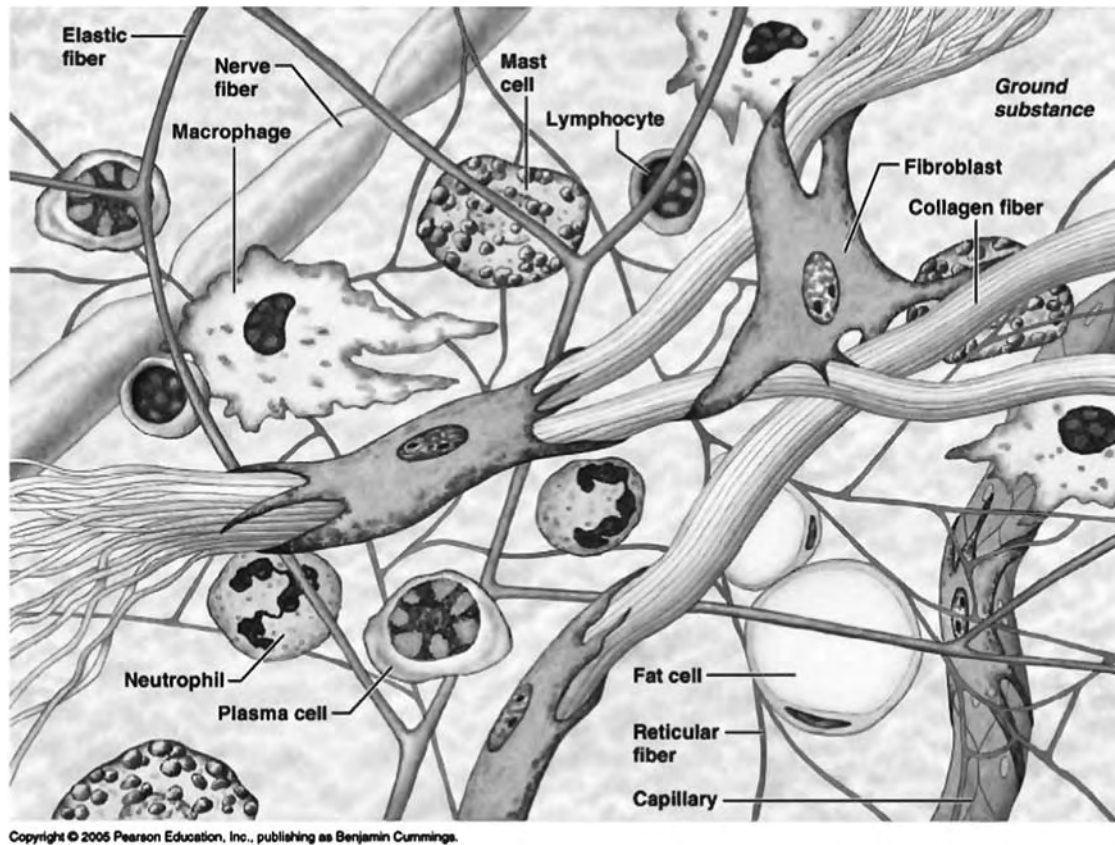

Fig. 1 Components of soft connective tissues.^[3] Soft connective tissues are comprised of tissue-specific cells (such as fibroblasts, chondrocytes, or adipocytes) and extracellular matrix (ECM). The ECM contains numerous proteins, many of which are fibrous in nature. Shown here are: (1) collagen, which provides tensile strength to the tissue, (2) elastin, which allows the tissue to stretch, and (3) reticular fibers, which are small collagen fibers that act as anchors for various cells. Notice that inflammatory cells and blood components (platelets and white blood cells) can also be found within the matrix of some soft CTs.

complex and dynamic as tissues repair with anatomical connections to restore function. Four overlapping stages in wound healing begin immediately following an injury: hemostasis, inflammation, proliferation, and remodeling (Fig. 2). Progression through these stages (which herein is termed “normal” healing) closes the wound and repairs the damage; however, restoring and rebuilding damaged tissue may continue for years post-injury. Herein, “normal” healing indicates the process by which a wounded CT largely recovers its normal function, but not necessarily its structure. Healing “well” means that function is recovered. Alternatively, “poor” healing indicates that the CT does not recover its normal function.

HEMOSTASIS (IMMEDIATELY POST INJURY)

Hemostasis refers to the process that stops bleeding or blood flow. In most CTs, this is the first process to occur during wound healing. From broken vessels,

platelets enter the wound site, contacting the exposed collagen ends.^[15] Platelets aggregate around the damaged matrix. When attached to the matrix, platelets release clotting factors (i.e., chemicals that signal the clotting of any broken vessels in the area).^[6] A fibrin clot, or hematoma, forms as a plug in broken vessels, which also provides a provisional matrix to anchor other cell types in the wound site.^[6]

Platelets then release growth factors into the wound site.^[15] Growth factors are a class of chemicals that regulate cell growth, cell migration, ECM production, enzyme production, and cell differentiation. In particular, platelets release platelet-derived growth factor (PDGF) and transforming growth factor-beta-1 (TGF β -1).^[6,12] Both of these factors stimulate migration of cells into the wound; PDGF is a chemo-attractant for inflammatory cells including neutrophils and macrophages,^[6] and TGF β -1 is a chemo-attractant for smooth muscle cells and fibroblasts.^[6,15] A list of growth factors and other chemicals important to CT healing is found in Table 2.

Table 1 Classification of CTs

Classification	Celltype	Specific CT	Example	Organization	Body location
CT proper	Fibroblast	Loose	Areolar	Disorganized matrix; varied collagen fiber diameter; loosely packed	Surrounding many of the body's organs
			Adipose	Tightly packed cells with some matrix between	Fat insulation throughout the body
			Reticular	Very small diameter collagen fibers; loosely packed; disorganized matrix	Bone marrow as an anchor for developing blood cells
CT proper	Fibroblast	Dense	Irregular	Densely packed collagen fibers in a disorganized fashion	Dermal layer of skin; joint capsules
			Regular	Densely packed collagen in aligned matrix	Ligament and tendon
Cartilage	Chondrocyte		Hyaline	Complex organization of type-II collagen; high water content	Articular cartilage, which covers long bone ends
			Fibrocartilage	Cartilage organized along lines of loading	Intervertebral discs; meniscus; symphyses
			Elastic	Cartilage containing elastic fibers as well	Ears
Bone	Osteocyte			Woven collagen fibers surrounded by mineralized matrix	Any bone within skeleton
	Osteoblast				
	Osteoclast				

INFLAMMATION (IMMEDIATE TO 2–5 DAYS)

Neutrophils, a type of inflammatory cell, follow signals from platelets and dominate the wound site within the first 24 h after injury.^[19] The role of the neutrophils is to clean the wound site so repair can follow. Neutrophils are phagocytic, that is, they ingest foreign materials, bacteria, damaged host cells, and damaged matrix.^[15,19] Mast cells, a second type of inflammatory cell, are also present in the wound within the first 24 h. Mast cells contain granules that are filled with enzymes, including histamine and active amines. When released, these chemicals increase permeability in the local blood vessels. Increased permeability allows fluid and large inflammatory cells to slip out of the local vessels and into the injured region.^[6,15,21]

On the second day following an injury, monocytes dominate the wound site. These cells quickly become macrophages, which are inflammatory cells that are essential to healing. Macrophages, highly phagocytic

inflammatory cells, have two essential roles. First, they engulf large debris-filled neutrophils, damaged matrix, and any leftover bacteria or foreign debris.^[6,15,19] Second, they release PDGF and TGF β -1 and -2, which further attract fibroblasts and smooth muscle cells to the wound site.^[15] In addition, macrophages also release other growth factors that stimulate cell proliferation and angiogenesis (new blood vessels formation), including vascular endothelial growth factor (VEGF), fibroblast growth factor (FGF-1 and -2) and interleukin-1 (IL-1).^[15,19] Signaling processes during inflammation are summarized in Fig. 2.

PROLIFERATION (2 DAYS TO 3 WEEKS)

Proliferation is the major reconstruction phase of wound healing. During this phase fibroblast proliferation and matrix rebuilding dominate. Fibroblasts

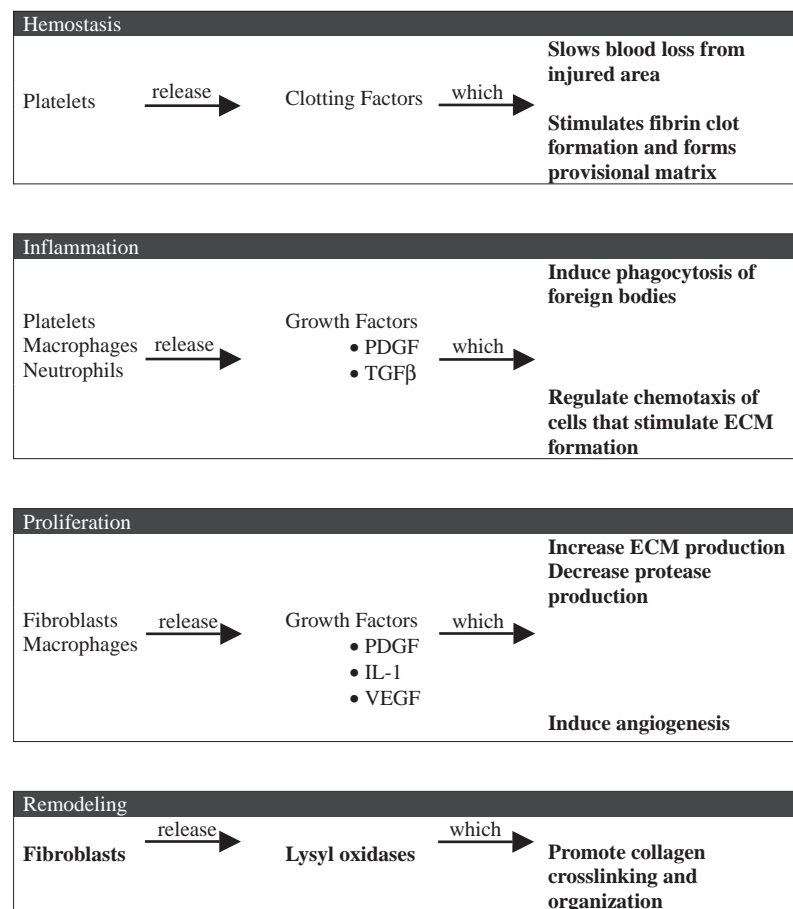

Fig. 2 Stages of healing. There are four overlapping stages of healing that must be coordinated spatially and temporally. Each stage utilizes a specific type of cell (column 1) which releases a chemical mediator (column 2) to perform a specific biological function (column 3). Growth factors often act as mediators in the healing process.

in the wound serve two roles. First, they contract the wound, bringing wound ends closer together. Second, they produce a disorganized ECM to replace the damaged tissue.

Fibroblasts in the wound site attach to the provisional fibrin matrix and produce type I and type III collagens, which are self-assembling, fiber-forming proteins. These new fibrils and fibers connect to the damaged ends of the wound, providing tensile strength. Fibroblasts also produce proteoglycans, ECM proteins that aid in fibrillogenesis and tissue hydration. In fact, many CT injuries remain overly hydrated for several weeks following this proliferative phase. The proliferative phase ECM is often called granulation tissue due to its lack of microstructural organization.

The major signal that regulates this exuberant ECM proliferation is TGFβ-1 (Table 2, Fig. 2).^[15] This growth factor is released from neutrophils, platelets, and macrophages and has three major effects on the ECM deposition by fibroblasts. TGFβ-1 increases the transcription of collagen, proteoglycans, and fibronectin (all ECM proteins),^[6,15] it decreases secretion of proteases (proteins that degrade matrix proteins),^[6] and it increases the secretion of protease inhibitors,

including tissue inhibitors of metalloproteinases (TIMPs) to protect the newly forming matrix.^[6]

With increased cell number and activity in the wound, there is an increased demand for oxygen and nutrients. Local signals, including low pH, low oxygen tension, and increased lactate stimulate cells in the wound to produce VEGF, FGF, and TGFβ-1 and -2.^[6] These growth factors stimulate angiogenesis (new vessel formation) to help keep up with oxygen demands.

REMODELING (3 WEEKS TO 2 YEARS)

The proteins laid down during the proliferative phase are disorganized. The matrix is usually composed of small diameter collagen fibers, and it is weaker than the surrounding healthy tissue.^[15] Remodeling of this weak, disorganized matrix begins within days of the injury, but it can continue for several years after the injury.^[7,10] During remodeling the weak collagen fibers mature. A chemical within the matrix, lysyl oxidase, aids in the cross-linking of these collagen fibers, which is associated with increases in strength and stability of

Table 2 Growth factors important to CT healing

Growth factor	Cell source	Target cell	Biological activity
TGF β -1, β -2	Platelet, macrophage, fibroblast	Inflammatory cells, fibroblasts, osteocyte	Chemotaxis, proliferation, matrix production
PDGF	Platelet, macrophage, fibroblast, vascular smooth muscle	Neutrophil, macrophage, fibroblast, vascular smooth muscle	Chemotaxis, proliferation, matrix production
FGF -1, -2	Macrophage, fibroblast	Fibroblast, chondrocyte, endothelial cells, osteocyte	Proliferation, chemotaxis, angiogenesis
IGF	Fibroblast, macrophage	Fibroblast	Proliferation, collagen synthesis
IL-1	Macrophage, neutrophil	Macrophage, fibroblast	Proliferation; collagenase synthesis, chemotaxis
CTGF	Fibroblast	Fibroblast	Matrix production
VEGF	Macrophage	Endothelial cells	Angiogenesis
BMP -2, -4, -7, -9	Bone precursor cells	Osteocytes	Cell proliferation, matrix production

the fibers (Fig. 2).^[6] Matrix in most uninjured CTs is strong and highly organized. By comparison, scar is weaker and more disorganized. The maximum strength of a naturally healing wound rarely reaches more than 80% of that of the surrounding healthy tissue.^[15] Stiffness and strength are compromised in disorganized scar tissue because recruitment of collagen fibers is less optimal from a microstructural perspective to bear loads and resist failure.

HEALING POTENTIAL OF SPECIFIC CONNECTIVE TISSUES

Specific types of connective tissues have similar healing principles, but each type of tissue has its own potential for healing (Fig. 3). In general, CTs that heal well have ample blood supply, innervation, and a randomly organized matrix. Tissues that heal poorly lack their own blood supply and innervation, and they can have (in their normal tissue) a highly organized matrix that is difficult to reproduce during healing.

Connective Tissues that Heal Well

Areolar and dense irregular connective tissues generally heal well. These tissues, which make up the covering layers for many organs and joints, and the deep (dermal) layers of the skin, have a relatively disorganized ECM (meaning that collagen fibers do not have a strong preferential direction), and they have variability in collagen fiber diameters. The major cell type for these two tissues is the fibroblast. Fibroblasts in these tissues produce type I and type III collagens, the same types that are produced during healing. In general, these tissues can bear functional loads in multiple planar directions.^[16] Areolar and dense irregular connective tissues are highly vascular and innervated, which gives these tissues ready access to plasma proteins, nutrients, oxygen, and inflammatory cells.^[16]

Connective Tissues that Heal Moderately Well

The healing potential of dense regular CT, such as ligament and tendon, varies by environment, loading

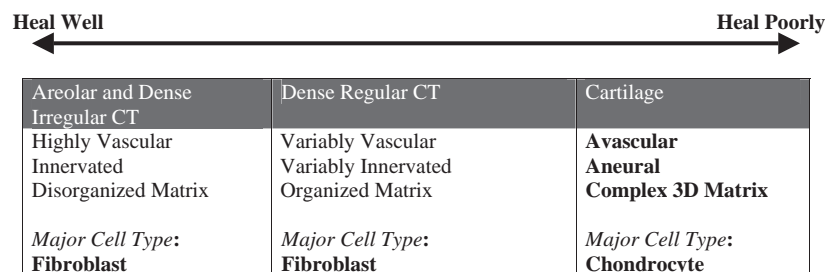

Fig. 3 Healing potential of soft CTs. Each CT heals to a different degree. Some heal very well, while others (such as articular cartilage) heal poorly or not at all. In general, healing potential correlates with the degree of innervation and vascularization of the tissue, and with the dominant cell type that is found within the tissue.

and complexity of the tissue. For example, ligaments that have a complex environment or reside within a joint capsule, such as the anterior cruciate ligament, do not heal well and often require surgical reconstruction.^[5] However, the extra-capsular ligaments (e.g., medial collateral ligament) heal without surgical intervention.

Most of these dense regular CTs heal moderately well with time. They have a highly organized matrix with tightly packed collagen fibers that align along an axis of load bearing. Examples are ligaments outside of joint capsules or tendons. These dense regular CTs have fewer fibroblasts than dense irregular or areolar CTs. Dense regular CTs tend to be poorly vascularized and moderately innervated, with the majority of nerves and vessels found in the outermost layers of the tissue (e.g., peritenon). During healing, a poorly organized matrix fills the injury, disrupting the normal fiber organization and reducing mechanical strength and stiffness. Long term, disorganization can leave the tissue at risk for further damage and compromise the overall health of a joint. Dense regular CTs do not heal to their original strength and stiffness. The resulting deficit can exist for many years following an injury.

Connective Tissues that Heal Incompletely

An example of a CT with severely limited healing potential is articular cartilage.^[9] Even small cartilage defects rarely heal on their own. Damage to articular cartilage can lead to premature osteoarthritis, which then causes pain and disrupts normal joint function. Mature cartilage differs from most other CTs in many ways. First, it does not have a blood, lymph, or nervous supply of its own.^[9] Second, in healthy cartilage the predominant cell type is the chondrocyte, which is responsible for maintaining the large portions of type II collagen and proteoglycans that are present in the normal tissue. These chondrocytes are surrounded by a dense ECM which keeps them sheltered even from immune recognition.^[9] Even though the chondrocytes continue to produce ECM throughout their lifespan, they do not respond to injury.^[18] Unless a cartilage injury involves the underlying bone, it only stimulates a brief and functionally insufficient response in cell proliferation and ECM production.^[18,22] This limited activity results in incomplete filling of the defect. When subchondral bone is involved in the injury it provides a blood supply to initiate a healing cascade. However, the injured region becomes infiltrated with fibroblasts (rather than chondrocytes), which fill the defect with fibrocartilage made of type I and type III collagens (rather than the original type II matrix) and with reduced level of aggrecan (a large proteoglycan to maintain hydration, even under large compressive

loads).^[22] The repair is less able to distribute compressive loads and resist wear than the highly specialized, articular cartilage tissue. Consequently, it is less able to resist joint degeneration and osteoarthritis. Larger cartilage defects frequently require surgical reconstruction or even joint replacement.^[22]

HEALING OUTCOMES

The “normal” healing process can only proceed when all of the cells, growth factors, and other chemicals are well coordinated both temporally and spatially. Alterations to this ‘normal’ cascade of events can result in delayed, incomplete, or pathological healing. Four categorical outcomes are associated with CT healing. They are normal repair (detailed above), excessive healing (extensive scarring), deficient healing (functionally deficient tissue), and complete regeneration.^[6] Excessive and deficient healing are pathological healing responses that occur when the orderly processes and conditions of healing are disrupted or absent.

Excessive Healing

Excessive healing, sometimes called fibrosis, occurs when too much ECM is deposited into the wound site. The result is an altered structure with pathological function. Clinical examples of excessive healing include keloids, hypertrophic scar, adhesions, contractures, cirrhosis, and nerve fiber blockage.^[6] Wounds with excessive healing generally express 2–3 times more TGF β -1 and 2–3 times more type I collagen than normal tissue.^[6,15] These wounds may also have an overabundance of myofibroblasts (causing excessive contracture) and increased mast cell density.

Deficient Healing

Deficient healing is the opposite of fibrosis. Insufficient ECM deposition into a wound leaves the tissue mechanically weakened. A common clinical example is a chronic ulcer, which is a nonhealing dermal wound. Deficient wounds may develop due to over-activity of inflammatory cells in the wound site.^[6] Ulcers are characterized by increased neutrophils, collagenase (an enzyme that degrades collagen), and reactive oxygen species. Deficient wounds do not heal until the inflammatory process is under control.^[6] Left untreated, an open wound site is prone to infection.

Regeneration

In contrast to wound repair, regeneration is the process by which injured tissue is replaced exactly as it was

before the injury. Most adult human tissues do not have complete regenerative capacities; however some adult organs will partially or completely regenerate when injured, including the liver, epidermis, some nerves, and bone. Fetal tissue can repair through regeneration.^[20] Interestingly, fetal tissue does not undergo the inflammatory process that takes place in adult tissues.^[20] By studying differences between adult and fetal tissues, science may learn how to regenerate injured adult CTs.

Tissue Engineering of Soft Connective Tissues

Tissue engineering methodologies are actively being sought to address healing deficiencies in soft CTs.^[9] For example, due to the limited of healing in articular cartilage (AC) and its critical role in joint motion, the need for an engineered repair tissue is particularly high. However, engineering AC repair is problematic because mature chondrocytes are slow to build or remodel tissue and because the ECM is micro-structurally and functionally complex. Cartilage ECM contains large quantities of type II collagen and proteoglycans. The resulting matrix attracts and holds water within the ECM, which stiffens the tissue for impact loads and also distributes contact pressure.^[9] Healthy cartilage is nearly wear-resistant and nearly frictionless. Fluid transport slowly allows more deformation (creep) during sustained loads.^[9] To engineer a repair tissue that mimics this behavior, the correct composition, hydration and organization of the ECM must be synthesized. Tissue engineering must then focus on (1) ways to attract, place, or differentiate chondrocytic cells into a cartilage defect with or without a matrix scaffold, and (2) ways to stimulate these cells to produce an appropriate ECM with collagen II and aggrecan. Undifferentiated mesenchymal cells can differentiate into chondrocytes and form cartilage with appropriate signaling. For example, mesenchymal cells exposed to TGF β -1 can be induced to differentiate into chondrocytes and form a cartilaginous matrix. In addition, the new chondrocytes must remodel and sustain the newly engineered tissue. Bone morphogenic protein-2 (BMP-2) and BMP-7 are potent stimulators of matrix proteins in cultured chondrocytes. However, recent studies show that the biological and mechanical behaviors of healthy AC are significantly altered in engineered cartilage.^[9] The compressive modulus of most engineered cartilage is substantially lower than healthy cartilage, although some improvement can be gained by controlled mechanical loading. Furthermore, gene expression of chondrocytes in healthy AC (e.g., type II collagen and aggrecan) is altered in engineered cartilage, including the undesirable upregulation of type I collagen.^[9]

While AC is only one example of tissue engineering, similar problems persist when engineering other CTs. Most engineered soft CTs have reduced potential for remodeling and integration into the surrounding healthy tissues. The result is a material that remains somewhat isolated from the native tissue. The remodeling of bone (discussed later) suggests that soft CT healing would benefit from a more optimal remodeling process. The “normal” healing process (Fig. 2) shows that temporally controlled signals to specific cell types are requisite to promote the “normal” healing cascade. A provisional matrix must be provided or generated to stabilize the wound until remodeling can restore a functional result in the neo-tissue. Angiogenesis is essential for healing of most tissues and its temporal stimulation appears necessary. Mechanical loading must be controlled, since it is stimulatory to the healing process and functional recovery of the CTs. All of these issues represent targets for tissue engineering to promote, accelerate, or improve soft CT healing.

BONE HEALING

Bone fracture healing involves an exquisite coordination of multiple cell and signal types. The early stages of this process are superficially similar to soft connective tissue healing (described above). However, unique processes in bone healing are required to form a dynamic mineralized tissue. To limit the scope of this discussion, only long bone fracture healing is considered. Long bones are perhaps the best characterized type of bone fracture, and their healing process includes aspects of both major classes of bone formation (i.e., endochondral ossification and intramembranous ossification).

CHARACTERISTICS OF BONE FRACTURE HEALING

Anatomy and Physiology of Long Bone Healing: General Definitions

Long bones include a long cylindrical shaft called the diaphysis, which is terminated on each end by an epiphysis. The diaphysis includes an inner bone marrow cavity, or medullary canal, surrounded by an outer cortex of compact or cortical bone. The epiphysis is surrounded by a shell of compact bone and contains an inner cavity filled with trabecular or spongy bone. A fibrous and cellular region, termed the periosteum, covers the outer surface of the cortex. Periosteum contains an outer fibrous layer, and an inner cellular layer, which houses bone precursor cells that become operative during fracture healing. There are two

general classes of bone formation. The first is intramembranous ossification, which primarily occurs during development of calvarial bones, and involves bone formation directly upon or within fibrous membranes that initially contain undifferentiated mesenchymal cells (Fig. 4). The second process is endochondral ossification, which occurs in growth and repair of long bones, and involves bone formation within a cartilage template matrix (Fig. 5).

Similarities to Soft Connective Tissue Healing: Soft Callus Formation

The early stages of fracture healing in long bones involve an array of spatially and temporally regulated events that culminate in stabilization of the defect with a fracture callus. The process can be separated into three processes (Fig. 6(1–3)), which overlap significantly, and in many cases occur simultaneously: (1) acute inflammatory response (hematoma), (2) bridging of the defect with soft callus (chondrogenesis), and (3) intramembranous ossification to form the hard callus. Each stage is vital for fracture stabilization. The first two stages have clear connections between these processes and the soft CT healing processes described previously. During the acute “inflammatory phase,” blood vessels are damaged and the fracture site is partially deprived of oxygen and nutrients that typically flow through the marrow and the bone matrix. In addition, the bone defect contains debris as a result of the trauma, and there is typically associated damage to the surrounding soft tissues. These events invoke an influx of inflammatory cells, including neutrophils, platelets, and macrophages, which initiate formation of a fibrous matrix, causing the periosteum to bulge outward. This mass of blood, debris, and cellular components, called a hematoma, forms within hours of fracture. In concert with this process, committed osteoblast precursors in the periosteum begin to proliferate and differentiate into mature osteoblasts. Concomitant with this inflammatory response, osteoblasts begin to form thin plates of woven bone in the periosteal region. This new “flat” bone tissue is formed via intramembranous ossification and is called bony callus.

In the days following this acute inflammatory response, factors secreted by infiltrating cells (e.g., macrophages, neutrophils) invoke ingrowth and proliferation of differentiated chondrocytes and undifferentiated mesenchymal cells, which are induced to differentiate into chondrocytes. This initiates a “proliferation phase” for cells in the area delineated by the initial hematoma, leading to synthesis of a cartilage soft callus. The soft callus and the bony callus stabilize

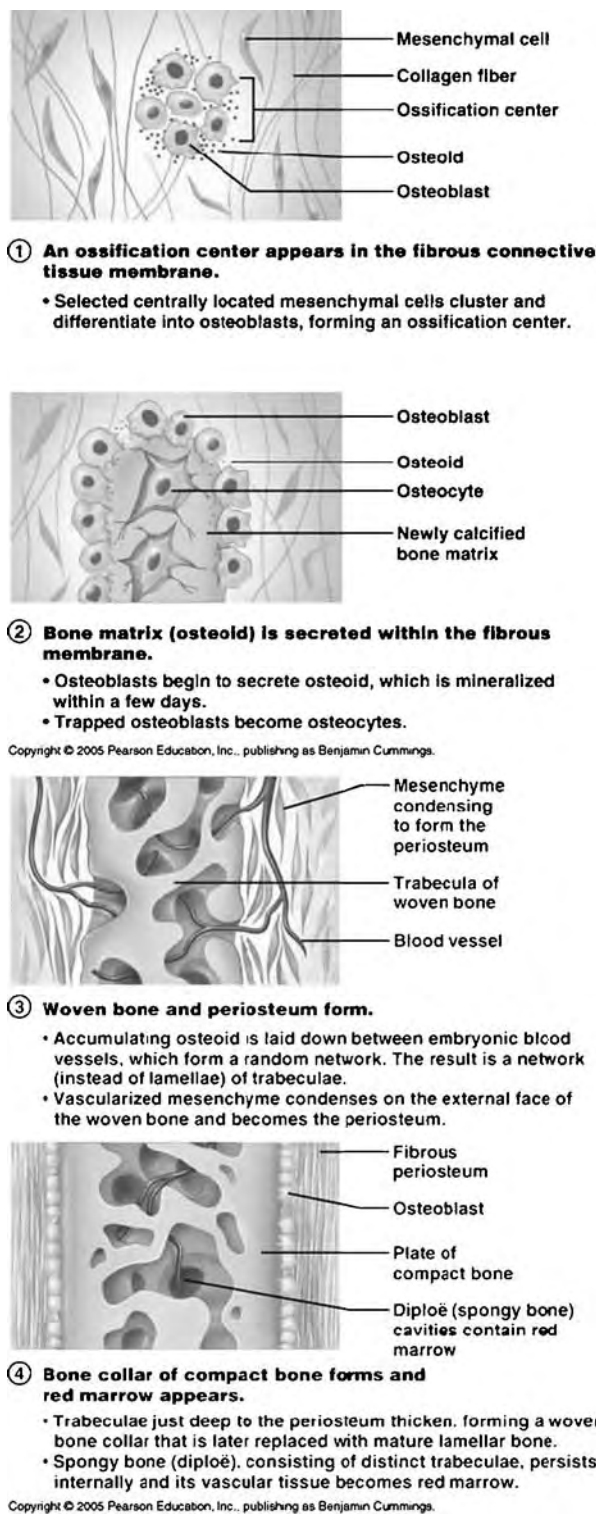

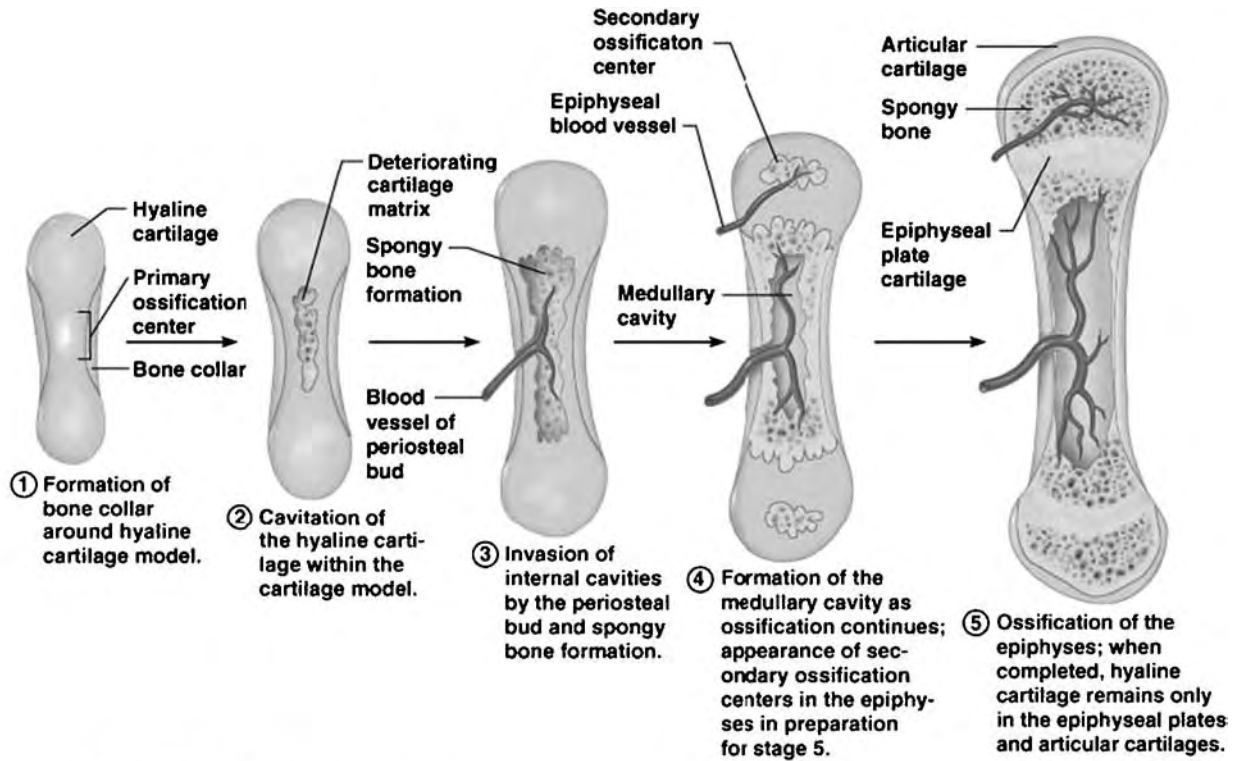

Fig. 4 Intramembranous ossification.^[16] Intramembranous ossification is a process that leads to the formation of the flat bones of the skull. During this process, bone forms within a fibrous membrane. A similar process occurs during the early stages of fracture healing to form a hard callus around the injured area.

Fig. 5 Endochondral ossification.^[16] Endochondral formation is a process that leads to the formation of long bones during development. During this process, cartilage forms to lay the structure of a bone. This cartilage calcifies and is then replaced by woven bone. A similar process takes place during fracture healing. In later stages of fracture healing, endochondral ossification replaces the soft callus that forms within the fracture site.

the fracture and provide a template for subsequent endochondral ossification. Remarkably, the entire, well-coordinated process of acute inflammation and bony and soft callus formation typically occurs within the first

2–3 weeks after bone fracture, and a variety of cells and inductive soluble signals orchestrate these events.

There are similarities between soft CT healing and the early stages of bone fracture. First, an initial

Copyright © 2005 Pearson Education, Inc., publishing as Benjamin Cummings.

Fig. 6 Fracture healing.^[16] Fracture healing occurs in overlapping stages, similar to the stages that occur during soft CT healing. Bone is unique, however, in that fracture healing includes ossification, the replacement of soft tissue with mineralized bone. In addition, the remodeling stage of fracture healing often leads to complete regeneration of bone into the site of repair.

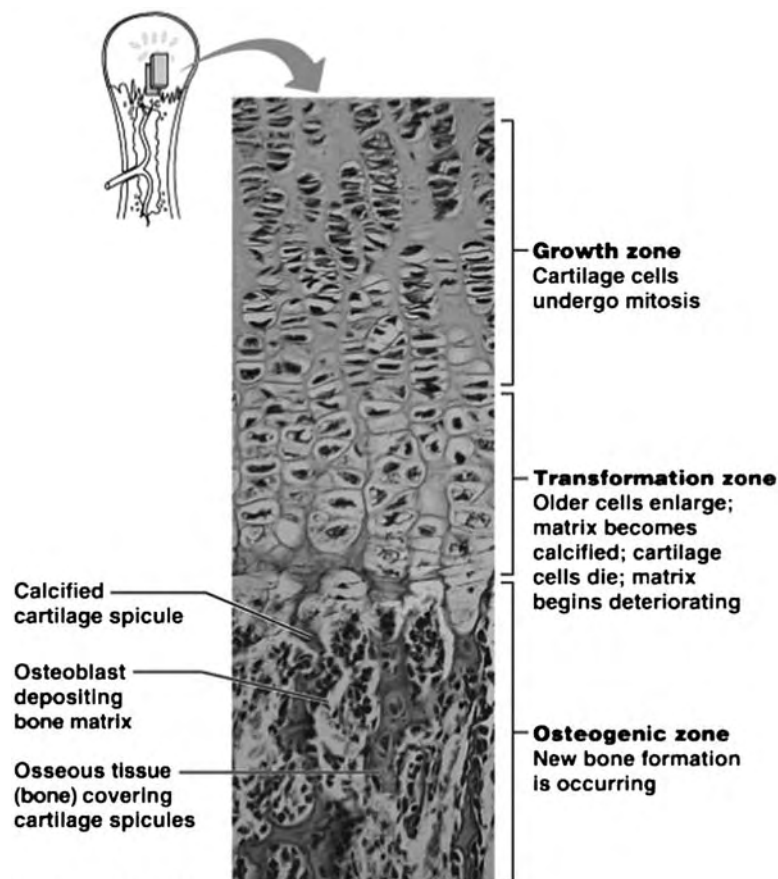

inflammatory response of the tissues to damage occurs. The initial 7–10 days after fracture involve formation of a hematoma, followed by inflammation and widespread proliferation of highly cellular fibrous tissues. The inflammation and proliferation processes are broadly similar to soft CTs. Second, many of the specific cell types involved in soft connective tissue healing are also operative during early bone healing. For example, undifferentiated fibroblasts (often termed “mesenchymal cells”) that reside in the bone marrow infiltrate bone defects within 24 h after fracture, and similar mesenchymal precursor cells enter bone defects from the periosteum within 72 h post fracture. These cells can differentiate into multiple cell types depending on environmental circumstances. Third, a provisional matrix is quickly established, providing a framework for subsequent remodeling of tissue and functional restoration.

Unique Characteristics of Bone Healing: Primary and Secondary Bone Formation

Despite the similarities between soft and hard connective tissue healing, there are also contrasts unique to bone. The primary distinctions stem from the ability

of bone cells to: (1) form mineralized tissue, either within a cartilage-based template matrix or within fibrous membranes (primary bone formation); and (2) remodel primary bone and ultimately regenerate the structure that existed prior to fracture (secondary bone formation). Primary bone formation in long bones occurs via endochondral ossification, and results in formation of a matrix of woven bone. Approximately 10 days post fracture, chondrocytes in the soft fracture callus enlarge or “hypertrophy” to form vesicular structures, and they begin to degenerate and stop synthesizing cartilage matrix. These hypertrophic chondrocytes then begin to degrade their existing matrix via secretion of proteases. This process leads to calcification of the matrix in a spatially-organized manner. The calcified cartilage then provides a substrate for synthesis of primary bone tissue by infiltrating osteoblasts, which form woven bone upon calcified cartilage substrates. The enlarged chondrocytes that remain then begin to undergo apoptosis, leading to a replacement of calcified cartilage with woven bone. The complete process of primary bone formation after fracture typically occurs in four weeks. The endochondral ossification that occurs during fracture healing is broadly similar to bone formation at the growth plate during long bone development (Fig. 7), in which

Fig. 7 Growth plate formation.^[16] During fracture healing, bone replaces cartilaginous structures that are initially laid down to structurally reinforce the area and restore normal anatomy. As bone replaces cartilage, the chondrocytes undergo changes, including hypertrophy. These changes are similar to the ones that take place during growth plate development (shown in this figure).

the region between the diaphysis and the epiphysis contains stacked layers of proliferating chondrocytes, hypertrophic chondrocytes, apoptotic chondrocytes, and primary woven bone.

An intriguing aspect of bone tissue repair is the ability of bone cells to remodel primary bone into a structure that is indistinguishable from the initial, intact bone. This process requires the coordinated activity of osteoclasts, which resorb the existing primary woven bone matrix, and osteoblasts, which synthesize new secondary bone tissue. The factors that influence bone remodeling are complex, extensive, and beyond the scope of this chapter. It is important to note, however, that this optimized remodeling process is a key aspect of bone healing that does not occur to the same extent in other CT healing.

CELLS AND SIGNALS IN THE FRACTURE CALLUS

Identity of Precursor Cells

Mesenchymal cells that migrate into the bone defect and differentiate into chondrocytes to form the cartilage-based soft callus, are thought to originate in the marrow, periosteum, and endosteum. These cells are capable of differentiating down several skeletal lineages; therefore, the signaling environment plays a prominent role in bone healing. Cellular components that direct inflammatory processes during the first hours and days post fracture are similar to those described earlier for soft CTs. Several of the key growth factor-producing cell types and corresponding growth factors are described below.

Key Soluble Signals

The acute inflammatory phase of fracture healing is characterized by infiltration of degranulating platelets, monocytes, and macrophages, each of which secrete important soluble signals. Degranulating platelets secrete platelet-derived growth factors (PDGFs), which promote growth of macrophages into the defect. In turn, monocytes and macrophages secrete fibroblast growth factors (FGFs) -1 and -2 and transforming growth factors (TGFs) - β 1 and - β 2, and thereby stimulate proliferation of fibroblasts, chondrocytes, and osteoblasts, as well as mesenchymal cells. Each soluble factor, along with vascular endothelial growth factor (VEGF), has a significant effect on the generation of a vascular supply within the defect (see “role of angiogenesis” section below).

CELLS AND SIGNALS DURING DEVELOPMENT OF PRIMARY BONE TISSUE

Bone fracture healing is a complex process that is tightly regulated in time and space by molecular and cellular effectors. The following provides an overview of signals vital to bone fracture healing, emphasizing signals that can be manipulated in tissue engineering.

Identity of Precursor Cells

Primary cell types that direct fracture healing are: (1) chondrocyte precursors from periosteum, endosteum and bone marrow, (2) osteoblast precursors from periosteum, (3) differentiated osteoblasts from bone matrix, and (4) undifferentiated mesenchymal cells derived from marrow and the periosteum. Chondrocytes are present in the defect area in the first days post fracture creating a cartilage template, which is ultimately remodeled and replaced with woven primary bone. Early in fracture healing osteoblast precursors from periosteum play a key role to form the bony callus. Osteoblasts also infiltrate the cartilage template to create woven bone via endochondral ossification. Mesenchymal cells are not committed to differentiate into a specific cell type, and therefore their ability to form cartilage callus or primary bone is strongly dependent on their microenvironment. For example, mesenchymal cells exposed to bone morphogenetic protein-2 (BMP-2) may be induced to differentiate into osteoblasts. A single injection of BMP-2 into a defect promotes generation of primary bone. In contrast, mesenchymal cells exposed to TGF β 1 may be induced to differentiate into chondrocytes and form cartilage. These examples demonstrate the importance of environmental factors for proper differentiation of mesenchymal cells during bone fracture healing.

Mechanical Signals

Mechanical forces influence remodeling of adult bone and, in turn, regulation of bone strength over time. The mechanobiology of bone is often summarized by Wolff's Law, which indicates that bone adapts to its mechanical environment by dynamic remodeling. The influence of mechanics on fracture healing is perhaps even more dramatic. Too much relative motion at the fracture site can result in a non-union, moderate motion in a stabilized fracture allows “normal” healing (Fig. 6), and very restricted motion can induce healing without robust callus formation. Mechanical stimulation is also vital to proper cartilage and bone development, and the mechanical properties of bone can be correlated to the load applied during development. Specifically, the mechanical environment influences

local gene expression by cells within a bone defect, and it is an important determinant of blood vessel ingrowth after bone fracture.^[4] Furthermore, mechanical forces have a pronounced effect on bone formation by osteoblasts and osteoblast precursor cells in cell and tissue culture.^[4] This evidence helps explain the role of mechanical forces during important fracture healing.

Role of Angiogenesis

Recent studies indicate that the growth of new blood vessels from a pre-existing vascular supply is particularly important for proper growth, regeneration, and healing of bone tissue.^[8,17] Blockage of angiogenesis inhibits endochondral ossification in the growth plate and also inhibits fracture healing. In addition, delivery of VEGF, a stimulator of angiogenesis, from materials in a critical bone defect has a positive effect on bone regeneration. There are several possible explanations for the positive effects of vascular ingrowth on bone generation. The vasculature may be vital to survival and proper function of pre-existing osteoblasts or may include cells that provide stimulatory signals to osteoblasts (e.g. endothelial cells). Alternatively, the vascular supply may be vital for differentiation of bone precursor cells or for recruitment of blood-borne stem cells capable of forming bone.^[13] For these reasons, and perhaps others, factors that influence ingrowth of a functional vascular supply are vital for proper growth, repair, and regeneration of bone tissue. These factors include the mechanical stability of a defect, as well as a variety of growth factors.

Roles in immune stimulation and fibroblast proliferation, several mediators of inflammation in the fracture callus also support fracture healing by inducing blood vessel growth into the callus. Growth factors that stimulate angiogenesis during fracture healing include FGF-2, PDGF-BB, BMP-2, BMP-4, BMP-7, and VEGF.^[1] VEGF is a particularly potent stimulator of angiogenesis, and it is synthesized by mesenchymal cells, osteoblasts, and chondrocytes during the first 7 days following fracture. Angiogenic factors also have direct effects on bone-forming cells. It is therefore difficult to specifically delineate the effects of growth factor-induced angiogenesis on bone healing. However, in the absence of VEGF bone does not heal or grow properly, and this effect has been largely attributed to inhibition of angiogenesis.

Key Soluble Signals

Compelling evidence in previous sections indicates that the mechanical environment and angiogenesis strongly influence fracture healing. However, the most potent direct effectors of bone regeneration may be

osteogenic growth factors. Soluble growth factors have widely variable effects on the cells that direct bone repair, as they can influence migration, proliferation, differentiation, and angiogenesis within a bone defect. The primary function of the factors secreted by cells during the inflammatory phase of fracture healing is to stimulate infiltration of appropriate cell and tissue types. Macrophages and platelets produce factors (e.g., PDGFs, TGF β s, FGFs), which invoke infiltration and proliferation of mesenchymal cells and chondrocytes in the fracture callus. These factors also stimulate angiogenesis, along with VEGF and tumor necrosis factor α (TNF α). The net effect of all of these factors is to load the fracture callus with chondrocytes, blood vessels, and undifferentiated mesenchymal cells, which creates an environment primed for the subsequent formation of primary bone.

Once a mature fracture callus has formed, cells produce several factors that more directly influence the activity of bone-forming cells (e.g., osteoblasts, and osteoblast precursor cells). Members of the TGF β superfamily of proteins, including TGF β -1, TGF β -3 and BMPs -2, -3, -4, -6, and -9, are particularly important in bone repair and regeneration.^[1,11] Although these factors affect chondrocyte and osteoblast proliferation as well as angiogenesis, their primary function is to induce differentiation of osteoprogenitor cells into functional osteoblasts. These factors exert their effects through serine/threonine kinase receptors on mesenchymal cells and pre-osteoblasts, setting off a signal transduction cascade that leads to expression of bone-specific transcription factors (e.g., Runx2/Cbfa1). These osteoblast precursor cells are then induced to become mature, bone-forming osteoblasts.

IMPLICATIONS FOR ENGINEERING TISSUE REGENERATION

Clinical Problems and Early Successes

The remarkable process of bone fracture healing portrayed in this chapter can be considered an optimal scenario, which is accurate in the large majority of fractures. However, failure of bone defects to heal (nonunion) occurs often enough to be a significant clinical problem. Bone loss can also be due to factors distinct from fracture, such as cancer resections, growth defects, and birth defects. The need for novel bone repair and replacement therapies is substantial, and continues to grow rapidly.

By understanding the healing processes, factors that affect bone healing may be exploited to promote de novo growth of bone tissue. For example, it is clear that protein growth factors are a vital component of the bone healing process, due to their effects on blood

vessel ingrowth and/or function on bone-forming cell types. These observations suggest that delivery systems should target protein growth factors to bone defect sites to improve or accelerate healing.^[14] Similarly, the influence of mechanics on bone fracture healing provides a mimetic basis for biomaterial scaffolds to support bone regeneration.

Opportunities in Mimicry of Natural Bone Healing

Despite significant progress towards directed bone regeneration, key aspects of the natural healing process have proven difficult to mimic (e.g., the timing of signaling molecules). Early secretion of growth factors related to chemotaxis and proliferation (e.g., FGFs, PDGFs) is followed by later secretion of factors that induce osteogenesis by bone precursor cells (e.g., VEGF, BMPs, TGF β). Similarly, early presence of immune cells and undifferentiated mesenchymal cells is followed by later presence of mature chondrocytes and osteoblasts. These characteristics of natural bone healing suggest that properly timed delivery of key growth factors or cells to a defect could significantly enhance healing or regeneration. The clear role of timing in proper bone healing represents an opportunity to develop approaches in which growth factor delivery, the presence of specific cell types, or the presence of blood vessels are temporally controlled.

Bone does not grow or heal properly when angiogenesis is artificially blocked.^[8,17] The importance of blood vessel ingrowth presents an opportunity to develop new approaches that promote angiogenesis in bone defects. Finally, participation of mesenchymal “stem” cells in natural bone healing suggests that these cells can be used in tissue engineering to regenerate bone (as well as other CTs) if they are properly delivered and exposed to appropriate signals.^[2] It is clear that multiple cell types derived from mesenchymal cells are involved in the early stages of bone healing and that mature bone contains multiple cell and tissue types.

Broader Implications for Regenerative Medicine

Despite the unique aspects of bone healing, there are central themes in the process that apply to healing of other CTs. The importance of precursor cells, the controlled presence of specific soluble signals, and the rapid promotion of angiogenesis are not unique to bone, or even unique to CTs. Precursor cells are a vital component of all tissue development processes and have been implicated in most regenerative processes in adult animals. Timed production and controlled concentration of inductive molecules (e.g., growth factors) is commonplace during development and regeneration of

a variety of tissue types, including neural, vascular, and cardiac tissues. In addition, angiogenesis is necessary to provide nutrients during development and regeneration of nearly all tissue types. Therefore, the lessons learned in a comprehensive analysis of bone healing apply to most CTs and to many other tissues. Approaches that mimic the complex process of bone healing using tissue engineering techniques are easily adaptable to healing of other CTs, as well as many other tissues.

CONCLUSIONS

This chapter provides a brief overview of wound healing in CTs and covers two broad topics: (1) healing stages and processes for soft CTs, and (2) the healing stages and processes for bone. The specific requirements all CT healing are discussed, including: (1) mechanical stability of the damaged tissues to initiate the healing process, (2) tissue specific and temporally staged cell and ECM signaling, (3) available cells (undifferentiated mesenchymal stem cells or tissue specific differentiated cells), (4) vascular and neural supply to support the entire process. The specific stages of soft CT healing are discussed, including: (1) hemostasis, (2) inflammation, (3) proliferation, and (4) remodeling. Also discussed are the unique processes of bone healing, including an optimized remodeling process that effectively regenerates the original tissue. Tissues that heal incompletely, or do not heal, have alterations to the “normal” processes or conditions, which in turn, can become targets for tissue engineering. But, these targets require an in-depth knowledge of conditions and signaling requirements, many of which are not completely defined. As these processes, as well as the biomimetic issues, are better elucidated, tissue engineering solutions will evolve in ways that benefit healing in all CTs.

Hearing Aids

Ian C. Bruce

Department of Electrical and Computer Engineering, McMaster University, Hamilton, Ontario, Canada

INTRODUCTION

A hearing aid is an electronic device for processing and amplifying sounds to compensate for hearing loss. The primary objective in hearing aid amplification is to make all speech sounds audible, without introducing any distortion or making sounds uncomfortably loud. Modern analog electronics have allowed hearing aids to achieve these goals and provide benefit to many sufferers of hearing loss. However, even if a hearing aid can reestablish audibility of speech sounds, normal speech intelligibility is often not fully restored, particularly when listening in a noisy environment. The development of digital hearing aids has opened the possibility of more sophisticated processing and amplification of sound. Speech-processing algorithms in digital hearing aids are being developed to better compensate for the degradation of speech information in the impaired ear and to detect and remove competing background noise.

NORMAL HEARING

The mammalian ear can be divided into three sections: the outer, middle, and inner ears (Fig. 1). The primary function of the outer ear is to funnel sound waves to the tympanic membrane (eardrum) in the middle ear. Vibrations of the eardrum caused by sound pressure waves are transferred to the oval window of the cochlea (inner ear) by the ossicles (articulated bones) of the middle ear. The mechanical system formed by the middle ear helps to create an acoustic impedance match, such that sound waves in the low-impedance air filling the external auditory canal are efficiently transmitted to the high-impedance fluid filling the cochlea, rather than being reflected back out of the ear.

Taking a cross section of the cochlea (Fig. 2) shows that it is divided into three compartments—the scala tympani, the scala media, and the scala vestibuli—each of which extends from the base to the apex of the cochlea. Sitting on the basilar membrane (dividing the scala tympani and scala media) is the organ of Corti, which houses the transducer cells of the cochlea, the outer and inner hair cells. The outer hair cells detect vibrations of the basilar membrane and produce amplification of those vibrations through a mechanism

known as electromotility.^[3] The inner hair cells synapse onto the auditory nerve fibers, which project to the auditory brainstem.

The transduction process from sound waves into neural impulses in the auditory nerve is illustrated in Fig. 3A. Motion of the oval window caused by middle ear movement creates a pressure difference across the basilar membrane. This pressure difference generates a wave that travels along the cochlea from the base toward the apex, causing displacement of the cilia of hair cells. Displacement of the cilia allows ionic currents to flow into a hair cell, modifying the receptor potential (i.e., the hair cell's transmembrane potential). In inner hair cells, this releases neurotransmitters to initiate neural impulses (discharges) in auditory nerve fibers, thus providing information to the brain about the sound vibrations received at the ear.

The mechanics of the basilar membrane are such that high-frequency sounds produce traveling waves that peak near the base of the cochlea and low-frequency sounds peak near the apex, as illustrated in Fig. 3B. Because each auditory nerve fiber synapses onto only one inner hair cell, each auditory nerve fiber encodes information about the basilar membrane vibration at one position in the cochlea. Consequently, auditory nerve fibers inherit the frequency-tuning properties of the cochlea, and each auditory nerve fiber has a best (or characteristic) frequency to which it responds.

Following from the transduction process described above, the auditory periphery is often regarded as a bank of band-pass filters. However, the electromotile behavior of healthy outer hair cells introduces important nonlinearities into the basilar membrane vibrations and the subsequent representation of sounds by auditory nerve fiber discharges. The predominant nonlinearity is compression, in which the basilar membrane vibrations do not grow linearly with sound intensity but rather are compressed for sound pressure levels (SPLs) between approximately 30 and 90 dB SPL.^[5] A related cochlear nonlinearity is suppression, in which the response to a sound frequency component is reduced because of the presence of a more intense component at a nearby frequency.^[5] Further nonlinearities are introduced by the inner hair cell and its synapse with an auditory nerve fiber. Auditory nerve responses exhibit adaptation that accentuates the

Fig. 1 Anatomy of the human ear, showing the division of the outer, middle, and inner ears. (A) pinna; (B) external auditory canal; (C) tympanic membrane (eardrum); (D) ossicles; (E) eustachian tube; (F) cochlea; and (G) auditory (cochlear) nerve. (From Ref. [1].)

onsets and offsets of sound components, and rectification and saturation are observed in auditory nerve discharge rates. This collection of nonlinearities is important in forming the neural representation of speech sounds.^[4,6]

HEARING LOSS

The two most common forms of hearing loss are conductive loss, which refers to dysfunction of the outer or middle ear, and sensorineural loss, in which

Fig. 2 A cross section of the human cochlea. (From Ref. [2].)

Fig. 3 (A) Schematic summarizing the transduction process in the mammalian cochlea, and (B) Illustration of the tonotopic organization of the cochlea. (From Ref. [4].)

the inner ear or the auditory pathways of the brain are impaired. The outer and middle ears are largely linear systems, and consequently, conductive dysfunction typically produces a simple linear reduction in the amplitude of acoustic signals as they are transmitted to the inner ear. Thus, loud sounds become quieter and quiet sounds may become inaudible. In contrast, the effects of sensorineural loss are more multifaceted. Because the cochlea is a highly nonlinear system, any impairment of cochlear structures (particularly the inner and outer hair cells) can lead to substantial distortion in the neural representation of acoustic signals, in addition to loss of audibility. Common causes of sensorineural impairment include exposure to loud sounds, aging, disease, head injury, and ototoxic drugs. At present, there are no medical or surgical cures for most forms of sensorineural hearing loss.

The loss of audibility of quiet sounds, either from conductive or sensorineural loss, is quantified by hearing thresholds. The hearing threshold is a measure of the SPL required for a tone of a particular frequency to be just audible to a listener. Hearing thresholds are computed using a decibel scale relative to the hearing thresholds of normal hearing listeners, referred to as decibel hearing level (dB HL). A pure-tone audiogram

is a plot of hearing thresholds as a function of tone frequency with -10 dB HL at the top and 110 dB HL at the bottom. An example audiogram is given in Fig. 4. By convention, the hearing thresholds for the left ear (LE) are plotted as Xs and those for the right ear (RE) as Os.

The degree of hearing loss is often categorized according to the pure tone average (PTA), which is the average of the hearing thresholds at 500 , 1000 , and 2000 Hz, the most important frequencies for understanding speech. A typical classification scheme for adults is:

0–25 dB HL	Normal limits
25–40 dB HL	Mild loss
40–55 dB HL	Moderate loss
55–70 dB HL	Moderate-to-severe loss
70–90 dB HL	Severe loss
90+ dB HL	Profound loss

Alternative classification schemes are also used, particularly for categorizing hearing impairment in children. The example audiogram given in Fig. 4 shows a bilateral, asymmetrical hearing loss, with a mild loss in the LE (PTA = 33 dB HL) and a moderate-to-severe high-frequency loss in the RE (PTA = 61 dB HL). The elevation of hearing thresholds with sensorineural loss can be well explained by the loss of auditory nerve

Fig. 4 An example audiogram showing hearing thresholds for the left ear (LE) and right ear (RE) of an individual with hearing loss.

sensitivity with dysfunction of the inner and outer hair cells.^[4,6]

There are several other aspects of sensorineural hearing impairment that are not captured by the audiogram, including reduction in the dynamic range of hearing, decreased frequency resolution, and decreased temporal resolution. Many of these perceptual impairments can be explained from the direct effects of damaged inner and outer hair cells on the transduction process in the auditory periphery, but the effects of sensorineural hearing loss on the central auditory pathways of the brain should also be taken into consideration.

The reduction in dynamic range for a hearing impaired listener is often referred to as “loudness recruitment.” In this phenomenon, the audibility threshold is elevated at a frequency suffering from hearing loss, but the intensity at which a tone at that frequency becomes uncomfortably loud is relatively normal. That is, there is an abnormally steep growth of loudness with stimulus intensity. This causes difficulties for prescribing gain in a linear amplification scheme for hearing aids: If quiet sounds are amplified enough to restore audibility, then loud sounds may be amplified to uncomfortably loud levels. It has long been presumed that loudness recruitment is owing to the more rapid growth of auditory nerve discharge rates with sound level because of loss of cochlear compression. However, recent physiological data contradict this theory and suggest that central mechanisms are required to explain loudness recruitment.^[7]

Decreased frequency and temporal resolution and reduced nonlinearities (such as compression and suppression) in an impaired cochlea lead to distortions in the neural representation of a single sound^[4,6,8] and to difficulties in separating out different sound sources in the complex acoustic “soundscape” in which we operate daily. For example, it has been shown that after loss of audibility is accounted for, individuals with hearing loss still require a higher signal-to-noise ratio (SNR) to understand speech with the same accuracy as those without hearing loss.^[9] Linear amplification schemes cannot compensate for such distortions; more sophisticated speech-processing algorithms will be required.

HISTORY OF HEARING AIDS

The first devices for amplifying speech were acoustic ear trumpets, a range of which was available by the 1600s. These used a tapered horn to collect sounds and funnel them to the ear. In addition to providing some amplification, ear trumpets could increase the SNR if the opening of the trumpet was pointed toward the talker. Around 1900, carbon hearing aids were

developed that consisted of a carbon microphone, a battery, and a magnetic receiver (a miniature loud-speaker), which could produce a gain of around 20 to 30 dB. A pair of carbon hearing aids joined in series, with the coupled magnetic receiver and carbon microphone referred to as a carbon amplifier, could generate even greater gain. In 1920, the carbon amplifier was replaced by a vacuum tube electronic amplifier, which had superior amplification capabilities, but the vacuum tubes required two large batteries to operate. It was not until 1944 that vacuum tubes and batteries became small enough to manufacture a one-piece body-worn hearing aid. During this time, carbon microphones were superseded by magnetic and piezoelectric microphones.

Immediately following the invention of the transistor, head-worn hearing aids using transistor amplifiers instead of vacuum tubes (and consequently smaller batteries) were introduced in the early 1950s. The behind-the-ear (BTE) hearing aid (as shown in the top panel of Fig. 5) was the dominant style for several decades. The invention of the integrated circuit and the electret microphone in the 1960s and 1970s lead to further miniaturization of hearing aid components and the increasing use of in-the-ear (ITE) style hearing aids

Fig. 5 Modern hearing aid styles: behind-the-ear (BTE); in-the-ear (ITE); in-the-canal (ITC); and completely-in-the-canal (CIC) Not shown is the earmold that connects to the BTE ear hook via a tube to deliver amplified sounds to the ear canal. (From Ref. [10].)

(shown in the bottom panel of Fig. 5). Continued reductions in component sizes lead to the introduction of smaller in-the-canal (ITC) and completely-in-the-canal (CIC) hearing aids (shown in Fig. 5) in the 1980s and 1990s. In the same time period, steady advances in the electronics of microphones, amplifiers, and receivers produced improvements in the fidelity of the audio processing by analog hearing aids. Recently, analog amplifiers have been replaced by digital signal processor (DSP) chips, allowing much more sophisticated amplification and processing of sounds by hearing aids.

MODERN HEARING AID STYLES

Current hearing aids are available in a range of styles from BTE to CIC. The typical locations of components in an ITC and a BTE hearing aid are illustrated in Fig. 6. The BTE aid delivers the amplified sound to the ear through an earmold (or earshell), which connects to the BTE ear hook via a sound tube.

Fig. 6 Typical component placement in an ITE A) and BTE B) hearing aid. Note that the amplifier is not shown in the ITE diagram. (From Ref. [10].)

Molds or shells are typically custom-made from an impression of the hearing aid user's ear, which leads to a comfortable fit in the ear canal and minimization of sound leakage around the mold or shell. Air vents are desirable in an ITE shell or BTE earmold to prevent moisture build-up in the residual canal (i.e., the air between the hearing aid and the ear drum) and to reduce the occlusion effect, in which low-frequency bone-conducted sounds (particularly the hearing aid user's own speech) resonate in the residual canal. However, venting provides an additional pathway for sounds to enter the ear and for amplified sounds coming from the receiver to exit the ear. This alters the effective frequency response of the hearing aid and provides an additional pathway for acoustic feedback from the receiver to the microphone, which can lead to feedback oscillations (whistling).

The smaller devices are less conspicuous and consequently are more cosmetically appealing to many hearing aid users. However, the larger devices can typically provide superior amplification and sound processing capabilities, because more powerful electronics can be packaged in the hearing aid. Another advantage of the larger styles is the greater physical separation between the receiver sound outlet and the microphone, which may help reduce acoustic feedback oscillations.

LINEAR AMPLIFICATION, COMPRESSION, AND FEEDBACK SUPPRESSION

The simplest approach to amplification in hearing aids is to apply a linear gain at each frequency that is dependent on the hearing loss at that frequency. As a rule of thumb, a linear gain of 75% of any conductive hearing loss and around 50% of any sensorineural loss should be applied. These general rules have been refined greatly through experimental testing to give a number of different amplification prescription formulas, which audiologists use as a starting point when fitting hearing aids. Recent results with a computational model of the auditory periphery suggest that these fitting rules are effectively restoring the average auditory nerve response to speech.^[11]

However, linear amplification may not be optimal, because of distortions that can be produced by waveform peak clipping in the amplifier or receiver at high input sound levels and because of loudness recruitment in an ear with sensorineural impairment. Reduction of the amplifier gain as a function of the input or output signal level via a fast-acting automatic gain control (AGC) is referred to as compression; slow-acting AGC can be used as an automatic volume control. Peak clipping at high levels can be avoided via compression limiting, in which the gain is reduced so that the output

level does not exceed some specified limit. Compression that acts over the normal range of speech sound levels is referred to as wide-dynamic-range compression (WDRC). An example of an input/output curve for a compression system is shown in Fig. 7A, with the gain vs. input level shown in panel B. Here, a gain of 30 dB is applied for all input signals that are lower than 40 dB SPL, the knee-point (threshold) of the WDRC. Above 40 dB SPL, the gain of the amplifier is reduced by 10 dB for each 20 dB increase in the input level, corresponding to a compression ratio of 2:1. At an input level of 100 dB SPL, the gain has consequently been reduced to 0 dB, i.e., no

Fig. 7 Example static characteristics of a compression system. (A) Input/output curve for a system with wide-dynamic-range compression (WDRC) with a 2:1 compression ratio for input levels above 40 dB SPL and compression limiting at an output level of 100 dB SPL, and (B) The amplifier gain vs. input-level function required to achieve the compression characteristics described in panel A.

amplification is applied. Compression limiting is applied for input levels above 100 dB SPL, so that the output level cannot exceed 100 dB SPL.

Compression can be applied identically to all frequencies, referred to as single-channel compression, or individually to different frequency bands, referred to as multiband compression. The motivation for multiband compression is that the amount of hearing loss may vary substantially between different frequency bands, and thus the desired compression characteristics may differ between frequency bands. However, multiband compression will tend to flatten out the frequency spectra of sounds, possibly making it harder to distinguish different sounds. Some multiband compression schemes have been developed to try to reduce spectral flattening.^[12,13]

In addition to the static compression characteristics described by the input/output curve, the rate at which the gain is adjusted with changes in the input (or output) signal level determines the dynamic characteristics of a compression system. The time it takes for a compressor to react to an increase in the signal level is referred to as the attack time, and the release time corresponds to the time taken to react to a decrease in signal level. By adjusting the attack and release times, as well as the static compression characteristics, it is possible for compression systems to avoid distorted and uncomfortably loud signals, to reduce the intensity differences between phonemes or syllables, to provide automatic volume control, to increase sound comfort, to normalize loudness, to maximize intelligibility, or to reduce background noise.^[10] Unfortunately, the required compression parameters are very different for each of these goals, and consequently any one compression scheme tends to provide benefit in some but not all aspects of compensating for hearing impairment.

A further use of AGC is to suppress acoustic feedback oscillations, if they can be reliably detected. Reduction of feedback oscillations can also be achieved via automatic phase control, via an internal (i.e., electronic) feedback path to cancel the external (i.e., unintentional acoustic) feedback path, or via frequency shifting by the amplifier to prevent the build-up of oscillations at a particular frequency. With the advent of digital hearing aids, more effective feedback suppression has been obtainable. This has permitted larger vents in earmolds and shells, reducing occlusion effects and providing more comfort to hearing aid users.

ADVANCED PROCESSING ALGORITHMS

To this date, no amplification and compression scheme has been found that can fully compensate for the

effects of sensorineural impairment in individuals with moderate-to-profound hearing loss. Consequently, a number of signal-processing algorithms have been developed to make the task of listening easier for hearing aid users. Although some of these processing strategies could be implemented with analog electronics, the processing power and flexibility of DSPs have greatly increased the number and effectiveness of advanced processing algorithms that can be realized in hearing aids.

One class of algorithm now widely used in hearing aids is referred to as single-microphone noise reduction. These algorithms attempt to detect and separate the components of the signal received by the hearing aid microphone that can be attributed to a talker (to whom the listener wishes to attend) and to “background noise” (which the listener wishes to ignore). Single-microphone noise reduction typically works well when the background noise sources have acoustic properties that are very different from speech and do not vary much over time, but these algorithms have difficulty when the noise sources are speech-like or vary rapidly, as is the case in most real-world listening conditions. A further problem with noise reduction is removing the noise components from a signal without degrading or distorting the target speech components, which could lead to loss of speech intelligibility. Consequently, single-microphone noise reduction algorithms in hearing aids are typically aimed at improving listening ease and comfort, rather than increasing speech intelligibility.

However, noise reduction that leads to intelligibility improvements can be obtained through the use of directional microphones and multiple-microphone algorithms known as beamformers. In this class of algorithms, sounds arriving from a desired direction (typically the direction the hearing aid user is facing) pass through unaltered, but sounds arriving from other directions are attenuated. Some hearing aids utilize microphones with fixed directionality patterns, while others electronically combine signals from multiple microphones such that the directionality can be switched. Adaptive beamformers attempt to detect noise sources and dynamically vary the directionality pattern to cancel them out.

For hearing aid users with very sharply sloping high-frequency losses, transposition of high-frequency components to lower frequencies can provide some improved speech clarity and intelligibility. However, only moderate shifts in frequency are possible, or the frequency spectra of sounds will become too distorted. An added benefit of frequency transposition is the reduction in acoustic feedback oscillations, as mentioned previously.

In various listening environments, different amplification, compression, noise reduction, and directionality

schemes may be required. Even before the introduction of fully digital hearing aids, digital memories for analog hearing aid parameters enabled users to manually switch between different parameter sets (referred to as “programs”) in different listening situations. Some hearing aids now use acoustic classification algorithms to detect the listening environment and automatically switch to the preferred program for that situation. The accuracy of algorithms in implementing automatic volume control and feedback suppression has meant that many hearing aids are now available without a manual volume control.

HEARING AID USAGE

Hearing aids can be a viable form of treatment for individuals with any degree of hearing loss, although those with profound losses are good candidates for cochlear implants. However, the audiogram itself is typically not a good guide to how much benefit will be gained from hearing aid use. In some cases, individuals with hearing thresholds small enough to be classified as “normal” may benefit from hearing aids if they experience hearing difficulties in everyday life. The prevalence of hearing loss in most developed countries is reported to be around 10% of the population. However, regular hearing aid usage is often as low as 20% in the hearing-impaired population. In addition, many cases of mild-to-moderate loss may be undiagnosed or not acknowledged by the sufferer. Overall user satisfaction with hearing aids remained around 59% from 1991 to 2001.^[14] While problems such as hearing aid fit, comfort, and price contribute to customer dissatisfaction, the major concern is lack of benefit in understanding speech, particularly in noisy listening environments. This indicates that there is substantial room for improvement in amplification and processing of speech by hearing aids.

FUTURE DIRECTIONS IN HEARING AIDS

Because linear amplification and conventional compression schemes do not appear to fully compensate for the effects of sensorineural hearing loss in many hearing aid users, there is growing interest in modeling the effects of cochlear impairment to develop sophisticated nonlinear amplification algorithms that maximally restore the neural representation of sounds to normal.^[4,6,8,11,13,15,16] The difficulties in applying this approach include how accurate the model of the ear needs to be, what amplification schemes should be considered, and how impairment of the neural representation should be measured. Simplified

cochlear models can lead to more straightforward amplification schemes, but important features of the normal and impaired neural representation of sounds may be neglected. On the other hand, a more detailed neural representation can lead to problems with choosing a suitable amplification scheme and a suitable metric of impairment. The latter difficulty has led to several investigations into how well models of the ear and subsequent neural processing can predict human speech intelligibility.^[17,18] As we gain a greater understanding of how the ear and brain process speech in normal and impaired cases, we will better know what approaches to amplification can optimally compensate for a particular hearing impairment.

Many hearing aid users have a bilateral loss and consequently wear a hearing aid in each ear. Hearing aid manufacturers are now developing wireless data links between digital hearing aids to facilitate coordinated processing by the devices in each ear. At low data-transfer rates, this will enable coordinated device programming and synchronized program switching. As higher data rates become feasible, it will be possible to transmit audio signals between hearing aids to perform beamforming and other binaural signal processing based on the signals received by the microphones in each ear. A high-rate wireless data system will also permit transmission of high-quality audio signals to a hearing aid from other audio devices such as telephones, televisions, car and home stereos, public address systems, and MP3 players.

CONCLUSIONS

Hearing loss can be a debilitating impairment in daily life, greatly affecting social interaction and making many work situations difficult. Until a cure for sensorineural hearing loss is discovered, hearing aids remain the primary treatment option for the hearing-impaired population. Continued innovations over more than a century have led to modern hearing aids that can provide benefit for many hearing-impaired individuals. However, hearing aids still cannot fully compensate for the effects of hearing loss to the same degree that, for example, eye glasses can compensate for the most common forms of visual impairment. Further improvements in amplification and speech processing by hearing aids are under investigation, while at the same time medical treatments for hearing loss are being pursued.

Hearing Mechanisms

Martin L. Lenhardt

Biomedical Engineering, Otolaryngology and Emergency Medicine, Virginia Commonwealth University, Richmond, Virginia, U.S.A.

INTRODUCTION

Helen Keller felt her deafness was far more of a handicap than her blindness in that deafness resulted in her social isolation. As the population ages, hearing loss, if not adequately remediated, will continue to socially isolate by impairing communicative interaction. Noise exposure is clearly a contributing factor to hearing loss, but so are ototoxic drugs, diseases, unhealthy lifestyles, and aging. Hearing aids offer the hope of enhancing social communication by providing appropriate level of amplification to the damaged ear. Simple amplification has been only partially successful, since only about 20 percent of the people who could benefit from aids actually use them. It was commonly accepted dogma that the rejection of hearing aids by the general population was attributed to cosmetics—too big, too bulky, too visible—but the true culprit was less-than-expected performance, more specifically, poor performance in ambient or reverberant noise when communicative demands were the highest. Microelectronics and miniaturization are ushering in instruments that are small with excellent performance. Design inspirations for innovation in size and performance have come from unexpected sources, one of which is from how unique animals have used sound to survive and prosper for hundreds of thousands of years. State-of-the-art digital acoustical processing intermixed with biologically inspired designs are beginning to propel hearing aids from something in your grandmother's drawer to vogue, wearable computing devices.

OVERVIEW

Biologically inspired approaches are providing new insights into amplification. The hearing aid is now becoming more than an amplifier; it is a digital device to preprocess speech before it is actually fed into the ear. Inspiration is all around us. For example, a small fly is a source for innovation in hearing aid microphone design. The fly, *Ormia ochracea*, can localize sound with about the same precision as humans using two small eardrums that are so close they almost touch. These eardrums, unlike those in humans, are

torsionally coupled or uncoupled such that the fly obtains information on the average sound displacement impinging on the eardrums as well as the difference. Differential coupling between two different modes of resonance of each drum provides the localization cues. The fly, sensitive to acoustic particle displacement, has only about 100 neurons for coding auditory information, contrasted to 30,000 in normal hearing humans. Neural thresholds vary from 55 to 95 dB sound pressure level (SPL); these thresholds are characteristic of moderate to severe deafness in human terms. Using silicon MEMS technology, a 1- by 2-mm silicon nitride microphone diaphragm has been developed to emulate the fly's hearing system,^[1] which, when connected in an array, can potentially advance hearing aid performance in noise, a very real human problem in understanding speech.

It is important to recognize that human auditory experience is very much different from that of all other animals in that much of our brain is specialized for processing speech and language. Acoustic detection and processing strategies, honed by selective environmental pressure to survive and reproduce, are variations and deviations from hearing mechanics evolved over millions of years. Vertebrates, especially those with restricted hearing by human terms, may offer novel biologically-based hearing aid designs. It is helpful at this point to define hearing in a universal vertebrate sense.

Hearing is the detection of far-field pressure waves, but also near-field particle movement as well as vibratory displacement. The receptor must, by definition of acoustic or auditory, be specialized and most sensitive to sound/vibration. So mechanical disturbances that are either distant (pressure), close (near field), or very close (substrate vibration) and that act on a specialized receptor can result in hearing. It is not helpful to define the ear as solely a hearing organ since the inner ear contains sensors that are stimulated by gravity, orientation, acceleration, and vibration. It is this multiplicity and redundancy in inner-ear function that offers hope for listeners with hearing impairment.

Fish have inner ears with four receptors that can detect sound. The macula neglecta is sensitive to near-field displacement, the saccule or utricle (in the hearing family) is a specialized sound detector, and some

fish have a lagena with adaptation for sound pressure detection. Excluded from the list is the lateral line sensitive to bulk fluid displacement and the variety of tactile receptors that could be activated by vibration. Why are there multiple sound detectors? Part of the answer lies in the very conservative feature of the sound sensors in the ear, the hair cell. Hair cells from fish, amphibians, reptiles, birds, or humans are very similar. The mechanical coupling is quite different; however, if enough energy is applied to the ear, in the proper way, some receptor will be driven. This leads to the obvious question: Do humans have more receptors in their ears that can be recruited into the hearing process? Answering comes by way of two examples from studies of deafened animals. Destroying the cochlea in guinea pigs does not create total deafness. The saccule, a vestibular detector of linear acceleration in the z plane, responds to sound and its presence is uncovered with cochlear destruction. The saccule responds to a wide range of sounds at levels exceeding the loss due to poor bodily coupling to airborne sound.^[2] The human saccule responds best to frequencies between 200 and 400 Hz at about 100 dB.^[3] The saccule has the frequency sensitivity to code some aspects of speech as the envelope, prosody, and possibly the fundamental and first harmonic, so why are there not saccular hearing aids?

Pigeons with ablated cochleae too can maintain hearing if a new window is created in one of the semicircular canal walls. The semicircular canals also contain hair cell receptors specialized for rotation detection. The window allows bulk fluid movement induced by sound. Since the fluid is incompressible, creating a new window or fenestration is needed to allow cilia displacement. The fenestration of the canal wall in deaf humans produces near normal hearing. Postoperatively, when stimulated by bone conduction, all patients with this procedure had only mild hearing losses (35–40 dB HL). These patients quickly habituated to initial dizziness, but had very poor speech discrimination.^[4] Clearly, the canal nerves are not wired to the auditory areas of the brain as with the saccule, but the restoration of hearing is most impressive.

In canal fenestration, sound, when presented to the skull as bone conduction, was the most effective mode of hearing. Bone conduction is a phylogenetic old means of hearing that has fallen into disuse in the hearing industry over the last 30 years. In the mid-1960s, almost half the hearing aids manufactured were bone conduction devices incorporated into glasses frames. Performance was not the issue, but as frames became smaller and lighter, they were less cosmetically adaptable as amplification platforms. Bone conduction hearing aids are still produced for middle-ear abnormalities and a few glasses configurations are also

available. One obvious advantage of bone conduction glasses is the application of microphone arrays for better processing of speech in noise. Certainly a saccular hearing aid is a possibility and the most effective sound route could be by bone conduction. The bone transducer is usually mounted to the skin by a band, but it can also be placed on a titanium screw permanently affixed into the skull. Bone-anchored hearing devices are commercially available and provide an alternative to skin placement.

Hearing on land started with bone conduction. When vertebrates moved from an aquatic habitat to a terrestrial one, the only option for hearing available was detecting substrate vibration. Vibrations were conducted through the bones of the body to the inner ear, i.e., bone conduction. The mechanism of hearing by bone conduction is experienced by all of us when we couple our heads to a vibrating surface. The process of hearing is different hearing by conventional air conduction. The head is first set into vibration and the bones (ossicles) in the middle ear lag behind due to inertia. The resulting phase difference between the head and ossicles results in mechanical stimulation of the cochlea. The eardrum, in bone conduction hearing, acts as a damper. All primitive reptiles, including the extinct forms, likely heard by bone conduction.

Reptiles in the mammalian line of evolution were small, thin-boned, and nocturnal. There was selective environmental pressure to detect the other world of sound in the much less dense medium of air. Mammals evolved air conduction hearing through a series of processes that turned the output of bone conduction hearing, the eardrum, into a sensitive input for aerial sound pressure. Driving aerial hearing was the need to detect species-specific vocalizations and localize them in space at a distance. Hearing evolved into a distance sensor in mammals and birds. The central auditory nervous system evolved as well into parallel neural pathways to separate and selectively attend to one signal embedded in ambient noise. Hearing takes place in our brains not in our ears. So the phylogenetic story of hearing is a change from bone conduction to air conduction and a progressive expansion of sound sensitivity at ever higher frequencies. Interestingly, the natural history of human hearing loss is a gradual collapsing of both sensitivity and frequency range. So losing hearing is much like sliding back down the evolutionary ladder.

THE EAR

The middle ear is a remnant of when vertebrates made the transition from water to land. Stem reptiles, the presumed common ancestor to present-day reptiles, birds, and mammals, had massive middle-ear bones.

Adding mass to an inertial bone conduction system improved substrate detections but rendered these animals effectively deaf to airborne sound. There were survival and reproductive advantages for reptiles to detect sounds in the air. This was accomplished by a gradual thinning and stiffening of the eardrum and lightening of the ossicle. It was the relative size of the drum in reference to the cochlear window (oval) that allowed for adequate impedance matching of vibration in air with that of the cochlear fluid/basilar membrane. Humans recover approximately 35 dB of the sound that would be lost due to the impedance mismatch. The middle-ear is not, however, a perfect transformer and is most effective at or near its resonance and much less effective above that point. Middle-ear resonance can be modeled as a Helmholtz resonator. The middle ear and the ear canal have been shown by modeling and direct measurements to possess a coupled resonance of about 2.9 kHz. The frequency response of the canal alone and the middle ear are depicted in Fig. 1. Note that the middle ear acts as a low-pass filter, attenuating frequencies above resonance at about 27 dB per octave. A similar high-frequency slope is seen in lizards, birds, and some mammals. Hearing aids, when coupled to the canal, eliminate the canal resonance gain and generally have a similar output-frequency slope. The middle ear attenuates high-frequency consonant sounds in reference to low-frequency sound and limits high-frequency emphasis hearing aid gain. Looking ahead, it is the high-frequency sounds that are the salient speech cues in regard to speech intelligibility, and it is these speech sounds that are attenuated by a low-pass middle-ear filter and sensory loss.

Resting on the basilar membrane in the inner ear are two types of sensory hair cells (see Fig. 3 in the article

Fig. 1 The frequency responses of the human ear canal and middle ear are contrasted with that of a typical hearing aid with a 50-dB SPL input. Note all act as effective low-pass filters.

Inner Ear Implants, p. 849), outer (OHCs), and inner (IHCs). The IHCs are sensory, but the OHCs are sensory and motor. OHCs change their volumes when stimulated by the brain, becoming active cochlear tuners/amplifiers. The basilar membrane is nonlinear in its vibratory response as a result of the contractive action of OHCs.^[5] That is, OHCs change the BM net stiffness, resulting in mechanical amplification to the IHCs. Without the motor action of OHCs, IHCs would respond only over a narrow intensity range. The OHCs allow for an expansion of sound dynamic range through compression and, conversely, a loss of OHCs produces hearing loss and loss of the range compression. IHCs respond over the range of about 70 dB (50 to 120 dB). IHCs in conjunction with OHC, respond over a range of 120 dB, that is, have a gain of 120 dB. Thus, OHCs compress the sounds coming into the ear to the IHCs, allowing an expanded dynamic range of about 110 dB, i.e., from just detectable to almost painful. Irreversible OHC loss is the first sign of cochlear injury resulting in hearing loss. In the normal cochlea, the OHCs control the growth of loudness and are an adaptive component for analyzing dynamic acoustic changes over time, the nature of our sound environment.

CORRECT FOR AUDIBILITY OR LOUDNESS

If there is a loss of OHCs resulting in less compression, there will be a reduction in hearing range, a hearing loss. Simple amplification to correct for this threshold or range deficit was assumed to be sufficient. Fixed or linear amplification was found to be insufficient and it represented a faulty strategy in all but the most severely deafened in whom auditory expectations were low. For a hearing aid to meet the impaired listeners' demands, it must keep soft sound audible but still soft, and loud sounds loud but not uncomfortable. So how do sound intensity and loudness relate in regard to hearing aid function?

Sound level is measured in decibels (dB). The decibel is a logarithmic unit defining the ratio between two sound levels. The reference sound unit used in hearing and electroacoustics is 20 micro Pascals (μPa). SPL in $\text{dB} = 20 \log (\text{pressure}/\text{reference})$. The sound pressures that the human ear can detect are also measured in dB SPL. Clinically, the mean threshold of a sample of normal listeners is defined as 0 dB hearing level (HL). Loudness is not measured in SPL, but rather tones. For the sake of brevity, loudness will be simplified by substituting dBHL in the loudness match data. In a loudness matching task, a listener will match the loudness of a tone with a reference tone at levels at/above threshold. For those with hearing loss, a small intensity change will produce a larger loudness

perception than normal ears. Loudness growth patterns in impaired ears are key factors in successful use of amplification.

In normal listeners, loudness of a 50-dB HL tone is matched to a tone of the same frequency at about 50 dB HL. A 70-dB HL tone is matched with a 70-dB HL tone, and so on. With varying degrees of hearing loss, loudness judgments differ from the norm. Note in Fig. 2 that those with a mild loss will match a tone at their elevated threshold (40 dB HL) to a tone just detectable (0 dB HL). They will match a tone of 30 dB above their threshold with a tone of 60 dB HL and tones at and above 40 dB above threshold will be matched in loudness just like a normal-hearing listener. Thus, this mildly hearing-impaired listener has an elevated threshold plus a rapid gain in loudness perception for soft sounds and normal loudness perception at high intensities. The presence of such loudness recruitment goes beyond fixed gain strategy of compression for loudness normalization.

A listener with a very high threshold of audibility will experience a very narrow range of rapid loudness growth, but will rate sound as uncomfortable at about the same level as the normal and mildly impaired listeners. Thus, each listener has different loudness needs. Those with mild losses require no gain at high levels, while those with severe and profound losses do. It is also evident that, even in these cases, there is loudness recruitment near the threshold of pain (120 dB HL). All hearing-impaired listeners have impairment for soft sound, but only some have impairment for loud

Fig. 2 Normal-hearing listener loudness balance is compared with listeners with varying degrees of hearing loss. The level on the abscissa is matched with the listener's actual threshold (ordinate). Note how loudness growth is hearing level-specific, due to the degree of hair cell loss.

sounds. Note in Fig. 2 that thresholds are only one defining characteristic of hearing loss. The need for loud sound amplification is only present in those with severe to profound hearing loss. These listeners have lost all of their OHCs and many of their IHCs. Listeners with less hair cell damage require little or no amplification for loud sounds since their loudness perception is normal. The relationship of hearing loss type and soft versus loud sound amplification is summarized in Table 1. In the past, the concept of fixed amplification was selected since the assumed impairment was lack of audibility. Hearing aids often delivered too much loudness and that was limited by either peak clipping or automatic gain control, neither of which was satisfactory to hearing-impaired listeners. What is evident is that the impairment in loudness and linear amplification is simply the wrong treatment strategy. When viewed from the perspective of loudness, why amplify normal loudness perception for loud sounds only because there is impairment in detecting soft sounds?

If soft sounds are amplified but remain soft, most sounds remain comfortable, and if loud sounds are not uncomfortable except at intense levels, then hearing aids would be mimicking the actions of the two types of hair cells in the inner ear. Hearing aid compression circuits functionally substitute for missing or damaged OHCs and adjust gain across the wide dynamic range of hearing. Linear growth in loudness is not physiologically normal. Linear amplification only fits the needs of some severely hearing-impaired listeners and only over a reduced range. Fixed amplification is certainly one factor in aid rejection. It has been evident over the last decade that hearing aids should mimic the loudness compression of OHCs in attempting to normalize amplified listening. One representative compression scheme is presented in Fig. 3. Note that there is a rapid growth in loudness for soft sounds and a reduced loudness range for loud sounds. The knee point can be shifted in intensity for different responses for different frequencies, allowing programmability

Table 1 The need for amplification of loud sounds is a function of the severity of the hearing loss

Hearing loss	Loudness and hearing loss	
	Amplification	
	Soft sounds	Loud sounds
No loss	No	No
Mild	Yes	No
Moderate	Yes	Some
Severe	Yes	Yes
Profound	Yes	Yes

Fig. 3 Linear amplification is contrasted with compressive amplification for one frequency. Compressive amplification can be adjusted to a listener's growth in loudness.

over a wide band of frequency channels, resulting in dynamic range compression. This process is termed wide dynamic range compression (WDRC). WDRC compensates for the loss of range compression with missing OHCs. Multiple filter band compression in WDRC was used more than on frequency channel. In most schemes, there is the adaptation stage, followed by band pass filter, and an adaptive output stage.

FIT THE NERVE, NOT THE AUDIOGRAM

Inner-ear biology reveals that 120 dB of sound intensity is compressed into the dynamic range (~ 50 dB) of IHCs by the motoric response of OHCs (Fig. 4). This range compression allows loudness coding of up to 120 dB in auditory nerve fibers (95% of which innervate IHCs). Auditory nerve fibers are all characterized by a best frequency, that is, a frequency that stimulates the fiber at the lowest intensity level. Fibers are also characterized by sharp high-frequency cutoff and a broad low-frequency response. As a result, fibers respond to a limited number of frequencies at or near threshold, but a much broader number of lower frequencies at high sound intensities. For this reason, loud sound perception may not be impaired for some listeners with hearing loss. The low-frequency areas of fibers are called tails and there is considerable tonotopic overlap (spatial alignment by best frequency) in adjacent fiber-frequency response. This nerve fiber overlap contributes to the 25 critical bands in the ear. Critical bands are band pass filters about 1.2 mm wide encompassing about 1300 hair cells and the nerve population that innervates them. For example, if two tones delivered to the ear fall within the same critical band, then the perceived loudness increases slightly in

Fig. 4 Response patterns of six theoretical auditory nerve fibers are depicted. Thresholds, firing rates, and saturation rates differ, allowing complex coding in the nerve.

reference to that of one tone. If the second tone falls in a different critical band, the resulting sensation will be much louder. In the former, there is competition for the same nerve fibers; in the latter, two distinct populations of fibers are responding. Loudness is therefore related to the place of stimulation in the cochlea as well as the intensity of stimulation. The concept of multiple-channel hearing aids is an attempt to imitate the critical bands in the speech frequencies.

Speech can be described acoustically as a fundamental frequency (about 120 Hz in men and 220 Hz in women) excited by the vocal folds with harmonics (formants) induced by subsequent vocal tract filtering. The acoustic energy in speech is focused in the fundamental and lower formant frequencies, but most of the information in speech is carried by high-frequency consonant sounds. Noise and silent gaps also play a key role in speech intelligibility, notably in stops, fricatives, and nasals. Since the basilar membrane applies a spatial mapping to frequency, such that energy peaks in speech will be represented as displacement maxima at different place locations on the basilar membrane, the transform of speech acoustical peaks to basilar membrane displace maxima is the speech place code for the fundamental (f_0) and the first three to four formants (f_1 , f_2 , f_3 , f_4). For lower formants and f_0 , there is phase locking of the auditory neurons to the speech frequencies, providing the basis of a second neural code, which becomes more central in hearing-impaired listening (see Fig. 4 in the article *Inner Ear Implants*, p. 849).

Hearing loss is generally high frequency, and the loss of OHCs reduces the tuning for the high-frequency speech components. With progressive hearing loss there is a proportional loss of speech information. When natural compression is lost, auditory nerve fibers are less sensitive and become more broadly tuned. Almost all frequencies can stimulate a fiber in a

damaged cochlea without functioning OHCs if the sound intensity is intense. Broad tuning is only exacerbated by linear amplification.

In the normal cochlea, f_1 and f_2 have distinct places of maximal excitation and this place code is well represented in the nerve. After hearing loss, i.e., loss of OHCs, f_1 spreads across much of the cochlea and f_2 shifts away from its expected place in a normal cochlea. f_2 is poorly represented in the place code, but some phase locking is present. The robust place and phase cues for f_2 are lost after hearing loss. In other words, f_3 is replaced by a broadly represented f_1 and overlaps the place code and critical bands for f_2 . This is one reason speech becomes intelligible. Amplification does to a limited degree restore the place and phase coding for f_1 , but does not restore the place code for the other formants. The neural substrate for speech perception is reduced for the hearing-impaired listeners. If the formant peaks of f_2 and f_3 are amplified, but not the harmonics between f_1 and f_2 , f_2 coding in the nerve will be partly restored.^[6] Speech can be maximally coded in the compromised nerve to provide linguistic information the brain is lacking.

Auditory nerve fibers are not homogenous; they are characterized by different response thresholds, dynamic ranges, bandwidths, and spontaneous firing rates. All contribute to speech coding. Manufacturers provide guidance to fitting a product based on a patient's audiogram falling within the recommended range of hearing loss. Such an approach is assumed to offer dispensers quick access to the appropriate instrument. Unfortunately, selecting an aid by the audiogram configuration only addresses the degree of threshold loss, not the loudness loss. It is the patient's loudness requirements that must be normalized by an aid. Ideally, one would fit the nerve and not the audiogram, so is WDRC sufficient in providing loudness signal processing parameters?

In WDRC, soft sounds are amplified more than loud sounds. In an example shown in Fig. 3, linear amplification is contrasted with rapid level-dependent tuning using nonlinear compressive amplification. In this example, a one-third order time varying narrow filter is used at lower levels and a linear first-order broad filter is used at high levels. Compression acts on the amplitude of the signal; as the input changes the output changes, but by a lesser amount. The ratio of the input to output is the compression ratio, which generally varies between 2 and 3. The objective is to mimic auditory nerve-fiber function at low and high levels within a critical band. The compressor should not introduce nonlinear distortion in each band, a problem with low-level amplification. Compression can be used in the speech preamp as well as the output.

WDRC automatically adjusts the gain across the audible range. For listeners with a mild hearing loss,

the dynamic range, defined as the difference between threshold and uncomfortable levels, may be 80 dB, whereas in a listener with profound loss, the dynamic range may be 30 dB or less. Hearing-aid software samples input intensity, then scales the output by selected compression to compensate for listener-specific loudness recruitment (growth in loudness). Loudness recruitment is usually frequency-dependent, so more than one band of compressive amplification is typically used with different compression ratios set in each band. Rapid multiband compression sets dynamic output levels to keep loudness from reaching uncomfortable levels using software programs, which are enabled to detect periodicities in speech envelope. WDRC aids in suppressing speech echoes in reverberant space, although this remains a problem in meeting high intelligibility expectations (see beamforming later in this article).

More complicated are the fitting strategies using high-frequency emphasis to address the issue of degradations in the neural speech code after OHC loss. Aids must provide sufficient gain to make inaudible sounds audible. Using one strategy as an example, low-level gain (Gain_L) is set initially by subtracting 20 dB from the hearing level. In the case of a 30-dB HL threshold at 2000, the gain would be 10 ($\text{Gain}_L = \text{HL} - 20$ dB). For thresholds above 60 dB HL, only half the gain is used as a rule of thumb, since the range between severely elevated threshold and uncomfortably loud is very small. Sufficient gain is needed to be comfortable, without reaching UCL. For a listener with a threshold of 70 dB HL, comfortable may require only 20 dB or less of gain above that need for detection of soft sounds. There are a number of gain-fitting programs that predict an average target gain formulated from specific assumptions about amplification and ear function. This is the starting point for fine tuning. It is almost a requirement to sample the gain in the ear canal between the hearing aid and eardrum to verify the fit. Additional fine-tuning can be very important once the aid is seated into the geometry of the ear, requiring true individual settings. This is accomplished by inserting a probe microphone between the hearing aid and the eardrum (Fig. 5). The frequency band gain compression characteristics can be adjusted as needed. Future user adjustment will be desired as the brain accommodates to amplified speech.

Directional microphones can suppress noise from behind a listener by using the microphone null with adaptive spectrum subtraction techniques. Just 6 dB suppression in the ambient noise can potentially increase discrimination by almost 40%. If an array of four microphones is used, combining fixed (time invariant) and adaptive (adjusts continuously), beamforming can result in an additional (<12 dB) noise suppression. The adaptive beamforming algorithm calculates the sum and difference of the incoming

Verifying the gain

Fig. 5 A method of verifying the real ear gain of a hearing aid is depicted. An ear canal probe is placed between the eardrum and aid to measure the exact SPL. An external microphone provides the reference.

signals. The difference will be primarily noise in spectrum subtraction from the sum (mainly speech). This is based on the assumption that speech and noise are uncorrelated; hence, the noise would be random in reference to any part of the speech spectrum. Noise will likely not be time-locked to speech and time delays due to reverberation can further reduce the noise. There are certainly various parameters to alter in an attempt to maximize the value of fixed, adaptive, and combination beamforming. An example of one early version using an eyeglass platform is depicted in Fig. 6.

BRAIN AIDS

Unlike the peripheral ears of mammals, the central auditory systems are plastic and rapidly reprogram in response to the conditions of the cochlea. Insults (noise, ototoxic drugs, infections, trauma, etc.) to the cochlea that cause loss of hearing (OHCs and IHCs) trigger reprogramming in the brain, especially in the neocortex.

Fig. 6 Key elements to an adaptive beamforming hearing aid. (Courtesy Planning Systems, Inc., Reston, Virginia.)

Cortical neurons are tonotopically organized, as is the cochlea due to the filtering characteristic of the basilar membrane on which the hair cells lie. Cortical neurons with best frequencies tuned to the corresponding damaged area of the cochlea change their frequency response by reprogramming lower in frequency. With increasing high-frequency hearing loss, more and more neurons are tuned to lower frequencies. The auditory brain seeks stimulation. Reprogramming raises two issues in regard to hearing aids.

- Fitting with a device that is not adaptive and programmable seems futile in the light of neural reprogramming in the brain, which is the basis of auditory processing, attention, and learning.
- Aids should not be fitted once; periodic reprogramming appears necessary. A digital device should be viewed as a speech processor coupled to a dynamic neural processor. The lack of refitting, as it were, may be a main contributing factor to lower-than-expected acceptance of hearing aids after purchase.

An interesting and related auditory reprogramming phenomenon is termed late-onset auditory deprivation. Patients using a single hearing aid in the presence of binaural hearing loss exhibit a curious loss of speech discrimination in the unaided ear. That is, speech discrimination declines in the nonamplified ear and discrimination is stable or improved in the aided ear. If the unaided ear is subsequently fitted, speech discrimination improves in the newly fitted ear to equal that of the first aided ear. The most salient explanation is that the brain reprograms to process the new speech information based on enhanced peripheral coding. The brain is favoring the amplified channel over the unamplified ear. Even if this is initially a matter of selective attention, brain reorganization seems to be involved. These data argue for binaural fitting, but also attest to the plasticity of the brain and its effects on speech processing and the need to keep assessing the hearing-aid fit.

LOOKING TO THE FUTURE

A plethora of unique auditory adaptations are present in reptiles.^[7] Turtles, for example, have been on this planet for more than 200 million years. They have outlived many species including the dinosaurs. All turtles have a unique hearing structure in their inner ears: fibroelastic strands that couple the middle ear bone to the wall of the saccule. Humans, having reduced the substrate coupling and increased the distance from their ears to the earth with bipedal posture, have reduced saccular stimulation. If, however, silicone fiber elastic strands are surgically placed through the footplate of the stapes and connected to the saccular

wall, the threshold for saccular hearing would be approximately 35 dB SPL. Functional air conduction hearing can be obtained and it may serve as an adjunctive medical procedure to a cochlear implant or a stand-alone method of hearing remediation.^[8] A saccular coupled hearing aid could be designed using some of the digital concepts highlighted in this review.

Another innovation is frequency transposition, which captures the high-frequency parts of the speech spectrum and lowers it into the audible spectrum. The concept is attractive in that speech is being frequency-compressed into the hearing-impaired ear since cues associated with the high-frequency sound are transposed. This approach has not generated substantial support. Failure is often attributed to inability to discriminate the new frequency transposed cues because discrimination is not very good in the low frequencies. While this is true for normal-hearing listeners, those with high-frequency loss have a larger low-frequency neural area due to reprogramming. Learning to use these aids takes time and training may be an important variable. Recall that f_0 and f_3 in vowels is shifted toward the high-frequency base of the cochlea and masked by a broadly represented f_1 . What happens when high frequencies are overlapped in f_0 and f_1 ? Place cues may be compromised, but some temporal information might persist. Software prespeech processing should be able to improve the outcomes with transposition aids. Ultrasonic modulating can also squeeze speech into the deaf ear. Tones from 20 to 100 kHz can be detected by bone conduction, but not by air conduction due to the filtering action of the middle ear. The deaf can detect these ultrasonic tones too, as long as there is some vestibular function present. Ultrasonic speech stimulates the auditory cortex and is an emerging hearing-aid technology.^[9,10]

Automatic speech recognition (ASR) systems are capable of reasonable performance today, although inherent variability remains. Speech features such as voicing, place of articulation, nasalization, etc., form contrasts that, in isolation, can identify phonemes. Feature detection in discourse is more problematic since acoustic features overlap. The use of short spectra features of speech on the order of 10–20 ms, as in short-term FFTs, can be applied to resynthesis of speech. A classification system would not have to construct the original speech, only a representation. ASR may not have the accuracy and speed for resynthesis today, but the potential to adapt ASR to the neural coding of speech may be the next breakthrough in hearing aids. With ASR, high-frequency consonants could be enhanced, vocal fundamental frequency and its harmonics reduced in intensity to limit expanded formant place code confusion and upward spread of masking. ASR could preprocess speech tailored to the listener. ASR algorithms should

increase the speech-to-noise ratio and reduce speech errors introduced by interspeaker variability.

CONCLUSION

The concept that hearing aids should be fitted to loudness loss and not hearing threshold is far from new, but is revived and obtainable through the use of digital signal processing techniques. The loudness of speech is proportional to the total number of auditory nerve fibers that are activated. Fibers fire synchronously by spatial (place on the basilar membrane) and temporal (time/phase locking) coding. The challenge for digital hearing aids is to preprocess or condition the speech signal to maximally stimulate the remaining sensorineural elements in the ear and brain. Biologically inspired innovation will certainly lead to novel approaches to aural rehabilitation. The reexamination of bone conduction hearing as a mechanism to deliver preprocessed sound to the ear with actuators' arrays, possibly subcutaneously implanted, on the skin of the head and neck is just taking place. Fly ears have stimulated research into miniature microphones needed for arrays in small, completely in the canal aids, which allow extracting speech from the ambient noise and preprocessing it for better neural stimulation. After all, we hear with our brains, not with our ears.

Heart Biomechanics

Jeffrey W. Holmes

Department of Biomedical Engineering, Columbia University, New York, New York, U.S.A.

INTRODUCTION

The heart is a remarkably efficient and durable mechanical pump composed of an extraordinarily complex biologic material. The field of cardiac biomechanics seeks to understand how the composition, structure, electrical activation, geometry, and hemodynamic environment of the heart interact to produce known physiologic behavior, and to apply this knowledge to understand and modify pathophysiologic responses that arise, as various disease processes affect the heart. Reviewing all that has been learned about heart biomechanics in a few pages is clearly impossible. Rather, this article is intended to serve as an introduction to the field, and therefore has the following goals: 1) to introduce the reader to the essential features of normal cardiac physiology that cardiac mechanics seeks to explain; 2) to introduce a general framework for analysis and modeling of problems in cardiac mechanics; 3) to point the reader to a number of more-detailed reviews of specific aspects of cardiac mechanics that have been well-studied; and 4) to highlight a few of the more exciting cardiac mechanics problems currently under investigation.

THE HEART AS A PUMP

The basic physiologic function of the heart is to pump blood, and well before most of the biochemical, structural, and physiologic details of muscle function were known, physiologists were already studying the pump function of the heart. One of the intriguing paradoxes of cardiac mechanics is that despite the immense underlying complexity and the fact that most known kinetic, mechanical, and geometric relationships in the heart are highly nonlinear, the overall pump function of the heart can be described with surprising accuracy by a few simple curves.

Ventricular Function Curves

With each beat, the chambers of the heart contract and relax, while a series of valves ensure one-way flow of blood. During the portion of the cardiac cycle termed diastole, when the heart is filling, the right ventricle

receives blood returning from the body through the veins into the right atrium (venous return), while the left ventricle receives oxygenated blood from the lungs through the left atrium. During the portion of the cardiac cycle termed systole, when the ventricles are contracting, valves prevent backflow into the atria and instead direct right ventricular outflow into the pulmonary artery and on to the lungs and left ventricular outflow into the aorta and out to the body. One way of understanding pump function of the heart is to look at the relationship between the input to that pump and its output. Possible inputs of interest might be the volume of blood entering the heart or the net pressure driving blood into the heart; outputs of interest might be the volume of blood pumped, the amount of pressure generated, or the mechanical work done by the heart. In fact, most of these different inputs and outputs have been plotted against one another by cardiac physiologists and used to analyze heart function. Two of the most popular plots, named after early physiologists who described or popularized them, are Starling's cardiac output curve, which considers the heart as a whole and plots right atrial pressure (input pressure) against cardiac output (output volume per minute), and Sarnoff's ventricular function curve, which focuses on the left ventricle and plots end-diastolic volume or pressure against mechanical work per beat (stroke work).^[1] Regardless of the choice of variables, the message is the same: The heart is able to increase its output dramatically in response to small changes in input over the normal physiologic range, until eventually a plateau is reached reflecting the maximal pumping capacity of the heart under a particular set of conditions (Fig. 1). The very important physiologic and clinical implication of this finding is that normal hearts under normal circumstances are able to pump blood as fast as it returns from the body, and the primary regulator of cardiac output is actually venous return.

Pressure–Volume Curves

What is the basis for the dramatic responsiveness of the heart to variations in input flows or pressures? A great deal of insight can be gained by plotting left ventricular pressure against left ventricular volume

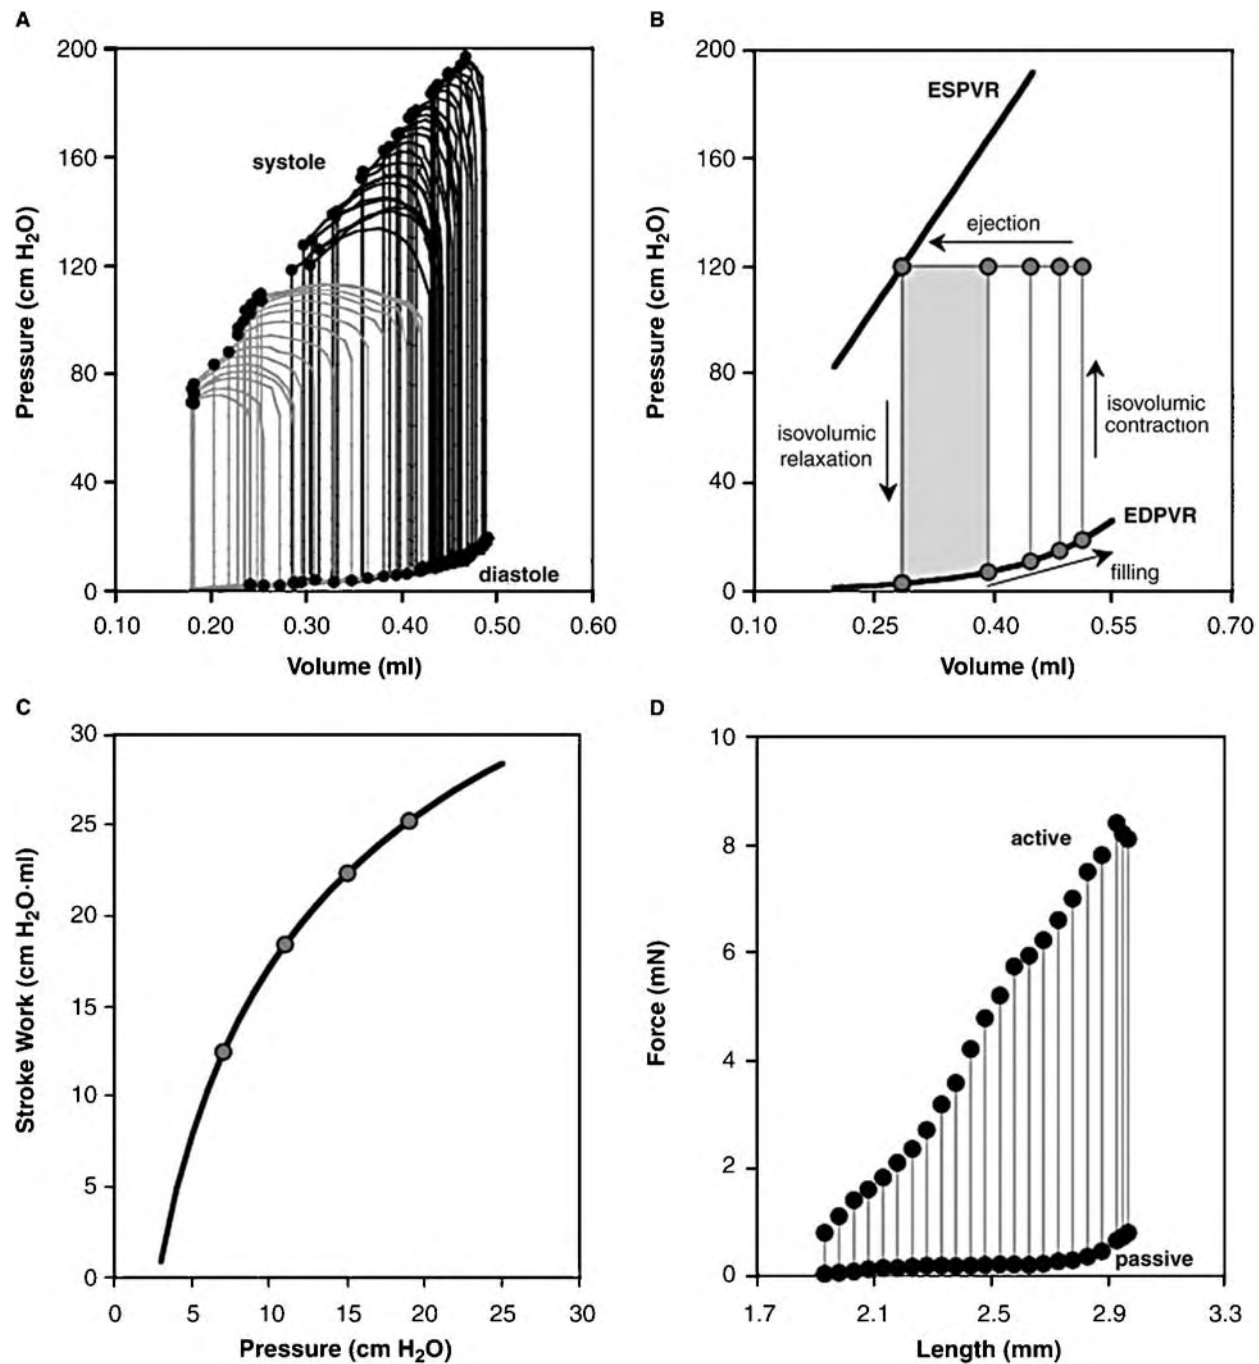

Fig. 1 Analysis of left ventricular pump function. Panel A: Pressure–volume loops from an open-chest anesthetized rat during occlusion of the inferior vena cava (gray) or the ascending aorta (black) to vary hemodynamic loading. Circles indicate end-diastolic and end-systolic corners of PV loops. Panel B: Simulated response to changing filling pressure while holding systolic pressure constant, based on linear ESPVR and exponential EDPVR fitted to data from panel A. As filling pressure increases, stroke volume and stroke work (indicated for first loop by shaded area) increase rapidly at first, then more slowly because of the exponential shape of EDPVR. Panel C: Plotting stroke work against filling pressure yields Sarnoff's ventricular function curve. Panel D: Isometric force–length data from an isolated rat right ventricular papillary muscle illustrate the similarity between muscle force–length relationships and chamber pressure–volume relationships.

over the course of the entire cardiac cycle. In the pressure–volume plane, the cardiac cycle is reflected in a counterclockwise loop: filling at low pressures, followed by isovolumic contraction, then ejection at

higher pressure, and finally isovolumic relaxation to return to the starting point (Fig. 1). While these curves were first produced for the frog heart by Otto Frank in 1898, their popularity for studying and teaching

cardiac physiology is largely because of the work of Drs. Kiichi Sagawa, Hiroyuki Suga, and colleagues beginning in the late 1960s. For the interested reader, their 1988 monograph on the pressure–volume relationship remains one of the best-written and most complete sources of history, data, and modeling regarding the use of pressure–volume loops in analyzing cardiac function.^[1]

The essential feature of cardiac function revealed by analysis in the pressure–volume plane is that the large number of trajectories that may be traced under different hemodynamic loading conditions is bounded by two simple curves, the end-diastolic pressure–volume relationship (EDPVR) on the lower right and the end-systolic pressure–volume relationship (ESPVR) on the upper left (Fig. 1). Restricting the discussion for this article to the left ventricle, the EDPVR reflects the behavior of the left ventricle during filling and is therefore determined by passive material properties of the myocardium plus a number of other factors such as ventricular geometry discussed later in this article. The ESPVR reflects the behavior of the left ventricle during systole and is therefore determined by the active material properties of maximally contracted myocardium plus other factors such as geometry. If all other factors are held constant for a given heart, experimental changes in hemodynamic loading conditions such as the inflow to the ventricle or the resistance to ejection will produce a range of different pressure–volume loops having their lower-right and upper-left corners on or very near the EDPVR and ESPVR (Fig. 1). Changes in these relationships can therefore be used to index and understand changes in cardiac function. In particular, the slope of the ESPVR has proved useful as an index of cardiac contractility. For example, administration of a drug that increases the contractile capacity of the myocardium (contractility) will shift the ESPVR of a normal ventricle upward and to the left without impacting the EDPVR.

While the utility of pressure–volume loops is hopefully evident, the question of how the ESPVR and EDPVR explain the ventricular function curves we examined earlier has still not been answered. The two keys to this question are that the shapes of these two relationships are different, and that under normal conditions arterial blood pressure is maintained within a narrow range. While the ESPVR is nearly linear in most situations, the EDPVR is highly nonlinear, with little pressure required to fill the ventricle at low volumes but much more pressure required to continue to fill the ventricle once it reaches higher volumes. Imagine starting from a very low end-diastolic pressure and gradually increasing it while maintaining end-systolic pressure at a constant value. The first PV loop would show substantial filling, then ejection to the ESPVR and relaxation (Fig. 1B). The next loop would

show slightly more filling (larger end-diastolic volume), then ejection to the same point on the ESPVR, and therefore a larger stroke volume and stroke work (area inside the PV loop); the fact that increased filling leads to increased ejection over the normal working range of the left ventricle is known in physiology as the Frank–Starling effect. Continuing the experiment, the trend would continue until the exponential shape of the EDPVR began to limit the increase in filling obtained with the next step in end-diastolic pressure, and therefore the resulting increase in stroke volume and stroke work (Fig. 1C). At some point, the EDPVR becomes so steep that additional increases in end-diastolic pressure no longer produce any change in left ventricular output, resulting in the plateau seen on ventricular function curves.

CARDIAC MUSCLE MECHANICS

As we work our way into this discussion of cardiac mechanics, it may seem we are simply replacing one question with another. The shape of observed ventricular function curves can be explained using the EDPVR and ESPVR, but how do the EDPVR and ESPVR arise? One more step in this discussion will bring us to the fundamental questions that have long occupied cardiac physiologists and biomedical engineers and that continue to define the field of cardiac mechanics today.

Force-Length Curves in Isolated Cardiac Muscle

Much of what is known about activation, contraction, and energetics of striated muscle was originally learned in isolated muscle preparations. Physiologists placed isolated muscles into baths allowing control of factors such as temperature, pH, and oxygenation, electrically stimulated these muscles to contract, and measured various features of muscle performance such as velocity of contraction, heat output, etc. From a mechanics standpoint, the most important feature of these experiments was the way in which the muscles were loaded and the terms that arose to describe forces acting on a muscle during contraction. To stretch a relaxed muscle to a longer length, small weights were hung from the muscle; as these weights represented the force the muscle experienced prior to contraction, they were referred to as the “preload.” In many experiments, an additional weight was positioned so that once contraction began, the muscle was required to lift both the initial (preload) and the additional load to shorten. The load experienced by the muscle only after it began to contract came to be known as the “afterload.” It is important to note that these loads

were always quantified in terms of force normalized by muscle cross-sectional area; although the term “load” has persisted in the physiology and clinical literature, in fact preload and afterload as originally defined refer to stresses experienced by the muscle.

Several basic relationships that emerged from this early work remain central to our understanding of the mechanics and energetics of isolated striated muscle. These include the relationship between systolic and diastolic force and muscle length (force–length curves), between afterload and muscle shortening velocity (force–velocity curve), and between energy liberation and afterload. Because of space limitations, only the force–length curve of isolated cardiac muscle will be discussed here. However, excellent reviews are available for those interested in more detail, regarding other aspects of the physiology of isolated cardiac muscle: Hunter, McCulloch, and ter Keurs^[2] published a mathematical model of cardiac muscle mechanics, which includes extensive comparison to available experimental data, while a slightly older review by Cooper^[3] is an excellent starting point for obtaining more information on the energetics of isolated cardiac muscle.

As unstimulated isolated cardiac muscle is gradually stretched beyond slack length, it is initially very compliant. However, as length increases the force required to achieve the next step in stretch rises exponentially, yielding a passive force–length curve very similar to the EDPVR of the left ventricle (Fig. 1D). If the muscle is stimulated to contract at each of these lengths and the isometric twitch force recorded, the resulting active force–length curve is very similar to the left ventricular ESPVR (Fig. 1D). Thus, it is apparent that much of the behavior of the left ventricle discussed above and reflected in the EDPVR and ESPVR likely results from basic properties of cardiac muscle. Much of the field of cardiac mechanics is currently devoted either to understanding these muscle properties and how they change in different situations or to understanding how to integrate these local muscle properties to quantitatively predict regional and global ventricular function *in vivo*.

A FRAMEWORK FOR CARDIAC MECHANICS ANALYSIS

At the essence of most solid mechanics and mechanics of materials problems is the desire to relate loading, deformation, and material properties to completely understand the response of a material or structure under expected loading conditions. Consider, for example, the simple beam problems familiar to any student who has taken an introductory strength of materials course. Shear and moment diagrams allow

the calculation of stresses on any cross-section of the beam given the type and location of applied loads; these stresses are the most useful specification of the load experienced by the material. Because the relationship between applied stresses and the resulting deformation (i.e., the material properties) is very simple in many engineering materials, predicting the resulting deformations from the computed stresses is straightforward. Simple material properties also make it easy to invert the problem, observing deformation, and computing what stresses must have been acting to produce that deformation.

In cardiac mechanics, the basic problem is the same: relating loading, deformation, and material properties to understand the response of the structure in various situations (Fig. 2). However, both the problem of determining what stresses act on the material under a given set of loading conditions and the problem of specifying the material properties are much more complex. Most of the field of cardiac biomechanics deals in one way or another with answering these two fundamental questions.

Determining the Stresses Acting on Myocardium

Unlike the simple beam-bending problem, in the case of the heart, the relationship between applied loads and the resulting stresses acting on a given region of the material (the myocardium) is quite difficult to establish and has several important determinants (Fig. 2). Although a similar discussion would be appropriate for the right ventricle, we consider here only the better-studied left ventricle. It is obvious that hemodynamic loading conditions affect the stress in the left ventricular wall; increasing the pressure inside the left ventricle must increase the associated wall stresses. However, the specific relationship between these two depends heavily on ventricular geometry. The left ventricle is a thick-walled, elliptical pressure vessel. In general, stresses are tensile in planes parallel to the left ventricular surface (around the circumference or along the longitude at any point in the wall), and compressive in the radial direction; the magnitude of these stresses depends in part on global geometric factors such as the ratio of the different radii of the ellipse to one another and the ratio of these radii to the wall thickness.^[4] The situation is further complicated by two additional factors. First, there is residual stress in the ventricular wall. In other words, when the left ventricle is completely unloaded, with no pressure difference between the inside and outside, the stresses in the wall are still nonzero.^[5] Second, because the material properties of the myocardium are not the same everywhere in the ventricular wall, different layers of the wall may bear

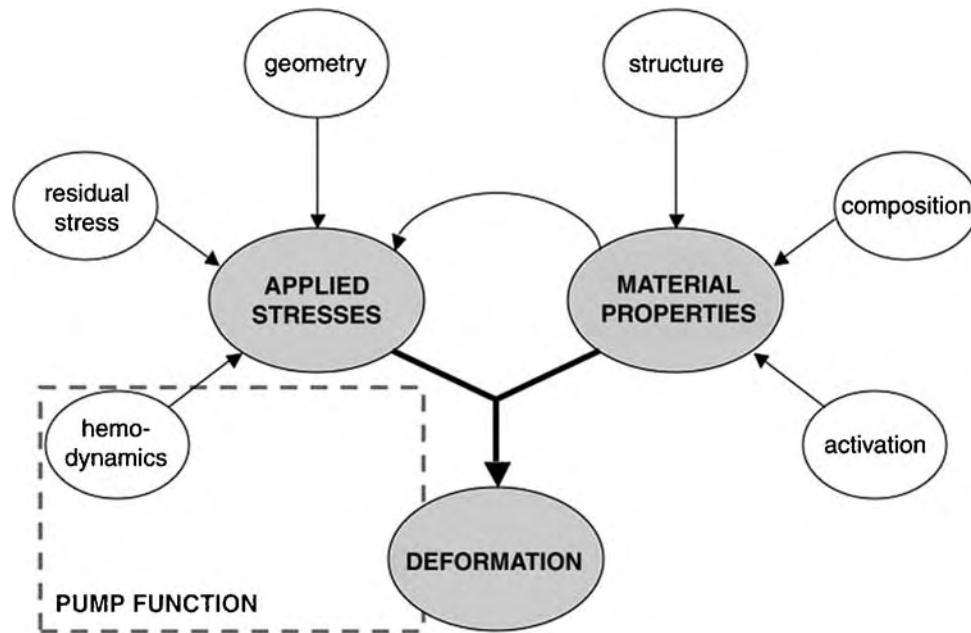

Fig. 2 General approach to problems in heart biomechanics. The overall goal is to relate loading, deformation, and material properties to understand the heart's response to a given situation or disease process. Remarkably, pump function of the heart can be described by a few simple relationships between hemodynamic loading and the volume of blood pumped by the heart. This type of analysis covers only the region of the diagram outlined by the dotted gray lines and describes the behavior of the heart without explaining the underlying mechanisms. More detailed analyses are complicated by a number of factors shown on the diagram and explained in more detail in the text. In particular, both determining the stresses acting on myocardium and appropriately describing the material properties of myocardium are difficult problems that occupy much of the current work in the field; much of the difficulty arises from the fact that these two problems interact (indicated by curved arrow in the center of the diagram).

different amounts of the overall load placed on the left ventricle, just as springs with different spring constants experience the same stretch but different loads when acting in parallel. The consequence of this last fact is that even given residual stress, loading, and geometry, stresses cannot be completely predicted without first knowing material properties.

One of the achievements of the field of cardiac mechanics over the past two decades has been the development of comprehensive, quantitative models of left ventricular geometry and fiber architecture. The groundwork for these models was laid by a pair of classic papers by Streeter and Hanna^[6,7] describing the left ventricle as a nested set of elliptical shells. However, the modern geometrically sophisticated finite-element models that currently allow iterative solution of the equations of equilibrium for a ventricle with prescribed active and passive material properties owe the majority of their development to the cardiac mechanics groups at the University of Auckland (New Zealand) and the University of California, San Diego. These extremely detailed, painstakingly developed models have been published for the dog,^[8] pig,^[9] and rabbit,^[10] pictures and examples of their use to investigate cardiac mechanics problems are available on the websites of these two groups.

Determining Material Properties of Myocardium

Like most biologic materials, passive myocardium is nonlinear, anisotropic, and viscoelastic. In addition, passive myocardium exhibits several more complex material behaviors under appropriate test conditions including preconditioning, hysteresis, and strain softening.^[11] However, the complexity of passive myocardium is only the beginning, as myocardium actively contracts with each heartbeat, cycling through a wide range of different material properties from those of passive myocardium to those of maximally contracting "active" myocardium and back again. The active material properties are both time- and history dependent and are again anisotropic, with more active stress generated along the local muscle fiber direction, but some active stress also generated perpendicular to the local fiber direction.^[12] Given such complexity, it is not surprising that much of the work to date in the field of cardiac mechanics has focused on describing, modeling, and understanding the passive and active material properties of myocardium.

There are two general approaches to determining the material properties of myocardium (Fig. 3).^[13] The first, more familiar from traditional engineering analysis, is to excise a specimen and test it in a

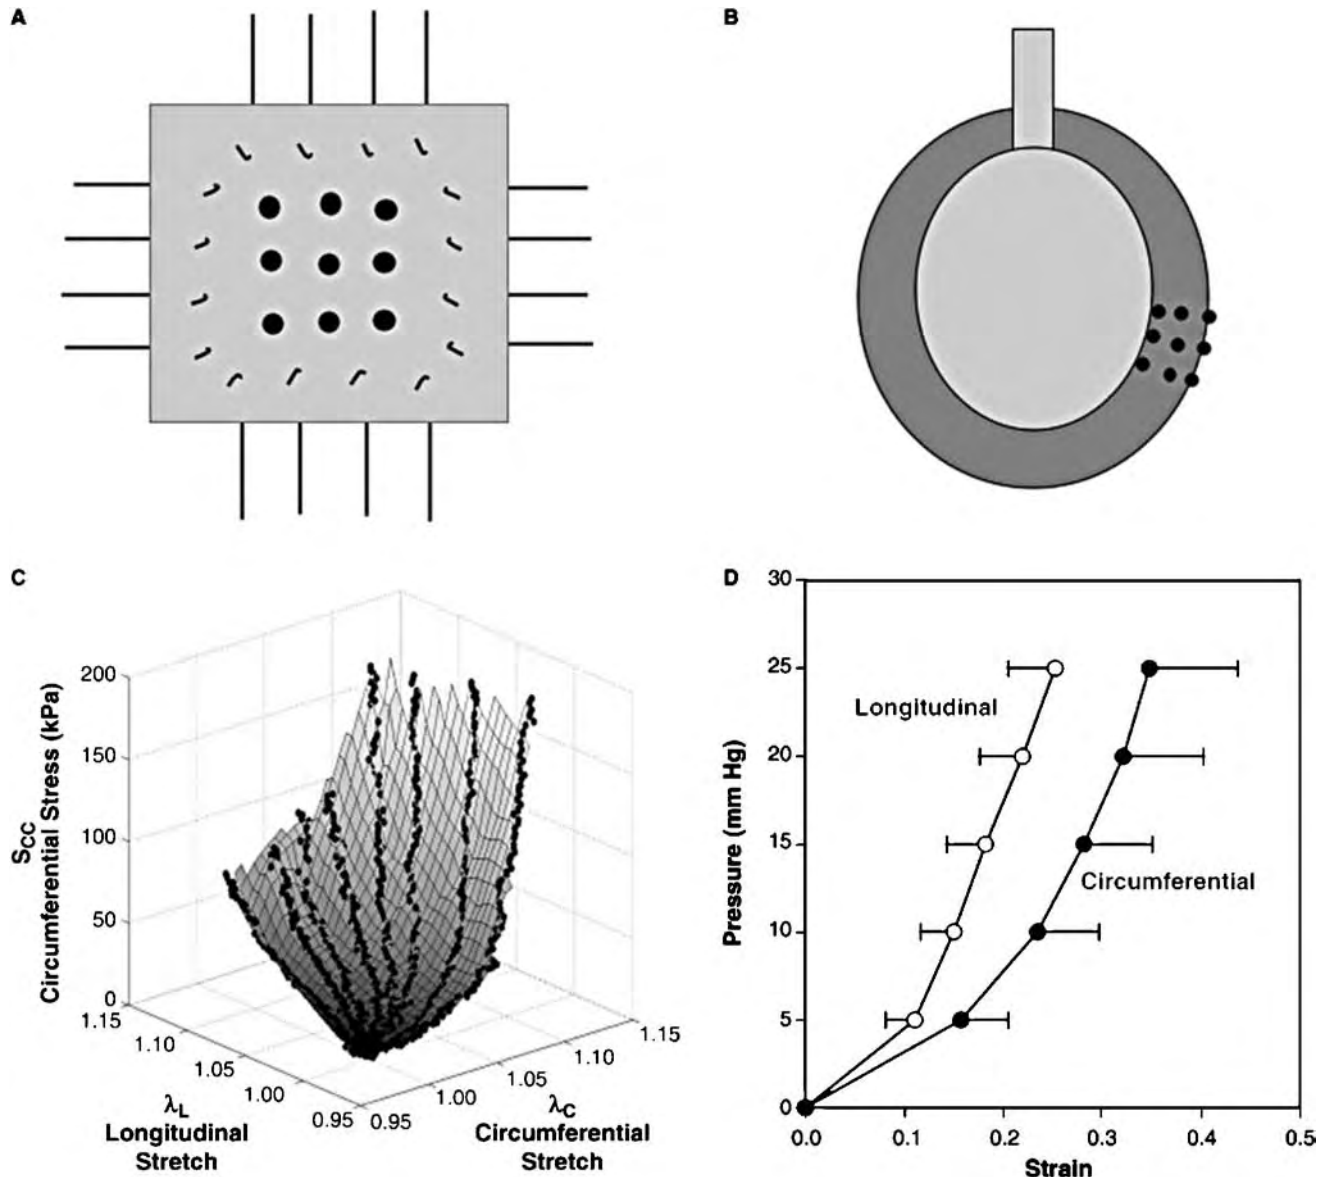

Fig. 3 Approaches to determining material properties of heart tissue. Panel A: For biaxial testing, an excised sheet of myocardium is connected to a testing device with sutures and hooks and subjected to multiple computer-controlled test protocols; deformation is tracked with markers and forces are measured. Panel B: Alternately, the intact heart may be fitted with a balloon that is inflated to known pressures and volumes while deformations in the wall are measured with implanted markers. Panel C: Biaxial test data (circles) and fitted stress surface from healing rat infarct. Biaxial testing provides more direct information on stress–strain relationships over multiple test protocols, at the expense of excising the tissue. Panel D: Data from inflation tests on isolated pig hearts. Pressure–strain data are obtained in the intact heart but only for a single test protocol; finite element modeling is required to estimate stress–strain relationships from the measured pressure–strain data.

computer-controlled testing device.^[14–17] Because myocardium is an orthotropic material, triaxial testing would be required to completely describe its three-dimensional material properties; however, these tests are very difficult to perform. Instead, most investigators have assumed the myocardium to be incompressible and performed biaxial testing. This approach has the obvious benefits that both the loading placed on the myocardium and its deformation can be accurately

measured. For passive myocardium, the main technical difficulty is preventing injury to the specimen that might cause edema, permanent binding of some muscle crossbridges (contracture), or other alterations in the material properties to be measured. For active myocardium, the technical challenges are even greater, as the myocardium cannot easily be maintained at a particular level of partial activation (representing a certain time during systolic contraction) while it is

tested, then shifted to another level of activation, and tested again. The best information about active systolic properties to date was obtained from biaxial testing of myocardium that was tetanized or placed in barium contracture to simulate maximal activation.^[12]

The second approach to determining material properties of myocardium is to leave the heart intact, measure deformation under a range of hemodynamic loading conditions, and attempt to deduce the material properties using a sophisticated model that accounts for all the other factors that impact deformation such as geometry, residual stress, etc.^[18,19] The obvious advantage of this approach is that it leaves the heart intact, so that material properties are much less likely to be disturbed by the testing.^[13] The disadvantage is that the stresses must be computed from the model and their accuracy is therefore only as good as the model; in addition, as the stresses depend on the material properties, the material properties must be optimized using an iterative procedure until the model-predicted deformations at a given loading state agree with the observed deformations. Because the match is never exact, deformation is three-dimensional, and the function describing the material properties typically has several constants, finding the true optimum (a global minimum for the optimization instead of just a local minimum) for a problem like this is very difficult. As with *ex vivo* biaxial testing, it is difficult but possible to inflate and deflate an isolated arrested heart and use the imposed pressures and resulting deformations to obtain a description of the material properties of passive myocardium; however, obtaining information across the entire range of possible active states that occur during a cardiac cycle in a beating heart is extremely difficult and little progress has been made in this area.

To this point, we have discussed only the methods used to obtain information on material properties, not how to specify those properties mathematically or to relate those properties to the structure and composition of the tissue. Constitutive modeling of myocardium is one of the more active and exciting frontiers of current cardiac mechanics research and is discussed in a separate section below.

Measuring Global and Regional Deformation in the Heart

In the attempt to relate loading, deformation, and material properties to understand the response of the heart in any given situation (Fig. 2), the measurement of deformation is the most straightforward. Global measures of deformation such as cavity volume can be obtained using a variety of imaging techniques including angiography (X-ray), ultrasound, and MRI as

well as using newer methods such as the conductance catheter. Measurement of regional deformation has been accomplished using sonomicrometers, implanted radiopaque markers tracked by high-speed X-ray, and more recently by MRI tagging. While these methods are a necessary part of any analysis, from the discussion above it should be clear that in many situations measuring deformation alone provides very little information on the underlying mechanics. For example, although it has been known for 30 years that a segment of myocardium tracked with sonomicrometers or markers shifts its pressure–strain curve to the right during acute ischemia, the fundamental question of whether this shift reflects a change in the material properties of the ischemic myocardium, a change in loading of the ischemic region, or a combination of these effects remains unanswered.^[20]

CURRENT FRONTIERS IN HEART BIOMECHANICS

While cardiac muscle and chamber physiology have been extensively studied by physiologists over many decades, and the molecular biology of heart disease is currently the primary focus of most cardiac research, the relatively small and relatively new field of cardiac biomechanics is just now entering an exciting phase where the basic tools and approaches have been developed and application to a range of important problems is possible. Here, we briefly outline two of the many promising current frontiers in cardiac mechanics.

Structural Constitutive Modeling

An equation that specifies the relationship between stresses and strains in a given material is called a constitutive equation. The development of these mathematical models of the material properties of biologic tissues is often referred to as constitutive modeling. Constitutive modeling of myocardium is one of the exciting frontiers of current cardiac mechanics research and was recently reviewed by Costa, Holmes, and McCulloch.^[13]

Historically, there have been three different approaches to constitutive modeling of passive myocardium. The first approach is phenomenologic. In this approach, the constitutive equation is treated simply as an equation to be fitted to experimental data, a concise representation of the material properties of passive myocardium. As passive stress–strain curves for myocardium are typically exponential in shape, most investigators have used exponential or power-law equations to describe these properties mathematically.

A typical approach is to use a form known as a Fung exponential, popularized for biologic tissues by Y.C. Fung. In this approach, the myocardium is usually modeled as an incompressible hyperelastic material described by a potential function called a strain energy function that relates stresses and strains (t_{ij} =Cauchy stresses, F_{ij} =components of the deformation gradient tensor, C_{ij} =components of the right Cauchy–Green deformation tensor, and p =hydrostatic pressure term used to enforce incompressibility) [Eq. (1)]

$$t_{ij} = -p\delta_{ij} + 2F_{iA} \frac{W}{C_{AB}} F_{jB} \quad (1)$$

Next, the strain energy function W is assumed to be some exponential function of the components E_{ij} of the Lagrangian finite strain tensor. For example, Guc-cione, McCulloch, and Waldman used the following form, which assumes the material is transversely isotropic with its primary material axis oriented along the local muscle fiber direction, in their model-based determination of passive canine myocardial material properties (f =fiber, c =cross-fiber, r =radial, and C and b_1 – b_3 are constant coefficients) [Eq. (2)]

$$W = \frac{1}{2} C(e^Q - 1);$$

$$Q = b_1 E_{ff}^2 + b_2 (E_{cc}^2 + E_{rr}^2 + 2E_{cr}E_{rc}) + 2b_3 (E_{fc}E_{cf} + E_{fr}E_{rf}) \quad (2)$$

One of the problems that arise when fitting these equations to data, especially in the case of iteration through a complex finite element model as discussed above, is the fact that most of the equations that have been chosen ad hoc by various investigators contain constants that are not independent of one another. One of the more novel contributions in recent years was made by Criscione, who developed constitutive equations with parameters that are linearly independent of one another to facilitate robust parameter estimation from experimental data.^[21,22]

The second general approach to constitutive modeling of myocardium is to try to select mathematical forms for the constitutive equations that are preferred because the forms of the equations themselves reflect some underlying properties of the tissue. Some of the best work of this kind was done by Humphrey, Strumpf, and Yin^[16,17] who formulated their strain energy function W as a polynomial function of the invariants of the right Cauchy–Green deformation tensor C and then designed computer-controlled biaxial tests to vary one invariant at a time and determine the appropriate order for each term in the polynomial. A very different approach that still falls in the same general category has been taken by the group at University of Auckland. They argued that the limit

to distensibility of the myocardium in any direction is set by collagen fibers that become essentially rigid once they are fully extended, and that the mechanics would therefore be best described using an equation that has poles in each direction (a “pole-zero” constitutive law) to reflect this structural feature.^[23]

This brings us to the final, most challenging, but potentially most exciting approach to constitutive modeling of passive myocardium. This approach, termed “structural” constitutive modeling, attempts to build a constitutive equation based on measured composition and microstructure. Early work in this area was done by Lanir and coworkers, with a specific formulation for myocardium published by Horowitz.^[24] Some formulations of this type postulate multiple fiber families and end up with so many parameters that it becomes impractical to obtain them by fitting experimental data. However, the most aggressive forms of this approach take the philosophy that as little as possible should be fitted, with most of the parameters based on direct measurements of tissue structure. We have taken this approach to constitutive modeling of myocardial scar tissue^[13] and fibroblast-populated collagen gels, and Sacks^[25] has employed measured fiber orientations in structural models of heart valves and pericardium. Matching experimental data using this approach is generally more difficult than with a phenomenologic approach; however, it directly challenges us to understand how tissue composition and organization give rise to mechanical properties, rather than just describing those properties in curves and equations.

Growth and Remodeling of the Heart

The geometry, structure, and composition of the heart are not static; the heart can adapt and remodel over time. Remodeling of the heart occurs during normal physiologic growth, during exercise training, and during many pathophysiologic processes. In particular, hemodynamic overload is known to induce growth of cardiac myocytes in distinctive patterns that depend on the type of overload. Experimentally increasing the pressure the left ventricle must generate with each beat, causes myocytes in the wall to grow preferentially wider; integrated over the entire left ventricle, the net result of this pressure-overload hypertrophy is an increased wall thickness and decreased ratio of radius to wall thickness. By contrast, increasing the volume of blood the heart must pump per minute causes myocytes in the wall to grow preferentially longer, the left ventricular cavity radius to enlarge, and the radius-to-wall thickness ratio to increase. It has long seemed evident that local mechanical signals sensed by the cells are likely important regulators of myocyte growth and

remodeling,^[26] but the specific mechanical stimuli that are sensed have not been clearly identified.^[27]

Cardiac biomechanics is making two important contributions to the understanding of cardiac growth and remodeling. First, the fact that the stresses in the left ventricular wall depend not only on hemodynamics but also on ventricular geometry has turned out to be of immense clinical importance for patients with heart failure. As discussed above, it is not possible to completely separate the effect of ventricular geometry on wall stresses from other factors such as material properties. However, it is clear that for a given cavity pressure and set of material properties, increasing the cavity radius or decreasing the left ventricular wall thickness will increase circumferential and longitudinal stresses in the wall. Therefore, the ratio of cavity radius to wall thickness is often used as a rough index of the relationship between cavity pressure and wall stress. In patients with dilated heart failure, the radius-to-wall thickness ratio is much higher than normal. The consequence is that myocytes feel a much larger systolic stress, or afterload, than myocytes in a normal heart at a given systolic cavity pressure; these myocytes are at a mechanical disadvantage when they try to contract. This means that patients with heart failure actually have two problems. The first is cellular: The cells have impaired calcium handling and force generation. But the second is geometric: Even if a dilated heart were composed entirely of normal myocytes, its function would be depressed purely because of the mechanical disadvantage imposed by abnormal geometry.

This insight has been very important to understanding and planning new therapies for dilated heart failure that have emerged in recent years. For example, a surgery known as the Batista procedure attempted to remove the geometric disadvantage for patients with severe heart failure by excising a longitudinal wedge of myocardium and joining the edges of the resulting defect, instantaneously reducing left ventricular radius.^[28] Although that surgery has recently fallen out of favor, a number of other procedures and devices currently under testing are based on the same concept of reducing or constraining cavity radius as a way to recover or preserve left ventricular function. Another strategy that appeared promising was temporary mechanical unloading of the left ventricle with left ventricular assist devices (LVADs). It was discovered that when patients in end-stage heart failure are placed on temporary LVAD support while awaiting heart transplantation, the ventricular remodeling process appeared to reverse, with dramatic reductions in heart and myocyte size over about a month of LVAD support.^[29] While some beneficial remodeling of cellular function also occurred during LVAD support, it turned out that the ratio of radius to wall thickness did not change in these hearts, suggesting that the

fundamental mechanical disadvantage associated with abnormal geometry in failing hearts is not improved by LVAD-induced reverse remodeling.^[30]

The availability of therapies like LVADs and myocardial constraint devices has opened up another opportunity for the field of cardiac mechanics to contribute to improved treatment strategies for heart failure. While most of the attention surrounding hypertrophy in the cardiology community is currently focused on the molecular mechanisms and signaling pathways underlying hypertrophy and remodeling, engineers have focused more on identifying the mechanical stimuli that initiate these cascades. Until recently, it could be argued that the molecular approaches were much more likely to lead to therapeutic advances as the pathways and mechanisms, once identified, could serve as targets for pharmacologic blockade or modification. However, with the advent of new therapies allowing the mechanical environment of the myocytes to be prescribed, the reverse argument may be made: If the mechanical inputs to the heart can be controlled and the inputs needed to achieve a particular pattern of remodeling specified, remodeling can be directed to achieve desired changes even before the underlying mechanisms are understood.

In the past, the primary approach that cardiac mechanics investigators have taken in identifying the mechanical stimuli responsible for cardiac growth and remodeling is to hypothesize which stimuli drive growth and remodeling, then set up adaptive models to determine whether the hypothesized “growth law” produces similar responses to those observed experimentally during various types of hemodynamic overload.^[31,32] These growth models are very useful screens for identifying potentially important mechanical stimuli. The success of one of these models in reproducing observed growth responses illustrates that a particular combination of stimuli could drive hypertrophy and remodeling, but does not prove that these stimuli in fact do so. A combination of growth models and direct *in vitro* tests of mechanical perturbations will be required to definitively identify the relevant stimuli and quantify the relationships between those stimuli and resulting growth.

CONCLUSIONS

The field of cardiac mechanics seeks to apply the methods and ideas of solid mechanics to understand the function of normal and diseased hearts. Dramatic advances have been made in measuring deformation in the heart, estimating stresses acting on the myocardium using sophisticated finite element models, and characterizing the material properties of myocardium.

The tools of cardiac mechanics analysis are now increasingly being applied to more fundamental questions such as how tissue structure gives rise to material properties and how mechanical signals drive growth and remodeling of the normal and diseased heart.

FURTHER READINGS

Owing to space limitations, only a small fraction of the relevant literature is referenced here, often giving preference to recent reviews rather than original sources on the argument that these reviews are more convenient starting places for a reader to begin learning about the field of heart biomechanics. In particular, I would like to recommend the following books and special journal issues as the best places to quickly obtain a more detailed overview of the problems, methods, and ideas that comprise the field. First, the history and basic principles of cardiac physiology, as well as some of the best early engineering analysis of cardiac function, are beautifully reviewed in the book “Cardiac Contraction and the Pressure-Volume Relationship” published by Sagawa et al. in 1988.^[1] Second, the book “Theory of Heart: Biomechanics, Biophysics, and Nonlinear Dynamics of Cardiac Function” contains a collection of articles reflecting the state of the art in cardiac mechanics research at the time of its publication in 1991.^[33] Next, in 1998 the journal *Progress in Biophysics and Molecular Biology* published a special issue on a range of topics in cardiac mechanics (Volume 69, Issues 2–3, pp. 151–572). In 2000, the *Journal of Elasticity* published a special issue on soft tissue mechanics in the cardiovascular system that contained several articles on the heart and on constitutive modeling (Volume 61, Numbers 1–3). Most recently, in 2001 the journal *Philosophical Transactions of the Royal Society of London A: Mathematical, Physical and Engineering Sciences* published an excellent special issue on computational models of the heart (Volume 359, Number 1783, pp. 1047–1337). Finally, to place readings on heart biomechanics into clinical context, it may be useful to consult a general textbook on cardiovascular medicine such as Braunwald’s *Heart Disease*.

INTRODUCTION

In today's world, the extraordinary composer Gustav Mahler would not have died of aortic valve disease. Instead, he would have become one of the more than 250,000 estimated annual recipients of a prosthetic heart valve.

This ability to replace a diseased heart valve with a prosthetic one has dramatically reduced the mortality associated with heart valve disorders. Unfortunately, this shining success story of modern medicine is only one side of the coin. The other one is a sobering complication rate associated with all contemporary heart valve prostheses. While the life-extending effect of replacement valves is undisputed, there is a high price to be paid in lost quality of life. If the prosthetic valve is made of titanium and/or pyrolytic carbon it requires life-long anticoagulation. In spite of decades of experience, anticoagulation is still a dangerous treatment. Suboptimal anticoagulation carries the threat of major clot formation, either leading to catastrophic immobilization of the valve leaflets or the downstream occlusion of a major blood vessel. If this blood vessel supplies the brain, the consequence is a stroke. In contrast, therapeutic and suprathreshold anticoagulation has a significantly increased risk of hemorrhage. In the younger population group, this risk prevents otherwise perfectly healthy individuals from living a physically active sports life. In the elderly, this bleeding risk often comes on top of hypertension and fragility of blood vessels. The consequence is often a life-threatening intracerebral hemorrhage. Against this background, there was great enthusiasm when heart valve prostheses were introduced that were made of bovine or porcine tissue and did not require anticoagulation. Unfortunately, it soon became evident that these bioprosthetic heart valves eventually degenerate and fail. While the relatively short life span of such tissue valves is mostly compatible with the natural life expectancy of older patients, it is seen to be

prohibitive in younger recipients. Moreover, the process of bioprosthetic degeneration is also much faster in young patients than in senescent ones.

Disappointingly, most of the limitations of replacement valves were already apparent 20 years ago. Since then, no fundamental breakthrough has occurred that addresses the underlying mechanisms of failure. On the contrary, the basic principles of tissue valve production remain largely unchanged. Improvements were rather of a symptomatic than of a principal nature. Post-fixation treatments aiming at the suppression of detrimental leaflet calcification, for instance, were partly successful but failed to provide a satisfying explanation concerning the mechanism of their effect. Therefore, the challenge with regard to improved tissue valves lies in our ability to unravel the key mechanisms determining the interaction of porcine or bovine tissue with the human recipient.

When elucidating these key mechanisms, one needs to keep in mind that there is already a conceptual contradiction that overshadows the idea of bioprosthetic heart valves: On the one hand, nature has provided us with the most compelling design of heart valve leaflets. These tissue membranes are only a few hundred micrometers thick but capable of withstanding the harsh mechanical forces of 3 billion heart cycles in the course of a lifetime. On the other hand, by being forced to choose animal tissue for the production of replacement valves, many of the advantages of native tissue are being lost again. The reason for this unwanted consequence lies primarily in the necessity to mask the immunogenicity of the animal tissue. If untreated, such heart valves would instantly be subjected to acute rejection and fail within days. The chemical cross-linking processes, however, which were adopted to eliminate immunogenicity, defy many of the reasons for choosing native tissue. The delicate mechanical function of natural leaflets, for instance, with their optimal stress-reducing design is partly lost by the cross-linking process. Moreover, these

cross-links were almost exclusively glutaraldehyde-based throughout the past three decades. The highly complex chemistry of this bifunctional aldehyde introduces chemical components that are thought to contribute to the propensity of the prosthetic leaflets to calcify. Most importantly, the delicate leaflet structure that physiologically withstands disproportional mechanical forces relies on the repair capabilities of the living tissue. Most regrettably, the cross-linking process, which is required to reduce immunogenicity, turns the living tissue into a nonvital structure devoid of such repair mechanisms.

In spite of all these critical observations, however, tissue heart valves are a blessing for many patients. Seen against the background of an increasingly critical attitude toward the complications of mechanical heart valve prostheses, bioprosthetic valves have captured a continually growing market share. In contrast to the exuberant enthusiasm of the 1970s and early 1980s, however, the positive driving forces behind tissue valves are much more sober today. Both clinicians and researchers have come to the realization that the only heart valve prosthesis that will ever be truly durable and free of serious complications will be one that consists of living and physiologically functioning recipient tissue. Yet, for those who have observed the slow pace of tissue engineering over the past 20 years, it is evident that no such heart valve will be clinically available for the majority of patients for a long time. This leaves us with the task of optimizing our dual armament of mechanical and biological heart valve prostheses for the foreseeable future. This is a formidable task, given the fact that conservatism has prevailed in this field for the past three decades. Characteristically, the only major deviation from the concept of the 1970s was the step toward unstented bioprostheses. Therefore, optimization needs to question more than the choice of a sewing ring, the transvalvular gradient or the incorporation of another anticalcification molecule. Optimization needs to start with the reassessment of the clinical niches for tissue valves. As much as the indications for tissue valves were too generously applied in the late 1970s and early 1980s, today's narrow limitation to the elderly represents resignation rather than optimization. Equally important to decide is whether we have achieved the main objective of tissue valve treatment, namely the suppression of xenograft immunogenicity, in the first place. If the answer is no, we ought to embrace this aspect with bold openness, bringing in the scientific tools that were not available when the idea of bioprosthetic heart valves was initially conceived. One such promising tool is today's ability to extract cellular antigenicity largely from the tissue. Another is the deeper insight into the complex world of cross-linking chemistry. An array of new approaches to tissue

fixation not only widens the spectrum of antigen masking, but by chemically engineering cross-links, tissue fixation becomes more controllable, thereby allowing the addressing of adverse aspects such as tissue stiffness or cytotoxicity.

CLINICAL NEED FOR TISSUE VALVES

The number of heart valve replacements performed annually has continued to rise over the past few years. While an estimated 175,000 heart valves were replaced in 1995,^[1] it was thought to be more than 250,000 five years later. Apart from this absolute increase in annual procedures, the share of bioprosthetic valves rose from 20% in 1995 to 40% in 2000 and is currently believed to be at about 50% of the overall sales. There is reason to believe that this share of the annual heart valve market represents a ceiling—at least as long as there is no fundamentally improved concept behind tissue valves. In return, such an improved concept requires research and development resources that would become available only if there was a commercial incentive. Therefore, an assessment of the short- to medium-term growth potential of the bioprosthetic heart valve market could provide us with an indication for the likelihood of such a development.

If one looks at the current indications for tissue valves, the majority are implanted into first-world patients of more than 65 years of age. Within this age group, practically all patients are already receiving bioprosthetic valves. A certain proportion is also used in young patients in developing countries where anticoagulation is difficult. However, sales in these regions are often subsidized. Thus, revenue with tissue valves is almost exclusively generated in the geriatric patients of Europe, North America, and Japan. It is therefore unlikely that the demand in the developing world will represent a market force in the near future. This is particularly regrettable in view of the needs of third world countries. Of a world population of almost 6.5 billion people, 5.5 billion live in developing countries. Typically, their emerging middle class is increasingly successful in persuading their governments to establish open-heart surgery because it's easier than tackling rheumatic fever. The combination of a young age at which these patient typically require heart valve replacement and the often difficult access to anticoagulation control represents the strongest theoretical motivation for the development of a truly durable bioprosthesis. Still, as long as the buying power of these countries remains weak, revenue generation will not reach a level sufficient to create a strong incentive for research and development.

Having conceded the limitations of revenue growth in the developing world, what are the chances that the

first world market grows beyond its core indication of geriatric aortic valve disease? Apart from geoeconomic limitations there are also anatomical limits to a market growth. Since tricuspid- and pulmonary-valve replacements make up a fraction of procedures, a potential expansion of indications will always be restricted to the aortic and mitral valve. Considering the fact that in developed countries diseased mitral valves are increasingly repaired and thus preserved, one can narrow the present picture even further: The majority of revenue-generating bioprosthetic tissue valves are being implanted into elderly, first-world patients suffering from aortic stenosis. There is certainly a good chance that tissue valves may additionally be implanted into aortic stenosis patients below the currently observed age limit of 60–65 years, should improvements modestly increase the life span of contemporary bioprostheses. Extrapolating the developments of the past three decades, such modest improvements are likely. In more than two-thirds of aortic stenosis patients currently falling under the age limit for tissue valves, the etiology of the disease is either degenerative or on the basis of an underlying bicuspid malformation. Even if younger than 65 years at the time of operation, these patients still tend to be beyond their prime when they need a replacement valve. The situation is different in the remaining third of patients with aortic stenosis, where the etiology is rheumatic. In contrast to patients with degenerative or bicuspid aortic stenosis, these patients often become symptomatic at a distinctly younger age. In a first-world environment, it would require fundamentally improved bioprosthetic heart valves to justify the implantation of tissue valves into this age group. Similarly, a majority of aortic incompetence patients falls into this category. Two-thirds are either of rheumatic etiology or caused by infective endocarditis. These patients usually become symptomatic between the 4th and the 5th decade. The remaining third of patients with aortic incompetence are suffering from a disease that affects the entire aortic root. If it is a connective tissue disease such as Marfan's disease, patients often become symptomatic as early as in their thirties. The smaller group of ankylosing spondylitis patients are normally in their mid-forties and that with syphilitic aortitis in their early fifties when symptoms may require surgery. The prospects for contemporary tissue valves look even less promising in mitral valve disease. As mentioned before, an increasing number of mitral valve disorders needing surgical intervention do not end up with a replacement valve. If the underlying condition is mitral stenosis, the etiology is rheumatic and the mostly female patients need a therapeutic procedure in their 4th and 5th decade. In pure mitral stenoses, balloon valvuloplasties have largely replaced open valvulotomies. Those needing a

valve replacement because of mixed mitral stenosis and incompetence are far too young for bioprostheses, even if a moderately improved durability of current tissue valves can be achieved. This leaves mitral incompetence as a last possible indication. Here, the age at which the disease becomes symptomatic again excludes current bioprosthetic heart valve concepts categorically: If the etiology is rheumatic, those needing a valve replacement often need it in their fourth decade. Apart from the young age group of these patients, surgical repair is increasingly considered for rheumatic mitral incompetence, even if it still remains a matter of controversy. Similarly, infective endocarditis mainly occurs in young to middle-aged patients. Thus, only mitral valve prolapse and ischaemic mitral incompetence are conditions that need surgical intervention from the 5th to 6th decade onwards, but most of these valves are also repairable.

What becomes obvious from such an assessment is the fact that a quantum leap in bioprosthetic heart valve development would be required to significantly increase the current market share of tissue valves. The only possible way of challenging this conclusion is to revisit our current approach to risk factor assessment. In order to do so, we first need to remind ourselves that there is only one reason for choosing a mechanical heart valve prostheses: the fear of reoperation as a consequence of tissue valve failure. In the decision-making process regarding the choice of prosthetic heart valves, this fear of a reoperation may bias our overall assessment of risk factors. There is reason to believe that such a bias does exist. Although dependent on the experience of a center, the mortality associated with reoperations seems lower than generally assumed. In centers routinely performing heart valve reoperations, the surgical mortality is only marginally higher than in first procedures.^[2] Held against the often life-threatening complications in patients with mechanical heart valves the reevaluation of risk factors may dramatically expand the indications for bioprosthetic heart valves. If such a reevaluation of risk factors resulted in the acceptance of one reoperation in a patient's lifetime, the majority of heart valve recipients in the developed world would be candidates for tissue valves. Furthermore, bioprosthetic heart valves have one other potentially life saving advantage: They usually degenerate gradually. In contrast to the catastrophic emergency a clotted or stuck mechanical valve presents, reoperations can be largely planned in tissue valves, although acute leaflet ruptures were also reported in early bioprostheses, albeit as extremely rare events.^[3,4]

Nevertheless, as long as the reoperation risk is seen to be higher than the risks of anticoagulation, the tissue valve market remains near its ceiling. With a life expectancy of close to 80 years in the developed world

and a mean life span of approximately 15 years for tissue valves, the margins for expansion are narrow. With a trend towards the lowering of the age threshold for tissue valves from 65 to 60, most of the nonrheumatic aortic stenosis patients needing surgery may eventually receive a bioprosthetic heart valve. Moderate improvements on the scale seen in the past 20 years may add the few extra years in durability, which would benefit those aortic stenosis patients blessed with particular longevity. For the vast majority of other indications, current tissue valves would need to at least double their life span. To achieve this goal, a fundamentally improved approach to tissue preservation would be required. Given the fact that most of the commercial producers of bioprostheses are also the market leaders in mechanical heart valves, the incentive for such an extraordinary research effort seems low. Seen against the background of a 30% risk of developing a thromboembolic complication within 20 years and an equally high 30% risk of experiencing a hemorrhage with a mechanical prosthesis,^[5] this prospect is rather dim.

HISTORICAL REVIEW

One of the driving forces behind open-heart surgery was the desire to replace diseased heart valves. When the pioneering efforts of Gibbon, Lillehei, and Kirklin in the first half of the 1950s eventually made it possible to access these valves openly, no prosthetic replacements were available. It took a few more years until simple mechanical prostheses enabled the first aortic valve replacement in 1960 and the first mitral valve replacement in 1961.^[6,7] The drive toward a biological replacement valve that does not require anticoagulation occurred almost simultaneously. As early as in 1961, Robert Frater began experimentally using autogenous pericardium for free-hand valves or parts of valves. Shortly thereafter, he developed a pantaloons-shaped substitute for the posterior mitral cusp out of autogenous pericardium that soon found its way into clinical practice.^[8,9] In 1962, Ross reported the first successful replacement of an aortic valve with an allogenic cadaver valve.^[10] The possibility of an antigenic response to these homografts was anticipated and soon confirmed by Mohri^[11] and Davies.^[12,13] However, since only the aortic wall portion of homograft valves seemed to degenerate with clinical consequence, not the leaflets themselves, the incentive toward an immune-quiescent tissue valve was not very strong. As a consequence, the push toward autogenic bioprostheses by Donald Ross^[14] was not carried by a strong enough clinical demand. Although the use of the patient's own pulmonary valve to replace his diseased aortic valve was first described in 1967, it took

more than two decades until the idea of autografts gained a significant following. On the contrary, the routine introduction of open-heart surgery created a worldwide bottleneck for allografts. It was therefore soon realized that this increasing demand for bioprosthetic heart valves could be satisfied only if animal tissue (xenografts) were acceptable. By denaturing the xenogenic proteins with mercurial solutions, freeze-drying, or formalin treatment, the masking of antigenicity was thought to be sufficient to allow the use of porcine tissue.^[15] This led to the first successful xenograft replacement of an aortic valve in a human in 1965.^[16] Although mechanical issues such as the mounting of the fragile muscular part of the right coronary cusp were subsequently resolved, it soon became evident that remnant immunogenicity was unacceptably high.^[17] It was concluded that fixation with monofunctional formaldehyde resulted in gradual detanning^[18] of the tissue, thereby unmasking immune and degradation sites. This led to the introduction of glutaraldehyde as a bifunctional aldehyde that resulted in distinctly longer durability of the prostheses than the one observed in early formalin-fixed valves. Two laboratories began independently experimenting with the use of glutaraldehyde for xenograft preservation: Robert and Carpentier in Paris and Hancock and Nimni in Los Angeles. The first such glutaraldehyde-preserved porcine aortic valve was clinically implanted in 1969. When it became obvious that glutaraldehyde-preserved xenograft valves showed signs of dystrophic calcification a multitude of anticalcification treatments were added without thoroughly understanding the mechanisms behind tissue mineralization. Assuming a central role of phospholipids in tissue calcification, one of the early anticalcification treatments aimed at the removal of lipids. Pioneered at the Hancock laboratories under the name "T-2 procedure" and essentially using a household detergent containing anionic surfactants to remove lipids after completion of fixation, it achieved only a moderate decrease in calcification.^[19] Alternatively, anticalcification treatments aimed at neutralizing the free aldehyde functionalities of glutaraldehyde and its reaction products, primarily via the formation of Schiff's bases with terminal aldehyde groups. Into this category fell amino-diphosphonates (ADP),^[20] amino-acid treatment such as L-glutamic acid developed by Grimm together with Sorin, and Urazole developed by Zilla with Medtronic.^[21] Although experimentally successful, only amino-oleic-acid found its way into broad use in a commercial second-generation tissue valve.^[22]

Apart from fixation and postfixation treatment, bioprosthetic concepts also differed in the source of tissue used. Although a wide range of material was initially evaluated, from human dura mater to fascia lata promoted by Åke Senning in Zurich, it soon boiled

down to the use of two main tissue sources: pericardium and aortic valve leaflets. In the earliest days of bioprosthetic heart valve replacement, pericardial substitutes were autogenous^[9] and aortic leaflet tissue was either allogenic^[10] or autogenic.^[14] Under the pressure of demand, Alain Carpentier initiated the almost uninterrupted advance of porcine valve bioprostheses in 1968. It did not take long, however, until the advantages of fully engineering the design of a tissue valve led to glutaraldehyde-fixed bovine pericardial prostheses. A boom in pericardial xenografts ensued, resulting in 10,000 clinical implants of Ionescu-Shiley valves within two years at Denton Cooley's Texas Heart Institute alone.^[23] Due to one single design error—namely the so-called “alignment stitch” at the commissure—these valves failed prematurely and discredited bovine pericardium for years. Although Carpentier addressed this issue together with Edwards from the beginning of the 1980s onward by mounting the tissue underneath the stent and not above, the surgical community remained skeptical until favorable clinical seven-year results were available.^[24] However, the woes of pericardial valves were not over yet. The flexing pericardial cusps rubbed against the cover fabric and accelerated ruptures.^[25] Eventually, by the mid 1990s it seemed as if pericardial valves were back apparently with results equal to those of porcine valves.^[26] This rehabilitation of pericardial valves allowed another development in the 1990s, which touched on a taboo of more than two decades: the possibility that insufficiently suppressed immunogenicity played a major role in xenograft failure. Autogenics developed a kit that allowed the surgeon to produce a bioprosthetic heart valve out of autologous tissue in the operating room.^[27,28] Unfortunately, the original concept of living autologous heart valve tissue soon had to be abandoned when the environmental stimulation of pericardial cells led to contracted and scarred leaflets. The subsequent inclusion of a fixation step—albeit brief and superficial—also eliminated the advantages of living tissue while reintroducing mechanical disadvantages. Although early failures led to the demise of the Autogenics concept, this approach for the first time addressed remnant antigenicity as a key issue. These ups and downs of pericardial heart valves are not unparalleled in the camp of porcine aortic valve prostheses. Inspired by the ability to produce lower profile valves with pericardium, St. Jude Medical developed a low profile version of a porcine xenograft. The increased angle of the free edge led to an increase in leaflet stress and the subsequent early failures of these valves resulted in the abandoning of the concept. While this failure eroded the bastion of porcine valve concepts through a design shortcoming, a seemingly novel alternative design approach recaptured clinical following in return. Initially driven by Biocor and

Fig. 1 Representation of modern bioprosthetic heart valves, with stented (left) and stentless models (right).

Tyrone David together with St. Jude (Toronto SPV), the aim was to reduce transvalvular gradients by eliminating the stent. Soon this concept was emulated by Medtronic (Freestyle) and Baxter (Prima) with the difference of representing more of a root prosthesis in the latter two (Fig. 1). While the advantage of a less obstructed outflow orifice remains undisputed, the other advantage of stentless valves, namely mobile commissures, soon gets lost by the distinct calcification of the aortic wall tissue of these prostheses. Nevertheless, stentless valve concepts have gained a significant following particularly in Europe and explants so far confirm that cusp mineralization and tissue degeneration at periods up to eight years are minimal.^[29–32]

All in all, the first generation of bioprosthetic heart valves appeared on stage with a bang but withdrew into early retirement soon after. Today's tissue valves differ relatively little from those of the late 1960s. The hailed new concept of stentless aortic valve prostheses is an adaptation of the homograft approach of the early 1960s to xenografts. Apart from fixing leaflet tissue in a way that preserves the natural crimp and from adding anticalcification treatments after fixation, bioprosthetic heart valves of the third millennium continue to be made of glutaraldehyde-fixed porcine aortic leaflets or bovine pericardium suspended on stents that do not dramatically differ from earlier designs. Only time will tell whether these minor improvements have a significant impact on the longevity of the prostheses. The long observation periods necessary for arriving at a conclusion certainly do not aid the speedy development of new concepts that would be required for a major breakthrough.

FAILURE OF BIOPROSTHETIC HEART VALVES

Although improvements to bioprosthetic heart valves were only moderate and incremental during the past three decades, the trend regarding primary tissue

failure points downward. In one of the biggest early series of first-generation porcine tissue valves implanted into 1648 patients between 1970 and 1980, a 10-year freedom from structural failure of 79% was found in the aortic position and 72% in the mitral.^[33] A comparable study was performed 12 years later, using second-generation porcine valves that had already undergone an anticalcification treatment.^[34] Ten-year freedom from structural failure was found in 92% of aortic valve replacements and 81% of mitral valve replacements. Although this 9% and 13% reduction in structural failure may overstate the actual situation because patients were almost five years younger in the first series, one can extrapolate from experimental studies^[35] that the introduction of more effective anticalcification treatments and the improved processing conditions in third-generation tissue valves have further reduced the incidence of structural failure. Although long-term clinical studies are not yet available, explants for nonvalve-related failures indicate that leaflet calcification is distinctly less than in previous series. In the mechanically less challenging aortic position, 10-year freedom from structural failure is thus not far from 100%, provided the patient selection remains above the cut-off age of 65 years. Recent reports on contemporary pericardial valves estimated the freedom from structural valve failure to be 97% at 17 years in aortic position and 94% at 14 years in mitral position.^[36]

The overwhelming failure mode of bioprosthetic heart valves is primary tissue degeneration. In the majority of cases, primary tissue failure leads to valve incompetence due to tears. In the mechanically more stressed mitral position, 75% of failed porcine prostheses showed rupture of a free cusp edge and 43% of the cusp belly.^[37] In only a small minority of bioprostheses does stenosis predominate as a result of excessive calcific degeneration. Overall, less than half of all failed first-generation tissue valves showed signs of calcification while cuspal perforations were the prevalent mode of failure.^[38,39] The relatively successful introduction of anticalcification treatments—at least as far as cusps are concerned—in second-generation prostheses promises that the balance between calcification and tissue degradation will shift even more toward degradation.

Generally, bioprosthetic degeneration starts long before implantation. During the initial 48–72 hours of transport between the abattoir and the plant, serious autolytic changes occur in the tissue, leading to the loss of tissue integrity primarily on a cellular level.^[40] The ability of these preimplantation damages of the bioprosthetic materials to augment calcific degeneration was demonstrated by various authors.^[41,42] Hypoxic injuries to cells concentrate a large amount of calcium in protrusions of the plasma membrane prior to

blebbing and shedding of membrane vesicles.^[43] Even under in-vitro conditions, hypoxically injured valvular interstitial cells calcified while uninjured controls did not.^[44] This in-vitro calcification emulated the one found in explanted bioprostheses by being localized in mitochondria and extracellular blebs. Mitochondria exposed to hypoxia were shown to undergo cyclic changes of swelling and shrinkage, followed by flocculation of their matrix. These densities are formed by lipolysis and signal the irreversibility of cell injury.^[45] Mitochondrial calcification is known to occur in association with these flocculent densities.^[46]

Upon implantation, plasma insudation into the tissue leads to the unphysiological deposition of blood components both inside the biomaterial and on its surface. Leukocyte adhesion and infiltration dominated by macrophages,^[47] destruction or separation of collagen fibers,^[48] and calcification follow. Apart from degenerative damages, these alterations also lead to a stiffening and thickening of the cusp tissue^[47] with the concomitant further loss of mechanical function. Other than the overgrowth of thick anastomotic intimal hyperplasia, tissue generally referred to as pannus, no endothelialization occurs with host endothelium, even after years of implantation and regardless of whether the prosthesis is stented^[49] or stentless.^[50] This lack of a nonthrombogenic surface endothelium facilitates microthrombi formation. After two months of implantation, extensive fibrin layers are found on the blood surface that are gradually replaced by a thinner fibrin coverage^[48] and mononuclear cells. Secondary mineralization of these surface appositions is referred to as extrinsic calcification. However, as much as all these aspects contribute to the overall failure of bioprosthetic tissue, there are principally four phenomena that are observed in connection with failing tissue valves: calcification, inflammation, mechanical damage, and pannus overgrowth, or a combination thereof (Fig. 2). Although all four are distinct events often occurring in isolation, they are capable of potentiating each other if they coexist. Calcification, for instance, is augmented in areas of mechanically induced collagen fractures. Similarly, inflammation is locally enhanced

Fig. 2 Typical appearance of failed tissue valves with calcification and pannus outgrowth (left) and degenerative tears (right) as the predominant lesion.

at sites of mechanical injuries and underneath the shear-force protection of pannus tissue.

Dystrophic Calcification

Prior to the advent of stentless xenografts, calcification was primarily a phenomenon of the cusps, and to a much lesser degree, of the wall remnants at the commissures. Although cusp calcification may occur at any site, it is usually seen in the commissural region and the basal region of the cusp belly. With the emergence of stentless xenograft valves, however, aortic wall calcification—a failure mode previously restricted to homografts—also became an issue. In spite of anticalcification treatments, wall calcification remains uninhibited and serious, defying one of the main arguments for stentless valves, namely commissure mobility. In contrast to the preferential location of cusp calcification, wall calcification affects the entire tubular segment of root prostheses.

Histologically, the differences in calcification patterns between leaflets and aortic wall tissue are even more distinct. While wall calcification of glutaraldehyde-fixed bioprostheses affects the inner and the outer layer of the tissue in a sandwichlike manner, cusp calcification occurs predominantly centrally in the spongiosa (Fig. 3). Differences are also seen on an ultrastructural level although the primary nucleation sites are mainly membranes of cell remnants or vesicular debris, regardless of the type of bioprosthetic tissue. In cusps and in pericardium, mineral deposits grow relatively uninhibited from the cellular nucleation sites into the loose collagenous structures of the vicinity. Overall, the morphology of calcium deposits is remarkably similar in porcine cusps and bovine

Fig. 3 Characteristic calcification pattern of a glutaraldehyde-fixed root prosthesis; calcium deposits are near the surfaces in the aortic wall (A), but centrally located in the leaflet spongiosa (B), often filling the entire cross-sectional area of the cusp.

pericardium.^[51] In aortic wall tissue, extracellular matrix (ECM) components such as elastin^[52–54] and collagen also participate in the calcification process, yet to a much lesser degree. However, the presence of large numbers of membranous vesicles in close proximity to elastin suggests that even part of the ECM calcification is facilitated by cell membranes.^[55]

Inflammatory Degradation

Every pathologist experienced with bioprosthetic explants is aware of the tattered and eroded appearance of explanted cusps (Fig. 4), with inflammatory cells often residing at the bottom of these excavations. Yet, inflammatory processes wait to be widely recognized as dominant pathogenetic factors of tissue failure partly because “burned out” explants sometimes do not even show traces of inflammatory cells. However, these are usually late observations at the end of the failure process and do not justify the trivialization of the problem. In the vast majority of explanted tissue valves, inflammatory cells were found either to cover the surfaces at almost monolayer density^[47] or focally infiltrate into the tissue.^[56] Since experimental work has shown that the initial macrophage- and plasma-cell-dominated process soon gives way to a more macrophage- and foreign body giant cell-dominated phenomenon, a flair of harmlessness ensued. Given the destructive potential of giant cells to erode even synthetic materials, it becomes obvious that these war-formations of macrophages are serious culprits of destruction. While multinucleation may lead to material failure only in synthetic implants, it appears to endow macrophages with an added powerful resorption capability to degrade and thus present extracellular components.^[57,58] Nevertheless, in a significant number of explants, mononuclear macrophages are still the predominant cell type among those inflammatory cells infiltrating below the prosthetic surface.^[59] In bovine pericardial heart valve prostheses, for instance, macrophages were regularly found

Fig. 4 Eroded surface of the cusp edge of a bioprosthetic heart valve, typically caused by chronic mononuclear inflammation.

invading and focally degrading the prosthetic collagen.^[32,60] Similarly, clinically implanted porcine valves also showed inflammatory cells inside the bioprosthetic tissue.^[47] Conspicuously, dense infiltrates of inflammatory cells were found in all valves that had failed due to tissue tearing.^[59,61] Given the particularly high levels of MMP-9 and other proteases secreted by macrophages,^[62] on top of insufficiently cross-linked degradation sites in the tissue, inflammatory degeneration emerges as a main player. Macrophage-rich areas are known to secrete MMPs constantly and produce lysis of the underlying substrate. The lytic activity also diffuses away into the surrounding tissue.^[63] The recently demonstrated synergism between proteolytic activity and mechanical strain in the degradation of pericardial tissue further highlights the detrimental role of inflammation in bioprosthetic tissue degeneration.^[64] Macrophage-mediated tissue degradation is further evidenced by the direct proof of collagen phagocytosis.^[65] In clinical series, as many as 82% of failed valves showed signs of collagen phagocytosis by macrophages by transmission electron microscopy.^[66] Others also found the presence of cross-banded collagen fibrils in cytoplasmic vacuoles of macrophages.^[67] Since some of these fragments had a periodicity of 100 nm, it appears as if not only collagen I but also collagen IV is degraded by macrophages. These fibrils were located in both electron-translucent and electron-dense vacuoles and colocalization with phosphatase activity identified some of the vacuoles as lysosomal. Although one could argue that macrophage infiltration is a consequence of collagen degeneration rather than its cause, numerous studies have demonstrated that phagocytosis of intact collagen by macrophages is a regular occurrence.^[68,69]

Proponents of the theory that tissue inflammation is unrelated to an immune response often relied on the claim that glutaraldehyde itself was proinflammatory. Grabenwöger has decisively refuted this hypothesis by demonstrating that macrophage infiltration as well as collagen phagocytosis and degradation also occur in tissue where extraction processes had thoroughly eliminated free as well as dissociable glutaraldehyde.^[68] At the same time, only those intact collagen fibers that were coated by a flocculent material of remarkable electron density were phagocytosed. This observation may well relate to an opsonization process. Since bioprosthetic tissue remains largely nonendothelialized and thus deprived of the VECAM/MCP-1 mechanism of leukocyte recruitment, opsonization is one key to local inflammation. Opsonization may occur either through preformed antibodies or as a result of more unspecific plasma proteins binding to the surfaces. Tang^[70] has shown that the strongest adhesion effect by plasma proteins is exerted by surface-bound fibrinogen, followed by IgG and albumin. As much as

unspecific opsonization with plasma proteins is likely, opsonization through preformed antibodies can be assumed to also play a role. A humoral immune response against tissue heart valves and the presence of circulating specific antibodies against glycoproteins of the bioprosthetic material^[71] has also been described, together with histological evidence for a certain degree of a low-level xenograft response. Although milder than in uncross-linked xenograft tissue,^[15] signs of xenograft rejection in the form of polymorphnuclear infiltrates were found both experimentally^[65] and in clinical explants.^[61] In 1984, Levy's and Schoen's groups had already provided a link between insufficient cross-linking and inflammation. By increasing the glutaraldehyde concentration from 0.1% to 2.0% they were able to mitigate an otherwise intense mononuclear and giant cell reaction.^[72] In analogy to Nimni's work of the 1980s in which enhanced cross-linking through long-range diamine extensions of glutaraldehyde cross-links achieved a mitigation of remnant immunogenicity, diamine extension also led to a distinct suppression of inflammation in our own experiments.^[73] In conventionally fixed, low-glutaraldehyde-treated porcine valves, in which we had demonstrated a low cross-link density, the inflammatory reaction was distinct, particularly in the fibrosa of leaflets. Infiltrating cells were identified as macrophages in their majority, but in the primate model the percentage of polymorphnuclear granulocytes was significant^[65] (Fig. 5). The preferential infiltration of the fibrosa of leaflets was in accordance with other studies that also found collagen-destructive macrophages primarily in the fibrosa.^[74] In contrast, inflammation could practically be eradicated when GA concentrations were increased and additional long-range bonds introduced. While spots of foreign body giant cells were occasionally still found in the adventitial area of this highly cross-linked tissue, leaflets were completely free of inflammation.^[75]

Fig. 5 Histological sections of glutaraldehyde-fixed porcine aortic root tissue after 6 weeks of experimental implantation. (a) Leaflet, 0.2% glutaraldehyde; (b) leaflet, 3% glutaraldehyde + L-Lysine. Note the distinct inflammatory infiltration and erosion of the fibrosa in the 0.2% group as opposed to a regularly unaffected, noneroded leaflet surface in the 3% glutaraldehyde-plus-diamine group.

One of the strongest alternative mechanisms for macrophage adhesion apart from opsonization is low shear stress. While the high shear stress in main arteries ($15\text{--}20\text{ dynes/cm}^2$)^[76] down-regulates adhesion molecules on the endothelial surface, the low shear stress in capillaries ($0.5\text{--}2.0\text{ dynes/cm}^2$) rather serves to up-regulate them, thereby facilitating diapedesis. This pathway is the likely force behind the strong inflammatory cell recruitment seen on the adventitial side of root prostheses.^[65] In the absence of an endothelium, as is the case on the blood surface of bioprosthetic heart valves, shear stress itself provides a similar, albeit mitigated, effect on its own. One would therefore expect direct macrophage adherence to flow-protected areas of the blood surface of bioprosthetic heart valves as a consequence of low shear stress. Flow-protected, low shear-stress areas on the blood surface include the surface of the fibrosa of the leaflets. Against the widespread belief that turbulences cause particularly high shear forces on this inflow surface, the opposite seems to be true: Bellhouse and Talbot used a quasisteady laminar model to describe the pulsatile vortex motion within the sinus. From these calculations, the shear stresses within the sinus are lower than those experienced on the ventricularis side of the cusp. Even if one needs to caution that these results are for laminar steady flow, and the Hill Vortex Model is a simple in-viscid flow model, which describes the complex nature of the pulsatile flow as quasisteady, it represents a valuable tool for such a flow situation. Calculations for arterial wall shear stresses are known to be extremely difficult and according to Ku,^[77] tend to represent estimates that may have errors as high as 20–50%. In the case of bioprosthetic heart valves, these estimates at least replace perceptions to the contrary by the strong evidence that the shear forces within the vortex-flow area of the sinus—including the fibrosa of leaflets—are lower than those on the ventricularis side. These theoretical considerations correspond with histological observations: Infiltrating inflammatory cells are found on the fibrosa surface rather than the ventricularis surface of leaflets^[65,74] as well as the inside of the lower sinus portion and the adventitial surface of root prostheses.^[65,73] In analogy, it is not surprising that the highest macrophage density is regularly found in completely flow-protected areas such as the interface between the prosthesis and surface thrombi^[37,78] or the prosthesis and pannus tissue.^[39] In contrast, inflammatory cells are practically always absent on the blood surface of the supra-commissural aortic wall of root prostheses,^[78] where high shear forces are further augmented by the systolic jet through the valve orifice.^[79]

Concluding these observations, it is unlikely that future valve designs will address these low shear-stress regions of bioprosthetic heart valves. Therefore, the

key to the suppression of inflammation seems to lie in mitigated opsonization. The successful reduction^[72] or elimination^[73] of inflammatory infiltrates through higher cross-link density demonstrated that cross-linking chemistry again holds a key to a pivotal problem of tissue valve failure.

Mechanical Injury

Native aortic valves function on the basis of a delicate combination of macro- and micromechanics. One of the basic macromechanical principles is the avoidance of cusp-bending at acute angles. A distinct dilatation of the annulus during systole results in the triangular stretching of cusp tissue, thereby avoiding bending at the commissures of more than 60° ^[80] (Fig. 6). Micro-mechanically, a sophisticated trilayered ultrastructural architecture ascertains optimal stress reduction. In principle, this trilayered architecture is based on a relatively smooth lamina ventricularis on the outflow side and a folded lamina fibrosa on the inflow side, separated by the sliding gap of the lamina spongiosa. When leaflets bend during valve opening, compressive stresses are generated on the inner surface of the bend and tensile stresses on the outside surface.^[81] When native leaflets flex radially, very little tension is generated in the outer ventricularis, since the already deeply folded fibrosa can be readily accommodated by the loose connection between the two that passes through the spongiosa.^[81] Moreover, even collagen fibrils—the steel cables of cusp support—have a series of complex built-in structural aspects that act as shock absorbers. Although collagen fibrils themselves are stiff and have a limited extensibility of 1–2% before breaking,^[55]

Fig. 6 Root mechanics of the aortic valve. While a native root shows a marked annular distension during systole and thereby a more triangular opening of the leaflets (right, top), the fixed annular diameter of prosthetic valves results in a much more acute bending angle of the leaflets during the outflow phase (bottom).

waviness allows aortic cusp collagen to strain up to 17%. Macrocrimping adds an additional 23%, pushing the overall strain acceptance to 40%.^[82] Together with the recoil effect of the elastic elements of the cusp tissue, this micromechanical shock-absorber principle leads to a 50% increase in cross-sectional cusp thickness in the relaxed state.^[83]

Bioprosthetic heart valves—stented or stentless—defy both main principles of valve mechanics: By either stent-mounting, or through glutaraldehyde fixation, annular dilatation during systole is either eliminated or dramatically diminished. As a consequence, the bending angle becomes acute and reverse curvature and buckling ensues. Vesely has hypothesized that tissue buckling may be an important failure mechanism of bioprosthetic heart valves.^[84] By eliminating the sliding gap between the ventricularis and the fibrosa as a result of cross-linking, a major means of stress distribution is lost. Furthermore, the loss of macrocrimping of the lamina fibrosa critically reduces stress acceptance. While macrocrimping was already lost as a result of pressure fixation of cusp tissue during manufacture of earlier generations of tissue valves, low-pressure fixation (St. Jude Medical Toronto Stentless Porcine valve: 2–4 mmHg) or zero-pressure fixation (Medtronic Freestyle Valve: 0 mmHg) was thought to preserve this crucial element of valve architecture. Observations by Sacks^[85] and those of Christie,^[86] however, suggest that the collagen fiber architecture of 0 mmHg-fixed heart valves, although locked in place by chemical fixation, may not be maintained over a sufficient number of cycles to be clinically beneficial. After only 6 months of implantation, radial and circumferential extensibility decreased by 30% and 80%, respectively.^[86]

In view of the dramatic loss of physiological valve mechanics, it is not surprising that major ultrastructural injuries such as severe collagen breakdown are regularly observed in the major stress zones of bioprosthetic heart valves.^[47] Collagen fibrils also lose their compact arrangement as early as after two months and are distinctly separated after two years.^[48] Not only does injured and fragmented collagen lead to an augmentation of local macrophage activity, but also to facilitated protease digestion. Cyclic fatigue of glutaraldehyde-fixed porcine aortic valve bioprostheses was shown to lead to a progressive loss of helicity of cusp collagen as well as loss of glycosaminoglycans from the cuspal ECM.^[87] While the first exposes collagen to both tissue-bound but still active^[88] gelatinases and proteases released by host inflammatory cells, the latter further contributes to tissue stiffness.

In clinically implanted bioprosthetic heart valves, nothing highlights the contribution of mechanical damage to the overall failure of tissue valves more than the distinctly higher failure rate in mitral than in aortic

position where the loading pressure is diastolic rather than systolic.

Pannus Overgrowth

With the emergence of stentless valve prostheses, myointimal host-tissue overgrowth became a significant reason for concern due to the fact that the suture line is closer to the cusps than in stented valves. Yet, overgrowth of this so-called pannus tissue is also a feared complication of stented and even mechanical heart valve prostheses. In the mitral position, for instance, a significant proportion of failed tissue valves showed pannus overgrowth on the inflow aspect.^[59]

Although the outgrowth of anastomotic intimal tissue onto the prosthetic surface is a multi-factorial event, inflammation certainly contributes to the provision of a sustained growth signal for myointimal tissue. One of the elements of inflammation in bioprosthetic heart valves is the chronic foreign body reaction against the sewing ring material. The dominant cells in this reaction are macrophages that are known to secrete an extended range of powerful cytokines, including IL-1, PDGF, bFGF, etc.^[89] Furthermore, Greisler demonstrated that the interaction of Dacron material—the main component of most sewing rings—with macrophages leads to a particularly strong up-regulation of growth factors such as bFGF.^[90] However, although it was shown that a foreign body reaction against inert materials such as Dacron provides an ongoing stimulus for macrophages to secrete growth factors, an additional specific immune response directed against the bioprosthetic tissue may significantly augment this phenomenon. Apart from enabling the presentation of foreign peptides to the immune system of the host, the augmented digestion of collagen by giant cells—wedged between the pannus and the bioprosthetic tissue—releases even more high-molecular weight peptides. These peptides possess a great chemotactic attraction for fibroblasts.^[91] Since giant cells are also known to secrete IL-1 β and bFGF in abundance—sometimes even after years^[92,93]—fibroblasts and myofibroblasts of the pannus tissue receive a distinct local stimulus for proliferation. In addition to this growth factor stimulus, the interaction of macrophages with T-helper cells leads to further IL-1 secretion, which augments the production of PDGF by SMCs.^[94,95] On top of up-regulating PDGF, the strongest known mitogen for smooth muscle cells, macrophage-derived IL-1 itself also regulates the growth, proliferation, and protein synthesis of fibroblasts.^[96–103]

Immune-activated macrophages are known to induce the vascular myointimal proliferation in heart transplant recipients, which ultimately leads to

ischaemic graft failure.^[104] Similarly, macrophages have been implicated in a hyperplastic intimal response in homograft heart valves, a phenomenon that was distinctly less pronounced in isografts.^[105] If the homograft recipients were immunologically pre-sensitized, this myointimal thickening was seen to be particularly prominent,^[105] further demonstrating the pivotal role immune processes appear to play in myointimal proliferation.

In order to tie insufficient masking of bioprosthetic antigens to myointimal pannus out-growth, however, one needs to correlate cross-link efficiency with macrophage activation and pannus outgrowth. For the interaction of biomaterials with macrophages, the triple sequence of events, namely adherence, spreading, and secretion of inflammatory mediators such as TNF- α , IL-1 β ,^[106] and IL-6,^[107] has been well established. Since spreading is additionally linked to the macrophage's ability to up-regulate its hydrolytic degradation potential, spreading is an essential element of antigen presentation by macrophages. Simply by increasing the glutaraldehyde concentration from 0.2% to 3.0%, a significant reduction of the spreading area of macrophages was observed.^[108] Since both groups had undergone thorough detoxification,^[21] this phenomenon cannot be explained by the cytotoxic effect of glutaraldehyde. Similarly, diamine-enhanced cross-linking at 3% glutaraldehyde not only resulted in the near abolition of an inflammatory response, but also in a significant suppression of pannus outgrowth. After six weeks of sheep implantations of aortic root prostheses, the length of the proximal pannus overgrowing the leaflet base was five times shorter in the enhanced, cross-linked group than in the conventional 0.2% GA-fixed roots (Fig. 7). Tissue was

Fig. 7 The suppression of inflammation is associated with a significant mitigation of pannus outgrowth: aortic root prostheses fixed at either 0.2% glutaraldehyde or L-Lysine-enhanced 3% glutaraldehyde showed a 3–4.5-times shorter pannus outgrowth onto the prosthetic tissue after 6 weeks and 6 months of implantation, respectively. Preoperatively, all root-prostheses had been thoroughly detoxified through glutaraldehyde pacification.

again thoroughly detoxified before implantation. When giant cells at the interface of pannus and prosthetic tissue were correlated with cross-sectional pannus area or pannus length, a direct correlation emerged between cross-link and giant cell density.^[73]

Therefore, in view of the dramatic mitigation of pannus outgrowth through better cross-linking of tissue, it seems important to extend the alert-list of immune and inflammatory phenomena that may contribute to bioprosthetic heart valve failure to the potentially leaflet-immobilizing phenomenon of anastomotic pannus outgrowth.

THE CRUX OF THE MATTER

In the past 40 years, bioprosthetic heart valves meant a blessing for hundreds of thousands of patients. Many of the initial patients, however, may have been better off with a mechanical prosthesis because they were young and their first-generation tissue valves calcified rapidly. The disappointment of the surgeons of these early implants was huge and many opinion leaders of today are veterans of this pioneering era. The resulting paradigm reserving bioprosthetic heart valves for the geriatric patient group has led to a biased assessment of risks associated with anticoagulation in mechanical valves. A paradigm shift on the basis of a consensus regarding the acceptance of a reoperation as a trade off for a better quality of life seems overdue.

Similarly, decades of tissue valve research were obsessed with calcific degeneration because first-generation prostheses failed on the basis of dystrophic mineralization. An urgent refocusing on the real culprit of bioprosthetic degeneration, namely inflammatory degradation and inflammation-triggered pannus overgrowth, seems to hold a key to a quantum leap in the development of longer lasting tissue valves.

Heart Valve Failure, Bioprosthetic

Peter Zilla

Paul Human

Deon Bezuidenhout

Christian Barnard Department of Cardiothoracic Surgery, University of Cape Town Medical School, and Grootte Schuur Hospital, Cape Town, South Africa

INTRODUCTION

The most sobering aspect in the search for causative factors in the degeneration of bioprosthetic heart valves is the necessity to capitulate before the single most important etiological factor: the absence of living tissue in all contemporary bioprosthetic heart valves. However, as long as tissue engineering concepts remain a future promise, this lack of vitality will remain an integral part of bioprostheses.

The second most powerful determinant affecting the fate of tissue heart valves is not even related to the bioprosthesis itself: It is the environment provided by the host. While only half of first generation tissue valves have failed after 15 years of implantation into recipients of more than 60 years of age, practically all of them have failed after 5 years in children.^[1] This dramatic early degeneration in children obliterates all differences one encounters in the various valve types in adults: Regardless of whether the prosthesis was a homograft, a pericardial xenograft, or a porcine xenograft, calcific degeneration became significant before five years of implantation.^[1] In a less dramatic but nevertheless still very distinct fashion bioprostheses also degenerate in an accelerated way in patients on dialysis.

Against this framework, the quest for understanding the basic triggers of prosthesis-related tissue valve failure has been largely unsuccessful. Within the chain of events leading to severe tissue degeneration the focus was often on isolated downstream aspects rather than the bigger picture. Although each of these aspects undisputedly plays a role in the gradual loss of the function of the bioprosthetic tissue, a more comprehensive mechanism behind this development has yet to emerge. Singling out phospholipids in the cell membranes or poorly suppressed membrane-associated alkaline phosphatase molecules reveals mosaic stones but keeps the mural hidden. To get to the bottom of etiological factors behind bioprosthetic tissue failure, one may need to revisit some fundamental principles behind the concept.

ADVERSE EFFECTS OF GLUTARALDEHYDE CROSS-LINK CHEMISTRY

The core principle behind xenograft heart valves is the necessity to mask antigenicity through cross-linking. Complacency regarding the relatively effective cross-linking agent glutaraldehyde (GA) represents one of the major areas of neglect of the past three decades. Not only did this conservative approach to tissue fixation lead to a lack of research into understanding and engineering of optimized cross-links, but it also led to an almost fatalistic acceptance of the adverse effects of commercial glutaraldehyde cross-linking. Whether these adverse aspects were the alleged procalcific effects of glutaraldehyde reaction products, the inability of cross-linking procedures to mask antigenicity and calcium-nucleation sites sufficiently, or the mechanical damage resulting from tissue stiffness; cross-link chemistry had been sacrificed on the altar of anti-calcification treatments. This complacent continuation with one and the same cross-linking process for 35 years was partly based on an illusion, namely the perception that glutaraldehyde ideally represents the keep-it-simple principle. Being a short di-aldehyde, even surgeons could comprehend the perceived straight-forward bridge-formation of this molecule between two amine groups in the tissue. When it slowly became clear that we only saw the tip of the iceberg, too much already hinged on this central element of bioprosthetic heart valve production to change the course easily. Today, we know that the GA-fixation process is much more complex than initially thought. By now it is generally accepted that the Schiff's base intermediates that are initially formed by the reaction of the aldehyde groups with the ϵ -amino groups of L-Lysine or hydroxylysine residues are only the starting point for a variety of subsequent reactions.^[2] However, in spite of decades of use of GA for the production of bioprosthetic heart valves, many of these reactions remain in the realm of speculation or hypothetical interpretation. Cheung and Nimni have suggested that the formed Schiff bases are stable and that cross-links

might be formed after aldol condensation followed by the formation of another Schiff base.^[2] These pioneers of glutaraldehyde cross-link chemistry also suggested that α - β -unsaturated Schiff's bases form, after which cross-linking can be achieved by reaction of L-Lysine ϵ -amine groups with the α - β -unsaturated Schiff's base (Michael addition), or by reaction of the aldehyde endgroup of the unsaturated Schiff's base with amine groups. A Mannich-type reaction between the protonated Schiff's base and the GA-related enol resulting in the formation of a secondary amine was also suggested.^[3,4] Aldol condensation and subsequent reaction with the ϵ -amino groups of proteins can result in the formation of aliphatic cross-links. The reaction of the secondary amines with other GA molecules followed by ring closure would lead to a six-membered dihydropyridine.^[3] Oxygen present in the cross-linking solution may oxidize dihydropyridinium-type cross-links resulting in the formation of substituted quaternary pyridinium-type cross-links.^[5] Last but not least, glutaraldehyde's propensity to autopolymerize after ring-formation to hemiacetals adds a further complicating aspect, namely the ability of tissue to store large amounts of the dialdehyde in the form of poly-hemiacetals and to release free glutaraldehyde after depolymerization later on. This vaguely understood and highly complex chemistry of glutaraldehyde makes it very difficult to establish any correlations between the chemical modifications that have taken place and the resulting biological behavior, particularly glutaraldehyde's suspected role in bioprosthetic tissue calcification. One directly assessable effect of glutaraldehyde, however, is tissue stiffness, which can increase up to twentyfold compared with native tissue.^[6] Considering the fact that commercially used concentrations of GA are still incapable of fully masking antigenicity, this is a high price to pay. Another easily assessable disadvantage of glutaraldehyde

is its toxicity—even at low concentrations—which is potentiated by the reservoir effect of polyhemiacetals in the tissue.

In the past various attempts have been made to achieve optimization of cross-linking chemistry *without* abandoning glutaraldehyde fixation altogether. In order to mask immune and degradation sites better, enhanced fixation was successfully attempted. By either increasing concentrations of GA alone or in combination with a bridging diamine such as L-Lysine in order to create additional longer-range cross-links between terminal aldehyde groups, calcification could be distinctly suppressed and degradability mitigated, but tissue stiffness further increased^[7] (Fig. 1).

Some clarity with regard to the alleged procalcific effect of GA could be reached through the blocking of residual aldehydes under low pH conditions. Grimm successfully used L-glutamic acid for leaflet detoxification, whereas our group tried to identify the most optimal detoxification agent and the most optimal reaction conditions in the more challenging aortic wall tissue. When we compared 12 different amino reagents from four chemical groups (low pKa aromatic amines, amino acids, low pKa N-heterocyclic compounds, and amino sugars), all 12 amino reagents were able to detoxify aortic wall tissue satisfactorily, with Urazole satisfying most of the demands on the process.^[8] Alternatively, diphosphonates, which are believed to act twofold on calcification, were used: Aldehyde stabilization occurs through binding via Schiff's bases and subsequent stabilization with NaBH₄, while restriction of crystal growth is thought to occur through direct diphosphonate binding to developing hydroxyapatite nucleation sites.^[9] The precise mechanism of the anticalcification effect of α -amino-oleic-acid (AOA[®])—the anticalcification substance incorporated into Medtronic's Mosaic and Freestyle valves—is not fully understood either, but it is thought that it also

Fig. 1 Correlation between pronase resistance of aortic wall tissue and calcification in the sheep and the rat model. By increasing the cross-link density through increasing glutaraldehyde concentrations and eventually through the additional introduction of diamine bridges (L-lysine), the degradation resistance goes up while tissue calcification decreases dramatically.

Fig. 2 Dramatic effect of glutaraldehyde detoxification on leaflet calcification. In contrast to aortic wall tissue where higher cross-link density is crucial, detoxification even at low glutaraldehyde concentrations practically eliminates calcification in leaflets.

binds with its 2-amino groups to free aldehyde groups. Residual aldehyde is pivotal for the binding of AOA, which is only effective on leaflet tissue, not on aortic wall.^[10] The fact that these detoxification treatments did not only remove tissue toxicity to an extent that endothelial cells could grow on the tissue^[8] but also significantly mitigated tissue calcification^[7,9,11] (Fig. 2) clearly proves that glutaraldehyde and its reaction products themselves contribute to calcification. The observation that leaflet calcification could be practically abolished without reversing GA cross-links refuted previous suspicions that GA cross-links themselves were the culprits of calcification.^[12]

Thus, one of the main thrusts of an engineering approach to cross-linking will be an optimization of cross-link efficiency *and* of tissue softness on the basis of a nontoxic cross-linking procedure. It is predictable that such an engineered cross-linking procedure will not be glutaraldehyde based.

FAILURE TO INACTIVATE CALCIUM BINDING SITES

Another principle behind bioprosthetic heart valve failure lies in the recognition of the fact that once nucleation is initiated, crystals tend to grow. Therefore, a deeper understanding of nucleation sites is required than the mere recognition that membrane phospholipids represent natural interaction sites for calcium ions. Recent insight into the structure and function of active calcium binding sites as well as into their ability to remain unaffected by contemporary cross-linking highlights the importance of a molecular focus on nucleation sites.^[13]

Although cellular elements were recognized as primary calcification sites for a long time, the process of calcification was mainly explained with passive

processes. The breakdown of an active gradient of a 10,000-times higher calcium concentration in the extracellular space and its uninhibited influx as a consequence of cell death and disintegration was seen as a main mechanism of early nucleation.^[14,15] It was hypothesized that phosphorus-containing sites such as phospholipids and proteolipids as well as enzymatic systems metabolizing high energy phosphates passively attract calcium ions.^[15] When it was discovered that alkaline phosphatase activity was still detectable after glutaraldehyde fixation,^[16] it did not lead to a revisiting of cross-link chemistry. It did, however, lead to an attempt to explain the anticalcification effect of Al^{+++} and Fe^{+++} with a competitive effect on the Zn^{++} and Mg^{++} binding sites of alkaline phosphatase.^[17]

A second look at the molecular events surrounding the calcium transport through the cell membrane and the molecular composition of active calcium binding sites made it clear that cross-linking approaches based on the utilization of ϵ -amino groups would not be able to prevent active calcium binding. By adapting the cross-link chemistry of the fixation process to the molecular needs of these calcium binding sites, membrane nucleation sites could practically be abolished.^[13]

Calcium plays an important role as an activator in the signaling of contraction in vascular smooth muscle cells. Calcium enters the cell via a passive voltage-gated channel and binds to intracellular calmodulin. The intracellular calcium-calmodulin complex activates phosphorylation of myosin and hence triggers smooth muscle cell contraction.^[18] In living cells, the intracellular free calcium concentration is approximately 10^{-7} M while the extracellular calcium concentration is approximately 10^{-3} M. The 10,000-times lower intracellular calcium concentration across the cell membrane is maintained by the action of the energy-dependent calcium pump Ca^{++} -ATPase, a transmembrane protein that can transport two Ca^{++} ions across the membrane

against a calcium gradient at the expense of the hydrolysis of one ATP molecule.^[19,20] Thus, calcium enters the cell by diffusion through gradient-dependent passive channels but is actively ejected from the cell via ATP pumps.^[21] In bioprosthetic tissue, cells are rendered nonviable by the fixation process. Apart from the loss of compartmental integrity of cells due to hypoxic disruptions prior to fixation, energy is not available in the cross-linked membranes and the calcium extrusion process is impaired. A longstanding theory held that membrane phospholipids bathing in the high concentrations of calcium form the nucleation sites for mineralization.^[22] It appears as if the Ca^{++} ATPase rather than phospholipids holds a key to membrane calcification.

The catalytic site of Ca^{++} ATPase comprising the ATP binding site and phosphorylation site were thought to be located on the cytoplasmic side with the high-affinity calcium binding site being buried in the membrane. Using site directed mutagenesis, two Ca^{++} binding sites were elucidated. Glu and Asp are associated with one site, Glu and Thr with the other, and Asp with both. This suggests that the two sites are distinguishable and that the spatial arrangement of Glu, Glu, Asp, Thr, and Asp can be superimposed in a membrane ion channel. Site-directed mutagenesis also revealed that an aspartate in the phosphate binding site is crucial for its catalytic effect.

A key to understanding calcium accumulation in the membrane was provided by the discovery that glutaraldehyde cross-links the ATP binding site of Ca^{++} ATPase but does not affect phosphorylation. Calcium can thus proceed with binding to the Ca^{++} binding sites but the subsequent transport across the membrane is blocked.^[23,24] This implies that lysyl residues are part of the ATP binding site. Alternatively, when carboxyl groups were cross-linked using carbodiimide-based fixatives, the Ca^{++} ATPase ability to phosphorylation was abolished.^[25] It was hypothesized that carbodiimide cross-links were introduced to the carboxyl groups on aspartate and glutamate side chains, thereby altering the tertiary structure of the Ca^{++} ATPase at Asp and Glu-rich Ca^{++} binding sites.

Similarly, calmodulin—a calcium modulator protein—binds up to four calcium ions, thereby transforming its structure and becoming activated. The activated calmodulin is able to interact with the myosin light chain kinase, causing contraction through phosphorylation. Calmodulin is a single chain of 148 amino acids, 25% of these, or 37, being either aspartate or glutamate.^[26] It is thought that the negatively charged carboxyl groups on aspartate and glutamate are crucially involved in calcium binding. Carbodiimide-based cross-linking of those aspartate and glutamate residues would then alter the spatial configuration of the protein, thereby inhibiting its calcium binding activity and

hence terminating the down-stream activation of phosphorylation. A further example for a molecule with a calcium binding site that is not accessible to glutaraldehyde but to carbodiimide-based carboxyl group fixation is alkaline phosphatase (AP). AP contains a calcium binding site whereby the calcium binding is coordinated by the carboxyl groups of Glu 218, Glu 274, Asp 289, and Phe 273, plus a water molecule. Mutations of any of these three—Glu 218, Glu 274, or Asp 289—result in a severe form of hypophosphatasia.^[27] Since the aspartate and glutamate amino acids are essential for the calcium binding potential of AP, carbodiimide-based cross-linking of carboxyl groups is hypothesized to prevent the escalation of phosphate concentrations through impairment of the phosphate hydrolytic mechanism.

If these membrane-located calcium binding molecules were really the mediators of membrane calcification, and the carboxyl group cross-linking of the aspartates and glutamates in their calcium binding domain were capable of blocking this reaction, it should be possible to suppress membrane bound nucleation sites in bioprosthetic tissue. In order to prove this, an extensive transmission electron microscopy study was performed whereby 16,000 individual calcium particles in bioprosthetic tissue either cross-linked with glutaraldehyde or carbodiimide were analyzed. The outcome of this analysis was impressive: Carboxyl group cross-linking dramatically suppressed membrane-bound nucleation sites, even if a carbodiimide treatment was added to a glutaraldehyde-based tissue fixation^[13] (Fig. 3).

The consequences of this observation are serious: First of all, by using a carboxyl group-based cross-linking procedure, the overall calcification of bioprosthetic tissue could be dramatically reduced. This is in accordance with the known phenomenon of a dominance of cell-associated calcification. Secondly, by eliminating the problem of cells acting as primary nucleation sites, decellularization attempts become less important. Thirdly, by eliminating the membranous nucleation sites, immediate fixation becomes less of an issue. Due to hypoxia-induced cell injuries, delayed fixation had significantly contributed to the calcification of bioprosthetic tissue.

REMNANT TISSUE IMMUNOGENICITY

The most fundamental principle behind the concept of xenograft prostheses is the assumption that immunogenicity is sufficiently suppressed. Although scientific proof has never been provided, there was a widely prevailing clinical perception that this assumption reflected the reality. Today, there is increasing

Fig. 3 Assessment of early calcification sites by transmission electron microscopy-based image analysis. There is a dramatic suppression of nucleation sites if carboxyl-group cross-linking (carbodiimide fixation) is used as opposed to amino group cross-linking (glutaraldehyde fixation).

recognition that the defense system of the recipient does in fact damage the implant through immune mechanisms.^[28-31]

It has long been known that the low-dose glutaraldehyde treatment applied to the fixation of bioprosthetic heart valves only reduces immunogenicity but does not abolish it. The low-grade fixation used in commercial valve preparation fails to alter membrane bound receptors or structural glycoproteins significantly,^[32] thus eliciting both cellular and humoral immune responses.^[30] Various groups, for instance, have demonstrated the generation of specific antibodies against pericardium fixed in 0.2% glutaraldehyde.^[30,33] The main criticism against these studies was the fact that their subcutaneous administration of immunogens hardly reflects the low-grade exposure to the immune system of intracardially placed bioprosthetic tissue. Yet, circulating antibodies were regularly detected in human recipients of bioprosthetic heart valves. In patients with porcine valves, specific antibodies were detected in as many as 58%.^[34] In homograft patients, 82% of recipients presented with a specific antibody response, 92% of which produced IgG against HLA class I antigens.^[35] In view of the role preformed antibodies play in the opsonization of antigen, the detection of preformed IgG antibodies in 67% of patients may certainly also have significance.^[29] Together, these IgG antibodies bind to the poorly masked tissue thereby inducing monocytes to both take up residence and differentiate into macrophages.^[36,37] In an attempt to mitigate tissue antigenicity, Nimni successfully increased the cross-link density in tissue.^[38] Subsequently, our own group investigated the ability of improved cross-linking of tissue to suppress specific circulating antibodies. While a significant antibody response was found against 0.2% GA-fixed tissue, there were practically no detectable graft-specific circulating antibodies in the enhanced fixation group (Fig. 4). When some of these circulating antibodies were identified, the strongest response was found against porcine fibronectin.

This discovery of a bioprosthetic immunogen other than the much-debated MHC molecules may be of particular importance in view of recent discussions surrounding MHC involvement in heart valves. Furthermore, the identification of fibronectin as immunogen also affirms previous studies in which extracellular matrix proteins such as collagen and elastin were found to elicit an immune response.^[39-41] It is against this background that we must see recent reports describing heart valve tissue as immune-privileged. The term immune-privileged was coined by the authors of a study that failed to detect class I antigens on valvular endothelial cells.^[42] This finding was not only refuted by others who did find class I antigens on valvular endothelial cells,^[43,44] but its overall relevance may be

Fig. 4 Densitometric scan of Western blot analysis showing IgG response to porcine fibronectin in New Zealand White rabbits following immunization and boosting with homogenates of glutaraldehyde-fixed porcine aortic wall tissue in Freund's incomplete adjuvant. It is obvious that conventional (0.2% GA) and higher glutaraldehyde fixation (1.0% GA; 3.0% GA) were incapable of suppressing a specific humoral antibody (Ab) response. Only high-density cross-linking with diamine-enhanced 3% glutaraldehyde abolished xeno-antigen recognition leading to a specific Ab response.

diminished in view of the observation of class II antigens rather than class I antigens contributing to bioprosthetic valve failure^[45] and extracellular matrix proteins being capable of inducing a strong specific antibody response.

The most crucial step in proving the involvement of an immune response in tissue valve failure going beyond inflammatory destruction, however, was the demonstration of a link between an immune response and calcific degeneration. In the past few years, both Vincentelli's and our own group have provided this proof independently. Vincentelli et al. demonstrated in 1998^[31] that xenogenic tissue fixed in 0.65% GA calcified 35 times more in the same animal model compared to fixed autologous tissue. Our group found a direct correlation between cross-link density, inflammation, and calcification in both the rat^[46] and the sheep model.^[47] By subsequently demonstrating threefold higher calcification in aortic wall tissue that was preincubated in serum containing high levels of graft-specific antibodies^[48,49] we were eventually able to provide a direct immune-calcification link (Fig. 5).

For many years, this missing link between an immune response and tissue calcification was the main argument for contesting a role of immune mechanisms in bioprosthetic heart valve degeneration. Still, after strong evidence for such a link has now been provided, it will take a while and further experiments to lessen the opinion-forming impact of a study published in the early 1980s by Bob Levy's group. These authors described bioprosthetic calcification in both T-cell deficient mice^[50] and in cage models that prevented the direct interaction of the bioprosthetic tissue with the cellular immune system.^[51] In the meantime, deeper

insight into immune mechanisms has discovered T-cell independent (TI) humoral immune responses, whereby TI type 2 antigens may activate CD5+ B-lymphocytes in the congenitally athymic nude mouse.

The categorical exclusion of immunogenicity as a contributing factor to bioprosthetic tissue degeneration in the 1980s and early 1990s certainly contributed to the fact that observations in this direction started late and the mechanisms involved are still unidentified. However, it is surprising that the obvious conclusion of a link between insufficiently masked immunogenicity and bioprosthetic degeneration had not been drawn earlier. Differences in mid-to long-term responses between allografts and autografts highlighted the role of immune mechanisms in bioprosthetic graft failure particularly strongly and as early as 30 years ago. Although the collagenous elements of aortic roots do not differ between allografts and autografts, only the aortic wall collagen of allografts but not of autografts calcifies after implantation. This observation alone should have raised early suspicions regarding the possibility of immune calcification.

Nevertheless, once the focus had shifted, supportive data kept coming in. In allografts, for instance, with their milder immune differences, trends in clinical studies began to suggest a role for immune degeneration. Yacoub found an increased prevalence of valve degeneration in patients who had circulating antibodies against MHC molecules.^[35,44] O'Brien's group also found an association between allograft valve dysfunction and HLA-DR mismatch, equally suggesting that elements of the antidonor immune response penetrate and damage homografts.^[45] In xenografts, an interesting study by Eishi et al. in

Fig. 5 Influence of a specific immune reaction between circulating antibodies and bioprosthetic aortic wall tissue on dystrophic calcification: After immunization of rabbits against aortic wall tissue, bioprosthetic tissue was incubated with either autologous preimmunization serum or autologous postimmunization serum. Calcification of the bioprosthetic tissue was distinctly higher if exposed to specific antibodies.

1996^[52] demonstrated in Takayasu patients requiring aortic valve replacement that the administration of steroids significantly suppressed calcification.^[52] Dahm et al. also contributed strong clinical evidence for the role of immune mechanisms in bioprosthetic valve failure. While 100% of patients with failed tissue valves had circulating antibodies against the bioprosthetic material, specific antibodies were found in only 25% of patients with intact valves.^[29] Further information contributing to the puzzle comes from Chauvaud.^[53] This report describes the observation that autologous pericardium failed to degenerate and calcify in a relatively large clinical series. Experimentally, it was also a rather recent observation that bioprosthetic tissue calcifies significantly less in the immune-tolerant Fischer rat than the other strains.^[54]

In spite of all the evidence, however, the lack of a meaningful hypothesis as to how an immune response augments tissue calcification emphasizes that we are still in a phase of observation rather than basic understanding. The main challenge ahead will thus be to both identify more tissue antigens eliciting a specific reaction and elucidate the exact mechanisms through which antibody binding facilitates degeneration. Once again, the medium- to long-term key to prevention seems to lie in either antigen removal or improved antigen masking. The discovery of the extracellular matrix being an antigen site that elicits a strong response makes it likely that cellular antigen removal without concomitant cross-linking or removal of ECM antigens will not succeed.

WEAKNESSES IN VALVE DESIGN

In porcine bioprostheses, valve design deals with the optimal suspension of cusps and commissural tissue on a frame in order to minimize potentially damaging stress and strain and to enable the surgeon to attach the valve to the patient's annulus with relative ease using a single row of sutures. In pericardial tissue valves, however, the term design implies significantly more than optimal suspension because the leaflet shape does not necessarily have to emulate native cusps and can thus be an integral part of the engineering efforts.

The overall goal of valve design is the minimization of stress concentrations within the cuspal tissue that may lead to early failure. At the beginning of such an engineering effort stands the assessment of the mechanics of native heart valves. Particularly, flexural stresses play an important role in limiting long-term durability. This highlights the necessity of an engineering approach that integrates material properties and cusp mechanics in a sophisticated way. Therefore, characterization and quantification of bioprosthetic leaflet motion during the opening and closing of the

valve is as important as the in-depth understanding of the fatigue life, compliance, and pliability of the prosthetic biomaterial.

Valve design is expected to profit significantly from technological progress both in computer modeling and in the development of test systems of recent years. Novel optical-based valve-imaging systems on the basis of a structured laser-light projection technique can obtain high resolution images of the complete valve leaflet-surface dynamically.^[55] One of the main shortcomings of previous modeling approaches has also been addressed: Mechanical properties of both native and bioprosthetic tissue were mostly evaluated on the basis of uniaxial testing that provided important qualitative information on the basis of non-physiological loading. After Mayne^[56] and Christie^[57] proposed equibiaxial testing that applies an equal level of tension to each test axis, Sacks developed full multiprotocol biaxial mechanical tests that include the entire range of physiological loading and thus provide sufficient data for constitutive computer modeling.^[58] Although these distinctly improved tools promise to reduce the influence of designer flaws on heart valve failure significantly, Vesely cautions against unanticipated failure modes^[59] that will always evade prediction. He argues that design flaws become evident only after a mode of failure has been identified and, as an example of unanticipated failure mode, mentions the chaotic vibrations that caused the crumbling of the Tacoma Narrows Bridge in 1940. Although bridges had been built for centuries, none of them had failed through this mode.

Vesely also used the example of a suspension bridge to demonstrate the main difference in challenge regarding the design of porcine and pericardial valves: Aortic valve cusps have a similar structure to a suspension bridge, where the main structural cables have the familiar upward curve as they approach the supporting towers. As the cable suspension becomes more vertical, the tension in the main cable decreases. In contrast, the almost cylindrical leaflet configuration in pericardial valves produces a nearly horizontal free edge that would imply extremely high tensile forces were it not for the fact that pericardial valve designers have been able to take advantage of the fact that the three leaflets lean against each other during coaptation.

Historically, probably the largest designer flaw was the so-called alignment stitch in the Ionescu-Shiley first-generation bovine pericardial valves. In recognition of the stress concentration around sutures through the pericardium, many designers have moved towards clamping the pericardial tissue between two solid surfaces. Possibly for cosmetic reasons, the Ionescu-Shiley valve employed a stitch near the free edge of the leaflet, exactly in the region that experienced particularly high membrane stresses. A large

proportion of these valves failed early, and pathological examinations indicated that the tear most likely originated at the site of the alignment stitch.^[60]

The second most consequential designer mistake was the attempt to change the height : diameter ratio (aspect ratio) of a porcine bioprosthesis in order to make the prosthesis as appealingly low profile as a pericardial valve. This BioImplant valve of the St. Jude range reduced the aspect ratio from 0.7 to 0.4.^[61] This dramatic reduction of the angle of the free edge of the porcine valve cusp led to a distinctly higher geometry-related stress. Early failures also forced this design into retreat.^[62]

A more recent development in valve design was the move towards stentless bioprostheses. The two main considerations behind this concept were on the one hand the reduction of outflow resistance due to a direct and indirect obstructive effect of the sewing ring and the stent, and on the other hand the theoretical advantage of mobile commissures. Since the aortic wall calcification occurring in all stentless models soon defied the advantage of mobile commissures, the only remaining advantage was the bigger orifice. The balance between a longer crossclamp time and a technically more challenging surgery on the one side and a larger orifice on the other has kept a lid on the gains in market share of stentless bioprosthetic heart valves.

Another shortcoming of test and prediction systems became apparent when Carbomedics-Sulzer launched their Photofix valve. Although photofixed valves performed well under in-vitro durability tests, they developed premature tears during clinical tests—most likely due to mechanical abrasion of the leaflets on the Dacron cloth of the sewing ring. It became obvious that the high-frequency in-vitro fatigue tests do not lead to the same leaflet loading as in-vivo implantations.

Overall, it appears as if both better insight into major design shortcomings of the past and significantly improved test and computation means have shifted the balance between designer flaws and biology-related reasons of failure further toward the latter.

WHERE TO?

If resistance toward paradigm shifts has stood in the way of a more progressive development in the field of bioprosthetic heart valves during the past 35 years, we are challenged to identify the creaks in the existing paradigms. We are also challenged to abandon the convenience and protection accepted paradigms provide. The main convenience of accepting an existing paradigm is to consent with the rest of the research community to take on digestible small bites rather than rock the boat and drown. By accepting this overall

approach, we can often achieve relatively much with regard to symptomatic improvements with relatively little pains. By not challenging, for instance, whether contemporary xenografts have managed to eliminate all detrimental aspects of xenogenicity and by accepting our decades-old approach to cross-linking as a tolerable compromise, we were able to focus happily on anticalcification treatments, minimally invasive surgery, or another few square millimeters of increased orifice areas.

What becomes increasingly clear, however, is the need to return openly to the drawing board. When venturing out initially to develop tissue heart valves, the main challenge clearly on everyone's mind was: How can we use animal tissue by making it unrecognizable as xenogenic and still preserve most of its mechanical function? Today we know that we partially failed in both: Albeit in a mitigated form, contemporary bioprosthetic heart valves continue to be recognized as foreign, while the cross-linking approach introduced a long list of disadvantages. So what do we need to do to make bioprosthetic heart valves unrecognizable as xenogenic and still preserve their mechanical function? The most likely answer is to eliminate xenogenicity and active calcification sites by rationally engineering cross-links in combination with support strategies that are done for the right reasons. One such support strategy could be decellularization of bioprosthetic tissue. The right reason for this is the elimination of cells as main carriers of antigens and calcification sites. A wrong reason may be to use it as a short cut to tissue engineering in the hope of cellular repopulation. Ingrowing connective tissue cells follow developmental signals in the matrix. A postdevelopmental mature matrix sends out the opposite signal: "Stay out, we are fine." Nothing demonstrates this principle better than homografts. These perfect emulations of an aortic root matrix remain mostly acellular for decades. Moreover, the demonstration of a degree of antigenicity residing in the extracellular matrix that is capable of triggering detrimental host responses makes it unlikely that decellularization will suffice without a concomitant cross-linking procedure. The need for such a concomitant cross-linking procedure, however, would almost certainly extinguish the last hope of repopulation with connective tissue cells because degradability is a cornerstone of remodeling. At the same time, deeper insight into the molecular mechanisms behind membrane-bound calcification sites and the ability for the first time to cross-link these sites effectively makes it less of an urgency to remove cellular remnants from the tissue. This condenses the focus area for a break-through development even further: cross-link engineering with particular emphasis on its molecular effect on antigen, calcification, and degradation sites on the one hand and its mechanical

effect on pliability, compliance, and break resistance on the other.

INTRODUCTION

This chapter presents a detailed description of the function, hemodynamics, and mechanics of the four valves in the human heart. Heart valve function is essential to human life as a fundamental component of the cardiovascular system. The entry is divided into two main sections for the two main types of valves: semilunar and atrioventricular. Each of these sections is subdivided into valve structure and function, hemodynamics, and valve mechanics. As a whole, the entry provides a comprehensive description of each of the valves. This information is based mainly on experimental data due to the lack of reliable computational or analytical data. Despite the many years of research that have been devoted to these valves, there is still controversy over the detailed function and mechanics.

HEART VALVES

The human heart uses four distinctive valves to control pulsatile blood flow through its chambers and into the circulatory system. These valves are categorized into two major groups according to their location and structure: atrioventricular valves, which control blood flow between the atria and the ventricles; and semilunar valves, which control blood flow to the lungs and the systemic circulation. On the right side of the heart, blood flow between the atrium and the ventricle is controlled by the tricuspid valve, and flow from the ventricles into the lungs via the pulmonary arteries is controlled by the pulmonary valve. These valves are subjected to pressures up to 40 mmHg. On the left side of the heart, the flow from the atrium to the ventricle is controlled by the mitral valve, and flow to the systemic circulation via the aorta is controlled by the aortic valve. These valves are subjected to higher loads than those on the right side, with pressures up to 150 mmHg. The four heart valves open and close systematically to enable forward flow. Only during

isovolumetric relaxation and contraction are all four valves closed simultaneously for 0.02–0.06 s.

SEMILUNAR VALVES

Semilunar Valve Structure

The aortic valve is composed of three semilunar cusps, or leaflets, contained within a connective tissue sleeve. A thin fibrous layer called the intravalvular curtain separates the aortic valve cusps from the anterior leaflet of the mitral valve. When the aortic valve is closed, the cusps are perfectly aligned and separate the left ventricle from the aorta (Fig. 1a). Along with the three leaflets, there are three recesses, which form a bulging cavity behind the leaflets called the sinuses of Valsalva. At the lower margin the sinuses become continuous with the left ventricle, and at the upper margin they join with the sinotubular junction, which is the inlet of the aorta just downstream of the sinus. This area surrounding the valve is called the aortic root (Fig. 1b). Each valve cusp and corresponding sinus are named according to their anatomical locations within the aorta. Two of the sinuses give rise to coronary arteries that branch off the aorta, providing blood flow to the heart itself. The right coronary artery is located at the right anterior sinus, and the left coronary is located at the left anterior sinus. The third sinus is called the noncoronary or right posterior sinus. Because the cumulative circumferential length of the aortic valve cusps is greater than the annular radius, a small overlap of tissue from each leaflet protrudes and forms a coaptation surface when the valve is closed. This overlapped tissue, called the lunula, helps ensure that the valve is sealed properly. When the valve is open, the leaflets extend to the upper edge of the sinuses of Valsalva. The sinuses of Valsalva aid efficient valve closure by sustaining helical flow patterns behind the leaflets and dampen mechanical stresses imposed by the pressure difference when the valve is fully closed. The overall elasticity of the aortic root provides

Fig. 1 (A) Closed aortic valve in an unloaded root. (B) Photograph of the aortic root, with its components. (C) Movat staining of porcine aortic valve leaflets: collagen = yellow, elastic fibers and cell nuclei = black, sGAG = light blue. F indicates the fibrosa side and V the ventricularis side. The three layers that compose the leaflet are identified in this image.

mechanical compliance, which reduces the mechanical loading on the valve.

The average aortic leaflet thickness is about 0.6 mm and varies considerably over the surface.^[1] The aortic valve leaflet appearance and size also vary depending on the leaflet. The posterior leaflet, for example, is generally thicker, has a larger surface area, and weighs more than the right or left leaflet,^[2] and the average width of the right aortic leaflet is greater than that of the other two.^[3] As shown in Fig. 1c, aortic valve leaflets have a complex, composite, trilayered structure consisting of the fibrosa, spongiosa, and ventricularis.^[4] Each of the leaflets is lined with endothelial cells and has a dense collagenous core adjacent to the high-pressure aortic side. The side adjacent to the aorta is termed the fibrosa and is the major fibrous layer within the belly of the leaflet. This layer bears most of the mechanical load of the leaflet. Beneath the fibrosa lies the spongiosa, which is a loose, watery connective tissue of varying thickness, fiber composition, and cellularity. This layer normally contains low quantities of collagen and elastin but large quantities of glycoaminoglycans (GAGs). The GAGs are responsible for the semifluid properties of the spongiosa, which enable this layer to reduce overall leaflet stresses due to

compliance mismatch between the layers.^[4,5] The ventricular surface of the leaflet is smooth in contrast to the ridged aortic surface to maintain laminar blood flow during systole.

The valve cusps are attached to a fibrous ring, or annulus, embedded in the ventricular septum. The aortic annulus separates the aorta from the left ventricle. According to echocardiographic measurements in healthy subjects the aortic root diameter is 35 ± 4.2 mm at end systole and 33.7 ± 4.4 mm at end diastole.^[6] High-resolution 3-D echocardiographic measurements of human aortic annular dynamics have shown that the maximum aortic orifice area occurs during early systole,^[7] and in vivo studies in sheep using radiopaque markers have shown this change in annular area to be $32 \pm 8\%$.^[8] The valve annulus also undergoes translation, primarily parallel to the aortic axis, which can be described as a line through the center of the aortic valve that runs parallel to the ascending aorta at the valve outlet. The aortic annulus moves toward the ventricle during systole and then recoils back toward the aorta as the ventricle fills during diastole. The annulus also experiences a slight side-to-side translation with a magnitude of approximately one-half the displacement along the aortic axis.

The overall anatomy of the pulmonic valve is similar to that of the aortic valve, but the dimensions of various structural components are different. On average, pulmonic leaflets are thinner than aortic leaflets, with an average thickness of 0.49 mm vs 0.67 mm.^[9] The main differences are that the sinuses are smaller in the pulmonary artery, and the pulmonic valve annulus is slightly larger than that of the aortic valve. M-mode echocardiography has shown a 3.15 ± 0.82 mm pre-systolic posterior motion of the pulmonary valve known as the A-wave. Although the origin of this motion is still under debate, it is likely associated with the motion of adjacent structures.^[10] In general, the motion of the pulmonic valve has not yet been fully described using more advanced imaging techniques.

Semilunar Valve Hemodynamics

The aortic valve opens during systole, when the ventricle is contracting, and then closes during diastole, as the ventricle relaxes. In healthy individuals, blood flows through the aortic valve accelerating to a peak value of 1.35 ± 0.35 m/s.^[11] The valve closes near the end of the deceleration phase of systole, with very little reverse flow through the valve. The adverse axial pressure difference causes the low-inertia flow in the developing boundary layer along the aortic wall to decelerate and then to reverse direction, resulting in vortices in the sinuses behind the aortic valve leaflets.^[12] This action forces the belly of the leaflets away from the aortic wall and toward the closed position. When this force is coupled with the vortices that push the leaflet tips toward the closed position, a very efficient and fast closure is obtained. In vitro studies have shown that the axial pressure difference alone is sufficient to close the valve.^[12] Thus, without the vortices in the sinuses, the valve still closes, but its closure is not as efficient as when the vortices are present.

The velocity profile at the level of the aortic valve annulus is relatively flat. There is a slight skew towards the septal wall (less than 10% of the center-line velocity), however, caused by the orientation of the aortic valve relative to the long axis of the left ventricle.^[13] The flow patterns just downstream of the aortic valve are of particular interest because of their complexity and relationship to arterial disease. Highly skewed velocity profiles and corresponding helical flow patterns have been observed in the human aortic arch using magnetic resonance phase velocity mapping.^[13]

The pulmonary valve flow profile is similar to that of the aortic valve, but the velocity magnitude is lower. Typical peak velocities at the valve outlet for healthy adults measured with 2-D and Doppler echocardiography are 0.75 ± 0.15 m/s.^[14] During acceleration the peak velocity is observed inferiorly, with this peak flow

rotating counterclockwise throughout the remainder of the ejection phase.^[15] The mean spatial profile is relatively flat, although a region of reverse flow occurs in late systole, which may be representative of flow separation. Typically, there is only a slight skew to the profile, and the peak velocity is generally within 20% of the spatial mean throughout the cardiac cycle. Secondary flow patterns can also be observed in the pulmonary artery and its bifurcation. In vitro laser Doppler anemometry experiments have shown that these flow patterns are dependent on the valve geometry and, thus, can be used to evaluate the function and fitness of the heart valve.^[16]

The ventricular surface of the leaflets experiences elevated shear stress during systole, when blood flows past the leaflets. On the aortic surface, oscillatory shear stress is experienced due to the vortices in the sinuses. To estimate the shear stresses on the leaflet surface, Laser Doppler Velocimetry (LDV) measurements were performed using a polymeric (polyurethane) trileaflet valve under pulsatile conditions. Weston et al.^[17] conducted two component LDV measurements inside a polyurethane valve as well as downstream of the valve. The maximum wall shear stress inside the valve was 79 dynes/cm² at a peak systolic flow rate of 22.5 L/min.

Semilunar Valve Mechanics

The aortic valve is exposed to a complex and harsh mechanical environment during the cardiac cycle. The leaflets are exposed to varying magnitudes of pressure, shear stress, and bending stress as they cyclically load and unload. Like most biological tissues, the aortic valve leaflets are anisotropic, nonhomogeneous, and viscoelastic. The collagen fibers within the fibrosa and ventricularis are crimped and entangled with no apparent directional preference in the unstressed state, but when a stress is applied, the elastin and collagen fibers become oriented primarily in the circumferential direction, with a lower concentration of elastin and collagen oriented in the radial direction.^[4] Vesely and Noseworthy^[18] found that both the ventricularis and fibrosa were stiffer in the circumferential direction than in the radial direction. The ventricularis was found to be more extensible radially than circumferentially, however, whereas the fibrosa had uniform extensibility in both directions. In lower concentrations, elastin fibers are oriented orthogonal to the collagen, and it is this mixed fiber structure that accounts for the anisotropic properties of the leaflets. The variation in thickness and composition across the leaflets is responsible for their nonhomogeneous material properties. Although the aortic valve leaflet as a whole is asymmetric in its distensibility, the basal region tends to be relatively isotropic, and the central region shows

the greatest degree of anisotropy.^[19] The elastin in the ventricularis consists of continuous amorphous sheets or compact meshes, whereas elastin in the fibrosa consists of complex arrays of large tubes that extend circumferentially across the leaflet.^[20] Mechanical testing of elastin structures from both the fibrosa and ventricularis has shown that the purpose of elastin in the aortic valve leaflet is to restore a specific collagen fiber orientation during cyclic loading.^[21] The viscoelastic properties of the valve are actually dominated by the elastic component over the current range of *in vitro* testing conditions, so that the viscous effects, which are largely responsible for energy dissipation, are small.^[4] The aortic valve leaflets are slightly stiffer than the pulmonary valve leaflets, although the extensibility and relaxation rates of the two tissues are similar.^[22] In biaxial studies of pulmonary and aortic valve leaflets,^[23] radial stretch was greater for the pulmonary leaflets than for the aortic leaflets, and circumferential stretch was similar. Thus, the ratio of radial to circumferential stretch was 6.0 ± 1.1 for the aortic leaflets and 9.0 ± 1.8 for the pulmonary leaflets.

Aortic valve leaflets have been shown *in vivo* to change length during the cardiac cycle.^[4] The cusps are longer during diastole than during systole, in both the radial and circumferential directions. Because the collagen fibers are oriented circumferentially, the valve is relatively stiff in this direction; therefore, the length variation is greatest in the radial direction. Because elastin is the primary element in the radial direction, the valve can undergo a great deal of strain, ranging from 20 to 60%.^[4,19] The strain in the circumferential direction is only about 10% due to the deformation restrictions imposed by the higher concentration of collagen fibers.^[19] The stretch in both directions results in an increased valve surface area during diastole. During systole, the shortening of the valve leaflets helps increase the effective orifice area during the ejection phase.

The aortic valve leaflets also undergo bending in the circumferential direction during the cardiac cycle. During diastole, when the valve is closed, each leaflet is convex toward the ventricular side. During systole, when the valve is open, the curvature changes, and each leaflet is concave toward the ventricle. This bending is localized on the valve cusp near the wall of the aorta, and this location is often thicker than the rest of the leaflet. Thubrikar used radiopaque markers to calculate the *in vivo* bending strains in canine aortic valves. The bending strains in the circumferential direction—calculated from the modulus of elasticity, thickness, and radius of the leaflet—were found to be 2% during systole and 2.2% during diastole.^[4] Because smooth bending requires internal tissue shearing, Talman and Boughner^[24] tested the shear stress vs shear strain characteristics both in the circumferential and

the radial directions of porcine aortic valve cusps. These results showed that the tissue behaves nonlinearly over the strain range. The average moduli at near-zero strains were less than 0.3 kPa and increased to more than 20 kPa at strains of approximately 0.9.

Although the pressure differential across the closed valve induces a large load on the cusps, the fibrous network within the cusps is effectively supported by the aortic wall and annulus. *In vivo* studies using radiopaque markers placed on canine aortic valve leaflets were conducted to estimate the leaflet stresses, using equations for membrane stress assuming a cylindrical geometry. The membrane stresses in the circumferential direction of the leaflet were 16.7 kPa during systole and 240.3 kPa during diastole.^[4] A finite element formulation was used to analyze the stresses based on a pressure gradient across the valve of 114.7 mmHg and a human aortic valve leaflet thickness of 0.6 mm.^[1] The maximum principal stress was found to be 220 kPa, which is comparable to the *in vivo* values. In a different study, the total diastolic stress in a valve leaflet has been estimated to be 250 kPa for a strain of 15%.^[4] The most recent finite element models include fluid coupling, aortic root compliance, and material fiber architecture. DeHart et al. used this type of model to demonstrate the effect of aortic root compliance on valve opening and closing configurations.^[25] This model predicts maximum tensile and compressive stresses of 91 and 8 kPa, respectively, during the cardiac cycle. The results from this study demonstrated that the presence of a compliant aortic root and directional fiber reinforcement will reduce the stress on the leaflets. In a comparative study of human aortic and pulmonary valves, the ultimate stress in the circumferential direction was 2.78 and 1.74 MPa for the pulmonary and aortic valves, respectively.^[26] The ultimate stress in the radial direction for the two valves was practically identical at 0.29 and 0.32 MPa for the pulmonary and aortic valves, respectively.^[26]

ATRIOVENTRICAL VALVES

Atrioventricular Valve Structure

Both the mitral valve and tricuspid valves are complex units comprised of an annulus, leaflets, chordae tendineae, and papillary muscles (PM). The annuli of these valves are located between the atrium and ventricle on the left and right sides of the heart for the mitral and tricuspid valves, respectively. The PM extend from the underlying myocardium. From the “belly” of each PM, several chordae tendineae extend, which insert into the leaflets or near the annulus, as well as into the left or right ventricular wall. This

arrangement provides continuity between the valve and ventricular wall to enhance ventricular function.

Although the annulus has been described anatomically as an incomplete structure, recent findings have redefined it as a vital component that promotes efficient valve closure and ventricular filling.^[27] The mitral and tricuspid annuli are elliptical rings composed of dense collagenous tissue surrounded by muscle. The anterior section of the mitral annulus connects to the aortic valve through the intravalvular curtain and is delimited by two cartilaginous masses called the annular trigones. In past years, researchers thought that this section of the mitral annulus was rigid, but a recent study has shown that it changes in length during the cardiac cycle.^[28] The sphincteric action of the annulus aids ventricular filling by expanding during diastole and facilitates leaflet coaptation by contracting during systole. Both human and animal studies of mitral annular dynamics have shown mitral annular contraction at the onset of left atrial contraction that continues until peak ventricular systole. In human studies, the annular area ranges from approximately 7.5 cm² during systole to approximately 10 cm² during diastole.^[27] Studies of the tricuspid annulus have also shown a change in annular area during the cardiac cycle, with a maximum annular area of 11.3 ± 1.8 cm² and a minimum area of 7.6 ± 1.4 cm².^[29]

The mitral annulus has a 3-D curvature that persists during the entire cardiac cycle.^[30] Based on recent studies, this geometry has been described as a 3-D saddle or a nonplanar ellipse. Using 3-D echocardiography, saddle heights of 1.2 ± 0.2 cm have been measured in humans.^[30] Although the geometry of the tricuspid annulus has not been fully described in humans, a recent study in sheep showed a saddle-shape annulus similar to that of the mitral valve.^[31]

The mitral and tricuspid annuli not only contract and bend, but also displace across the apical-basal axis of the ventricles during the cardiac cycle. During systole, the mitral and tricuspid annuli move apically 10 and 15 mm,^[26,32] respectively, from their most basal positions during diastole. The movement of the annulus toward the atrium during diastole may play a role in ventricular filling, possibly increasing the efficiency of blood flow into the ventricle.^[33]

Although there is valve-to-valve anatomical variability in mitral valve leaflets, several features are observed consistently in all normal mitral valve specimens (Fig. 2). The leaflet section of the mitral valve consists of a continuous veil of tissue,^[34] which inserts into the muscular annulus ring of the mitral orifice. The two major leaflet sections—the anterior and the posterior leaflets—are separated by two commissural sections located in the anterolateral and posteromedial sections of the annulus ring that are characterized by fanlike chordae tendineae insertions. This commissural section

is part of the posterior system; thus, the posterior leaflet in 92% of cases^[34] contains three scallops. The major central scallop is usually called the posterior leaflet; the other two are identified as the posteromedial commissural scallop and the anterolateral commissural scallop.

The anterior leaflet has a significantly larger area than the posterior leaflet and covers most of the mitral orifice during coaptation. The mitral valve has on average a leaflet surface area two times larger than the mitral orifice.^[35] The residual tissue enables the two leaflets to overlap during valve closure, producing a tight seal. Because the anterior leaflet covers most of the mitral orifice, it is subjected to a larger load than the posterior leaflet. Three major zones can be identified on both leaflets: a rough zone in the distal section, a clear zone in the center of the leaflet, and a basal zone at the annulus. Both the rough and basal zones have chordae tendineae insertions, but the clear zone is membranous, relatively smooth, and free of chordae tendineae insertions.^[34]

Unlike the mitral valve, the tricuspid valve has three leaflets: an anterior leaflet, a posterior leaflet with a variable number of scallops, and a septal leaflet (Fig. 3). The tricuspid valve is larger and structurally more complicated than the mitral valve, and the separation of the valve tissue into distinct leaflets is less pronounced than in the mitral valve. The leaflet surface is similar to that of the mitral valve, and the basal zone is present in all three leaflets.^[36]

The mitral and tricuspid leaflets are both composed of three layers: an atrial endothelial layer called the atrialis, an intermediate layer of fibrous material called the spongiosa, and a ventricular endothelial layer called the ventricularis. The atrioventricular valve leaflet tissue is primarily collagen-reinforced endothelium but also contains various types of cells, non-myelinated nerve fibers, and blood vessels, making them complex biological systems. Recent research has shown that interstitial cells in atrioventricular valve leaflets have a contractile phenotype.^[37] Therefore, the function of these leaflets may not be passive, although most researchers believe that the contractile nature of these cells is most likely related to leaflet tone.

The main function of the chordae tendineae is to prevent leaflet prolapse during ventricular systole. These “tension wires,” in addition to holding the leaflets in place during systole, maintain the geometrical conformation of the mitral valve and play an important role in left ventricular function. The chordae tendineae extend from both PM and insert into different sections of the leaflets. The chordae are characterized using a nomenclature based on insertion location with marginal, intermediate, and basal chordal insertion groups. This nomenclature also accounts for differences in composition, size, mechanical

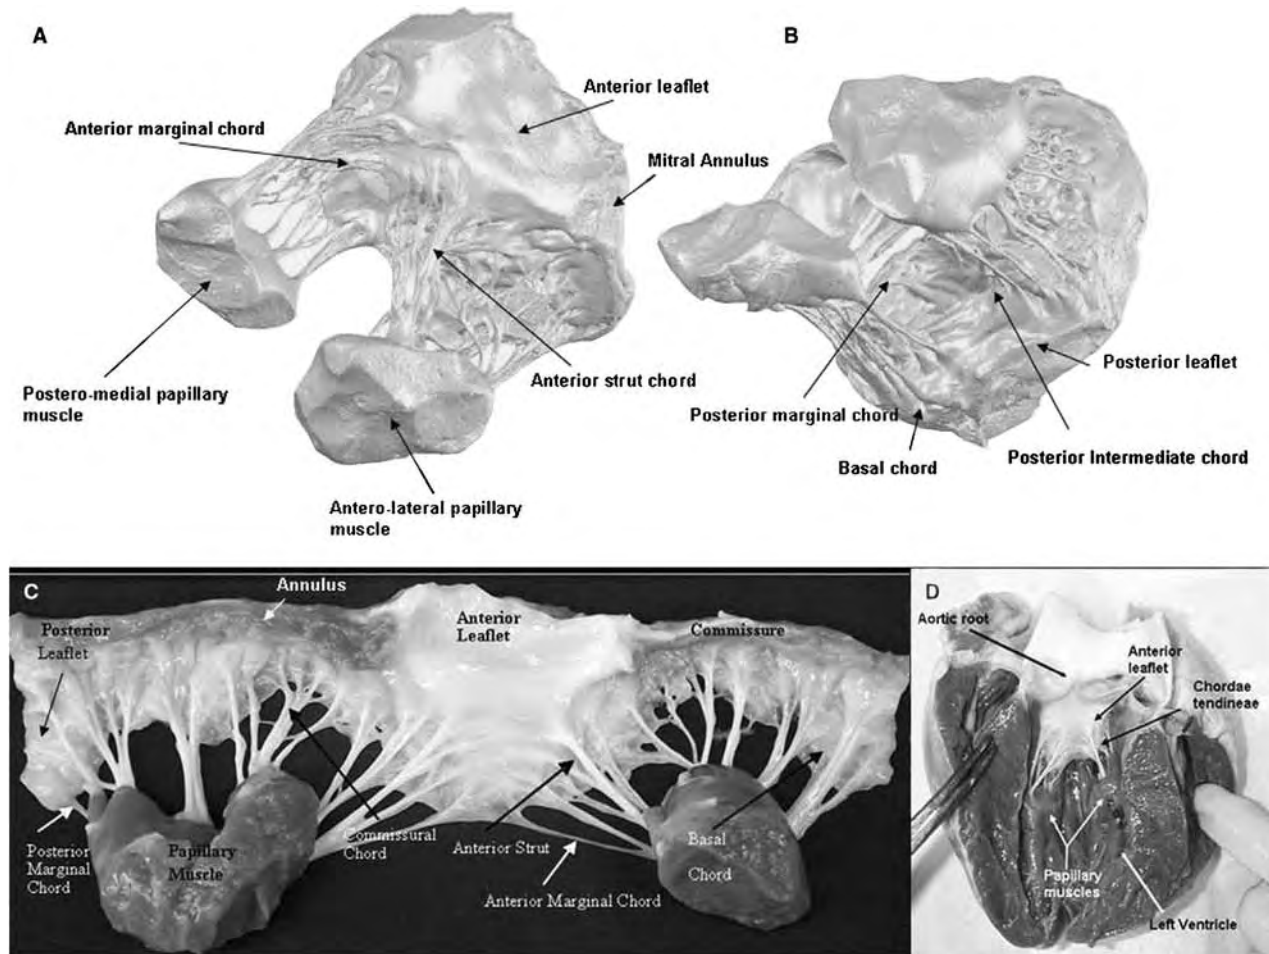

Fig. 2 Anatomy of the mitral valve. (A) Anterior view of a porcine mitral valve from a microCT reconstruction. (B) Posterior view of the same microCT reconstruction. (C) Photograph of an extended porcine mitral valve. (D) Photograph of a mitral valve within the left ventricle.

characteristics, and function. The marginal chordae extend from the PM or branch off from other chords and insert into the free margin of the anterior or posterior leaflet. The intermediate chordae originate at the PM and insert into the body of the ventricular surface of the leaflets. The basal chordae originate at the PM and insert adjacent to the posterior annulus. Normally, only two intermediate, or strut chordae, insert into the body of the anterior leaflet. The anterior strut chordae are subjected to tension during both diastole and systole. During systole, they bear a significant portion of the load on the anterior leaflet, thus preventing its prolapse, whereas during diastole, they restrict anterior motion of the leaflet, thus preventing the anterior leaflet from extending into the aortic outflow tract.^[38]

The chordae tendineae consist of an inner core of collagen surrounded by loosely meshed elastin and collagen fibers with an outer layer of endothelial cells. Recent studies of porcine chordae have also shown vascularization in some of the chordae. Both veins and

arteries run longitudinally through the intermediate layer of the chordae in a helical manner.^[39]

Porcine and human mitral valves are similar in structure, and they have similar chordae tendineae lengths.^[40] Thus, because there are limited data on the cross-sectional area of human chordae, most studies rely on porcine data. Using a porcine model, Sedransk et al. observed that on average the marginal chordae were 68% thinner than the basal chordae and that the chordae on the posterior leaflet were 35% thinner than their counterparts on the anterior leaflet of porcine mitral valves.^[41] By observing excised porcine chordae through a calibrated optical microscope, Liao et al. also found that assuming circular cross-sectional areas and uniform thickness, the average cross-sectional areas were $0.38 \pm 0.18 \text{ mm}^2$, $0.71 \pm 0.25 \text{ mm}^2$, and $2.05 \pm 0.40 \text{ mm}^2$ for the marginal, basal, and intermediate chordae, respectively.^[42]

In the mitral valve, the two PM (Fig. 2) protrude from the left ventricle with their tips pointing to their

Fig. 3 Anatomy of the tricuspid valve. (A) Photograph of an extended tricuspid valve sectioned at the middle of the septal leaflet. The leaflets and PM are identified in the structure. (B) Photograph of an excised tricuspid valve identifying major chordal types.

respective commissures,^[43] thus directing their chordae to relatively symmetrical insertions into the valve. The tricuspid valve has three PM (Fig. 3A and B). The anterior papillary muscle, which is the largest, attaches to the valve at the commissure between the anterior and posterior leaflets. The posterior PM is located between the posterior and septal leaflets, and the smallest PM—the septal muscle—sometimes is not even present. Using transesophageal echocardiography, both the length and cross-sectional area of normal human mitral PM have been measured in vivo.^[44] These results show that in humans, the mitral valve PM contract approximately 4 mm during systole.

Atrioventricular Valve Hemodynamics

During isovolumic relaxation, the pressure in the left atrium exceeds that in the left ventricle, causing the mitral valve cusps to open. Blood then flows through the open valve from the left atrium to the left ventricle during diastole. The initial filling is enhanced by the active relaxation of the ventricle, which helps maintain a positive transmitral pressure gradient. A peak in the mitral flow curve, called the E-wave, occurs during the early filling phase, with normal peak velocities ranging from 50 to 80 cm/s.^[45] Following active ventricular relaxation, the fluid begins to decelerate, and the mitral valve partially closes. In late diastole, the atrium contracts, and the blood accelerates through the valve again to a secondary, lower velocity peak, termed the A-wave, with normal E/A velocity ratios ranging from 1.5 to 1.7.^[45]

The tricuspid flow profile is similar to that of the mitral valve, although the velocities in the tricuspid valve are significantly lower because it has a larger valve orifice. The peak early (E-wave) and late (A-wave) flow velocities across the tricuspid valve have been measured with Doppler echocardiography to be 0.51 and 0.35 m/s, respectively.^[46] Therefore, the E/A velocity ratios for the tricuspid valve are similar to those of the mitral valve.^[46] By contrast, the timing of

tricuspid valve opening is slightly different when compared with the mitral valve. Because the peak pressure in the right ventricle is less than that in the left ventricle, the right ventricular pressure falls below the right atrial pressure faster than the corresponding time for the left side of the heart. Thus, there is a shorter right ventricular isovolumic relaxation time, causing the tricuspid valve to open earlier. Additionally, tricuspid valve closure occurs after mitral valve closure, because the electrical stimulation of the left ventricle precedes that of the right ventricle.^[14]

Mitral valve fluid dynamics studies using magnetic resonance imaging (MRI) have shown that a large anterior vortex is normally present at the onset of partial valve closure as well as following atrial contraction.^[47] Bellhouse^[48] first suggested in an in vitro model that vortices generated by ventricular filling aid the partial closure of the mitral valve following early diastole and that without the strong outflow tract vortices, the valve would remain open at the onset of ventricular contraction. Later in vitro experiments suggested, however, that both flow deceleration and partial valve closure were due to an adverse pressure differential in mid-diastole, even in the absence of a ventricular vortex.^[49] Thus, although the vortices may provide additional closing effects in the initial stage, the adverse pressure gradient appears to be dominant in mitral valve closure. A more unified theory of valve closure includes the importance of chordal tension, flow deceleration, and ventricular vortices, with chordal tension being a necessary condition for the other two.^[50]

Atrioventricular Valve Mechanics

The mechanics of the mitral and tricuspid valves are complex, and there are limited studies on this subject. More studies have been performed on the mitral valve, because it sustains higher loads and, consequently, is more prone to disease. Although limited information is available on tricuspid valve mechanics, they are expected to be similar to those of the mitral valve.

The leaflet loading depends on the transmitral pressure, annular geometry and dynamics, coaptation geometry, chordae tendineae tension distribution, and contact forces between the leaflets. The curvature generated by the billowing of the leaflets during systole has been shown to be of mechanical importance, because it reduces the stress on the anterior leaflet.^[51] Additionally, a simplified computational model of the anterior leaflet has shown that the secondary curvature induced by the mitral annulus saddle shape is also a stress-relieving characteristic.^[52] This model proposes that a saddle height-to-commissural diameter ratio of approximately 20% generates the minimum stress configuration for the central region of the anterior leaflet under systolic loading. In a nonlinear, fluid-coupled, finite element model of the mitral valve, Einstein et al.^[53] predicted that the peak principal stress (254 kPa) during the cardiac cycle would occur in the belly of the anterior leaflet during peak systole (Fig. 4).

Sacks et al.^[54] and He et al.^[55] described *in vitro* not only the material characteristics of the anterior leaflet under physiological loads, but also how the underlying collagen matrix influences valve mechanics during coaptation by controlling directional strain through collagen fiber locking (Fig. 5). During valve closure, the anterior leaflet stretches in both the circumferential and the radial directions. Because the collagen fibers in the central region of the leaflet are arranged mainly in the circumferential direction, the leaflets become significantly stiffer in that direction as the collagen fibers uncrimp. A plateau at principal circumferential strains of 1.4 and radial strains of 1.2 indicates that the collagen fibers are uncrimped, thus limiting further deformation induced by the transmitral pressure. No material creep was observed during this plateau at constant transmitral pressure. Peak strains persist until the transmitral pressure decreases, after which the material returns to its relaxed conformation. Similar strain behavior was observed in the central region of the posterior leaflet,^[56] with some notable differences. The strain rates were lower in the posterior leaflet than those measured in the anterior leaflet, and a compressive strain at the beginning of valve closure was observed. Grashow et al.^[57] recently performed biaxial testing on the central region of the mitral valve anterior leaflet under physiological loading conditions. This study not only demonstrated the nonlinear response and anisotropy of the central anterior leaflet, but also found that the material response was independent of strain rate. As a result, the material was described as quasielastic and anisotropic. All these studies have been limited to the central regions of the mitral leaflets, which are relatively homogeneous. Small angle light scattering,^[54] however, has demonstrated that other regions of the anterior leaflet have more complex

collagen fiber distributions. Therefore, different material responses are expected for different regions of the leaflets.

Leaflet coaptation geometry is highly dependent on chordal insertion and chordal tension distribution. Nazari et al.^[58] described theoretically how valve leaflet stress distribution is directly related to chordae tendineae distribution. During coaptation, the load on the leaflets is transferred sequentially to increasingly larger chordae, leading to an optimal mechanical configuration during peak systole. He et al.^[59] defined a characteristic triangular structure between chordae that is fundamental to valve function. This triangle is formed when a smaller chordae branches off a larger chordae and the chordae insert to form a triangle between the two chordae and the leaflet. The disruption of this “He” triangle can lead to mitral regurgitation. Lomholt et al.,^[60] using an *in vivo* porcine model, showed that the dynamic tension on the intermediate chordae was three times as large as that on the marginal chordae, with a peak systolic tension of 0.7 N for the intermediate chordae and an average tension of 0.2 N on the marginal chordae. More recently, Jimenez et al.^[61] confirmed *in vitro* that the intermediate chordae hold significantly larger loads than the marginal chordae, with remarkably similar forces to those found *in vivo* (intermediate chordae=0.66 N, marginal chordae=0.22 N). Additionally, they found no significant differences between porcine and human chordae tendineae loads. Recent studies have also demonstrated that the saddle shape of the annulus results in a more even distribution of loads among the various chordae tendineae.^[62]

Recent studies have revealed differences in the mechanical characteristics of the chordae, which may be associated with their function. Uniaxial tensile tests have shown that porcine marginal chordae fail in response to significantly lower tension than the basal chordae. Because the marginal chordae have a smaller cross-sectional area, however, the basal chordae have significantly lower failure stress.^[41] Investigation of the tensile properties of chordae tendineae showed a nonlinear stress–strain relationship.^[63] The smaller chordae with cross-sectional areas of 0.001–0.006 cm² had a modulus of 2×10^9 dynes/cm², whereas larger chordae with cross-sectional areas of 0.006–0.03 cm² had a modulus of 1×10^9 dynes/cm². A more recent study confirmed that the extensibility of the chordae increases with diameter, whereas the modulus of elasticity decreases with increasing diameter.^[42] In this study, transmission electron microscopy observations showed that thicker chordae had a smaller collagen crimp period, which allowed increased strain on thicker chordae before the fibers locked. Although the cross-sectional area occupied by the collagen fibers was constant (49.2% on average), the thicker chordae had

Fig. 4 Time course of principal stress on the mitral leaflets and annulus during the cardiac cycle. Initially, when the valve is fully opened, the largest stresses are concentrated around the trigones of the mitral annulus. As the valve is loaded by the transmitral pressure, the principal stress is transferred to the belly of the anterior leaflet during closure (Einstein 2005).

a larger average fibril diameter with a lower fibril density.

PM contraction, in conjunction with leaflet geometry and chordal loading, determines the force distribution on atrioventricular valves. An *in vitro* study of porcine mitral valves showed PM loads on the order of 4.4 N for

the posteromedial PM and 4.1 N for the anterolateral PM.^[64] This model did not simulate PM contraction; therefore, these results represent only the force present in the PMs due to valve closure without accounting for annular motion, ventricular motion, or PM contraction. PM material characteristics have also been studied using

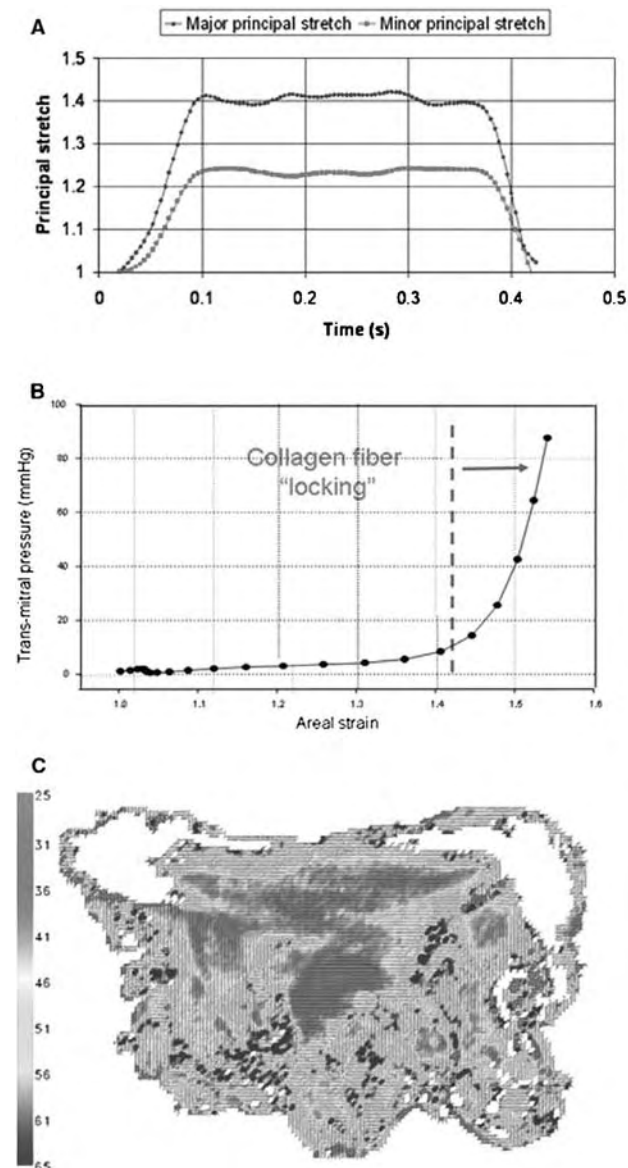

Fig. 5 (A) Graph of the major and minor principal stretches on the belly of the anterior leaflet during valve closure. As observed, the tissue is highly anisotropic. (B) Plot of trans-mitral pressure (load) vs the areal strain, demonstrating the nonlinear response of mitral leaflet tissue to physiological loads. The rapid rise in the curve is explained by collagen fiber locking. (C) Collagen fiber orientation map of the mitral valve anterior leaflet. Red represents circumferentially oriented fibers, and blue represents radially oriented fibers. Source: From Springer (see Ref. [54]).

animal tissue. Pinto and Fung^[65] demonstrated in unstimulated rabbit PM tissue that the relaxation function is independent of stretch ratio for strains under 30%. Creep tests with unstimulated PM tissue have also shown large elongation (creep strain) under a constant load. Under cyclic uniaxial testing, unstimulated PM tissue reached a steady-state hysteresis loop after

preconditioning that was unaffected by strain rate—typical of a pseudoelastic response. For both uniaxial loading and unloading, the stress on unstimulated PM tissue varies as an exponential function of strain.^[66] All these characteristics describe the viscoelastic nature of the unstimulated PM tissue.

The force from active myocardial contraction around the mitral annulus has not been measured directly. However, Einstein et al.^[53] using a nonlinear, fluid-coupled, finite element model of the mitral valve, estimated that the largest stresses around the annulus ring occurred during late diastole and early systole in the trigonal areas, which are the most rigid areas of the annulus. The elevated stresses in the trigone areas are transferred to the bellies of the leaflets during valve closure (Fig. 4).

SUMMARY

The four valves in the heart are complex biological systems, which have developed to serve specific functions. Their geometry, material characteristics, and biological components interact to provide extremely efficient functional characteristics and long-term durability under complex mechanical conditions. Heart valves are an example of how nature through evolution is one of the most elegant designers.

FUTURE DIRECTIONS

The understanding of heart valve mechanics is instrumental to the development of new technology to address the growing problem of heart valve disease in our aging population. Currently, most valve pathologies are addressed through palliative repair techniques or replacement with biological or mechanical prostheses. Both of these options are invasive, however. Current repair techniques have shown substandard long-term results, and current valve prostheses expose patients to life-threatening complications. A better understanding of the tissue mechanics, hemodynamics, and biological structure of both healthy and pathological valves is critical to the development of both effective and enduring repair techniques, as well as improved bioprosthetic valve choices such as tissue-engineered valves. Additionally, new imaging techniques and computerized models may aid in future surgical planning and the development of improved repair procedures.

INTRODUCTION

The first reported mechanical heart valve surgery, which involved a caged ball valve design, was performed by Judson Chesterman in 1955 in England. The patient passed away 14 hours later as a result of mechanical failure of the heart valve. This was followed by the first long-term success in 1961, when Dr. Charles Hufnagel implanted caged ball heart valves into eight patients for aortic insufficiency.^[1] Six of the eight patients survived the operation. This marked the first breakthrough in the design of the artificial heart valve, which is capable of reducing turbulence and blood trauma through the use of biocompatible materials and ingenious designs. During over 40 years of heart valve research and development, the design of heart valves has diversified into a myriad of more than a dozen brands, each varying in mode of operation. The most commonly used designs are the Starr-Edward caged-ball valve, the Bjork-Shiley and Medtronic-Hall tilting disc valves, and the St. Jude Medical and CarboMedics bileaflet valves. Unfortunately, even after many years of experience and success, artificial heart valves are still plagued by the problems of thrombosis and thromboembolism, tissue overgrowth, infection, anticoagulant-related hemorrhage, and valve failure due to material fatigue or chemical change.^[2] This article describes the mechanical durability of the aforementioned valve types, their fluid dynamic characteristics, and the implication of thrombus formation and deposition as a result of the flow structures that arise.

TYPES OF MECHANICAL HEART VALVES

Generally, mechanical heart valves (MHVs) are divided into caged-ball valves, tilting disc valves and bileaflet valves (Fig. 1). The stationary supporting metal struts and the mobile occluders used in these valve designs are typically made of pyrolytic carbon and/or titanium that may be coated with pyrolytic carbon. The material used for the sewing ring cuff is usually Teflon. The only ball-and-cage valve presently available in the United States is

the Starr-Edwards 1260 aortic caged ball model, used since 1966. Its design consists of a radiolucent silicone ball encased by a closed Stellite-alloy cage. The radiopaque wire struts emanate from the valve housing and are spaced 120 degrees apart. They converge at the distal end of the valve forming the apex of the cage. The tilting disc design consists mainly of a circular occluder mounted and secured on a metal strut that controls the range of occluder motion. A slight obstruction downstream of the minor orifice is inherent in the tilting disc design as a result of the protruding metal strut and occluder disc. The Medtronic-Hall and the Bjork-Shiley monostrut tilting disc valves represent the tilting disc designs presently used. The bileaflet prosthetic designs currently available in the United States are the St. Jude Medical (SJM) and CarboMedics valves. The bileaflet valve consists of two semicircular leaflets that are attached to the valve housing with hinge mechanisms. The bileaflet valve design provides a relatively large orifice area for a small valve size; consequently, there is a smaller pressure drop across the valve.

DURABILITY OF MECHANICAL HEART VALVES

The valve design configuration affects the load distribution and dynamics of the valve components, which, in conjunction with the material properties, determines the durability—notably wear and fatigue life. The flow through valves results in little wear in terms of shear on the surface of valve components because blood contains no rigid particles. The transvalvular pressure generated at and after valve closure predominantly determines the load on valve components such as the housing ring, strut, seat stop, and occluder. The impact of the occluder on the housing ring or seat stop and hinges plays a primary role in structural failure of MHVs. Polymers such as silicone rubber, polypropylene, Delrin, and Teflon used in early valves were rejected due to poor wear and fatigue performance. Since the mid-1970s the prevalent materials used in MHVs are titanium, chrome-cobalt alloy, and pyrolytic carbon. Pure pyrolytic carbon was recently

developed to be stronger and more biocompatible than current silicone-alloyed pyrolytic carbon.^[3]

The failure modes of valves are grouped into two categories: failure by intrinsic mechanisms or by extrinsic mechanisms. Failures by intrinsic mechanisms are inherently related to design and material properties such as fatigue fracture, and to abrasive wear or biochemical attack. Extrinsic mechanisms are externally generated interference with the motion of a valve's occluding mechanism. These include massive thrombotic obstruction causing impingement of occluders on the adjacent anatomy, or lockup.^[4] The intrinsic failure mechanisms will be discussed first.

Before pyrolytic carbon was used for MHVs, occluders fabricated from polymers had to be designed to rotate and distribute the wear. The early caged ball valve has a long clinical history. There have been failure reports of uncured silicone rubber balls degrading due to absorption of lipids, but properly cured balls have worked well, with no documented structural failures. The early Bjork-Shiley valves used a Delrin occluder, but had problems with heat sterilization, deformation, and high wear rate. Presently, all tilting disc valves use pyrolytic carbon for the disc and titanium or graphite carbon coated with pyrolytic carbon for the housing ring. There have been strut fractures and failures of the Bjork-Shiley convexo-concave valve design, which led to the withdrawal of this design from clinical use in the mid-1980s.

Fig. 1 (a) Starr-Edwards caged-ball valve, (b) Medtronic-Hall tilting disc valve, (c) St. Jude Medical bileaflet valve.

All bileaflet valves have a pivot-hinge mechanism so the mechanical loading is mainly applied to the pivot-hinge and housing ring. There have been some cases of leaflet escape and a cracked orifice ring, but the wear in the hinge area is not a problem. Because there is so little wear between pyrolytic carbon parts, the design of current bileaflet MHVs can ensure a lifetime of operation in patients. However, in reality there are still some incidences of structural failure. The hinge regions of bileaflet and tilting disc valves are vulnerable to localized thrombosis, which in turn may restrict occluder motion. In addition, the rigid circular orifice ring of a MHV is an unnatural configuration for a heart valve, which may lead to increased loading on the orifice ring or sewing ring.

MECHANICAL HEART VALVE WEAR AND FATIGUE FAILURE

Wear is loss of solid material mass as a result of external force on the material. It usually occurs in the contact area between solid materials. There are two types of wear mechanisms that occur on the housing and leaflets in the mechanical heart valve: impact wear and friction wear.^[5] Impact wear occurs between the pivot and hinge stop in the hinge regions of bileaflet valves, between the free edge of the leaflet or ball and the valve ring or cage as a result of the opening and closing action of the valve, and between the seat stop and disc in tilting disc valves. Friction wear occurs predominantly between the leaflet pivots and the bottom of the hinge cavities in the housing of bileaflet valves and between the disc and monostrut, or similar occluder retention mechanism, in tilting disc valves. Recently, cavitation damage that occurs inside or near the gap between the leaflet free edge and the housing at valve closing, has been identified as another wear mechanism that will be discussed in the next section. Impact, friction, and cavitation should be taken into account in the design of MHVs. In early valve designs, occluders made of polymeric materials demonstrated significant wear in clinical use, ultimately causing valve dysfunction. The poor wear performance of polymeric occluders greatly reduced the durability of early MHVs. The polymeric materials were soon replaced by pyrolytic carbon, which has excellent wear performance and biodegradability. Pyrolytic carbon was used to coat the occluder and housing ring surfaces to improve the durability of the MHV. It is estimated from wear tests that MHVs coated with pyrolytic carbon can operate for the lifetime of the patient—more than 50 years.

Metals are prone to fatigue failure. Their polycrystalline nature contains structural characteristics that may produce dislocations under mechanical loading. These dislocations can migrate when subjected

to repeated loading cycles and can accumulate at intercrystalline boundaries, ultimately leading to the formation of microfissures. These fissures grow slowly until they reach a critical size that can propagate and cause fracture. This fatigue failure typifies metal fracture under cyclic loading. There have been reports of fatigue failure of the valves that use titanium and chrome–cobalt alloy. The detailed reasons behind these failures remain undetermined, but it is evident that existing internal flaws, surface defects, and welds can increase the propensity for fatigue failure.

Pyrolytic carbon has a turbostatic structure that has no crystalline order between the atomic layers in the lattice, so mobile dislocation cannot exist. Accordingly, fatigue has not been a problem for pyrolytic carbon, although recent data suggests that cyclic fatigue-crack growth occurs in graphite/pyrolytic carbon composite material.^[6] This work suggests a fatigue threshold as low as 50% of the fracture toughness, so cyclic fatigue is viewed as an essential consideration in the design and life prediction of heart valves constructed from pyrolytic carbon. The FDA now requires detailed characterization of the pyrolytic carbon materials used in the various valve designs.

MECHANICAL HEART VALVE CAVITATION

Surface pitting and erosion observed on certain clinically explanted MHVs manufactured from pyrolytic carbon may be attributed to cavitation that occurs under normal physiological conditions in the human body. Substantial pitting gives rise to rough occluder surfaces, which may act as potential regions for thrombus formation and probable sites of crack growth in the valve components. Therefore, cavitation is another potential source of structural failure. Cavitation is the rapid formation and collapse of vapor-filled bubbles, usually as a result of a transient reduction in local pressure below liquid vapor pressure.^[7] The violent collapse of cavitation bubbles (also known as implosion) generates an intense shock wave and a high-speed re-entrant jet that can cause damage to the nearby solid boundary surface. The cavitation damage typified by pitting on the component surfaces may ultimately cause MHV failure.

There are three essential factors that must exist concurrently in order for MHV cavitation to be provoked: regional low pressure, nuclei, and sufficient time. Of these three factors, regional low pressure is key to the initiation of cavitation. It is usually associated with the closing motion of the MHV and always occurs on the inflow side of the mitral valve. There is substantial evidence demonstrating that MHV cavitation is related to jet flow through the gap between the occluder (disc or leaflet) and seat stop or valve housing ring, when the occluder impacts the housing ring.

Cavitation is closely linked to valve closing fluid dynamics, which in turn is related to valve design. There are two types of cavitation: vortex and transient bubble cavitation.^[8] Vortex cavitation is initiated by low pressure in the core of the vortex. Jets occur at valve closing, and the mixing layer of jet flow teems with vortices that initiate vortex cavitation. Jets can be subdivided into squeeze and transvalvular jets, both of which may initiate vortex cavitation. Squeeze jets occur between the occluder and the housing when the leaflets of tilting disc valves or bileaflet valves impact the seat stop or the wall of the housing ring. Transvalvular jets are generated by transvalvular pressure at valve closing. Sometimes the tension wave generated during valve closure is strong enough by itself to initiate cavitation typified by bubbles. This is called transient bubble cavitation. Both vortices and tension waves can initiate cavitation. They play a primary role in the inception of cavitation, but their overall contributions are not clearly understood. Investigation into the mechanisms of cavitation in MHVs is an active area of research.

APPLICATIONS OF FLUID MECHANICS

Blood flowing through prosthetic valves encounters a reduction in the cross-sectional area within the valve housing. This sudden reduction in flow area inevitably leads to a pressure drop across the valve. The viscosity of the fluid coupled with the turbulent effects causes an irreversible loss of pressure, which leads to a total loss in fluid mechanical energy. In general, caged ball valves have a greater pressure drop compared to other valve configurations. Porcine prosthetic valves also have smaller orifice areas compared to their mechanical valve counterparts, and hence generally produce a greater pressure drop. The valve configurations that produce the least amount of resistance to flow are the bileaflet and tilting disc designs. These two designs provide a relatively streamlined configuration that minimizes the impediment to forward blood flow.

The effective orifice area (EOA) is a measure of describing how well a valve design utilizes its primary or internal orifice area. A higher EOA corresponds to a smaller pressure drop and a smaller energy loss. The EOA of a particular valve can be calculated by measuring its pressure drop and flow rate:

$$\text{EOA}(\text{cm}^2) = \frac{Q_{\text{rms}}}{51.6(\Delta p)}$$

Q_{rms} is the root mean square systolic/diastolic flow rate (cm^3/s) and Δp is the mean systolic/diastolic pressure drop (mm Hg). For example, the EOA of a mitral valve can be calculated by measuring the diastolic flow

rate (Q_{rms}) and the mean diastolic pressure drop across the valve. Tables 1 and 2 list in-vitro EOA values for various valve types in the aortic and mitral positions, respectively.

Regurgitant flow is the sum of the reverse flow occurring during valve closure and the leakage flow after valve closure. The amount of regurgitant flow depends on the valve configuration and the closing dynamics of the leaflets. Almost all valve configurations have a certain amount of regurgitant flow. In the bileaflet mechanical valve, for example, leakage jets were observed originating in the hinge regions. With their soft and flexible leaflets, bioprosthetic heart valves have a smaller degree of regurgitant flow than their mechanical valve counterparts. An improperly designed or malfunctioning valve may display an increase in the regurgitant flow, so it is important that emphasis be

placed on the quantification of this retrograde flow. Tables 1 and 2 list regurgitation values for various valve types in the aortic and mitral positions, respectively.

IN-VITRO FLOW FIELD MEASUREMENTS WITH VARIOUS MECHANICAL VALVES

The flow field distribution of a Starr-Edwards 1260 aortic caged-ball valve design is characterized by an annular jet that flows over the silicone ball, impacts the aorta wall, and then follows the aorta farther downstream.^[9] Peak aortic values of approximately 2 m/s were measured and are comparable to those observed in other valve designs. The maximum peak forward velocity obtained 12 mm downstream of the valve was

2.2 m/s, decreasing to 1.8 m/s 30 mm farther downstream. A large wake was observed immediately downstream of the ball. This wake develops early during the acceleration phase and then grows into a region of reverse flow of 0.2 to 0.25 m/s that persists to the end of systole. High turbulent shear stresses found in regions of high-velocity gradients range from 1800 to 3500 dynes/cm² and are located at the edges of the jets. The ball seats nicely into the cage, thereby eliminating a large amount of regurgitant flow that comes mainly from the reverse flow during closure.

Two jets are typically observed in the Bjork-Shiley Monostrut and Medtronic-Hall tilting disc configurations, one from the major orifice and another from the minor orifice.^[9,10] The velocity magnitudes and turbulent shear stresses of the major orifice jet are typically larger than those of the minor orifice jet. The orientation and shape of these jets with respect to the streamwise direction changes with the position of the occluder disc as the valve opens and closes. At peak systole 7 mm downstream of the Bjork-Shiley Monostrut tilting disc valve, the velocities of the major orifice and minor orifice jets were measured at 2.1 m/s and 2 m/s, respectively.^[10] Regions of flow separation were observed between the jets and adjacent to the wall in the major orifice region. A stagnation region, which persists during the acceleration and deceleration phases, was observed adjacent to the wall in the minor orifice region. High turbulent shear stresses are located

in the jet shear layers and in the wakes of the disc and struts. The turbulent shear stress values are between 1200 and 3500 dynes/cm² and tend to be higher immediately distal to the valve.^[10] Leakage jets were observed to emanate from the perimeter of the valve through the gap between the occluder and valve housing.^[11] A study by Meyer et al.^[12] reported a large spike in the regurgitant flow during the early phase, which was attributed to the squeeze flow phenomena. The velocities and turbulent shear stresses measured were as high as 3.7 m/s and 10,000 dynes/cm², respectively.

The St. Jude Medical and CarboMedics bileaflet valve configurations divide the forward flow into three regions: one central orifice flow and two lateral flows. The primary differences between the bileaflet valves presently used are in the hinge designs, internal orifice diameter of the valve housing, the occluder opening angle, the occluder traveling arc, and the curvature of the leaflets. The hinge design determines the occluder opening angle and traveling arc and influences the washout, local flow dynamics, and flow patterns generated within the hinge.

Studies show that three jets characterize antegrade flow: one central jet and two lateral jets.^[9,10,13] Typically, the lateral jets have higher velocity magnitudes than the central jet. Taken 8 mm downstream of a SJM bileaflet valve and along the centerline of the valve, the velocities of the lateral jet and the central jet measured

during peak systole were 2.25 m/s and 1.95 m/s, respectively.^[13] Flow separation was observed adjacent to either side of the channel wall. Three jets were still present 13 mm downstream, but the central jet dissipated 20 to 30 mm downstream, whereas the lateral jets persisted for several centimeters more before merging with the surrounding, slower-moving fluid.^[13]

High turbulent shear stresses occur at regions of high-velocity gradients, such as at the edge of the lateral jets and in the region distal to the valve leaflets. Bileaflet designs exhibit lower turbulent shear stresses than the tilting disc and ball-and-cage designs. Peak aortic values were typically higher than those in the mitral valve because of the latter's lower transvalvular velocity. Leakage jets were observed exiting from the hinge region, between closed leaflets, and through the gap between the valve housing and the leaflets of the SJM and CarboMedics bileaflet valve designs.^[14,15] Two jets were observed emitting from each hinge and one from the gap between the leaflets after valve closure. Side jets from the valve periphery were occasionally observed, but they were not fixed and tended to change location with each cardiac cycle. The velocity and turbulent shear stress magnitudes of these leakage jets, as a result of the constricted flow regions, were typically at or above 2 m/s and 5000 dynes/cm², respectively.

A certain degree of regurgitant flow is usually incorporated into the design of a bileaflet MHV to ensure washout of critical areas of the valve, such as the hinges and regions between the leaflet edges and housing. This washout is intended to prevent flow stasis that may be created in the vicinity of the hinge regions and upstream of the valve housing during valve closure, in order to minimize or eliminate the formation of thrombosis, which still poses a significant problem.^[16] Recent studies have shown the importance of the bileaflet MHV hinge geometry in influencing the characteristics of leakage flow structures, such as the leakage velocities and turbulent shear stresses, within and near the hinge region.^[14,15] The constricted flow area at the hinge region of these MHVs, coupled with the pressure difference across the bileaflet valves during closure, is a location in which the fluid can be subjected to high turbulent shear stresses. These studies have suggested the hinge mechanism as the most critical part of the bileaflet MHV because it directly influences valve durability, functionality, and thrombus formation. SJM and CarboMedics prosthetics models have similar hinge geometries, except that in the former the hinge mechanism is streamlined and has a curved profile, and in the latter the hinge geometry has sharper corners and less streamlined edges. The peak velocities observed during the leakage phase in the SJM Regent valve and the CarboMedics CPHV models were 1.5 m/s and 3.17 m/s, respectively.^[14,15]

BLOOD–MHV INTERACTIONS

Shear stress can lead to thromboemboli formation by inducing blood cell damage, thus exposing tissue factor to the plasma, and/or by activating the platelets directly. The shear stress magnitudes shown to cause damage to both red blood cells (RBCs) and platelets have been quantified. RBCs are vulnerable to lethal damage at shear stresses of 1500 to 4000 dynes/cm², and by shear stresses as small as 10 to 100 dynes/cm² in the presence of foreign surfaces. Sublethal damage occurs at 500 dynes/cm².^[16] Platelets have been shown to undergo damage after exposure to 100 to 500 dynes/cm².^[16] Platelet damage is also dependent upon the duration of the shear stress. Platelet damage increases linearly with time during exposure to a constant shear stress implying that shear-induced platelet damage is cumulative.^[16] Shear-induced platelet activation has been studied in viscometers and is also a function of magnitude and duration.^[16] At 150 dynes/cm², platelet aggregates are formed after 300 seconds. Aggregates form at 600 dynes/cm² after 30 seconds, and at 6500 dynes/cm² in less than 5 milliseconds.^[16] These studies also show that as the magnitude increases, formed aggregates tend not to separate when the force is discontinued.^[16] This behavior points to a different mechanism for platelet activation at higher levels of shear stress.

Clot initiation caused by the presence of MHVs can occur via three basic pathways: 1) phospholipid and/or tissue factor exposure to blood during cell damage caused by excessive shear stress; 2) platelet activation caused by exposure to excessive shear stress; and 3) contact activation by foreign materials. Clotting occurs in three steps: initiation, amplification, and propagation. In the tissue factor pathway, a cell or cells are ruptured during the initiation phase to expose tissue factor (TF) to the blood. In the plasma Factor (f) VII binds to TF, thus activating it to fVIIa. This complex activates fX and fIX, and fXa can activate fV. On the cell surface, fXa can bind with fVa to produce small amounts of thrombin, which can activate platelets and fVIII during amplification.^[17] During amplification, platelets adhere to the damaged tissue and are activated. The thrombin generated earlier enhances platelet adhesion, thus fully activating platelets and also activating fV, fVIII, and fXI.^[17] Large-scale thrombin generation takes place during the propagation phase, leading to the formation of fibrin that enmeshes the platelets and stabilizes the clot.^[17]

At levels above 60–80 dynes/cm², stable platelet aggregation occurs in a cone and plate viscometer.^[18] The exact mechanism behind this pathway is not as clearly defined as the TF pathway, but the basic steps are as follows. During initiation, the binding of vWF in the plasma to GPIb on the platelet membrane leads to

a transmembrane flux of Ca^{2+} .^[18] This influx of Ca^{2+} activates the platelet and leads to the amplification phase, during which GPIIb–IIIa interacts with adhesive proteins to mediate platelet–platelet interaction and subsequent aggregation.^[18] GPIIb–IIIa usually binds to fibrinogen, but under high-shear conditions it binds to vWF to mediate platelet aggregation.^[18] Thus, this pathway may not be dependent upon fibrinogen, because vWF both activates the platelets and supports platelet cohesion. The mechanism by which propagation occurs is not clear.

Contact-activated clotting is initiated by the binding of fXII to a negatively charged surface, thus forming fXIIa.^[19] The proteins prekallikrein (PK), fXI, and high-molecular-weight kininogen (HK) are then activated by fXIIa, and PK and fXIa bind to the foreign surface through HK.^[19] On the surface, fXIIa binds PK to kallikrein and fXI to fXIa, and kallikrein generates additional fXIIa. Kallikrein also hydrolyzes HK into its activated forms and releases bradykinin.^[19] Thus, HKa–PK and HKa–fXI complexes are formed on the surface near fXIIa. During amplification, fXIIa acts on these complexes to form surface-bound Hka–kallikrein and Hka–fXIa complexes.^[19] The Hka–fXIa complex activates fIX to fIXa, which acts in a cascade to form thrombin, which in turn activates platelets. Kallikrein is released to activate more fXIIa and convert existing fXIIa to fXIIa, which is still activated but is no longer bound to the surface, so that it can activate more PK.^[19] In addition, fibrinogen is adsorbed to the material surface. A buildup of a layer of proteins on the material helps mediate platelet adhesion and subsequent tissue growth.^[19]

When a valve is implanted, a layer of thrombus usually forms on the sewing cuff. Over time the thrombus either may organize into avascular fibrous tissue or may evolve into granulation tissue and growth of capillaries to form vascular tissue.^[20] This tissue eventually becomes a layer of endothelium of variable completeness and uncertain functionality, which may or may not exhibit anticoagulant activity and may even show procoagulant activity.^[20] The extent of tissue growth, as well as the type, depends upon the location of the valve. Lower pressures lead to greater thickness and more extensive vascularization.^[20] In animal studies, early anticoagulant therapy has been correlated with a reduced tissue thickness. If tissue growth is excessive, it may overgrow the margin of the sewing ring and interfere with valve function.^[20] Some factors leading to this overgrowth (pannus) formation are fabric damage, low-flow conditions, inadequate or inconsistent anticoagulation therapy, the degree of foreign body interaction, and fibroblast activity.^[20] Over time, extension of this overgrowth onto the MHV mechanism can cause narrowing of the orifice, interfere with occluder motion, or act as a site for emboli formation. Reducing the flow

through the orifice results in increased shear stress through the valve and increased areas of stagnation downstream of the valve, predisposing the valve to gross thrombosis. The worst problems are seen in the tricuspid position, most likely because the pressures are lowest here.^[20] Contact activation of platelets by pyrolytic carbon has also been documented, although the importance of this activation in thromboemboli formation is not known.^[21]

In-vitro blood studies with both porcine and human blood have correlated blood damage with both forward flow and leakage flow through MHVs. In a study with porcine blood using a Bjork-Shiley monostrut disc valve, hemolysis was shown to increase with time during both forward flow and leakage flow for the mitral and aortic positions.^[22] Furthermore, in comparisons of hemolysis between the aortic and mitral positions, the mitral position was shown to be more damaging than the aortic position during forward flow, whereas the aortic position was more damaging during leakage flow.^[22] This difference can be attributed to higher turbulent stresses during backflow in the aortic position than in the mitral position, due to a higher transvalvular pressure.

Cavitation was also studied, and it was found that when it occurred its contribution increased with the duration of the cavitation. If the duration was long enough, cavitation became the dominant hemolysis mechanism.^[22] Hemolysis contributions during forward flow and leakage flow were about the same, but considering that leakage affects only 2–5% of the flow, this contribution is significant.^[22] Leakage flow studies on the Medtronic Parallel valve and the SJM standard, high-leaker, and low-leaker prototype valves, using markers for platelet activation and blood element damage in human blood, showed that platelets were activated and damaged in a time-dependent fashion, with activation and damage increasing with time.^[23] Additionally, the high-leaker prototype valve showed more platelet activation and blood damage than the SJM standard valve.^[23] This result shows the effect of leakage magnitude on blood damage and platelet activation. Although a larger leakage area results in lower shear stresses during the leakage phase, a higher leakage flow through the valve exposes more of the blood to high shear stresses encountered during leakage flow. Thus, there is an optimal leakage area that minimizes blood damage.

It has been shown conclusively that elevated shear stress can activate platelets. However, transiently activated platelets would not lead to thrombus or emboli formation if they were not afforded an opportunity to adhere to a surface and/or to one another. In order for a thrombus or emboli to be of sufficient pathological size, millions of platelets must be activated and form an aggregate. Studies using a 10-micron filter to retain platelet aggregates while applying a predetermined pressure leading to elevated shear stress have shown

that activation and aggregation can occur with 8 milliseconds.^[24] Thus, activated platelets that are brought together could aggregate in a very short time period.

In a model of a stenosis with a subsequent enlargement, radiolabeled platelets were used to determine the locations of highest adhered platelet density at different physiological flow rates.^[25] In this model, the stenosis generates a region of high shear stress in which platelets are activated, and the enlargement induces flow separation and consequent recirculation regions.^[25] As expected, this study showed that net platelet density was elevated in areas of flow recirculation and reattachment.^[25] Furthermore, the extent of the platelet density correlated with the length of the recirculation region.^[25] Thus, under the effect of shear stress alone, emboli are most likely to develop in recirculation areas, and they may or may not attach in areas of stagnant flow to become thrombi. Similar recirculation regions are observed in the immediate vicinity of MHVs in the aortic and mitral positions. These regions of recirculation allow platelets to aggregate, with the primary adhesion occurring downstream. Under the influence of tissue overgrowth or an exposed sewing ring, platelets may also attach at these locations as a result of contact activation or shear stress activation and subsequent adhesion.

Studies focusing on the fluid mechanics properties of the Starr-Edwards ball valve, the Bjork-Shiley tilting disc valve, the Medtronic-Hall tilting disc valve, the SJM bileaflet valve, and the CarboMedics bileaflet valve have correlated areas of high shear stress, stagnation, and flow separation to thrombus formation.^[26] The Starr-Edwards ball valves are vulnerable to high-wall shear stresses that can lead to endothelial cell damage. Additionally, high turbulent shear stresses during forward flow, coupled with high-velocity reverse flow relative to the surrounding stagnant flow, create regions of separation that can lead to platelet aggregation.^[26] Explanted valves have demonstrated thrombus formation in the cage area, lending credence to the thrombogenicity of this type of flow field combination.^[26]

The designs of the Bjork-Shiley and Medtronic-Hall tilting disc valves lead to a wake formation behind the valve struts and disc, and these regions exhibit flow separation due to a combination of high velocity and nearly stagnant flows.^[26] Valve explants have demonstrated thrombus formation in this stagnation region on the underside of the disc. Bileaflet valves are also vulnerable to high turbulent shear stresses during both forward and leakage flows. They also exhibit asymmetric separated regions with flow reversal around the perimeter of the housing, with larger spatial dimensions near the hinges adjacent to the lateral jets as well as high regurgitant flow volumes that lead to high shear stresses.^[26] Coupled with adjacent stagnant flow, these high shear stresses could lead to thrombus

formation in the hinge area.^[26] The Medtronic Parallel valve demonstrated such thrombus formation in clinical trials. It passed all preclinical trials, including animal blood studies, in forward flow. However, once this valve was implanted in clinical trials, many patients experienced thromboembolic complications, and valve explants showed thrombus deposition in the inflow region of the hinge area.^[26] The St. Jude and CarboMedics bileaflet valves have also demonstrated thrombus formation in the hinge area.^[20,27]

Because MHVs have been implanted successfully since the 1960s, much patient data is available detailing the success or failure rates of many valve types. According to a collection of such data, it can be seen that valvular thrombosis is most common in the mitral position.^[28] Additionally, bileaflet valves and single disc valves have about the same risk for thromboembolism and valve thrombosis. The ball valve appears to have a slightly lower risk for valve thrombosis, and thrombosis occurs gradually in this valve.^[28] One advantage of the bileaflet valve over the single disc valve may be that one leaflet may function even if the other does not. However, both valves can unexpectedly cease functioning if the hinge is obstructed.^[28]

FUTURE DIRECTIONS

Future emphasis in prosthetic valve research is to improve valve design in terms of better hemodynamic performance, such as lower peak forward and regurgitant flows with reduced turbulent shear stresses and velocity gradients. Improving hemodynamic performance would also reduce blood damage and platelet activation caused by elevated turbulent shear stresses. Progress must also be made toward developing improved materials that are not only durable and biocompatible, but that also enable valve designs to better approximate native valve function. These improvements must be intimately coupled with progress in computational, in-vitro, and animal testing methodologies.

INTRODUCTION

Lineage fidelity of a stem cell may not be as strictly governed as was once thought. This lineage plasticity is most easily studied with hematopoietic stem cells because, even in humans, they are readily obtainable from blood and bone marrow, and the assays to define them are well-characterized, having been the subject of studies for over 30 years. Because of the ease with which they can be obtained from humans, hematopoietic stem cells (HSCs) are an ideal source of cells, which, if truly plastic, could be exploited for the therapeutic repair of damaged and diseased tissues of any type. However, to harness this potential, these cells must be easily identified and isolated from different sources, effectively expanded *ex vivo*, and evaluated functionally by assays that test the desired potential. In order to study and eventually utilize HSCs for the treatment of human diseases, these cells must be expanded *ex vivo* without change in the identifiable and functional phenotype. The largest impediment to the successful development of these expansion methods has been the difficulty in accurate identification and enumeration of HSCs.

HEMATOPOIETIC STEM/PROGENITOR CELL ASSAYS

The “gold standard” for assaying the HSC is the ability of a single cell to reconstitute long-term hematopoiesis in a myeloablated host.^[1] A variety of *in vitro* and *in vivo* assays have also been developed to identify stem cells (Table 1). Phenotypic characterization using flow cytometry is useful not only for the initial isolation of cells that are enriched for HSCs, but also because it has the potential to allow the rapid, relatively inexpensive determination of culture status.^[2] It is widely accepted that the cell-surface glycoprotein CD34 is expressed on almost all human cells with

discernable hematopoietic potential.^[3] Recently, additional markers have been used to fractionate the CD34⁺ cells further and to identify more primitive stem cells.^[4] In particular, cells expressing CD34⁺/CD38⁻ or CD34⁺/Thy-1⁺ phenotype are highly enriched for very primitive hematopoietic cells.^[5,6] However, the identification of CD34⁻ cells with hematopoietic and reconstituting potential has also been reported,^[7] and these cells may be able to lose or gain the expression of CD34 depending on the cell cycle.^[8,9] The combination of these cell-surface markers with fluorescent dyes that indicate cell proliferative status has become a method of choice for isolating HSCs. Hoechst-33342 staining has been used to define a small subset of murine and human bone marrow (BM) cells (Side Population or SP), which are highly enriched for long-term reconstituting HSCs,^[10] and the mitochondrial dye rhodamine-123 has been used to further subdivide primitive stem cells.^[11] Unfortunately, the relationship between the HSC phenotype and its function or genotype is based on uncultured cells; this relationship rapidly dissociates in *in vitro* culture environments^[12] making the dependability of these phenotypic markers as a predictor of biological potential doubtful.^[4] More recently, the expression of endoglin, an ancillary transforming growth factor β receptor, has been identified on murine stem cells and may be used as a functional marker.^[13] In human mobilized peripheral blood, (MPB) side scatter low cells that expressed high levels of aldehyde dehydrogenase (SSC^{lo}ALDH^{hi}) generated colony-forming units (CFUs) and multiple cell lineages both before and after long-term culture and correlated positively with time to engraftment in humans.^[14] However, reconstitution of a myeloablated host with these SSC^{lo}ALDH^{hi} cells alone would be required prior to the use of ALDH as a human HSC marker.

In vitro functional assays have been developed to allow specific lineage-restricted and multi-, bi-, and monopotent subpopulations of hematopoietic

Table 1 HSC^a and HPC^b assays

Assay	Species	Target cell population/comments
<i>Phenotypic markers</i> (Flow cytometry)		
• CD34 ⁺ , Thy-1 ⁺ , Lin ⁻ , c-kit ^{lo} , CD38 ⁻	Human	Subset of HSCs; questionable dependability of phenotypic markers as predictor of biological activity
• Lin ⁻ , Sca-1 ^{hi} , Thy-1.1 ^{lo} , c-kit ⁺	Murine	Same as above
• Side population (SP) defined by Hoechst-33342 staining	Human/murine	Enriched HSCs
<i>In vitro</i> (Long-term culture)		
• Colony-forming assay (CFU, BFU, HPP-CFC)	Human/murine	HPC
• LTC-IC	Human/murine	Primitive HPCs; do not enumerate HSCs
<i>In vivo</i> (Animal models)		
• CFU-S	Murine	Primitive HPC and subset of HSCs (depending on the assay endpoint) forming colonies on the host spleen upon transplantation; exhibition of highly variable self-renewal and differentiation of even the most phenotypically homogeneous CFU-S populations
• Long-term repopulation assay (LTRA) (Syngeneic/xenogeneic transplantation of HSC into SCID, NOD/SCID mice, or sheep, etc.)	Human/murine	HSC; gold standard of HSC assay; xenogeneic microenvironment may produce a less conducive environment for homing, growth, and differentiation of human HSCs

^aHematopoietic stem cell.

^bHematopoietic progenitor cell.

progenitor cells to be detected and quantified. These methods require the provision of appropriate soluble, cell, or matrix-bound factors essential to the support and stimulation of the progenitors being assessed. The CFU, burst-forming unit (BFU), and high-proliferative potential colony-forming cell (HPP-CFC) assays enumerate committed hematopoietic progenitor cells, which form colonies of differentiated cells on semisolid culture media.^[15,16] These progenitors are therefore operationally defined as CFUs with the suffix indicating their lineage commitment. For example, CFU-GM is a progenitor committed to the granulocytic and macrophage lineages. Although some progenitors with multi-lineage differentiation potential can be detected, these progenitors display only limited self-renewal capacity *in vitro*.

An *in vitro* assay that has shown greater specificity for quantifying hematopoietic cells that appear to be more primitive than most colony forming cells (CFCs) is the long-term culture-initiating cell (LTC-IC) assay in which cells are co-cultured with hematopoietic supportive stromal feeders, with or without exogenous cytokines.^[5] The LTC-IC assay fulfils the HSC criterion of being able to initiate and sustain myelopoiesis, but not the two other criteria of self-renewal and long-term lymphopoiesis.^[17]

The colony-forming unit-spleen (CFU-S) assay is an *in vivo* clonal assay in which bone marrow or spleen cells are transplanted into lethally irradiated recipients whose spleens are harvested and analyzed after 8 (CFU-S₈) and 12 (CFU-S₁₂) days.^[18] The colonies of hematopoietic cells appearing on the spleen surface represent different populations of cells where CFU-S₈ cells are predominantly unipotential and CFU-S₁₂ cells are multipotential. Although transplanted HSCs do not generate CFU-S₈, at least a subset of HSCs produce CFU-S₁₂.

The most stringent assay for measuring HSC activity is the long-term repopulating assay (LTRA) because it requires donor cells to fulfill the criteria that define HSCs—the ability of self-renewal, differentiation, and reconstitution of hematopoiesis in the transplant host. In the murine system, syngeneic mice are used as donors and hosts to avoid rejection. In xenogeneic transplants, human HSCs are transplanted in immune-incompetent animals^[19–21] to demonstrate not only multilineal differentiation but also self-renewal and repopulating ability. However, since human HSCs need to repopulate a xenogeneic microenvironment that may be less conducive to HSC homing, growth, and differentiation than the human microenvironment, these assays may not enumerate all human HSCs.^[17]

Fig. 1 Definition of hematopoietic stem cells (HSCs).

Recently, the use of hematopoietic stem cells to reconstitute liver, heart, brain, and muscle in animals,^[22–25] as well as in humans receiving these cells for bone marrow reconstitution,^[26] has raised the possibility of plasticity of cells with a pluripotent rather than a defined multipotent capacity (reviewed by A. Liebmann-Vinson and S. C. Presnell in the article titled *Stem Cells* elsewhere in this encyclopedia). This apparent plasticity is controversial and may simply be the result of cell fusion in the setting of tissue damage^[27–29] or of opportunistic changes in the cell cycle in the context of empty hematopoietic niches.^[30,31] In either case, the definition of the hematopoietic stem cell may be changing to not only a cell that is capable of self-renewal, differentiation, and reconstitution but also one that can either reconstitute or fuse with cells of other tissues as well (Fig. 1). This cell fusion can occur both in the presence or in the absence of tissue damage^[26,32] and may be affected by progeny of HSC such as macrophages since, at least in a murine knockout model for the liver enzyme fumarylacetoacetate hydrolase, replacement of the enzyme by the host HSCs took place only after engraftment had occurred.^[33–35]

CELL SOURCE

From a clinical and bioprocess aspect, the two major issues for ex vivo expansion are the source of the hematopoietic cells and the extent of purification. Several sources of hematopoietic stem and progenitor cells are used for clinical therapies including BM, MPB, and umbilical cord which are collected by various procedures from the patient or from human leukocyte antigen-(HLA-)compatible donors.^[33,36,37] There are significant differences in the quantity and quality (in terms of their proliferative and engraftment abilities and responses to hematopoietic growth factors) of the hematopoietic samples collected from these sources, which also serve as the starting material for ex vivo expansion, although there is currently no consensus as to the best starting population.^[38] BM and MPB are considered to be the best sources of stem and progenitor cells for clinical HSC transplantation. Over the last 10 years, however, umbilical cord blood (CB) has been investigated as an alternative source of

HSCs for the allogeneic transplantation to patients lacking an HLA-matched marrow donor.^[39] CB may be an ideal universal stem cell source because it can be collected easily and provides a potential source of HSCs to patient groups underrepresented in transplant registries. Compared with recipients of adult stem cell sources, those who receive CB may be more tolerant of HLA-mismatch, because they exhibit less graft-versus-host disease (GvHD), a benefit that may be attributed to the increased number of immature dendritic cells and naïve T cells contained within the graft.^[40,41] CB also has lower levels of contamination with common viral pathogens.^[38] However, even though CB is rich in stem and progenitor cells, the number of stem cells obtained is low due to the small volume collected (~100 ml). Hence, the vast majority of CB recipients have been children with an average weight of 20 kg. A nucleated cell dose of $1.5 \times 10^7/\text{kg}$ (or $1.7 \times 10^5 \text{ CD34}^+$ cells/kg) in the CB HSC graft defines a threshold below which an inferior clinical outcome may be achieved.^[42] Hence, the widespread use of cord blood HSCs clinically will depend upon the development of methods for the successful expansion of HSCs ex vivo without compromising engraftment, differentiation capability, and maintenance of the stem cell pool.

CB may be more responsive to growth factors and may be capable of greater expansion than the BM or MPB HSCs, but it is unclear whether the regenerative stem cell pool can be equally maintained. In vitro expansion protocols using the cytokines stem cell factor (SCF), granulocyte colony stimulating factor (G-CSF), and megakaryocyte growth and development factor (MGDF) in one- and two-step culture systems have been successful at expanding committed and primitive progenitor cells, but not at expanding and renewing the HSC population.^[43,44] A recent Phase 1 clinical trial augmented CB HSC transplantation in 28 patients with CB cells expanded in vitro and found no significant improvement in engraftment but did find a reduction in the number of $\text{CD34}^+/\text{lin}^-$ cells available after in vitro culture, suggesting failure of stem cell expansion in this system.^[45] Optimization of ex vivo expanded CB products with the goal of enhancing HSC self-renewal and expansion would provide an ideal stem cell for not only HSC transplantation protocols, but also other in vivo protocols for repair of non-hematopoietic tissues. Addition of proteins, such as Wnt,^[46] or improvement of the scaffold in the culture environment may provide the signals required for HSC expansion.

STEM CELL ENRICHMENT

The ideal phenotype or purity of the starting cell population(s) for the inoculation of ex vivo expansion cultures has not yet been characterized.

Unfractionated hematopoietic cells derived from both adult and umbilical cord sources contain mature blood cells and are developmentally heterogeneous. For clinical use, different methods have been used to enrich for hematopoietic stem and precursor cells.^[37] Some clinical trials have used only CD34-enriched allogeneic grafts with the advantage of harboring fewer T cells and therefore less chance of the patient dying from GvHD, but with the disadvantage of delaying engraftment resulting in prolonged neutropenia and an increased risk of dying from infection.

CD34⁺ cell fractions from different sources may possess different proliferation and expansion potentials.^[47,48] Although the number of CD34⁺ cells may be less in CB compared with adult sources, Kim et al.^[48] indicated that CD34⁺ cell fractions derived from CB may possess higher numbers of CFCs with a greater proliferative capacity. In comparison with grafts selected for CD34⁺ cells, transplantation of whole BM mononuclear cells (MNCs) can support rapid neutrophil and platelet engraftment and long-term stem cell engraftment, presumably due to the presence of accessory cells, such as stromal cells, which also enhance ex vivo expansion cultures.^[49,50] Despite the 10-fold expansion of CFU-GM in these studies using BM MNCs and stromal cell feeders, the earlier progenitor/stem cell pool (represented by LTC-IC and CD34⁺/Lin⁻ cells) was reduced to less than half of the input amount.^[49,50] In contrast, a bioreactor culture will support the same number of total cells and CFU-GMs and will have the same volumetric culture requirements for clinical-scale ex vivo expansion regardless of the extent of purification of the input cells.^[51,52]

MESENCHYMAL STEM CELLS

BM stroma provides structural and instructional support for hematopoiesis. Considerable progress has

been made in the identification and characterization of precursors for the stromal tissue of BM, although this very small (0.01–0.0001% of the total nucleated cells) and heterogeneous population still lacks conclusive morphologic and molecular characterization.^[53,54] Nevertheless, evidence for a developmental hierarchy of stromal cells within the BM is strong, pointing to the existence of multipotent mesenchymal stem cells (MSCs), capable of forming a spectrum of specialized mesenchymal and a variety of connective tissues (Fig. 2).^[54–56] In addition to BM, MSCs have been identified in CB^[57] as well as in peripheral blood,^[58] thus widening the potential availability of MSCs for clinical use if these cells can be positively identified and enriched from these sources.

In vivo analysis of MSCs has been augmented by the development of in vitro functional assays, (colony-forming unit-fibroblast; CFU-F), which demonstrate the ability of clonogenic progenitor stromal cells to form a variety of differentiated cell types.^[59,60] Despite the fact that antibodies to several cell surface antigens that recognize MSCs exist, there is a lack of monospecific and unique molecular probes to identify these cells unequivocally in situ. The monoclonal antibody STRO-1, which identifies an as yet uncharacterized cell-surface antigen expressed by a small heterogeneous population of adult BM MNCs, appears to be a suitable candidate.^[61] Further research is clearly required before we can fully exploit the biological potential of MSCs for therapeutic purposes. However, these cells are already in use therapeutically in clinical trials, including for the replacement of marrow stromal tissue damaged by chemotherapy as part of cancer treatment,^[62] as vesicles for gene therapy in the treatment of mesenchymal tissues,^[63] and for the ex vivo expansion for autologous repair of bone and cartilage defects as well as osteoporosis.^[54,64] The capability of these cells to inhibit ongoing immune responses, such as GvHD and graft rejection is also being exploited in stem cell and organ transplantation protocols.

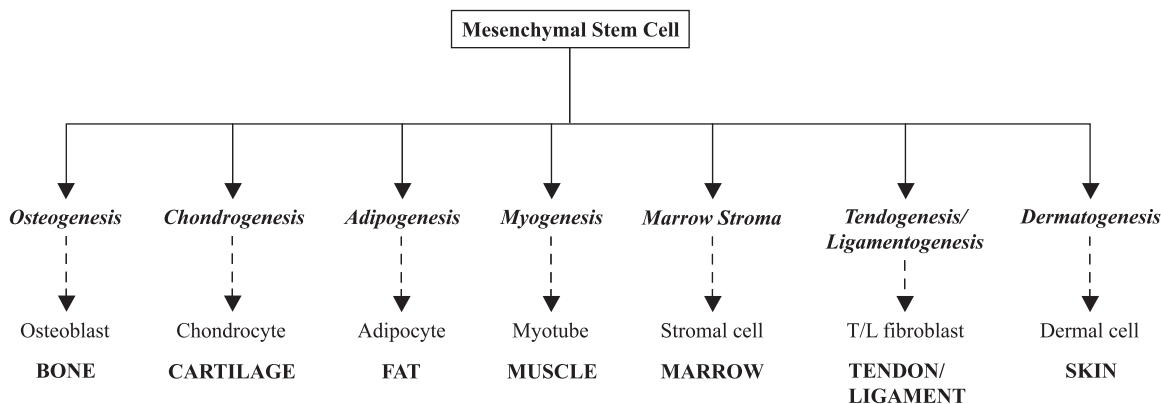

Fig. 2 Mesenchymal differentiation pathway. The differentiation process involves stepwise cellular transitions from the mesenchymal stem cell (MSC) to highly differentiated end-stage phenotypes.

CONCLUSIONS

The immense therapeutic potential of stem cells requires the existence of assays for the accurate identification, isolation, and evaluation of stem cells. With the limited understanding, the investigators in the field still imply properties of stem cells to mixed populations; ideally, to claim a function for a cell population, a homogeneous population should be purified and functionally tested. With the advent of techniques for expansion, approaches that use a combination of cell types, including HSCs and MSCs, in different proportions may be possible for future cellular therapy, each cellular mixture formulated to treat a unique tissue and a specific disease.

Hemocompatible Materials

Agnese Magnani

Federica M. Piras

Department of Chemical and Biosystem Sciences and Technologies, University of Siena, Siena, and University Center "Colle di Val d'Elsa," Colle di Val d'Elsa (SI), Siena, Italy

INTRODUCTION

Contact of blood with a foreign surface triggers the activation of a number of proteases of the *intrinsic pathway* of the coagulation cascade, which terminates in the formation of clots of fibrin, originated by thrombin-catalyzed cleavage of fibrinogen. The clot formation is the most important concern preventing even more widespread applications of biomaterials that contribute significantly to the quality and effectiveness of the world's health care system. Various strategies have been used to improve the blood compatibility of artificial materials although a truly hemocompatible surface does not exist yet.

All synthetic foreign materials are blood compatible in the sense that they do not have the intrinsic capacity of inducing the specific, evolution-selected mechanisms that lead to the thrombus formation. These mechanisms occur directly only with natural materials such as collagen and tissue factors. In contrast, artificial materials acquire thrombogenicity only after first interacting with blood, and the event responsible for the transformation of the inert polymer to an active surface is the interaction of plasma proteins with the surface that then initiates foreign-surface thrombosis. Although these statements pose an oversimplification, they suggest a critical role for protein adsorption in thrombosis on foreign materials. Processes such as protein adsorption, platelet and complement activation, and fibrin polymerization are all surface-induced phenomena and depend to a large extent on the properties and composition of the outer few atomic layers of a material. The successful design of materials for use as blood-contacting devices, thus demands both advanced techniques for surface analysis and adequate criteria for surface property determination, with the intent of correlating the molecular events occurring at the interface with the chemistry and the hemocompatibility of the biomaterial. Fundamental progress in design of new materials with improved hemocompatibility will, moreover, be determined by a deeper understanding of the nature of interfacial phenomena, mainly protein and platelet interactions with surfaces.

In the following discussion, the various surface and interface aspects of blood-contacting materials will be considered together with some of the different strategies commonly used for improving material hemocompatibility.

SURFACE MODIFICATION STRATEGIES FOR IMPROVING HEMOCOMPATIBILITY

Various strategies have been followed for enhancing material hemocompatibility with most of them related to surface modification approaches;^[1] in particular: 1) strategies for creating inert materials and 2) strategies for developing active materials.

Inert Materials

Much of the effort in biomaterials research over the past 35 yr has been directed toward the development of materials that do not react with platelets and coagulation factors. A number of approaches, often conflicting, have been developed and researchers have primarily focused their efforts on modifying surfaces of existing polymeric materials. This approach is reasonable as it is only the surface chemistry of the material that should dictate its biological responses. Despite the success in reducing protein and cellular deposits on some materials, a truly hemocompatible surface has not been achieved.

A popular method to improve the blood compatibility of materials is to increase their surface hydrophilicity by surface-incorporation of hydrogels, which permit the retention of large amounts of water providing the surface with minimal interfacial energy similar to biological tissues. Although the surface-incorporation of hydrogels produces protein-resistant surfaces, a large *ex vivo* study of a variety of materials, containing hydrogels incorporated at their surface, concluded that hydrogels do not possess low thrombogenicity.^[1] Surfaces have also been coated with hydrophilic polymers such as poly(vinyl pyrrolidone)

(PVP). The PVP is generally used to increase lubricity and ease catheter insertion, but its utilization also provided beneficial effects on thrombogenicity and bacterial adhesion.^[1]

Immobilization of the water-soluble synthetic polymer poly(ethylene glycol) (PEG) is a very popular means of making a biomaterial surface more protein and cell resistant. The protein-surface interactions have theoretically been modeled in the presence of PEG, concluding that steric repulsion by surface-bound PEG was largely responsible for the prevention of protein adsorption. The PEG and block copolymers poly(ethyleneoxide)/poly(propyleneoxide) (PEO/PPO) have been inserted into surfaces^[1] or combined to other strategies^[2] in an attempt to increase surface hemocompatibility. While the *in vitro* results have looked very promising, the lack of correlation between *in vitro* and *ex vivo* studies is of concern. More recent efforts with plasma-deposited tetraglyme^[3] have led to surfaces which adsorb very low amount of fibrinogen, suggesting that previous attempts at using PEG modification have not been successful because of the inability to achieve the desired ultralow levels of adsorbed protein.

The observation that surfaces coated with albumin did not support protein adsorption and platelet adhesion led many investigators to use either albumin coating or surfaces alkylation, which enhances albumin affinity, to improve materials hemocompatibility. Albumin adsorption is stated to lower material thrombogenicity, as it does not possess the peptide sequences to enable interaction with platelets and leukocytes or the enzyme receptors in the coagulation cascade. Albumin has been extensively immobilized on polymeric surfaces, and cellulose membranes (Cuprophane), used as dialysis membrane materials, were alkylated with long carbon chains^[1] to enhance albumin adsorption.

Based on the hypothesis that a surface similar to the external phospholipid membrane of cells should be blood compatible, various approaches have been pursued to incorporate phospholipids into surfaces, including phosphorylcholine coated or blended materials. *In vivo* observations proved that platelet adhesion was significantly reduced on phosphorylcholine-containing surfaces.^[4] The mechanism of action of such materials is however unclear, although the low protein adsorption observed on these surfaces has been attributed to their high free-water fraction.

The blending of a copolymer, consisting of polar and nonpolar blocks, to a base polymer has been considered a useful means of improving hemocompatibility of materials. Copolymers with an amphiphathic structure, added in low concentration, demonstrated the ability of migrating to the base polymer surface during and after fabrication. The

polycaprolactone-polysiloxane block copolymers have been used to lower the thrombogenicity of cardiopulmonary bypass and hemodialysis components by using surface-modified additives (SMA)-blended polymers or SMA-coated surfaces. A clinical evaluation of the effect of SMA on cardiopulmonary bypass circuits demonstrated a reduction in platelet interactions with no effect on complement activation.^[5]

The incorporation of fluorine into materials is another investigated strategy to improve blood compatibility. Fluorine groups are believed to inhibit protein adsorption and platelet adhesion because of their low surface energy. Fluoroalkyl groups as chain extender have been used to realize nonthrombogenic polyurethane, and a number of fluorinated SMA have been developed.^[1]

Plasma treatment is another surface modification technique, which results in a covalently attached coating on the surface of a substrate. Various materials were treated with a variety of monomers in plasma reactors, but the comparison of many plasma-modified surfaces did not allow to identify a modification chemistry that was superior to the base material in terms of platelet or leukocyte activation.^[6]

A number of synthetic polymers have been synthesized or modified^[7,8] to prepare polymers with heparin-like activities and then incorporated into polymer matrices or surfaces to enhance their hemocompatibility.^[7-10]

Self-assembled surface layers have been envisioned as useful templates to nucleate or organize ordered, designed biomaterials.^[11] Self-assembled monolayers (SAMs) of alkylsilanes on poly(dimethylsiloxane) (PDMS) have been used as model system.^[12] They have been demonstrated to lower platelet and fibrinogen deposition than surfaces composed of hydrophilic head groups in a canine *ex vivo* arteriovenous shunt model.

Active Materials

The limited successes of the previously discussed surface treatments for enhancing hemocompatibility have encouraged researchers to pursue also other strategies. The most popular and the one that started the field of bioactive materials is the heparinization of surfaces, although the incorporation of other antithrombotic and antiplatelet agents into material surfaces is gaining popularity.

Depending on its molecular weight and structure, heparin is able to inhibit, in association with its cofactor, antithrombin III, the serine proteases: thrombin and factor X. Heparinized surfaces should also help to minimize platelet activation. Heparin has been covalently, ionically, and physically incorporated

to various substrates utilizing a number of chemistries. The main concern has been that once immobilized, the heparin should be able to assume its native conformation and interact with antithrombin III. If heparin is bound ionically to the surface, then it can be slowly released over time. Selected techniques to produce materials that release heparin at biologically significant rates have been investigated.^[1] The thromboresistance of materials based on controlled release appears to be because of the microenvironment of heparin in solution at the blood–material interface. A commercial procedure to ionically bind heparin (Durafllo II) has been used to coat cardiopulmonary bypass circuits and other devices. While the heparin coating is able to reduce thrombus formation, during clinical trials, its effect on complement, contact activation, and inflammation has been contradictory.^[1]

To make the activity of immobilized heparin longer than that reached with ionic linkages, the molecule has been covalently immobilized to material surfaces. The conformation of the attached heparin and the point of attachment are critical factors determining the catalytic efficiency of the immobilized biomolecule. Heparin has been covalently bound to surfaces by different methods.^[1] The most popular chemistry for covalently binding heparin to surfaces of plastics, glass, and steel is the Carmeda method^[13a] The technique used provided highly stable coatings with low thrombogenicity that have been demonstrated to retain good efficacy *in vivo*. In this case, a beneficial effect on *in vivo* bacterial colonization of treated polyurethane central venous catheters was also observed.^[1]

Recently, a comparison of heparinized materials obtained by the Durafllo and Carmeda methods showed no dramatic differences between the two surfaces in clinical trials.^[13b]

Bioline coating is a newer surface-heparinization method that is used to cover components of extracorporeal perfusion circuits.^[14] The effectiveness of this surface coating is associated with platelet preservation, amelioration of inflammatory response, and reduction of fibrinolytic activity during cardiopulmonary bypass. Surface heparinization limited to the oxygenator and the arterial filter had similar results as totally surface-heparinized circuits.^[15]

Agents other than heparin have been surface immobilized to inhibit thrombin, and thereby enhance material hemocompatibility. Among these, hirudin has some advantages compared to heparin, because it has no influence on platelet function, has no immune-mediated platelet-activating activity, and, most importantly, does not require the presence of endogenous cofactors such as antithrombin III. Thus, hirudin has been covalently bound to different surfaces with the aim of improving their blood compatibility

and its controlled release has been exploited.^[1] Another approach involves the immobilization of thrombomodulin, an endothelial cell-associated protein that inhibits thrombin by the activation of protein C. Thrombomodulin has been immobilized on different surfaces and both its anticoagulant activity and the ability to reduce platelet adhesion have been demonstrated.^[1,16]

The inevitable presence of platelets on biomaterials dictated the interest to incorporate antiplatelet agents into materials. Prostaglandins, prostacyclins, and their conjugates with heparin have been incorporated into various material surfaces.^[1] Antiplatelet agents based on inhibiting fibrinogen binding to activated platelet GPIIb/IIIa receptors have been used to reduce surface thrombogenicity via drug release. A novel approach was to exploit endogenous S-nitrosoproteins in plasma to produce NO from immobilized cysteine to minimize platelet adhesion on polyurethane and poly(tetrafluoroethylene) (PTFE).^[17]

Surface thrombogenicity can also be lowered by the lysis of fibrin clots on artificial surfaces. Fibrinolysis can be promoted by inducing surface generation of plasmin. Plasminogen has been directly immobilized, or selectively adsorbed by the immobilized lysine, onto surfaces and then converted to plasmin, so that the surfaces acquire fibrinolytic activity.^[1]

It is intuitive to believe that the ideal surface for vascular grafts/artificial hearts will consist of an intact luminal endothelial cell layer. Dacron [polyethyleneterephthalate (PET)] and PTFE have been seeded with endothelial cells in a preliminary clotting step,^[18a] and encouraging results have been obtained *in vivo* experiments with dogs.^[18b] Several attempts have been made to modify materials to give them a higher affinity for endothelial cells. For example endothelial cells have been seeded on CO₂ plasma-treated polystyrene precoated with substances able to promote endothelial cell adhesion.^[18c] Seeding this surface with endothelial cells (ECs) significantly reduced the number of adhered platelets. Moreover, polystyrene and PTFE surfaces modified by NH₃ plasma facilitated the attachment of ECs.^[18d] Surfaces precoated with fibrinogen or fibronectin^[18e] or containing Arg-Gly-Asp (RGD) peptides^[18f] resulted in higher number of adhered cells.

The recent development of stents for maintaining patency in coronary arteries after angioplasty introduces metallic surfaces to the circulatory system. In lowering metal thrombogenicity, the interest was firstly directed toward heparin-coated stents. These have been then supplanted by rapamycin-eluting stents that have the effect of eliminating *in-stent* restenosis for at least six months after deployment.^[19] Other strategies have been used to enhance the stent hemocompatibility by coating the metal surface with polyurethane and

parylene, or hyaluronic acid, or antiplatelet agents to reduce platelet adhesion.^[1]

SURFACE ANALYSIS^[20–22]

Determination of Surface Properties

To achieve a more complete understanding of the molecular-level interactions between foreign materials and biological systems, surface properties, (surface structure, surface hydrophobicity/hydrophilicity ratio, and surface charge) and subtle surface parameters (surface compliance, functional group distribution and orientation, surface domain distribution, surface dynamics, surface contamination, etc.) should be addressed.

Surfaces have some peculiar characteristics. They are: 1) uniquely reactive; 2) inevitably different from the bulk; thus, traditional techniques used for bulk structure analysis are not suitable for surface determination; 3) readily contaminated; and 4) dynamic—surfaces can restructure in response of the local environment. Enrichment or depletion of surface components may occur as a result of both diffusion processes from/to the inside of the matrix of the material and reactions with the environment adjacent to the material surface. For these reasons, the techniques that can directly probe this interface are of extreme importance.

Surface analysis of materials should provide data on elemental composition of the surface region, surface

functional groups, extent of the preferential orientation of the functional groups, elemental depth profiles, surface crystalline order, surface domain structure, surface energy, and surface topography.

Surface Property Measurements

Many methods are available for surface characterization, with each providing a unique piece of information about the nature of the surface. Table 1 summarizes the characteristics of many common surface analysis methods.

Sample analysis is guided by two general principles:

1. All methods used to analyze surfaces may also alter the surface; the surface analyst must be aware of potential damage of the method.
2. More than one surface analysis method should be used whenever possible to reduce the possibility of artifacts and to obtain the several pieces of information necessary to build a complete picture of the surface. Information from multiple surface analysis methods is often corroborative and synergistic in developing an understanding of surface structure.

Specific Methods for Surface Analysis

Only the most common surface analytical methods are considered here. As many review articles have been published on each method,^[20–22] they are briefly

Table 1 Surface analytical techniques for biomaterials surface characterization

Technique	Principle	Depth analyzed	Lateral resolution
<i>Microscopic methods</i>			
SEM	Secondary electrons emission from a surface struck by an electron beam	5 Å	40 Å
AFM	Measurement of the forces between a tip and a surface	5 Å	1 Å
<i>Spectroscopic/spectrometric methods</i>			
ATR-IR spectroscopy	Molecular vibrations induced by the absorption of IR radiation	1–10 μm	
XPS	Emission of electrons of characteristic kinetic energy induced by x-rays	10–250 Å	8–150 μm
SIMS	Secondary ions emission induced by primary ions bombardment	10 Å–1 μm ^a	500 Å
<i>Thermodynamic methods</i>			
Contact angle	Liquid wetting of surfaces for estimating surface energy	3–20 Å	1 mm ^b

^aStatic SIMS ~ 10 Å; dynamic SIMS to 1 μm.

^bThe size of a small drop is 1 mm.

discussed only in terms of the information they provide. These methods can be grouped as

1. Microscopic methods
2. Spectroscopic/spectrometric methods
3. Thermodynamic methods

Microscopic methods

The simplest picture of a sample surface is provided by the optical microscopic observation, which tells us how homogeneous the surface is. The utility of optical microscopy can be extended by the use of specialized methods including polarized microscopy, interference and differential contrast microscopy, fluorescence microscopy, and confocal microscopy.

A more detailed picture of surfaces is provided by scanning electron microscopy (SEM). The SEM image of surfaces provides 3-D-like topography. The major disadvantage of this microscopy is that nonconductive materials need to be coated with a very thin layer of metal, typically Au. The energetic electrons can damage beam-sensitive samples, including polymers and biological structures; thus, modern instruments utilize a field emission source that can operate at very low accelerating voltages (100 eV).

A much more advanced image of surfaces at the molecular level is obtained by scanning tunneling microscopy (STM), atomic force microscopy (AFM), and the so-called scanning probe microscopies (SPM, a generalized term to indicate the AFM modes). The STM measures electrical current and therefore is well suited for conductive and semiconductive surfaces. However, images of biomolecules on conductive surfaces can be obtained. In AFM, instead of recording tunneling current, the deflection of a tip mounted on a flexible cantilever owing to surface forces between the tip and the sample surface is measured. As the AFM measures forces, it can be used with both conductive and nonconductive surfaces. The AFM can operate in contact, semicontact, and noncontact modes. Moreover, operating the AFM in liquid opens the possibility of observing biological samples in a physiological environment, surface restructuring of polymeric materials in aqueous media, and interfacial phenomena such as protein adsorption on solid surfaces. The SEM and AFM are very useful when used in conjunction with other surface analysis methods; e.g., data on surface roughness are very useful in the interpretation of x-ray photoelectron spectroscopy (XPS), secondary ion mass spectrometry (SIMS), and contact angle measurements, which are known to be strongly affected by surface roughness and texture.

Spectroscopic/spectrometric methods

Infrared (IR) spectroscopy provides information on the molecular structure of materials observing the vibrations of molecular units excited by the absorption of specific frequencies of energy in the IR range. The attenuated total reflection infrared method (ATR-IR) has been widely used for biomaterial surface characterization. In ATR, the IR spectroscopy is coupled with the physical phenomenon of total internal reflection to enable the study of molecular vibrations within the surface regions of the material. The ATR provides molecular structure, conformation, crystalline, and secondary bonding information about the sample surface region. It has been successfully used to study the solid–aqueous interface *in situ*^[23,24] by monitoring interfacial phenomena such as protein adsorption to surfaces with the intent of correlating the molecular events occurring with the surface chemistry and hemocompatibility.

Other “surface sensitive” IR techniques are: external reflection IR that provides extreme surface sensitivity and gives information on the orientation of molecules at the surface; photoacoustic methods based on IR heating and sample expansion for probing the surface; diffuse reflectance IR, whose advantage is that it requires little or no sample preparation prior to analysis; and finally, IR microscopy and IR imaging, which combines the surface sensitivity with lateral resolution.

The XPS is an important technique for the surface characterization and analysis of biomaterials. This technique, based upon the photoelectric effect, provides an elemental analysis of the top 10–100 Å of any solid surface that is vacuum compatible. It has several advantages, i.e., high information content, the speed of analysis, the low damage potential, and the ability to analyze most samples with no specimen preparation. The disadvantages are the need for vacuum compatibility and the possibility of sample damage by x-rays. The vacuum limitation can be overcome by cooling the sample at liquid nitrogen temperatures. The angle-dependent XPS mode gives a nondestructive depth profiling analysis.

The SIMS produces a mass spectrum of the outermost 10 Å of a surface. Like XPS, it requires complex instrumentation and an ultrahigh vacuum system. The method provides unique information complementary to XPS for an understanding of surface composition. Secondary ion mass spectrometry methods are distinguished in static and dynamic SIMS depending on the ion dose used. Dynamic SIMS is surface erosive and enables the analyst to perform a depth profile of a specimen extending from the outermost atoms to a micron or more into the sample. However, because of the damaging nature of the high-flux beam, only atomic fragments can be detected. Static SIMS induces

minimal surface destruction so that intact molecular fragments can be detected. These molecular fragments contain specific chemical information closely related to the surface composition. Spectral interpretation is assisted by specialized methods.

The advances that have been made in SIMS instrumentation [e.g., development of time-of-flight (ToF) mass analyzers] and data analysis methods (e.g., multivariate analysis) in the past 20 yr have resulted in static ToF-SIMS now being an important and widely used surface analysis technique for characterization of biomaterial surfaces.^[25]

Thermodynamic methods

Contact Angle Measurements. This method provides the surface energy of surfaces. The surface energy is directly related to its wettability and it is a useful parameter that frequently correlates with biological interactions. Experimentally, there are a number of ways to measure the contact angle. The contact angle methods are unique in that the equipment required is relatively simple and inexpensive. Although interpretation of the results obtained is dependent on a number of assumptions, each of which is somewhat controversial, a first-order interpretation is possible and has proven to be useful in many areas of surface science.

Newer methods

Nowadays, there are other surface characterization techniques that are becoming important for

biomaterial surfaces characterization. They are summarized in Table 2.

PROTEIN ADSORPTION

Protein adsorption is the first event occurring at the blood–material interface. The process occurs under complex conditions owing to the fact that the plasma phase of blood contains many different proteins and each protein is present at a characteristic concentration that can differ greatly from that of the other proteins (Table 3).

Several models have been developed to describe the adsorption of proteins onto solid surfaces.^[26,27] In these models both the thermodynamic and/or the kinetic parameters have been evaluated. The very rapid initial protein adsorption typically observed appears to be diffusion limited. The thermodynamics of protein adsorption is not easily described in terms of the familiar concepts of free energy, enthalpy, and entropy because these properties are measurable in reversible processes, whereas protein adsorption appears to be essentially irreversible. The irreversibility of the process can be explained in terms of protein size. Multiple bonding between the relatively large contact face of the protein molecule and the surface can in fact occur, and it is unlikely that all these bonds will break simultaneously. The irreversible adsorption isotherms cannot, however, be correctly analyzed to calculate a true equilibrium constant and free energy.

A more reliable insight into the thermodynamics can be obtained by the heats of adsorption. The studies

Table 2 New surface analytical techniques for biomaterials surface characterization

Technique	Principle
Sum frequency generation (SFG)	The SFG is an optical probe of surfaces and interfaces, where light is generated at a frequency, which is the sum of the frequencies of two incident optical fields.
Surface-enhanced Raman spectroscopy (SERS)	The SERS provides greatly enhanced Raman signal from Raman-active analyte molecules that have been adsorbed onto certain specially prepared metal surfaces.
High resolution electron energy loss spectroscopy (HREELS)	Vibrational spectroscopy of a highly surface-localized region, under ultrahigh vacuum.
Ion scattering spectroscopy (ISS)	Elastically reflected ions probe the outermost atomic layer of the sample surface.
Rutherford backscattering spectroscopy (RBS)	The RBS is based upon bombarding a sample with energetic ions and measuring the energy of the backscattered ions.
Extended X-ray absorption fine structure (EXAFS)	The EXAFS refers to oscillatory structures that appear in the high energy side of characteristics X-ray absorption edges of elements.
Scanning Auger microscopy (SAM)	An electron beam is scanned over the surface and the electrons excited from the surface are energy analyzed to detect Auger peaks.
Surface plasmon resonance (SPR)	An SPR is excited at a metal/dielectric interface by a monochromatic light beam.
Synchrotron methods	By accelerating electrons to near the speed of light in a large, circular ring, energies covering a broad range of the electromagnetic spectrum (IR to X-rays) are emitted.

Table 3 Some plasma proteins

Protein	mg/100 ml serum	MW
Albumin	3500–5500	69,000
IgG	800–1800	150,000
IgA	90–450	150,000–200,000
IgM	60–250	900,000
IgE	~300	190,000
Fibrinogen ^a	200–450	340,000
vWF ^a	1.5–5.0	80,000

^aAdhesive plasma proteins responsible for platelet interaction.

in this direction^[26] support the importance of entropic factors in the adsorption process, which arise from changes in water binding to the surface and the protein. The irreversibility of protein adsorption does not prevent, however, the exchange of a previously adsorbed protein with other bulk proteins.

In the understanding of the adsorption events occurring at the blood–solid surface interface, four principles should be mainly taken into account.

1. Adsorption is essentially limited to a monolayer, i.e., the protein molecules that directly interact with the surface are within a monolayer and the excess proteins on the surface should be considered as a deposit.
2. The driving forces determining the composition of the adsorbed protein layer are the intrinsic surface activity of each plasma protein and its bulk concentration in the plasma.

3. Surfaces vary in their ability to adsorb selectively and cause changes in the reactivity of proteins.
4. The ability of an adsorbed protein to influence platelet adhesion and activation depends not only on the amount of that protein, but also on its reactivity, as determined by changes in its orientation or conformation.^[28–30]

Monolayer Model

The evidence for the existence of a monolayer of adsorbed proteins comes most clearly from studies with single-protein solutions in which saturation can often be observed in the adsorption isotherm (Fig. 1). Usually the plateau value falls within the range expected for a close-packed monolayer of protein ($0.1\text{--}0.5\ \mu\text{g}/\text{cm}^2$ depending on the diameter and orientation assumed for the protein). Moreover, studies on the adsorption from complex protein mixtures or plasma also give values that fall in this range, supporting the monolayer model. The competition between the different plasma proteins adsorbing to a surface reflects the availability of a limited number of sites, and the multilayer deposition model would not be expected to lead to the observed protein discrimination by the surface. There are some limitations in the use of the monolayer concept even though it appears to be a good “zero-order” approximation to what really happens in blood. These limitations concern protein–protein interactions that may occur in whole blood, and the fact that both the orientation of the protein and the true surface area available for adsorption per

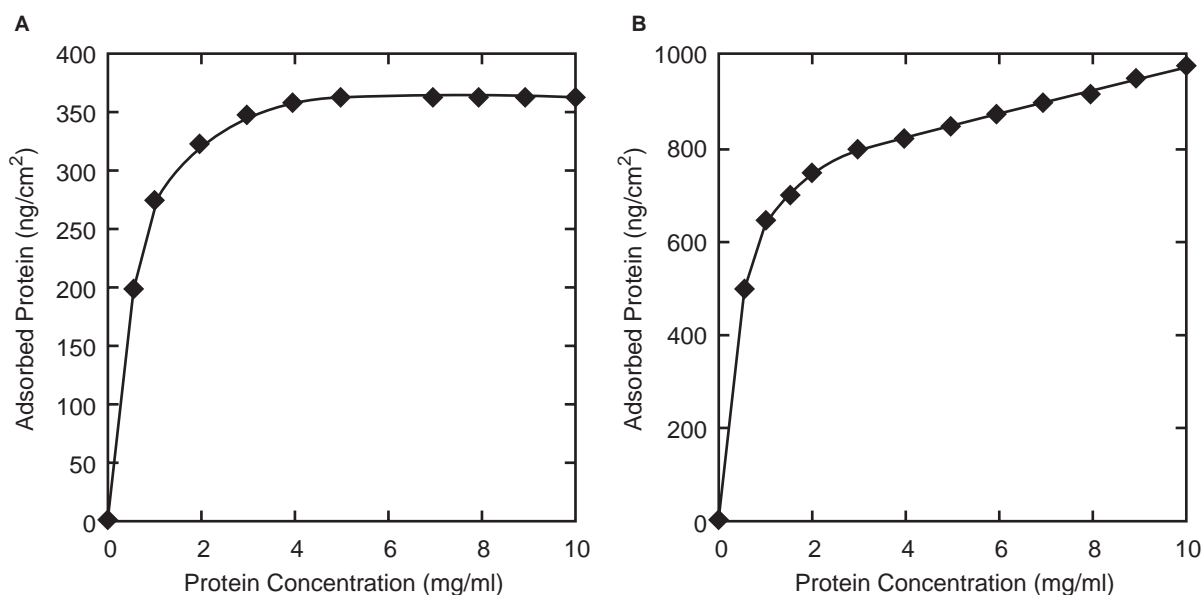

Fig. 1 Monolayer concept: Langmuir (A) and Freundlich (B) adsorption isotherms. The amount of the adsorbed protein is plotted vs. the bulk protein concentration in the solution from which adsorption took place.

protein molecule are not known. Both the classical Langmuir isotherm (true plateau) and the Freundlich isotherm (slow rise) (Fig. 1) have been observed for protein adsorption to solid surfaces.^[29] The monolayer model does not give any information about protein orientation and fibrin formation.

Competitive Adsorption

Adsorption from blood plasma is selective and the surface phase results enriched in certain proteins. Because the number of adsorption sites per unit area is limited, the solid surface can only accommodate a small fraction of the total protein typically present in the bulk phase. As the plasma proteins vary greatly both in their concentration in the bulk phase and in their intrinsic abilities to adsorb to surfaces, some proteins will be adsorbed preferentially. Despite the fact that fibrinogen is only the third most concentrated protein in plasma, after IgG and albumin, materials exposed to blood are typically enriched in fibrinogen in the adsorbed phase. An opposite behavior is observed for albumin owing to its low intrinsic surface activity, although it is the most abundant protein in plasma. The adsorption of fibrinogen from plasma, on the other hand, exhibits some unusual behaviors. On certain surfaces, fibrinogen adsorption is maximum at intermediate dilutions of plasma (Fig. 2). In addition, fibrinogen adsorption from whole or moderately diluted plasma is higher at the very early adsorption times. This is termed the “Vroman effect”^[30] and it is a very clear example of the unique effects of competitive adsorption on both the steady state and the transient

Fig. 2 Representation of the “Vroman effect” for fibrinogen adsorption from plasma.

composition of the adsorbed layer that forms from plasma.

However, studies of surfaces exposed to plasma showed that several different proteins are present in the adsorbate even if enrichment in certain proteins can occur. The concept of a complete “domination” of the adsorbed layer by only one protein (such as fibrinogen), thus, is not very realistic.^[29] Moreover, both the overall surface features and the overall structural stability of a protein have to be considered as key variables for the adsorption process.^[29]

The Influence of Surface Chemistry

The outcome of the competitive process of adsorption is an adsorbed film that is richer in some proteins than others. Because each protein has a different tendency to adsorb onto each type of surface, the outcome of the protein competition is surface chemistry dependent, and the composition of the adsorbed film may be different for each type of biomaterial. Moreover, the composition of the adsorbed layer may change strongly with time. These are the fundamental facts that are believed to underlie at least some of the differences in blood compatibility among various biomaterials, and many of the strategies for improving biomaterial hemocompatibility have been based upon these observations. Most of them resulted in attempts to produce biomaterials that would preferentially adsorb the “right” protein (e.g., an inert one such as albumin), excluding more reactive proteins, e.g., fibrinogen, that tend to favor thrombus formation, or attempts to prevent the formation of the natural-forming mixed layer by the preadsorption of an inert protein to the surface. Efforts have also been made to evade the entire question of the adsorbed protein layer composition by developing nonfouling surfaces. Surfaces bearing polyethylene oxide (PEO) have been shown in many studies to be particularly effective in making a biomaterial surface more protein and cell resistant.^[31] Recent studies with plasma-deposited tetraglyme, as already mentioned, have led to surfaces with ultralow-adsorbed fibrinogen.^[3] Also heparinized polymeric surfaces through an ionic bond have been demonstrated to adsorb low amounts of proteins, without inducing any conformational changes in the adsorbed species.^[24]

Influence of the Conformation and Orientation of the Adsorbed Proteins on Their Bioactivity

Proteins in the adsorbed phase may undergo both noncovalent structural transitions and covalent changes. Although the covalent changes (e.g., fibrin formation and cross-linking, plasmin-catalyzed degradation of adsorbed fibrinogen, and cleavage of adsorbed factor

XII) are undoubtedly a major determinant in the response of blood to synthetic materials, the non-covalent transitions of the adsorbed proteins also play an important role in the interaction with blood.

When proteins adsorb to solid surfaces, they may change their native conformation because of their relatively low structural stability and their tendency to unfold to allow further bond formation with the surface. In spite of these conformational changes, many proteins retain at least some of their activity in the adsorbed state.^[23] In addition, proteins may undergo time-dependent transitions upon their adsorption to foreign surfaces. Many indirect evidences suggest the existence of multiple “states” of adsorbed proteins, which implies a transition step in the formation of such mixed populations.^[29] The concept of transition from a reversibly adsorbed protein to a more tightly held one is included in several models of protein adsorption from single-protein solutions at the solid–liquid interface, and it is also used to explain the time-dependent fibrinogen displacement occurring at the plasma–surface interface.^[30] During the residence time, i.e., the time the protein spends adsorbed on the surface before its “state” is probed, many orientational transitions may occur if the protein continues to interact with the surface provoking the unfolding of the protein and largely reducing the adsorbate elutability.^[32]

Finally, the orientation of proteins in the adsorbed phase is an important concept because proteins are not uniform across their surface. As proteins are not very free to rotate once adsorbed, owing to multiple bonding, a fixed array of the protein surface is exposed to the bulk phase. The degree of uniformity in such orientation is not known, calculations of protein–surface interaction energies in a wide array of orientations of the adsorbed protein against a theoretical plane^[33] suggest that the orientations favoring the greatest possible degree of contact between the face of the protein and the plane are preferred.

These findings are important because they appear to suggest a way that differences in hemocompatibility among different biomaterials may be generated (e.g., by altering the availability of epitopes on adhesive proteins for the cell- and platelet-surface receptors). These processes are important even though the *in vivo* significance of all these changes is not known, and whether the transition changes play a significant role in determining blood compatibility is not clear.

PLATELET INTERACTION WITH BIOMATERIAL SURFACES: INFLUENCE OF THE ADSORBED PROTEINS

The adhesion, activation, and aggregation of platelets, followed in some cases by embolization of platelet

thrombi, is an accepted description of the sequence of events that occur upon exposure of foreign surfaces to flowing blood. The platelet-surface interactions with adsorbed proteins are based on the presence of adhesion receptors in the platelet membrane that bind to certain plasma proteins. Some proteins present in plasma (Table 3) first adsorb on the surface and then mediate platelet adhesion through receptor binding. The proteins strongly adhesive for platelets are fibrinogen, fibronectin, vitronectin, and von Willebrand factor (vWF). The vWF is believed to play a dominant role in platelet binding to subendothelial tissues under high shear conditions, while fibrinogen mediates adhesion to foreign surfaces.^[29] The “platelet Vroman effect” (a maximum in platelet adhesion on surfaces preadsorbed with diluted plasma) also supports the importance of platelet–fibrinogen interactions in mediating platelet adhesion to foreign surfaces.^[29]

Exactly what properties of the material and/or the adsorbed protein layer are critical in causing such activation and what role is played by locally generated concentrations of soluble agonist such as thrombin remain unclear. It is thought, however, that the behavior of fibrinogen, the major protein in plasma known to promote platelet adhesion to foreign surfaces, is especially important.^[34] Studies of the time- and surface-dependent transitions of fibrinogen and the subsequent observation that these transitions can influence the ability of platelets to adhere^[30] are all consistent with a specific mechanism of the adhesion and activation of platelets. The rate and the degree of transformation of adsorbed platelet-adhesive proteins such as fibrinogen appear to be controlled by the surface properties of the polymer, so that the reactivity of a surface to the platelets is in turn dictated by the degree to which the adhesive protein has been converted from a reactive form to an unreactive form. That is, the properties of the surface to which the adhesive protein is adsorbed influence both the “amount” and the “bioreactivity” of the protein itself, which, in turn, affect the platelet response.

CONCLUSIONS

The complexity of the interactions between materials and blood makes the development of hemocompatible surfaces very difficult. Biomaterials research is focused on developing materials that have fewer risks and greater benefits. Stents that “actively” prevent restenosis are a great example of how surface modification of metals can result in a dramatic clinical effect. Inert materials are protein and platelet resistant, but they do not prevent thromboembolic phenomena *in vivo*. On the other hand, incorporating anticoagulants into

surfaces reduces thrombin production, but this may not be sufficient to prevent platelet adhesion and activation. Thus, which approach will ultimately be successful is impossible to predict. Perhaps, the failure to produce an ideal blood-compatible surface merely reflects our limited understanding of the complex blood-materials interaction.

Progresses in design hemocompatible materials will be then determined by a deeper understanding of both the surface properties of materials and the interfacial phenomena originating at the blood-material interface.

INTRODUCTION

The vascular network efficiently transports blood to and from the capillaries in organ systems where the transfer of oxygen and metabolic waste products occurs. Although the arterial tree consists of successive branches of decreasing diameter, the total cross-sectional area at each branching generation increases because of the larger number of vessels present in each generation. Newton's concept of fluid viscosity is a crucial parameter, and its exclusion from hemodynamic models gives inaccurate results. The rheological properties of both blood and the vessel wall must be incorporated into any hemodynamic theory that aims to adequately predict physiological flow. The simpler mathematical models assume steady flow and, although blood flow is pulsatile, useful information can be gathered from these steady flow models. Under certain simplifying assumptions, models of pulsatile flow employing either the linearized or nonlinear Navier–Stokes equations have been solved along with the governing equations of wall motion. The flow velocity patterns derived from such models are in good agreement with measured values. Owing to pulsatility of flow, pressure pulses are generated in the vessel walls, which propagate down the arterial tree as waves. These waves are attenuated as they progress down the length of a vessel and are reflected at branching points or locations where impedance mismatch occurs.

The structure of the venous system is similar to the arterial system, except for the fact that it is under much lower pressure. Negative transmural pressures may develop across the venous vessel walls, which may lead to their collapse. Even under normal operating conditions, the veins are partially collapsed, and the flow through such tubes of noncircular cross-sectional area is different from that in the arteries. Flow patterns have been implicated in the development of many vascular diseases such as atherosclerosis and aneurysms. Disease states may alter the local hemodynamics such as to escalate the deleterious effects.

PROPERTIES OF THE CIRCULATION

Although the human circulatory system has been of interest to man for many centuries, William Harvey's treatise on the subject (*Anatomical Exercise on the Mode of the Heart and Blood in Animals*, published in 1628) is generally accepted as one of the earlier milestones toward a scientific study of cardiovascular physiology.^[1,2] Contrary to the prevailing notion at that time, Harvey correctly inferred from surgical observations that blood constantly recirculates within the body, moving from the heart to the arteries and back to the heart from the veins. Stephen Hales, who reported his various investigations on circulatory function in his *Haemastatics* (published in 1733), is also regarded as a pioneer of the field of hemodynamics.^[1,2]

Application of fluid mechanics principles and analysis requires information about the basic geometrical environment in which such fluid motion takes place. It is therefore essential to have quantitative knowledge of dimensions such as the lengths or cross-sectional areas of blood vessels at various parts of the circulation. Many studies have been conducted to accumulate such information, and Table 1 lists the geometrical parameters of the canine circulation gathered from such studies. The aorta, which is the prominent trunk of the vascular network, displays a significant taper, terminating with a cross section that is about one-sixth of that at its origin.^[1] Because the number of vessels at any given generation of branching in the general arterial tree is much larger than the number at a previous generation, the total cross-sectional area of vessels increases as one moves away from the heart. Between the secondary branches such as the femoral and common carotid arteries and the vessels of 100 μm diameter, the total cross-sectional area increases three- to fivefold.^[1] The network of blood vessels that carry blood from the heart to the lung and back is called the pulmonary circulation, which contains 12% of the total volume of blood. The system of vessels transporting blood to all the other tissue (excluding the heart) is called the systemic circulation, and it carries 83% of the total blood volume.

Table 1 Model of vascular dimensions in a 20-kg dog

Class	Vessels	Mean diameter (mm)	Number of vessels	Mean length (mm)	Total cross-section (cm ²)	Total blood volume (ml)	Percentage of total volume

VISCOSITY OF BLOOD

A fluid is defined as a substance that deforms continuously when subjected to a shearing force.^[3] Consider two parallel plates separated by a distance h that contain fluid in between them. A tangential force F is exerted on the upper plate while keeping the bottom plate stationary such that the upper plate moves with a constant velocity of u cm/sec relative to the lower plate. Then, the fluid near the top plate will move at velocity

u while the fluid near the bottom plate will be stationary, i.e., a velocity gradient u/h is set up in the fluid between the plates. This velocity gradient, also represented by du/dy , is called the rate of shear. If the area of the plates is A , then the shearing stress is the shearing force divided by the area (F/A). Fluids in which the shear stress is directly proportional to the shear rate are called Newtonian fluids.

$$\tau = \mu \dot{\gamma} \quad (1)$$

where, τ is the shear stress (N/m^2), $\dot{\gamma}$ is the shear rate (sec^{-1}), and μ is the constant of proportionality called the coefficient of viscosity. The units of μ are N sec/m^2 , which is also referred to as Poise. Viscosity, referred to by Sir Isaac Newton as a “lack of slipperiness,” is a fundamental property of fluids that represents a kind of internal friction between adjacent fluid layers.^[1] Non-Newtonian fluids are those in which the shear stress varies nonlinearly with the shear rate, and in such cases, the ratio of shear stress to shear rate at any given shear rate is called the apparent viscosity. Certain fluids initially resist deformation to increasing shear stress, but eventually deform at a particular stress value, i.e., they have a yield stress. Some fluids that have a yield stress and a subsequent nonlinear relationship between τ and $\dot{\gamma}$ can be described by empirical relationships such as Casson’s equation

$$\sqrt{\tau} = \sqrt{\tau_y} + k\sqrt{\dot{\gamma}} \quad (2)$$

where, τ_y is the yield stress and k represents plastic viscosity. Blood is a complex fluid consisting of formed elements suspended in plasma. The formed elements consist of 95% red blood cells, 4.9% platelets, and about 0.13% white blood cells. When a sample of blood is centrifuged, the red blood cells collect at the bottom of the tube where they occupy approximately 45% by volume of the total blood sample. This volume percent of red blood cells in blood is called hematocrit. Human plasma has a density of about 1.035 gm/cm^3 , and its viscosity coefficient varies between 0.011 and 0.016 Poise.^[3] Tests of whole blood have shown that it more or less follows Casson’s equation, and at high shear rates (above 50/sec), the apparent viscosity approaches an asymptotic value of approximately 0.035 Poise.^[3] It is thus reasonable to assume that blood acts as a Newtonian fluid at high shear rates, which in general is true in the macrocirculation. Blood viscosity is dependent on temperature and plasma protein content, and increases with increasing hematocrit. The yield stress of blood increases with fibrinogen concentration and hematocrit.^[3]

VESSEL WALL PROPERTIES

To better understand the flow of blood, it is essential to understand the function of the biological conduits that carry it. Pulsatile flow in the circulation continually distends and contracts the vessel wall, and knowledge of the behavior of the vascular wall under such forces provides crucial information in analyzing hemodynamic states. The response of the vessel wall is related to its structure as defined by the cellular and extracellular components that comprise the wall material. All vessels in the macrocirculation have a similar structure and

possess more or less the same components, with only the proportion of these components changing at various parts of the circulation. The wall can be divided into three concentric layers, the intima, the media, and the outermost layer, the adventitia. The inner surface of the intima is lined with a single-cell thick layer of endothelial cells that in some sense serves as the biochemical mediator between blood and the vessel wall. One interesting fact about the endothelial cells is that they alter their morphology in accordance with the shear stress they experience, and they orient themselves in the direction of these stresses. In parts of the circulation, such as arterial bifurcations, where no uniform flow pattern exists, they are more round in structure, disoriented, and proliferated.^[4] The endothelial cell layer is supported by a thin layer of subendothelial connective tissue, and the outermost layer of the intima is the internal elastic lamina, which is a fenestrated sheet of elastic tissue. The media is composed of alternating layers of smooth muscle cells and elastic tissue with interspersed collagen fibrils. The elastic fibers, which are the cause of the elasticity of the vessel walls, contain elastin and microfibrillar components. The external elastic lamina is a layer of the media that demarcates the media from the adventitia. The adventitia itself is composed of dense fibrous tissues in which the nerves, blood vessels, and lymphatics that supply the vessel wall are embedded. Approximately 70% of the vascular wall is composed of water.^[1]

The arteries are classified as elastic or muscular, depending on the composition of the media. The aorta, the arteries that branch from the aortic arch, and the iliac arteries are called elastic as they contain well-defined alternating layers of elastic lamellae and smooth muscle cells.^[4] The elastic lamellae are connected to each other by thin strands of interlamellar elastic tissue, thus forming a three-dimensional (3-D) network through the vessel wall. Further down the arterial tree from these large vessels, however, the composition of medial layer contains a greater proportion of smooth muscle cells, and thus most of the arteries in the circulation are muscular. Smooth muscle fibers run obliquely between the elastic lamellae in elastic arteries, but are more circumferentially oriented in the muscular arteries. The vessel walls in the pulmonary circulation are thinner and less muscular than those in the systemic circulation, because the pulmonary circulation is a lower pressure system. Veins have a very thin intima and media with a small proportion of smooth muscle cells, while the adventitia is thick, containing abundant collagen.^[4] Fig. 1 shows the proportion of elastic, muscular, and fibrous tissues in various vessels. It can thus be appreciated that the vessel wall is far from being a homogenous and isotropic (same properties in all directions) material, as it contains various components in different orientations.

Fig. 1 Size and composition of blood vessel walls. (From Rushmer, R.F. *Organ Physiology: Structure and Function of the Cardiovascular System*; Saunders: Philadelphia, 1972; 135.)

The mechanical response of blood vessels to hemodynamic changes depends primarily on the orientation and interconnectivity of three components: elastin, collagen, and muscle.

The mechanical properties of materials are usually characterized by recording their stress–strain relationship. Those materials that deform when a force is applied on them, but instantaneously return to their original configuration when the force is removed are called elastic materials. Elastic materials that have a linear stress–strain relationship are called Hookean materials, and the ratio of stress to strain is called the elastic modulus. If the stress–strain relation is nonlinear, an incremental elastic modulus is quoted, which represents the slope of the stress–strain curve at a given length. The stress–strain curve of vascular tissue is nonlinear. Certain materials behave as a solid, possessing elasticity, strength, and stability of form, as well as a liquid, displaying characteristics such as flow depending on time, temperature, rate, and amount of loading. Such materials, which include blood vessel walls, that demonstrate both viscous and elastic behavior are called viscoelastic. If a blood vessel is subjected to a sudden increase in pressure (step increase), then it takes a finite amount of time for the radius of the vessel to reach a steady value. If subjected to a constant load, the vessel wall will continue to extend (called creep behavior), and if it is held at a constant distension, the stress decays over time (called stress relaxation). These are properties of all viscoelastic materials. Three variables, force, length, and thickness are measured to characterize the viscoelasticity of the vessel wall.^[1] To characterize the time-dependent, viscous properties of vessel walls, they are subjected to sinusoidal pressures, and the corresponding oscillations in radial distension are recorded. In contrast to an elastic material, viscoelastic materials will display a phase lag between these oscillations. This phase lag is a

measure of the viscosity of the material. Because of this wall viscosity, the stress–strain ratio for blood vessels is characterized by a complex viscoelastic modulus E_c .

$$E_c = |E_c|e^{i\phi} = |E_c| \cos \phi + i|E_c| \sin \phi \quad (3)$$

where, $|E_c|$ is the magnitude of the modulus, which represents the ratio of amplitudes of the pressure–radius curves, and ϕ is the phase lag between these two curves (positive ϕ represents pressure leading radial distension).

FLUID DYNAMICS CONSIDERATIONS

To develop an understanding of blood circulation, many fluid dynamic models have been constructed. It is useful, as is common in science, to initially consider the simplest of models, and then to progress to more complex ones only after the preceding stage has been suitably assimilated.

Steady Flow

One basic model developed in the mid-1850s, which nevertheless provides useful conclusions, is based on experiments done by Poiseuille on flow through small-bore tubes. The empirical expression (called Poiseuille's law) he derived relating the rate of flow through the tube to the pressure gradient across the tube length and the fourth power of the tube radius was independently arrived at by Hagen using theoretical formulations, and is now known as the Hagen–Poiseuille equation:

$$Q = \frac{\pi R^4 (P_1 - P_2)}{8\mu L} \quad (4)$$

where, Q represents the average volumetric flow rate, R is the radius of the tube, P_1 is the pressure at the beginning, and P_2 the pressure at the end of a tube of length L , and μ is the coefficient of viscosity. The equation is only valid for steady, fully developed (i.e., far away from the entrance), laminar flow of a Newtonian fluid through a straight, rigid cylindrical tube, and under those conditions, it also depicts that the velocity profile across the diameter of the tube will be parabolic in nature.

True Poiseuille flow is not established anywhere in the circulation,^[5] and it is helpful to evaluate the effects and validity of the assumptions made in the derivation to understand why this is so. Flow in the circulation is pulsatile and, thus the assumption of steady flow, i.e., the assumption that the fluid is not subjected to any acceleration or deceleration is not valid. Fluid dynamic models of pulsatile flow will be considered below. The simplification that the tube wall is rigid is invalidated as vessel walls are viscoelastic and distensible. The assumption of Newtonian behavior is reasonable in relatively large arteries as the shear rates in these arteries are high enough, and so is the condition that the fluid in contact with the tube wall does not move if the wall does not move (no-slip).

The derivation of the Poiseuille equation also assumes that each particle of liquid moves at a constant velocity in a path parallel to the cylinder wall, which implies that the fluid moves in a series of concentric laminae, with each successive lamina slipping against the viscous friction of the lamina outside it.^[1,2] When flow proceeds in such an organized and deterministic fashion, it is considered laminar. Under certain conditions, however, the orderly pattern of laminar flow is disturbed, and an irregular, random motion sets in. Such nondeterministic and unorganized flow is called turbulent flow, and portions of fluid move both axially and radially, forming eddies and vortices.^[1] At this point, it may be useful to introduce a nondimensional parameter that is widely used in fluid mechanics, called the Reynolds number (Re).

$$Re = \frac{\rho VD}{\mu} \quad (5)$$

where ρ represents the density of the fluid, V is the mean velocity of flow, D is a characteristic length (e.g., tube diameter), and μ is the coefficient of viscosity. The Re represents the ratio of inertial forces to viscous forces, i.e., if Re is large, the inertial forces predominate, whereas if Re is small, viscous forces will dominate fluid flow. The Re also provides an index to classify the flow as laminar or turbulent. In general, flow is said to become turbulent at Re above 2300, approximately. This is not a decisive threshold though, and nonlaminar flow may set in at Re below this

value.^[1] Some of the mean values of Re in the circulation of a 70 kg man are 1500 in the ascending aorta, 640 in the abdominal aorta, 200 in the femoral artery, 1400 in the inferior vena cava, and 1600 in the main pulmonary artery.^[1] Although none of these values are above 2300, these represent the averages, and the peak Re in the large vessels can be considerably higher (9400 in ascending aorta and 7800 in main pulmonary artery). Thus, transient turbulent flow may develop in the ascending aorta and the main pulmonary artery. Flow in all other vessels remains laminar.

The fact that vessels in the circulation are short, curved, and/or branched goes against the assumption of fully developed flow, and the effects of these factors have been investigated.^[1,4,5] When blood enters a vessel, the velocity profile immediately after the entrance is blunt (Fig. 2A), and there exists a steep velocity gradient near the wall owing to viscous friction while the inner core flow is considered inviscid. This outer portion of fluid, which contains the velocity gradient, is called the boundary layer. As the flow progresses down the vessel, the viscous effects propagate toward the axis of the tube, thereby retarding successive layers of fluid. To maintain a constant flow rate across the cross section, the core fluid accelerates. Flow is considered fully developed when the boundary layer reaches the axis of the vessel and a parabolic velocity profile is established. The length of vessel required to establish a fully developed flow is called the entrance length or inlet length, and the flow in this region is said to display entrance effects. The Poiseuille equation is not valid in the entrance region, and as most vessels are not long and straight, entrance effects tend to predominate in the circulation. Entrance effects also exist during start-up flow, which may be the case in the ascending aorta, as the flow almost stops during end of diastole and “starts” again during systole.^[4]

Blood vessels are rarely straight, and their curvature has a marked effect on flow owing to the generation of secondary flow motions that distort the velocity profiles deduced from Poiseuille flow.^[4,5] If it is assumed that the flow is fully developed before it enters the curve (Fig. 2B), then the fluid at the center has a higher velocity than that at the wall. Consequently, as it enters the bend, the central fluid has a higher centrifugal inertia and will resist following the curvature, more than the fluid closer to the wall. This results in the movement of the faster fluid toward the outer wall, where it displaces the slower moving fluid toward the inner wall. The resulting axial velocity profile is skewed toward the outer wall. This movement also sets up “secondary” flows (inset of Fig. 2B), over and above the “primary” axial flow.^[1,4] The flow in the curved part of the tube thus follows helical streamlines rotating in two different directions. It can be seen that the outer wall experiences higher wall shear stress. If

Fig. 2 The effect of complex geometries on flow. (A) Entrance length, δ is the boundary layer thickness at some distance x ; (B) steady flow in a curved tube, inset shows secondary flows; and (C) flow through a symmetric bifurcation, the solid line in the top branch is the velocity profile in plane, and the dotted line is the velocity profile in the perpendicular plane. [Panels (A) and (B) from Caro, C.J.; Pedley, T.J.; Schroter, R.C.; Seed, W.A. *The Mechanics of the Circulation*; Oxford University Press: Oxford, U.K., 1978. Panel (C) from Pedley, T.J. *Fluid Mechanics of Large Blood Vessels*; Cambridge University Press: Cambridge, U.K., 1980.]

the flow at the entrance to the curved tube is blunt, as in the case of the ascending aorta leading to the aortic arch, then all the fluid across the cross section has essentially the same inertia. In this case, the flow lines are not displaced outward by the centrifugal force, but the pressure at the outer wall increases. This increase in pressure at the outer wall must be balanced by a decrease in kinetic energy (Bernoulli's theorem, described below), and the higher velocities are now established at the inner wall.^[1,4,6] It may be noted that blood flow through entrance regions and curved segments is further complicated by the unsteadiness of flow in the circulation, possible noncircular vessel cross sections, and wall distensibility.^[3] In pulsatile flow, the entrance region also becomes transient.^[6] The steep velocity gradients in entrance regions and the secondary flows in curved tubes increase the rate of energy dissipation, which is manifested by an increase in pressure drop for the given flow rate.^[5]

Vessel branching is very common in the vasculature and for the most part, the cross-sectional areas of the daughter branches are smaller than that of the parent vessel, but the sum of their areas is larger than the parent vessel cross section. The same applies for the vessels that converge, i.e., the veins and the vertebral arteries combining into the basilar.^[1] The simplest form of branching is a symmetric bifurcation, as shown in Fig. 2C. The fluid dynamic effect of vessel branching is in some sense a combination of the effects of entrance length and curvature.^[5] Thus, the walls along the apex of the bifurcation (also called flow divider region) experience a higher wall shear stress, because the velocity profile is skewed toward the outer curvature. In contrast, the opposite (inner) walls experience low wall shear stresses, with possible flow separation and reversal. Flow separations are more likely if the distribution of flow rate in the daughter branches is unequal or if the bifurcation is not symmetrical, as in the case of a side branch coming off a parent vessel. As would be expected, secondary flows are also observed during experimental studies in bifurcation models.

Pulsatile Flow

The fact that the heart contracts during systole to eject blood into the vasculature and relaxes during diastole to fill implies that the flow through the circulation is time dependent. This pulsatility generates complex flow patterns that cannot be deduced from steady flow models. Hemodynamic models incorporating pulsatile flow have been developed, the most popular amongst them being the Womersley models. Womersley^[7] developed a series of mathematical models of blood flow that sequentially incorporated higher degrees of complexity, moving from the analysis of pulsatile flow in a

long rigid tube to that of flow in elastic tubes, and eventually considering the tethering of blood vessel walls by perivascular tissue and wall viscoelasticity. It may be helpful to examine his model of pulsatile flow in a rigid tube, to appreciate the process of incorporating pulsatility and its consequences.

The general mathematical equations describing fluid dynamics are called the Navier–Stokes equations, which are based on Newton’s second law (conservation of momentum).

$$\rho \vec{a} = \rho \vec{g} - \nabla p + \mu \nabla^2 \vec{v} \quad (6)$$

where, ρ is the density of the incompressible fluid, a is the acceleration, g is gravitational acceleration, p is the pressure, v is velocity, and μ is the viscosity. The term on the left represents the inertial forces, the first term on the right represents body forces (gravitational forces), the second term represents pressure forces, and the last term, viscous forces. For flow through a tube, it is convenient to express the equations in terms of cylindrical coordinates. If, for example, the direction along the axis of the tube is z , the radial direction is r , the circumferential direction is θ , t represents time, and the velocities in these three directions are v_z , v_r , and v_θ , respectively; the Navier–Stokes equation along the z direction can be expanded and written as

$$\begin{aligned} -\frac{\partial p}{\partial z} = & \rho \left(\frac{\partial v_z}{\partial t} + v_r \frac{\partial v_z}{\partial r} + \frac{v_\theta}{r} \frac{\partial v_z}{\partial \theta} + v_z \frac{\partial v_z}{\partial z} \right) \\ & - \mu \left(\frac{\partial^2 v_z}{\partial r^2} + \frac{1}{r} \frac{\partial v_z}{\partial r} + \frac{1}{r} \frac{\partial^2 v_z}{\partial \theta^2} + \frac{\partial^2 v_z}{\partial z^2} \right) \end{aligned} \quad (7)$$

where the body forces have been neglected. Similar equations can be written for the r and θ directions. These equations are the same as Eq. (6), rearranged such that they equate the decrease in pressure per unit length (left hand side) to the inertial forces (first term on right) minus the viscous forces (second term on right). The acceleration in the inertial term includes not only the rate of change of velocity with time (called local acceleration), but also the effect of convection of fluid particles (convective acceleration). The convective acceleration terms contain the products of velocities and their derivatives, and are therefore nonlinear. In addition to the Navier–Stokes equations, most fluid dynamic models also employ the principle of conservation of mass (the continuity equation). This equation is written in cylindrical coordinates as

$$\frac{\partial v_r}{\partial r} + \frac{v_r}{r} + \frac{1}{r} \frac{\partial v_\theta}{\partial \theta} + \frac{\partial v_z}{\partial z} = 0 \quad (8)$$

Eqs. (7) and (8) are the equations that govern fluid motion when large changes in temperature are negligible, such that conservation of energy need not be

employed. In general, the three components of velocity (v_z , v_r , and v_θ) and the pressure p are unknown for a given flow. The three Navier–Stokes equations (in three directions) and the equation of continuity give four equations with which to determine these four unknowns. After conducting an order of magnitude study, Womersley neglected the nonlinear terms, thereby facilitating a solution by considering the linearized Navier–Stokes equations. Many such linearized models apart from Womersley’s have been developed.^[1,4] For the first Womersley model, which analyzes the axisymmetric, laminar flow of an incompressible Newtonian fluid in a rigid cylindrical tube, the radial velocity component drops out of the equations (from axisymmetry) and so does the radial motion (from tube rigidity). The flow is irrotational and, hence, the circumferential component also drops out of the equations. Only the axial component of velocity remains, and the reduced continuity equation states that this velocity will be constant along the axis. The axial velocity is then a function of radius and time alone. For these assumptions, the Navier–Stokes equation in the z direction reduces to

$$-\frac{\partial p}{\partial z} = \rho \left(\frac{\partial v_z}{\partial t} \right) - \mu \left(\frac{\partial^2 v_z}{\partial r^2} + \frac{1}{r} \frac{\partial v_z}{\partial r} \right) \quad (9)$$

Further, it was assumed that the pressure gradient is a sinusoidal function of time only, expressed as

$$\frac{\partial p}{\partial z} = P e^{i\omega t} \quad (10)$$

where, P is a constant representing the amplitude of the pressure gradient pulse, and ω is the angular frequency. It follows then that the velocity will also be of similar form

$$v_z = w e^{i\omega t} \quad (11)$$

where, w , the magnitude of the velocity, is a function of r only and not of time. Substituting Eqs. (10) and (11) in Eq. (9),

$$-P e^{i\omega t} = i\omega \rho w e^{i\omega t} - \mu \left(\frac{\partial^2 w}{\partial r^2} + \frac{1}{r} \frac{\partial w}{\partial r} \right) e^{i\omega t} \quad (12)$$

and introducing a nondimensional radius $\hat{r} = r/R$, where R is the radius of the tube, the above equation becomes

$$\frac{\partial^2 w}{\partial \hat{r}^2} + \frac{1}{\hat{r}} \frac{\partial w}{\partial \hat{r}} - i\alpha^2 w = \frac{PR^2}{\mu} \quad (13)$$
