In one such approach, Mikos and coworkers used sodium chloride particles as a fugitive phase for the fabrication of porous poly(L-lactic acid) (PLLA) foams.^[4] In this particulate leaching approach, a composite of the polymer with the salt particles (porogen) is first prepared by dispersion of the salt particles in a polymer solution. Following drying of this composite, the salt porogen is leached out by dissolution in water. While this process yields foams with ρ_{rel} in the range of 0.08–0.15, the pore morphology is at best partially open, with cubic pores surrounded by wall leaflets. This pore morphology is a direct consequence of use of salt as porogen. Spherical pores with improved interconnectivity and open-pore architecture can be obtained by the substitution of gelatin spheres for the salt porogen. Significant limitations of this approach include: 1) the need for physical contact between the porogen particles to ensure efficient extraction of the porogen, which narrows the porosity range considerably; 2) high crystallinity in the polymer phase to ensure the structural integrity of the polymer-salt composite; and 3) small foam thickness typically 2–5 mm due to diffusional constraints and issues related to phase separation of the polymer and porogen. Thicker foams can be prepared by a variation of this approach where the polymer and salt particles are first sintered around the glass transition temperature of the polymer followed by annealing prior to leaching.

Nevertheless, the salt leaching technique remains an important development in the fabrication of biodegradable polymer foam scaffolds for TE and remains a popular method due to its simplicity. Recently, Chen et al. have utilized ice particles to achieve similar results.^[5]

Pore formation using a non-water-soluble fugitive phase

Recently, Shastri and coworkers reported the fabrication of polymeric cellular solids by using hydrocarbon particles (porogen) as a template.^[6] This approach differs from the fugitive phase removal process as applied to the fabrication of porous ceramics and metals in the following manner:

1. The fugitive phase is removed by extraction in a solvent that is a nonsolvent for the polymer at moderate temperatures ($<100^{\circ}\text{C}$). This ensures rapid solidification of the polymer around the hydrocarbon template particles due to precipitation of the polymer phase.
2. The fugitive phase is introduced into the polymer phase by simple dispersion of the porogen in a high

viscosity solution of the polymer, thus eliminating the need for sintering.

3. Because the polymer phase is a viscous solution, blending and dispersion of noncompatible inorganic and organic phases can be easily achieved without affecting overall macroporosity.

With this approach, polymer foams with porosity as high as 90% and compressive moduli of over 5 MPa have been fabricated using a variety of degradable and nondegradable polymers. Furthermore, because the polymer phase can be modified by an additive approach, and the processing conditions are anhydrous, polymer foams containing water-soluble and water-insoluble inorganic salts, polymers, and colloids can be fabricated with no significant loss in macroporosity. Since the hydrocarbon porogen is actively extracted by dissolution, by the appropriate choice of the hydrocarbon porogen, polymeric porous solids possessing either a continuous open-pore or an isolated closed-pore architecture may be prepared (Fig. 1). The former is ideally suited for TE applications and has been extensively explored in this context.^[7,8] Yet another interesting structural characteristic of foams produced by the hydrocarbon templating process is the presence of microporosity within the polymer phase, which is a direct consequence of both the nucleation and growth of solvent bubbles and the phase separation of the polymer during the extraction phase (Fig. 2). Because a viscous polymer solution is used to disperse the porogen particles, the success of the hydrocarbon templating approach is dependent on finding a solvent for the porogen that is a nonsolvent for the polymer and miscible with the theta (ideal) solvent for the polymer phase. For degradable polyesters and other common nondegradable polymers such as polystyrene, polycarbonate, and polymethylmethacrylate, low-boiling alkanes such as pentane and hexane satisfy the requirements for a nonsolvent as they are miscible with chlorinated hydrocarbons, which are typical solvents for these polymers. Miscibility with the polymer solvent is key in ensuring a rapid precipitation of the polymer phase around the porogen.

In a variation of the hydrocarbon templating approach, Ma and coworkers have used an assembly of spherical paraffin particles, annealed to form a continuous bonded phase as a template, to produce porous polymeric foams with spherical-interconnected pore architecture.^[9] Using this method they have produced foams of PLLA and PLGA with a pore distribution in the range of 100–500 microns. However, the spherical geometry of the porogen poses two constraints: 1) the porosity cannot be manipulated independent of the pore size; and 2) all the porogen particles have to be in intimate contact with each other to ensure integrity of the annealed paraffin template.

Fig. 1 Scanning electron micrographs of PLA and PLGA foam produced by the hydrocarbon templating process. Note the presence of a continuous polymer phase with open-pore architecture (A), spherical open-pore architecture (B and C), and isolate closed-pore architecture (D). The pore shape and interconnectivity are a function of hydrocarbon template morphology and concentration, respectively, in the polymer phase.

Phase Separation

Phase separation remains an easy and simple way of introducing porosity into a polymer phase. However,

Fig. 2 Scanning electron micrograph of the cross-section of the polymer phase in PLGA foam produced by the hydrocarbon templating process, revealing the presence of a well-defined microporosity. The source of the micropores is most likely a combination of nucleation and growth of solvent bubbles and polymer phase separation.

controlling the segregation of the polymer and solvent phase is complex and typically results in narrow control over porosity and pore characteristics. The key to this process is finding a polymer-solvent combination that can yield a high-phase-segregated structure under conditions in which the solvent can be rapidly either evaporated or sublimed. Foams possessing microcellular architecture can be readily prepared by the phase separation approach.^[10] Some commonly used polymer solvent combinations are naphthalene:PLLA,^[11] supercritical carbon dioxide:PLGA,^[12] and dioxane:PLGA.^[13] Pore shapes can range from circular to elongated^[14] with high aspect ratios depending on the solvent:polymer combination. Due to the relatively mild processing conditions, proteins, peptides, and growth factors can be introduced directly into the polymer phase during the foaming process, thus enabling scaffold-based delivery of bioactives.^[11,12] Scaffold-based delivery of growth factors is an important aspect of TE.

Sintering

The process of sintering entails the thermally induced bonding of particles under pressure. Sintering is a very common approach for the production of porous ceramics. Because sintering requires intimate contact between particles, void volume is severely diminished, and therefore sintering yields articles that are quite dense, with porosity rarely exceeding 50%. Due to the low porosity, extensive pore interconnectivity is absent in sintered articles, making them less attractive for TE applications. In order to increase the porosity in a sintered article, one can combine a thermally stable, water-soluble fugitive phase (spacing agent) such as salt or gelatin with the polymer phase during the

sintering, thus creating an avenue for the introduction of additional porosity upon a removal of this phase.^[15] Porous hydroxyapatite cylinders are processed using this approach.

Textile Processing

Nonwoven fibrous meshes of poly(glycolic)acid (PGA) and PLLA having porosity >90% have been produced using standard textile processing techniques.^[16] Although polymer meshes and felts do not fit the definition of a polymer foam or cellular solid in that they lack a cellular structure, they do share some functional characteristics such as low thermal conductivity and acoustic dampening. Nonwoven PGA meshes have been extensively explored in TE applications with a high degree of success.^[17] Because meshes constitute a random arrangement of discrete polymer fibers, they are structurally weak, i.e., easily compressed. However, their structural stability can be vastly improved by bonding the fibers with a secondary polymer binder.^[18] Such reinforced structures are structurally closer to polymer foams as the bonding process results in the formation of struts (fibers) and vertices (bonded fiber clusters).

INTRODUCTION

Eras of civilization have frequently been named for materials discovered and subsequently used extensively by humans (e.g., the Stone Age, the Bronze Age, etc.). Toward that end, the 20th century might appropriately be labeled as the Plastics Age or, somewhat more broadly, the Polymer Age. Whereas biological polymers (e.g., DNA, proteins) have been present since the origins of life, the development of synthetic polymers and the realization that long-chain molecules could exist are relatively recent milestones on the materials calendar. Indeed, it was only in the 1920s that the concept of a polymer or macromolecule came to be grudgingly accepted, slowly displacing the colloid theory that suggested that macromolecules were nothing more than aggregates of small molecules.^[1] The subsequent two decades witnessed the rapid development of many types of synthetic fibers, plastics, and elastomers, including Dacron, nylon, and Spandex. Also, guiding principles for the successful linking of monomers into high-molecular-weight polymers were established. The remainder of the 20th century saw explosive growth in new polymers and their applications. Today, polymers are ubiquitous, from commodity plastics such as plumbing pipe, food wrap, and trash bags, to highly specialized and tailored materials for use in aircraft components, personal computers, and health care.^[2]

A key reason for the broad acceptance and appeal of polymers is that they are the most versatile of all materials, spanning the range of mechanical properties from soft gels and rubbers to extremely strong fibers. This versatility is a direct consequence of the great latitude conferred by design of the repeat-unit structure and control of chain length (or molecular weight) and chain architecture. While most polymers are based on carbon backbones, inorganic backbones (e.g., silicones) add yet another dimension to the tailoring of material properties. A key aim of this article is therefore to introduce basic ideas of how polymer structure affects properties. A short discussion of the implications of these ideas in the design of polymeric biomaterials will follow. Several examples of such materials are discussed in some detail in additional

entries of the encyclopedia. This article concludes with a summary of opportunities and challenges in polymer science for the next two decades and beyond.

INTRODUCTION TO STRUCTURE/PROPERTY RELATIONSHIPS

Small Organic Molecules

The properties of small organic molecules (melting point, for example) depend intimately on the structure of the molecule and principally on four factors: 1) size; 2) symmetry; 3) internal flexibility (presence or lack of bond rotations); and 4) strength of intermolecular forces. A consideration of how these dictate properties of small molecules is instructive in understanding structure/property relations in polymers. Melting (or fusion) is a first-order thermodynamic transition, and the melting temperature, T_m , depends on the ratio of the enthalpy and entropy of fusion:

$$T_m = \Delta H_m / \Delta S_m \quad (1)$$

Melting points typically increase with molecular size, as evidenced by tracking the properties (gas \rightarrow liquid \rightarrow grease \rightarrow wax \rightarrow resin) of n-alkanes as a function of carbon number. Highly flexible molecules that are reasonably symmetric crystallize readily because the conformation(s) required in the crystal (for example, the extended zig-zag conformation for n-alkanes) are easily adopted. Such materials have rather low melting points even at high molecular weights, since considerable entropy (translational and rotational) is gained on melting and thus ΔS_m is large. Branching can lower melting points by reducing the ability of a molecule to pack tightly into a crystal, thus lowering the enthalpy of fusion. Moreover, branching introduces asymmetry that can inhibit crystallization when the material is rapidly cooled, the result being an amorphous solid or glass. In cases where branching is extensive and does not lead to lack of symmetry, melting points can actually increase vs. linear counterparts due to loss of conformational flexibility and hence lower entropies of fusion. Rigid molecules such as anthracene tend to

have high melting points due to a low entropy of fusion, as only translational entropy is primarily gained on melting. Similarly, molecules with strong intermolecular forces (e.g., hydrogen bonds) have high melting points, usually not due to the need to overcome these forces on melting but rather as the result of their persistence in the molten state affording low entropies of fusion. For this reason, benzoic acid has a relatively high melting point for its molecular weight. These same four factors applied to polymer repeat units, along with chain orientation and extent of crosslinking, are the primary determinants of polymer properties. These points will be illustrated with polyethylene and vinyl polymers derived from mono-substituted ethylenes as examples, followed by a brief discussion of polyesters.

Glass Transition Temperature

A glass is appropriately defined as material having the structural properties of a liquid, namely disorder, and the mechanical properties of a solid; it has a glass transition temperature, T_g , above which the material can flow. The idea of a melting point is easily appreciated but T_g is perhaps less familiar and thus deserves a brief discussion here. Cooling of a molten substance can lead to crystallization at T_m and is accompanied by a rapid drop in volume as shown in Fig. 1 (except for odd substances such as water). The crystalline substance will continue to drop in volume, albeit slowly, as

Fig. 1 Plot of specific volume vs. temperature, contrasting the formation of a glass vs. crystals from the melt.

determined by its coefficient of expansion. However, under certain circumstances it is possible to bypass T_m and form a supercooled liquid that eventually forms a glass. This process, known as vitrification, can occur if cooling is rapid, the viscosity of the melt is very high, and/or the molecular structure of the substance is either asymmetric or large and difficult to pack into a crystal. At T_g , molecular motion effectively ceases. However, unlike T_m , the value of T_g depends upon the cooling rate, with rapid cooling “freezing-in” higher energy molecular conformations and organizations. Therefore, it is common to see T_g reported as ranges, and it is important to specify cooling or heating rates in measurements of T_g .

Polymers^[1,2]

Polyethylene and polymers from mono-substituted ethylenes

Consider first molecular weight, using the n-alkane series as an example with high molecular weight and linear or high-density polyethylene (HDPE) as the upper limit.

Several important points derive from inspection of samples of polyethylene and some lower-molecular-weight solid n-alkanes such as paraffin wax (roughly 30–40 carbons). The wax, a highly crystalline substance, is easily broken into small pieces with a fingernail, whereas the polymer resists such damage and is seen to be a very tough flexible material. Molten wax has a low viscosity in contrast to polyethylene. More significantly, and unlike the wax, fibers can be drawn from the molten polyethylene very easily. The reason is that the molecules of polyethylene are long enough to physically entangle with one another, thus supporting the ability to form fibers from the melt. The entanglement molecular weight is roughly the length of a molecule at which the properties of polymers begin to manifest themselves. It is dependent upon the chemical structure of the polymer, but most entanglement molecular weights are in the range of 2000 to 20,000 g/mol.

As expected, the viscosity of a molten polymer will rise dramatically with molecular weight since chain entanglements will inhibit the ability of molecules to move past one another. Many other properties such as melting point and tensile strength do not continue to increase with molecular weight but reach an asymptote. (However, the tensile strength can be increased substantially by chain orientation.) This is because, at

long chain lengths, polymer chains behave as a collection of shorter independent segments. In the case of polyethylene, the asymptotic limit for T_m is about 140°C . This relatively low temperature is the result of high chain flexibility and thus a high ΔS_m .

Polymers such as linear polyethylene crystallize easily due to the highly symmetric repeat unit and high chain flexibility. However, polymers rarely crystallize completely. Crystallization can begin at multiple points along a long polymer chain, eventually trapping segments of disordered or amorphous chains between crystallites. Therefore, materials such as HDPE are semicrystalline (Fig. 2), with a T_m for the crystalline component and a T_g for the amorphous regions, with the degree of crystallinity being about 70–80%. The T_g for polyethylene is approximately -50 to -90°C , and hence this polymer at room temperature is a composite of crystals and liquid-like amorphous regions. The toughness of polyethylene at room temperature is due to the ability of the amorphous regions above their T_g to absorb mechanical impact. Semicrystalline polymers are typically translucent due to light-scattering by the crystallites. Their solubilities can effectively be nil until temperatures rise to close to T_m , and this is why HDPE containers can be used to store gasoline even though a mixture of alkanes might be expected to dissolve the polymer readily at room temperature because of similar molecular structures.

Mechanical extension of a semi-crystalline polymer typically leads to “necking-down” in the drawn region as chains are pulled out of crystallites and oriented in the stretch direction. Extensive orientation in gel-spun, ultrahigh-molecular-weight HDPE affords fibers the tensile strengths of which exceed that of steel on a weight basis.

Molecular symmetry can affect both the melting point and the degree of crystallinity. Low-density polyethylene (LDPE) has occasional short alkyl branches

Fig. 2 Morphology of a typical semicrystalline polymer such as linear polyethylene. It is kinetically easier for the chains to fold on themselves during crystallization rather than form long extended structures.

that serve to disrupt chain packing and thus lower the degree of crystallinity to about 50% and the T_m to 105 – 110°C vs. about 140°C for the linear material. LDPE is softer (and tougher) than HDPE due to its lower crystallinity.

The effect of symmetry is particularly pronounced for polymers derived from mono-substituted ethylenes such as polypropylene.

This repeat unit as drawn is misleading in that there are two possible configurations at the methine carbon ($-\text{CH}-$) and the arrangement of these along a chain leads to three possible isomers (here $R = \text{methyl}$):

After polyethylene, polypropylene is the second most important polymer in terms of annual world production, and it is only the isotactic form of polypropylene that is produced. This material has a higher T_m (165 – 170°C) compared with HDPE, the principal reason being that the methyl groups reduce the conformational flexibility of the chain in the melt, affording a lower ΔS_m . Its T_g is about -10°C due again to restricted bond rotations, and hence, compared to polyethylene, it is not flexible at lower temperatures. Interestingly, the laboratory that discovered catalysts to produce HDPE many decades ago also produced isotactic polypropylene, but the material was ignored since it was not thought that a backbone with pendant methyl groups would have a higher melting point than polyethylene. As pointed out earlier in our discussion about small molecules, branching can lower T_m but that is principally if there is no regular placement of branches and no stereochemical control at the branch points. (This assumes that there are no strong intermolecular forces acting to depress the entropy of the melt; see the discussion on polylactide and polyglycolide.) Isotactic polypropylene has a very regular structure and its conformational flexibility dictates its thermal properties. The higher T_m makes this material useful in a variety of medical applications (e.g., plastic syringes and tubing) because it can be sterilized in an autoclave without coming too close to its T_m .

It is interesting to compare the structures of linear polyethylene and isotactic polypropylene in the crystalline regions. In polyethylene, the chains adopt a zig-zag conformation as is the case in crystals of small-molecule n-alkanes. In polypropylene, by contrast, the pendant methyl groups force the chains to be helical. An analogy exists with the secondary structure of polypeptides; for example, poly(glycine) prefers the β -sheet structure whereas polypeptides with bulky side chains adopt an α -helix.

Polystyrene is another important material derived from a mono-substituted ethylene where R is a benzene ring. Commercial polystyrene is exclusively the atactic form and, because this isomer is irregular, the polymer does not crystallize and therefore is transparent. This is an attractive property and accounts for the widespread use of polystyrene in petri dishes and related lab supplies. Its T_g is about 100°C due to restricted chain flexibility by virtue of the rather bulky phenyl substituents, and hence the material is rather brittle at room temperature. Like T_m , the T_g of a polymer reaches an asymptote with molecular weight, the 100°C value is the limiting T_g for atactic polystyrene.

Poly(vinyl chloride) or PVC, where $R = \text{Cl}$, is another important atactic polymer. Besides its widespread use in plumbing pipe and connectors, it is a familiar lab staple in the form of flexible Tygon tubing. Tygon is PVC containing a plasticizer such as 2-diethylhexyl phthalate (DEHP). PVC has a T_g of about 85°C , significantly higher than that of polypropylene because of the slightly larger size of the pendant Cl but more significantly due to stronger intermolecular forces stemming from the polar C-Cl bond. At T_g , intermolecular forces need to be overcome to allow chain segments to move relative to one another. Addition of a plasticizer, which is typically a low-volatility liquid with good solubility in the polymer, serves to disrupt intermolecular forces and hence depress the T_g . In Tygon, the T_g is below room temperature. It is interesting that the material keeps its physical shape rather than forming a puddle of high-viscosity polymer plus plasticizer, and the explanation is that PVC contains a small amount of tiny crystallites (perhaps from short segments of syndiotactic repeat units) that act to hold the material together.

Another means of lowering T_g and thus increasing material flexibility is to copolymerize vinyl chloride with monomers such as vinyl acetate. At least some readers will recall long-playing phonograph records which were frequently made from such copolymers.

Polyesters

Polyesters represent an important class of materials with broad applications as biomaterials. Poly(ethylene

terephthalate), PET, is a ubiquitous material known as Mylar in film form and Dacron in fiber form. Woven Dacron mesh is used for large-diameter vascular grafts. PET, with its rather regular structure, is a semi-crystalline polymer with a T_m of about 265°C and a T_g near 85°C .

Polycarbonates are formally polyesters of carbonic acid, the most popular being the material with the trade names Lexan or Merlon. The repeat unit, which is symmetric, is more complex and less flexible than that of PET, and thus polycarbonate will typically form a glass (T_g ca. 150°C) on cooling; hence the polymer is transparent.

The polymer is rigid at room temperature, and it is tempting to think that all glassy polymers below their T_g might be brittle. Polycarbonate is remarkably resistant to impact vs., for example, glassy polystyrene, as evidenced by the properties of compact discs (polycarbonate) and their holders (polystyrene). Polycarbonate has sub- T_g short-range molecular motions associated with the flexible carbonate group that serve to absorb significant impact energy. Such energy-absorbing mechanisms are not available in polystyrene. Similar sub- T_g motions account for the flexibility of PET fibers and films at room temperature.

Both PET and polycarbonate hydrolyze very slowly and are not useful as biodegradable materials. However, simple aliphatic polyesters such as poly(glycolic acid) and poly(lactic acid) are well-known biodegradable polyesters. (They are sometimes referred to as polyglycolide and polylactide, respectively, because they are frequently prepared from dimers of the acids.)

PGA is semicrystalline (typically ca. 50% crystallinity) with a T_m of 225–230°C and a T_g of about 35–40°C. The small $-\text{CH}_2-$ group allows close packing in the crystal and strong dipole interactions among esters, and only rather unusual solvents such as fluorinated alcohols can dissolve the polymer. PLA, like polypropylene, has two possible configurations at the methine carbon. Since lactic acid is made naturally as the L-isomer, the pure (isotactic) polymer derived from it is called poly(L-lactic acid) or PLLA. This material is also semicrystalline (35–40%), but with a lower T_m (ca. 175°C) than PGA, presumably due to methyl groups acting to partially shield dipole-dipole interactions. The T_g of PLLA is around 60°C v 40°C for PGA, consistent with the idea that the methyl group increases rotational barriers along backbone bonds. Copolymers of the D and L isomers of lactic acid are readily made and these are amorphous as expected from their atactic structure. Also, copolymers of lactic and glycolic acids (PLGA) are of great interest because degradation rates can be controlled for a variety of applications in tissue engineering and drug delivery.

Dilution of the polar ester group by methylene units reduces intermolecular forces and thus lowers both T_g and T_m compared with PGA. An example is poly(ϵ -caprolactone), a semicrystalline polymer that has a T_m of 60°C and a T_g of about -60°C .

Cross-linking and Orientation

The molecular origins of structure/property relationships discussed above apply to both small molecules and polymers. However, two additional parameters affect polymers in unique ways. The first is cross-linking, which involves primary bonds (chemical cross-linking) or secondary bonds (physical cross-linking) and affords what are termed polymer networks. Light cross-linking of low- T_g polymers gives materials known as elastomers, and these have the typical properties of a rubber band. Cross-linking raises T_g , as chain motions are now restricted by network junction points. Heavy cross-linking can give very hard, brittle materials, as T_g will rise above room temperature and molecular motions will be too restricted to contribute significantly to impact energy absorption (e.g., toughness). A biopolymer example is keratin, the major constituent of hair and fingernails. Keratin in hair is lightly cross-linked via disulfides from coupling of neighboring cystine amino acids, and the ability to introduce a “permanent wave” takes advantage of the reversibility of disulfide

formation and cleavage via redox chemistry. Fingernails have a much higher disulfide cross-link density, and hence they are harder. (Tortoise shells are even more highly cross-linked.)

Polymer networks can be prepared by covalently linking chains into what is effectively a single molecule using high-energy radiation such as gamma rays, light, or a wide variety of chemical reactions (e.g., disulfide formation). It is also possible to exploit strong intermolecular interactions to afford materials with the properties of a polymer network, yet retaining the ability to reprocess the material upon heating. A classic example is the segmented polyurethanes, which contain a low- T_g block and are cross-linked via thermally labile hydrogen-bonded domains. These have the “snap” of a rubber band but are reprocessable, and are termed thermoplastic elastomers.

New Synthesis Strategies

Polymer chemists continue to explore and optimize polymerization reactions as well as discover new reaction schemes and catalysts that afford a tight molecular weight distribution (MWD), afford more precise control over backbone composition and repeat unit stereochemistry, and allow for the creation of novel chain architectures.

Particularly interesting advances have been made in the area of “living” polymerization, a term for a system where propagating chain ends remain active throughout the duration of the reaction. For example, it has long been thought that free radical polymerization would not be amenable to the characteristics of a living polymerization (e.g., a linear dependence of molecular weight with monomer conversion) due to the inherent high reactivity of radicals. However, it has been discovered over the last decade that it is indeed possible to achieve living polymerization character provided that the number of active radical species is very low at any given time. This can be done by reversibly capping active chain ends using stable nitroxide radicals, halides via redox chemistry with selected transition metals (called atom-transfer radical polymerization, or ATRP), or reversible addition-fragmentation polymerization (RAFT).^[3] On another front, it was believed about 15 years ago that polyethylene and polypropylene were mature technologies, although that has changed dramatically with the advent of new transition metal catalysts^[4] that, for example, afford fine control of the extent of branching (and hence the degree of crystallinity) of polymers of ethylene and small amounts of α -olefins. The new catalysts are also producing old polymers with a high control of stereospecificity. One recent example is syndiotactic polystyrene.

Finally, polymerization reactions are being developed that yield polymers having interesting chain architectures, such as block and graft structures. Chain architecture is important in that compositionally different regions of a polymer chain can contribute different properties. For example, styrene-butadiene-styrene triblock polymer will self-assemble upon cooling from the melt into various thermodynamically stable morphologies depending on the relative lengths of, and thus volume fractions of, the blocks. At about 20 vol% polystyrene, the material is composed of a low- T_g polybutadiene continuous phase and small (ca. 20-nm diameter) spherical domains of atactic polystyrene (T_g of 100°C). The domains are interconnected by virtue of the block polymer chain structure, and hence this material behaves as an elastomer with cross-linking via the glassy polystyrene domains. Such a material is a thermoplastic elastomer, because it can flow if heated above the T_g of polystyrene.

Whereas block and graft copolymers have been known for some time, new polymerization methods such as ATRP are expanding the number of examples of these systems.

More complex architectures, such as multiarm stars and dendrimers,^[5] are being targeted as polymerization chemistry becomes more versatile. Star polymers (multiarm structures emanating from a central core) are of interest principally for the large numbers of chain ends. For example, a 4-arm star polymer will typically have a lower T_g and a lower viscosity than a linear polymer of a similar total molecular weight. Dendrimers are a special class of star-like polymer that have regularly placed branched repeat units. Construction of such a polymer can begin with a core to which a monomer capable of branching is attached (divergent approach), or conversely by making highly branched arms and then connecting these to a core as a final step (convergent approach). Dendrimers typically have poor physical properties in the solid state due to the absence of chain entanglements. However, their interiors have open volume in which to bind drugs and an exterior with a very high concentration of functional groups due to the high degree of branching. These characteristics make dendrimers of great interest in medical applications, for example, as vehicles for delivery of genes to cells.

CHALLENGES AND OPPORTUNITIES: THE NEXT 20 YEARS

Polymer science and engineering will continue to be a key discipline for the design and development of new classes of materials with new or improved applications in medicine. One snapshot of where the field might be heading is derived from a recent report focusing on

similar challenges and opportunities for the Department of Defense,^[6] and a section of that report written by the author is amended here as it might apply to biomaterials development.

Modeling Will Be a Routine First Step

The creation of new polymers will begin with a broad evaluation of properties using high-level modeling and simulation to determine critical parameters (isomeric structure, molecular weight, degree of chain orientation) that influence a property of interest. In particular, modeling will be employed to predict complex organization of functional low-molar-mass molecules and polymers, as is beginning to be done for the difficult problem of predicting protein folding motifs. Modeling will also extend to synthesis routes to define the best approach, as well as to processing. Much guiding information will be in hand prior to doing “wet chemistry.”

Synthesis and Processing Will Become Seamless

Synthesis and processing are typically separate operations. This will change over the next two decades as opportunities to carry out simultaneous synthesis and processing emerge. This idea is not new (e.g., reaction injection molding or chemical vapor deposition), but it will become more widespread. Of particular interest will be polymers and small molecules that self-assemble into ordered molecular structures (e.g., liquid crystals) or morphological structures (e.g., block copolymers). Combinatorial synthesis of polymers will become more routine, and the emergence of combinatorial processing approaches to rapidly identify conditions for fabricating polymers to achieve maximum properties is anticipated.

Polymer Synthesis Will Boast Sequence Control

Nature has evolved machinery to precisely control the sequence of amino acid additions and hence the primary structure of polypeptides. However, conventional polymerization techniques have limited opportunities for the control the sequence of addition of two or more monomers. Block copolymers are possible due to successive addition of monomer charges to active chain ends, and alternating copolymers can be obtained under special circumstances. However, there currently is no viable means to prepare, for example, vinyl-type copolymers with sequence control (e.g., poly [(monomerA)₁-(monomerB)₂]_n). This is in stark contrast to peptide synthesis on ribosomes within

biological cells, which employ a template to code for specific amino acids that are enzymatically linked. A major opportunity and challenge presents itself for the sequence-controlled polymerization of a wide variety of monomers using systems that mimic the functions of ribosomes. Template-directed polymerizations are energetically uphill due to the decrease in entropy resulting from monomer ordering, and in living systems the requisite energy is supplied by ATP. Electrochemical polymer synthesis is an attractive option in that properly patterned electrodes may simultaneously serve as solid templates for synthesis and as energy sources. Other lessons from biology, such as self-assembly and development of hierarchical structures, will continue to be borrowed and built upon.

The Definition of Structure in Polymers Will Rival That of Low Molar Mass Materials

Polymers are by their very nature complex materials, typically having a distribution of chain lengths, isomer content, degrees of orientation, and fractional crystallinity (if any). Thus, structure in polymeric materials is frequently ill-defined compared with small molecules. This difference will gradually disappear over the next two decades as long-chain molecules are synthesized with greater compositional and structural precision. The implications will be significant in that very precise structure/property relationships will be possible, and maximization of properties through the integration of modeling, synthesis, and processing will be realized.

The Impact on Nanotechnology

Many common examples exist of nanoscale (one dimension of <100 nm) materials, including block copolymer films and collagen fibers that function as scaffolds for tissues and organs. However, there will be an increasing push to exploit the properties of individual molecules, or very small aggregates of molecules, for the next generation of multifunctional biomaterials. For example, carbon nanotubes and collections of only a few organic molecules are being studied as components of diodes, transistors, and memory elements. The ability to create well-defined organic polymer structures and manipulate these to form complex and functional arrangements will drive a revolution in information storage and processing, sensing, and communications. This effort is predicted to impact biomaterials and biomedical devices in many

ways, including the design of surfaces with specific and predictable protein adsorption characteristics, and stable and reliable interfaces between cells and electronic materials, both inorganic and organic.

Hybrid Materials Systems Will Be Ubiquitous

Opportunities will continue to arise for the use of polymers as components in hybrid materials systems along with metals, ceramics, and/or electronic materials. Familiar composite materials (e.g., graphite-reinforced epoxy) will see increased uses, but significant potential is seen for new materials combinations such as organic electroactive materials and silicon for hybrid electronic and optical devices in, for example, biosensors.

SUMMARY

Polymers represent the most versatile class of materials because of their adaptability to increasingly precise control of structure and properties. Thus, it is anticipated that polymers will continue to be exploited in many and, in some cases, highly specialized biomaterials applications.

Polymers Used in Tissue Engineering

Vasif Hasirci
Deniz Yucel

Department of Biological Sciences, Middle East Technical University, Ankara, Turkey

INTRODUCTION

Tissue engineering is an extension of the biomedical materials field and involves scaffolds (preferably biodegradable and polymeric) seeded with autogeneous cells. Polymers are large molecules, which can be found in the nature and also prepared in the laboratory (synthetic). Biocompatible and biodegradable polymers degrade to low-molecular-weight biocompatible products and are gradually replaced by the growing tissue. The goal is to have a properly and faster healing tissue. In this article the various polymer types used in tissue engineering are presented.

A polymer is a structurally ordered macromolecule made up of a large number of atoms.^[1] The molecules of a polymer have a relatively small unit, the monomer that repeats itself many times to form the polymer. The polymerization reaction takes place via addition or condensation of monomers to construct the main backbone of the polymer chain. Polymers are extensively used in medicine, in applications such as surgical devices, implants, drug delivery systems, biosensors, and tissue engineering.

A biomaterial is designed to substitute, complement, or completely take over the function of a diseased or incapacitated tissue or organ and polymers constitute a major portion of the biomaterials available for human healthcare alongside natural materials, metals, and the ceramics. Biomaterials are required even though the best solution for aiding or substituting tissue and tissue function is an autograft, because tissue transferred to the affected site from the patient's own body is either in limited quantity or not sufficiently "healthy" to transfer. Allografts (tissue from another member of the same species) and xenografts (tissue from another species) have a much lower success rate than with the autografts.

TISSUE ENGINEERING

Tissue engineering is by far the most exciting new field of biomaterials. It has gained so much popularity that it is being considered as a field of its own and the field is now frequently called "biomaterials and tissue

engineering," in contrast to "biomaterials" of a few years earlier. A variety of tissues are being engineered using this approach including artery,^[2] skin,^[3] cartilage,^[4] bone,^[5] and ligament.^[6] Several of these tissues are now in or are nearing clinical use.

A number of researchers have offered their definitions of what tissue engineering is. According to one, it is "the application of engineering principles to create devices for the study, restoration, modification, and assembly of functional tissues from native or synthetic sources".^[7] Another definition is that it is "the application of the principles and methods of engineering and the life science toward the fundamental understanding of structure–function relationships in normal and pathological mammalian tissue and the development of biological substitutes to restore, maintain, or improve functions".^[8] Two pioneers of the field, Langer and Vacanti (1993), have defined it as "an interdisciplinary field that applies the principles of engineering and the life sciences toward the development of biological substitutes that restore, maintain, or improve tissue function".^[9] It actually is the process of creating living, physiological, three-dimensional tissues and organs utilizing specific combinations of cells, cell scaffolds, and a variety of chemical and biological signals (Fig. 1).^[10] First, a source of cells derived from the patient or from a donor is required. These cells could be stem cells, the undifferentiated cells with capability to be converted into a variety of cell types, or differentiated cells of the desired tissue. Since most of the cells in our tissues have an extracellular matrix as a physical support, an anchorage site and source for signals, a number of biological signals inherent in these tissues need also to be provided. Thus, engineering of surfaces of 2-D and 3-D biodegradable physical supports is an essential task for the success of tissue engineering. The tissue growth in or on these scaffolds in the laboratory before being transferred to the recipient (the patient) is required for tissue engineering applications. The efficacy and safety of both the materials and the cells must be tested for their approval by regulatory authorities. Here, a crucial parameter is the interface between the two ingredients, and the reactions at the interface between the composite structure and the tissue.

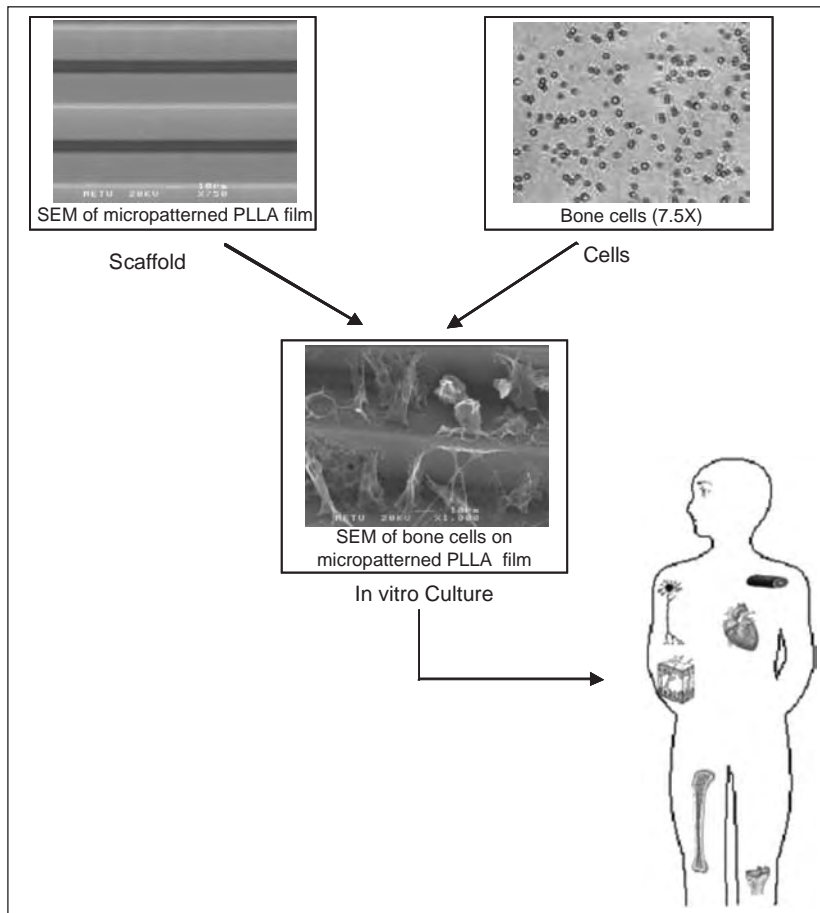

Fig. 1 Schematic presentation of tissue engineering concept using a bone tissue engineering model.

Cell Source

The cell sources used in tissue engineering are:

- Autologous cells (from the patient)
- Allogeneic cells (from a human donor)
- Xenogeneic cells (from another species)

The best cell source for tissue engineering is obviously the patient's own cells, in other words, autologous cells, especially because it eliminates the risk of rejection or adverse tissue reactions.^[11] The problem associated with autologous cells is the questionable healthiness of these cells and also the quantity of cells that could be harvested from a patient who probably is in need of extra healthy cells. Besides, these cells are at an advanced stage of development, and therefore, do not have so many cell divisions to go through. Until recently, it was thought that tissues of an adult would not have any stem cells and existence of such cells was only known in embryos and newborn animals. However, stem cell populations were found in many adult tissues and even amongst the nerve cells in the mammalian brain.^[12] Stem cells have a great potential for proliferation and differentiation. For example, the cells in the

bone marrow can differentiate into cells circulating in blood as well as into osteoblasts and chondrocytes.

Importance of ECM and Scaffold: Housing the Cells

Extracellular matrix (ECM) consists of proteins (collagen, laminin, fibronectin, etc.) and glycosaminoglycans (hyaluronic acid, chondroitin sulfate, heparan sulfate, etc.), is a shelter for cells and forms the skeleton of the tissues. These are large molecules, each with domains involved in cell recognition, adhesion, spreading, differentiation, and proliferation.^[13] The most important group for cell adhesion is the arginine–glycine–aspartic acid (RGD) sequence, which has been initially identified as a minimal sequence required to mediate cell adhesion to the ECM molecule fibronectin,^[14] and has since been found to be present in a wide range of molecules, including the blood circulating fibrinogen. After the discovery of RGD sequence, many such small adhesion-mediating peptide domains have been identified within ECM molecules.^[15] These peptides interact with a class of cell surface adhesion molecules called integrins.^[16] A member of the integrin family consists of a common

beta chain and variable alpha chain and is very diverse.^[17] Integrins are known to mediate many aspects of cell behavior through triggering a number of signaling pathways, some of which are related to cell adhesion, while others are related with differentiation. Therefore, an intense research activity is observed in the direction of influencing the integrin binding to material surfaces, which in return influence ECM ordering leading the cells to follow suit.

At this point ECM needs to be studied, for it is the natural material that carries the cells, and that is what a biodegradable carrier needs to mimic. The ECM is not only a surface on which cells reside but is an active source of physical and chemical signals influencing cell behaviour. Of a large number of scaffolds fabricated from various kinds of materials, a very large fraction are of polymeric origin because of their biodegradability and suitability for functionalization and attachment of biosignal molecules. Researchers, therefore, incorporate a variety of factors such as RGD sequences, growth factors and surface patterns on biodegradable polymeric films and foams.

Processed extracellular matrix (decellularized) scaffolds, such as small intestinal submucosa (SIS), urinary bladder submucosa (UBS),^[18] and porcine heart valves^[19] are also used as scaffolds; however, there are concerns over adverse immune response.^[19]

Properties of an Ideal Cell Carrier

The cell carrier, or as it is widely known, the scaffold, for tissue engineering should meet several design criteria:^[20]

1. Scaffold should preferably be biodegradable and eventually eliminated
2. Scaffolds should be biocompatible; neither the carrier, which is predominantly a polymer, nor its degradation products should provoke adverse responses (inflammation, toxicity, carcinogenicity, thrombosis, etc.) *in vivo*
3. Surface should have appropriate chemistry and physical properties that permit cell adhesion, cell growth, spreading, and regaining functions it had before harvesting
4. Scaffolds should be highly porous to provide space for cell adhesion and proliferation, ECM accumulation, and present minimal diffusional constraints during culture
5. Material should be conveniently processable into 2-D and 3-D forms, and mechanically strong enough for implantation into the recipient.

None of the currently available materials satisfies these requirements sufficiently, and therefore, surface

modification, attachment of biological cues, or formation of composites is employed. Thus, the tissue engineers started incorporating natural or modified cell-signalling molecules into the scaffolds to interact with specific receptors and elicit selective cellular responses, proliferation or differentiation. It has been recognized since the mid-1970s that three-dimensional structures are an important component of engineered tissue development.^[21] The properties, especially pore size, pore size distribution and connectivity, pore orientation, if the carrier is a mesh-like structure the fiber dimension, and form are important characteristics in addition to the chemical properties of the material.

MATERIALS USED IN BIOMATERIALS AND TISSUE ENGINEERING

Polymers, natural materials, metals, and ceramics have all contributed to the medical field.^[20] Metals and ceramics are not biodegradable, their processability is very limited, and the capacity of their surface or the bulk to be modified is very limited in comparison to polymers and natural materials. That is why polymeric materials have received more and increasing attention and are being widely used in tissue engineering.

Among the polymers suitable for tissue engineering are natural polymers, such as collagen, hyaluronic acid, chondroitin sulfate, agarose, and alginate.^[11] Synthetic biodegradable polymers, such as poly(lactide), poly(glycolide), polydioxanone and polycaprolactone, and nondegradable polymers like polyvinyl alcohol, polyethylene, polyethylene glycol, polypropylene oxide (Pluronic), and silicones are among the most frequently used. Rarely hydroxyapatite and bioglasses are used as tissue engineering carriers. Porous hydroxyapatite have been used to house osteoprogenitor cells derived from the periosteum or the bone marrow.^[22] Since the ceramic materials degrade over a long time *in vivo*, they are not widely used. In contrast, polymers could be designed to have a range of degradation time extending from very short (days) to long (several months). In addition, polymeric cell carriers could be processed in the form of fibers, fibrous meshes, porous sponges, or foams, which create an interconnective labyrinth of pores and channels just as needed for the cells.

Polymer Stability: Degradable and Nondegradable

Among the many properties desired in a tissue engineering carrier, degradability has an important place. Polymers degrade in the biological medium by simple and/or enzymatic hydrolysis. It is not a simple task to

identify the actual cause of degradation and the level of contribution of each degradation path, and therefore, in this manuscript biodegradation and degradation have been used interchangeably. Polymer degradation is influenced by the hydrophilicity in the side chains and the backbone, by the crystallinity and porosity.^[23] Ideally, a biodegradable polymer considered for medical applications should have adequate mechanical properties to match the application (strong enough for the duration of in vitro processing and for a certain time after implantation), and should be fully metabolized to biocompatible molecules once it degrades.

The rate and mode of degradation are important. Although most tissues, particularly bone, can tolerate degrading materials, even slowly degrading implants elicit a foreign body response. In bone, where bone tissue formation may be observed adjacent to a non-degradable implant, the mechanical properties of the final hybrid tissue may be poor compared to native tissue. Thus, materials degradable within an appropriate time frame are strongly preferred. Degradation is initiated when water penetrates the bulk of the polymeric system, attacking primarily the amorphous regions and converting long polymer chains into shorter, water soluble fragments by hydrolysis.^[24] This leads to an increase in overall crystallinity of the remaining polymer. Degradable polymers have two main routes of passive hydrolysis: random scission and unzipping. Both routes, however, involve chain scission (lysis of the polymer backbone by water) that leads to a variety of chain lengths depending on the mode of degradation. In the case of unzipping, hydrolysis starts from chain ends while in random scission bond breakage occurs randomly. In unzipping, the products are monomers and polymers with no chains of intermediate length, while in random scission the products are polymer chains cleaved statistically. Degradation may also be initiated by a biologically active process involving enzymes. Degradation also occurs on the side chains of the molecules but this category is not as important as the backbone cleavage.

Another category of materials are called “erodible” or “bioerodible” simply because they are removed by solubilization of the polymer rather than by bond breakage.^[24] This leads to removal of implants from the implantation site through loss of material from the implant surface.

POLYMER SOURCES

There are two sources of polymers used in tissue engineering: synthetic and natural (Table 1). The main biodegradable synthetic polymers include polyesters, polyanhydrides, polyorthoesters, polycaprolactone, polycarbonate, and polyfumarate, while the natural

origin polymers include collagen, alginate, agarose, hyaluronic acid derivatives, and chitosan. Among the man-made polymers, polyglycolide, polylactides, poly(caprolactone), and poly(dioxanone) constitute the major polymer groups that have been studied as matrix materials.

Important Synthetic Polymers Used in Tissue Engineering

Poly(α -hydroxyesters): polylactides (PLA) and polyglycolides (PGA)

Naturally occurring hydroxy acids, such as glycolic, lactic, and ϵ -caproic acids, have been polymerized to create an array of useful biodegradable polymers for a variety of medical applications.^[25] Polylactides, polyglycolides, and their random copolymers [Poly(lactide-*co*-glycolide) (PLGA)] belong to the family of aliphatic α -hydroxy polyesters (Fig. 2). They have been used extensively to fabricate scaffolds for engineering tissues.

PLA and PGA are often synthesized by ring-opening polymerization of the cyclic diesters, glycolide or lactide.^[26] Catalysts such as antimony, zinc, or lead are used in the polymerization process. The chemical structures of PLA and PGA are similar, except that the PLA has a methyl pendant group instead of a H in the backbone, and this difference in structure is the basis of all the significant differences observed in their properties, such as in degradation rate, T_g , T_m , and hydrophilicity. The higher hydrophobicity of PLA limits its water uptake and decreases its degradation rate.^[27,28] When a copolymer PLGA is formed, its properties depend on the ratio of LA and GA present.^[26] Passive hydrolytic scission, which involves random cleavage of polymer backbone by simple hydrolysis of the ester linkages, is the primary mode of degradation. Hydrolytic scission eventually forms the monomers, lactic acid (incorporated into the tri-carboxylic acid cycle and eliminated from the body as carbon dioxide via the lungs), and glycolic acid (excreted in the urine or incorporated into the tri-carboxylic acid cycle).

PLGA polymers have characteristic degradation ranging from days to years, depending on specific formulation, processing conditions, and initial molecular weight.^[10] Lactic acid is a chiral molecule, and therefore, exists in L and D forms. The L isomer is the biological metabolite. When this stereoisomerism is taken into consideration, the polymer poly(L-lactic acid) (PLLA) is a completely stereoregular polymer as poly(D-lactic acid) (PDLA). Poly(D,L-lactic acid) P(D,L-LA), on the other hand, is an amorphous polymer where D and L forms are mixed in the polymer

Table 1 Polymers and cell types used in some tissue engineering applications

Application area	Cell type	Polymer	Reference
Bone tissue engineering	Osteoblasts	PLA/calcium metaphosphate	[106]
		PLLA/hydroxyapatite	[107]
		Silk fibroin films	[64]
		Starch/cellulose acetate	[80]
		Chitosan/alginate	[81]
	Bone marrow stromal cells	RGD modified alginate hydrogel	[108]
		Poly(caprolactone)	[36]
		PHBV foams	[109]
		Calcium phosphate loaded collagen foams	[109]
		Starch/polycaprolactone blend	[110]
Cartilage tissue engineering	Chondrocytes	Collagen film crosslinked with carbodiimide and glutaraldehyde	[62]
		PLGA	[32]
		Poly(caprolactone)	[36]
	Mesenchymal stem cells	HYAFF 11	[77]
		PHBV	[88]
		Poly(NIPAAM-co-AAc)	[103]
		Poly(caprolactone)	[111]
Skin tissue engineering	Fibroblasts	Type I collagen matrix	[113]
		PLGA/collagen mesh	[112]
	Endothelial cells, keratinocytes and fibroblasts	Collagen/glycosaminoglycans	[90]
Blood vessel tissue engineering	Smooth muscle cells and endothelial cells	PGA mesh and PLGA film (respectively)	[31]
	Venous endothelial cells and vascular smooth muscle cells	PLGA nonwoven mesh	[114]
Liver tissue engineering	Hepatocytes	Alginate	[115]

chain even though the chemistry is that of pure polylactic acid. Since amorphous regions are more susceptible to penetration of water, the rate of hydrolysis is much higher when copolymers or nonstereoregular PLA are used. In the body, the initial degradation occurs until the molecular weight decreases to around 5000 Da, at which point biological degradation takes over.^[25] The final degradation and resorption of the poly(α -hydroxy acid) implants involves inflammatory cells (such as macrophages, lymphocytes, and neutrophils). These alpha-polyesters are hydrophobic, therefore, insoluble in water, and are degraded rapidly in acidic aqueous media. These thermoplastic polymers are generally formed into films, tubes, matrices, fibers, meshes, and open-cell foams (Fig. 3) using standard

processing techniques. These polymers form rigid films and foams which crumble upon degradation, sometimes creating crystalline particulates that remain in the implantation site for years, leading to mechanical damage or sterile sepsis.^[10] In addition, the acid nature of the products cause pH drop at the implantation site damaging cells and neighboring tissue.

PGA itself is highly crystalline (45%–55%), has a T_m of 220°C–225°C and a T_g of 35°C–40°C.^[24] Because of its high degree of crystallization, it is not soluble in most organic solvents; the exceptions are highly fluorinated organics such as hexafluoroisopropanol. PLLA is a semicrystalline polymer with 37% crystallinity, and has a T_m of 175°C–178°C and a T_g of 60°C–65°C, while P(d,l-LA) is an amorphous polymer.^[24]

Fig. 2 Chemical structure of (A) PGA, (B) PLA, (C) PLGA.

The degradation rate of PLLA is much slower than that of P(d,l-LA), requiring more than 2 years to be completely absorbed. The 50:50 glycolide and lactide copolymer degrades faster than either homopolymer.^[24] The 10:90 copolymer (10% l-lactide and 90% glycolide) was developed by Ethicon as an absorbable suture material under the trade name Vicryl and degrades within 3–4 months. These polymers have gained the approval of the U.S. Food and Drug Administration for human clinical use in a variety of applications, including sutures.^[29] However, in spite of their wide use in a variety of biomedical applications, their acidic degradation products^[30] and lack of functional groups for further modification limit their usefulness.

The use of PLA and PLGA in tissue engineering scaffolds is very common. In order to give an idea, a few examples are cited. In constructing a tissue-engineered blood vessel, Niklason and Langer^[31] used PLGA- and PGA-based scaffolds and seeded endothelial cells onto PLGA films and bovine aortic smooth muscle cells onto PGA mesh. PGA meshes seeded with smooth muscle cells developed into a tissue-like appearance and dense, albeit disorganized, cell structure after 4 weeks in a static culture. Shi et al.^[32] constructed 90% porous PLGA (50:50) scaffolds through solvent casting/salt leaching to culture chondrocytes for cartilage restoration. Moreover, Hasirci et al.^[33] reported that disk-shaped PLGA (85:15) foams represented a promising scaffold for scaling up rat hepatocyte culture.

Poly(ϵ -caprolactone)

Poly(ϵ -caprolactone) (PCL) is an aliphatic polyester, that can be prepared by ring-opening polymerization of caprolactone like the PLA and the family (Fig. 4).^[24] It is semicrystalline, with a T_m of 59°C–64°C and a T_g of –60°C. The polymer can be degraded enzymatically as well as hydrolytically.^[25] Low molecular weight

Fig. 3 Scanning electron micrograph of a PLLA foam.

PCL in particulate form is reported to be taken up by macrophages and degraded intracellularly.^[34] It has a degradation time of about 2 years, a period generally longer than desired for tissue engineering applications and slower than those of PGA or PLA.^[24] It, however, has the capability to form blends and copolymers with other biodegradable polymers and could therefore be rendered suitable for tissue engineering.

Williams et al.^[35] produced a computer-designed, porous PCL scaffold with selective laser sintering (SLS), a rapid prototyping technique. Bone morphogenetic protein-7 (BMP-7) transduced fibroblasts were seeded and the construct was implanted subcutaneously as potential bone and cartilage implants. The results indicated that this carrier was suitable for tissue engineering. Cao et al.^[36] designed an osteochondral construct by coculturing osteogenic and chondrogenic cells. The 3-D porous PCL polymer scaffold was prepared by fused deposition modeling. Both cell types proliferated, migrated, linked in their scaffold compartments, integrated at the interface, and produced different extracellular matrices. High osteocalcin and high alkaline phosphatase were found indicating the suitability of this system to osteochondral defect repair.

Polyanhydrides

The anhydride bond is more unstable against hydrolytic attack than esters, amides, and ethers.^[15] Their

Fig. 4 Chemical structure of PCL.

P

relatively high degradation rate is both an advantage and a limitation. Degradation of polyanhydride devices is initiated by access of water into the device and can be controlled by the hydrophobicity of the monomers. They are known to be biocompatible,^[37] susceptible to hydrolysis, and degrade rapidly through surface erosion.^[26] Ibim et al.^[38,39] compared poly(anhydride-*co*-imide) polymers to PLGA and revealed poly(anhydride-*co*-imide) polymers to be equally biocompatible to PLGA and able to support endosteal and cortical bone regeneration. Thus, they identified poly(anhydride-*co*-imide) polymer scaffolds as a potential implant for orthopedic surgery, specifically in weight-bearing applications. Extensive engineering of copolymer anhydrides has yielded formulations with a range of mechanical properties, degradation times, and chemical reactivities.^[15]

Polyfumarates

Poly(propylene fumarate) (PPF) is a viable alternative to the frequently used polyesters, PLGA family, because of their biocompatibility and biodegradability in many biological applications. The main advantage of this polymer, however, is its unsaturated structure which makes it suitable for curing after implantation or processing.^[26] Thus, they are very suitable for injectable applications. It was reported to be evaluated as an injectable scaffold in the form of a composite with β -tricalcium phosphate (β -TCP).^[40]

Peter et al.^[41] using human BMP-2 releasing PLGA microspheres, reported that the mesenchymal cells seeded on PPF scaffolds showed an increased ALP activity, osteocalcin secretion, and mineralization. Payne et al.^[42] studied culturing of rat marrow stromal osteoblasts encapsulated in gelatin microparticles on crosslinked PPF and showed that these cells exhibited a high viability, proliferation, and phenotypic expression on PPF.

Synthetic poly(amino acids)

These constitute a class of polymers based on natural amino acids linked by amide and nonamide bonds, including ester, iminocarbonate, urethane, and carbonate to obtain polymers with desired properties, such as predetermined composition with desired sequences, chain length, T_g , crystallinity, and hydrophobicity.^[10] They are produced either through the use of molecular biology techniques or solid state synthesis, with the desired amino acid sequences to carry the pendant groups, sequences, or the properties needed for cell adhesion, spreading, and proliferation and differentiation.^[20] They are also designed to possess improved mechanical properties, easy processability,

appropriate stability, well defined composition.^[10] As a result of the production methods, they possess a fixed molecular weight or a narrow molecular weight distribution. Since the degradation products are naturally occurring amino acids, they are expected to cause a very low level of biological response.^[25]

Most poly(amino acids) are highly insoluble due to their high crystallinity and are nonprocessable materials.^[25] A major problem appears to be the difficulty in reproducing and controlling their degradation in vivo because of patient-to-patient variation. Another problem is the antigenicity of the poly(amino acid) polymers containing three or more amino acids.

Among the many polymers in this family, poly(tyrosine carbonates) show promise in orthopedic applications due to improved behavior of degradation products in bony sites.^[43] These polymers possess three potentially hydrolyzable bonds: amide, carbonate, and ester. The carbonate group hydrolyzes at a faster rate than the ester group, and the amide bond is not labile in vitro.^[43] By variation of the structure of the pendant R group, polymers with different mechanical properties, degradation rates as well as cellular response, could be prepared.

Betre et al.^[44] studied artificial elastin-like polypeptide (ELPs), composed of a pentapeptide repeat, Val-Pro-Gly-Xaa-Gly (Xaa is any amino acid except Pro), and cultured chondrocytes in ELP coacervates for cartilaginous repair purposes. The cells maintained a rounded morphology and chondrocytic phenotype (synthesis of ECM of sulfated glycosaminoglycans and collagen). Jeschke et al.^[45] showed that coating synthetic scaffolds with tailor-made, cyclic RGD-peptides helped maintain attachment of human and pig chondrocytes.

Holmes et al.^[46] synthesized self-assembling peptide scaffolds by solid-state-phase peptide synthesizer and revealed that these peptide-based scaffolds served as ideal substrates for neurite outgrowth and synapse formation.

Poly(ortho esters)

Poly(ortho esters) are a family of synthetic degradable polymers that have been under development for many years.^[25] Originally, poly(ortho esters) were prepared by the condensation of 2,2-diethoxytetrahydrofuran and a dialcohol.^[47] Upon hydrolysis, these polymers release acidic by-products that autocatalyze the degradation process, resulting in degradation rates that increase with time. A new type of poly(ortho ester) was synthesized based on the reaction of 3,9-bis(ethylidene 2,4,8,10-tetraoxaspiro [5,5] undecane) with various dialcohols.^[48] These poly(ortho esters) are not hydrolyzed to release acidic degradation products, and

therefore, do not degrade at an increasing rate due to autocatalysis.

Poly(ethylene oxide) (PEO) and poly(ethylene glycol) (PEG)

The ethylene oxide monomer is composed of an epoxide ring, as two corners of the molecule consist of $-\text{CH}_2-$ linkages, the third corner is an oxygen, $-\text{O}-$, and by addition of a catalyst, the monomers form a chain having the repeat unit $-\text{CH}_2-\text{CH}_2-\text{O}-$. Poly(ethylene glycol) (PEG, also known as PEO at high molecular weights) is hydrophilic, soluble in water and in organic solvents, including aromatic hydrocarbons (not aliphatics), lack of toxicity, and absence of antigenicity and immunogenicity.^[49] Considering these properties, PEG can be used for many biomedical and biotechnological applications, especially as a biomaterial.

Multiblock copolymers of PEO are being developed as prosthetic devices and artificial skin and as scaffolds for tissue engineering.^[50] These materials undergo both hydrolysis (via ester bonds) and oxidation (via ether bonds). Degradation rate is influenced by PEO molecular weight and content, and the copolymer with the highest water uptake degrades most rapidly.

PEO is currently FDA approved and is one of the most commonly used synthetic polymers for tissue engineering.^[51] PEO, and the chemically similar PEG, are hydrophilic polymers that can be photocrosslinked with UV and in the presence of photoinitiators after modifying each end of the polymer with either acrylates or methacrylates and hydrogels are then formed.

Thermally reversible hydrogels have also been formed from block copolymers of PEO and PLLA^[52] and of PEG and PLLA.^[53] Degradable PEO and PEG hydrogels have also been reported as block copolymers of PEO and PEG with PLA.^[54] A newer, synthetic hydrogel block copolymer, P(PF-*co*-EG) has been created for use as an injectable carrier for bone and blood vessel engineering.^[55]

Important Natural Polymers Used in Tissue Engineering

The naturally derived polymers consist of bioactive proteins (enzymes, growth factors), structural proteins (collagen, an ingredient of the ECM), and polysaccharides (glycosaminoglycans, alginic acid, chitosan). Among the first tissue regeneration materials are the collagen–glycosaminoglycan scaffolds of Yannas et al.^[21] who tried to create the dermis of skin. Since these materials are used after reconstitution, their natural properties are somewhat less satisfactory than before removal from their natural environment, and therefore need to be improved. Along this line, their degradation

rates are controlled and mechanical properties increased through chemical crosslinking by glutaraldehyde, formaldehyde, carbodiimide, epichlorohydrin, etc.

Animal origin/protein-based polymers

(a) *Collagen*. Collagen is the most abundant protein in animals (it makes up 30% of all proteins in the human body)^[25] and because of its high mechanical strength and good resistance to degradation, it has been utilized in a wide range of products in the medical industry. More than 20 genetically distinct collagens have been identified.^[56] They are mainly responsible for maintaining the structural integrity of the body and are mainly found in tendons, bone, cartilage, and skin. Collagen is arranged in fibrils with a 67 nm axial periodicity and the fibrils consist of triple helices approximately 300 nm in length and 1.5 nm in diameter. Only collagen types I, II, III, V, and XI self-assemble into fibrils. Collagen fibril formation is finalized by the removal of the telopeptides (the terminal procollagen peptides) by specific procollagen metalloproteinases. Some collagens form networks (types IV, VIII, and X), as is the basement membrane mostly made of type IV.^[56] Type I collagen occurs throughout the body, except in cartilage. Type II collagen occurs in cartilage, the developing cornea, and in the vitreous body of the eye. Type III collagen occurs mainly in the wall of blood vessels and hollow intestinal organs and copolymerizes with type I collagen. Collagens are mostly synthesized by the cells comprising the ECM: fibroblasts, myofibroblasts, osteoblasts, and chondrocytes.

Collagen can be obtained by extraction and purification of natural tissue or as specific recombinant polypeptides. Its mechanical properties can be controlled by crosslinking using chemical agents such as glutaraldehyde, formaldehyde, carbodiimide, or by physical treatments such as UV irradiation, freeze-drying, heating, and dehydration, and thus make it suitable for use in a variety of biomedical applications, including tissue engineering (Fig. 5).^[51] It has also been reported as blends with hyaluronic acid,^[57] chitosan,^[58] and PEO.^[59] Collagen is naturally degraded by metalloproteases, specifically collagenase, and serine proteases allowing for its degradation to be locally controlled by cells present in the engineered tissue.^[51]

Wakitani et al.^[60] seeded chondrocytes in collagen gels to repair articular cartilage defects. The chondrocytes maintained their phenotype and new cartilage was observed as early as 4 weeks. The grafted tissue remained as cartilage over 48 weeks. Orwin and Hubel^[61] investigated collagen sponges as carriers for epithelial and endothelial cells, and for keratocytes to construct corneal tissue. To overcome the loss of transparency caused by contraction of the collagen gel

Fig. 5 Scanning electron micrograph of a collagen foam.

by keratocytes, they prepared a dispersion of collagen in dilute acid, pH 4, followed by freeze-drying. Thus, constructed acid-swollen sponges were expected to have less fibrillar structure, and therefore scatter less light than fibrils formed at neutral pH. Ber et al.^[62] investigated guiding osteoblast cells from rat bone marrow on micropatterned collagen films crosslinked with carbodiimide (EDC), glutaraldehyde or by dehydrothermal route (DHT). It was observed that the cells seeded on calcium phosphate deposited collagen films have a high osteoblastic phenotype expression (alkaline phosphatase activity), emphasizing the effect of mineral presence on osteoblast differentiation.

(b) *Silk*. Silks, are a group of fibrous proteins produced by a wide range of insects and spiders.^[63] They consist of helical, β -sheet, or cross- β -sheet secondary structures. Spider dragline silk from *Nephila clavipes*, and cocoon silk fibroin from the silkworm, *Bombyx mori*, have characteristic β -pleated sheet secondary structures with extended polypeptide chains, in which the carbonyl oxygens and amide hydrogens are at near right angles to the long axis of the chain and the sheet. The interchain interactions are through intra- and inter-hydrogen bonding and van der Waals interactions. Because of the impressive mechanical properties, silk proteins are important materials for use in biomaterials, especially in controlled release, as sutures and as scaffolds for tissue engineering.^[64] Silks are insoluble in most solvents, including water, dilute acid, and alkali. Silk has the advantage of being easily chemically modified due to the availability of amine and acid side chains on some of the amino acids. Its composition can be genetically tailored to provide it with moderate specific features, such as molecular weight, crystallinity, solubility, and slow rates of degradation in vitro and in vivo. There are, however, some concerns, such as inadequate removal of sericin from silkworm silk leads to biocompatibility problems, slow degradation of

crystalline (β -sheet) regions prolongs removal time, aborted proteolytic attack by macrophages and giant cells lead to encapsulation and the formation of a granuloma, and potential sensitization to silk fibroin resulting in an allergic response upon exposure to the biomaterial. On a brighter note, silk fibroin can be processed into foams, films, fibers, and meshes.

Minoura et al.^[65] compared silk fibroin and collagen films in terms of supporting attachment, spreading, and growth of the L-929 fibroblast and found them to be equivalent in their ability to support cell attachment and physiological morphology. Sofia et al.^[66] studied silk fibroin films in vitro by seeding with osteoblasts. The films were chemically bonded with RGD sequences to promote increased adhesion. The increase in alkaline phosphatase levels, upregulation of bone-specific transcripts, and calcification levels over 4 weeks showed the response of osteoblast cells to silk fibroin films. Unger et al.^[67] reported that various human cells from different tissues (e.g., epithelial cells, fibroblast, glial cells, keratinocyte, osteoblast) adhered and spread over a nonwoven silk fibroin net and maintained their growth, making it a potential cell carrier.

(c) *Fibrin*. The conversion of a soluble plasma protein fibrinogen to an insoluble fibrous protein fibrin is initiated by the enzyme thrombin.^[68] The polymerization step causes both end-to-end and side-to-side aggregation of fibrinogen to form fibrin fibers.

Ye et al.^[69] constructed a 3-D fibrin gel scaffold for blood vessel tissue engineering. Human myofibroblast cultures isolated from human aortic tissue were suspended in fibrinogen solution and seeded into 6-well culture plates for cell development for 4 weeks and supplemented with different concentrations of aprotinin. Results of tissue development studies on 3-D fibrin gel structures showed homogenous cell growth and confluent collagen production without any toxic degradation or inflammatory reactions. Pellegrini et al.^[70] showed that fibrin is a suitable substrate for keratinocyte cultivation and transplantation. Their results showed that when fibrin-cultured autografts bearing stem cells are applied on massive full-thickness burns, the “take” of keratinocytes is high, reproducible, and permanent.

(d) *Other protein-based polymers*. A series of recently introduced casein- and soy-based biodegradable thermoplastics have joined collagen as a source of natural protein-based biomaterials.^[23] They are reported to be less susceptible to thermal degradation, and therefore, can safely be processed at elevated temperatures as scaffolds for tissue engineering.

Animal origin/polysaccharide-based polymers

Polysaccharides have generally been underutilized as biomaterials.^[71] A number of studies are pointing to

the critical role of saccharide moieties in cell signaling and in immune recognition, thus increasing the awareness of this important category of polymers. Recently, the development of new automated synthesis techniques made production of biologically active oligosaccharides more plausible than before. One major property of polysaccharides is their capability to form hydrogels. They can form gels by hydrogen-bonded and by ionic interaction. Hydrogen-bonded gels are mainly formed by agarose via thermal gelation, and by chitosan via pH modification. Alginates and carrageenans, on the other hand, form ionically crosslinked hydrogels.

(a) *Chitosan*. Chitosan is obtained by partially deacetylating chitin that is found in arthropod exoskeletons.^[71] Commercially available preparations have degrees of deacetylation ranging from 50 to 90%. It is a linear copolymer of $\beta(1 \rightarrow 4)$ linked D-glucosamine and a variable number of N-acetyl-glucosamine. The average molecular weight of chitosan varies in the range 50–1000 kDa, depending on the source and preparation procedure. It is semicrystalline and the degree of crystallinity varies with the degree of deacetylation. Crystallinity is maximum for both chitin (0% deacetylated) and fully deacetylated (100%) chitosan, and minimum when there is an intermediate degree of deacetylation. Chitosan is normally insoluble in aqueous solutions above pH 7 but in dilute acids with pH lower than 5 it becomes soluble because of the protonation of the amine groups. Gel fibers can be drawn from viscous solutions to form high-strength fibers. Chitosan and its parent molecule, chitin, have been shown to exert chemoattractive effects on neutrophils in vitro and in vivo. In vivo, chitosan is degraded by enzymatic hydrolysis by lysozyme, which appears to target acetylated residues. The degradation products are chitosan oligosaccharides of variable length. The degradation rate appears to decrease with crystallinity and this, in return, is controlled by the degree of deacetylation. Highly deacetylated forms (>85%) exhibit the lowest degradation rates and may last several months in vivo. Derivatization modifies the molecular packing and increase the amorphous fraction, allowing more rapid degradation. Chitosan-based implants have been found to initiate minimal foreign body reaction with no major fibrous encapsulation.

Porous chitosan structures can be formed by freezing and lyophilizing chitosan-acetic acid solutions.^[72] Pore size can be controlled by varying the freezing rate and hence the ice crystal size.^[71] Pore orientation can be directed by controlling the geometry of thermal gradients during freezing. The mechanical properties of chitosan scaffolds are mainly dependent on the pore sizes and pore orientations.

Tuzlakoglu et al.^[73] constructed a 3-D chitosan fiber mesh for potential use in bone tissue engineering

applications. Chitosan fibers were produced by a wet spinning and they had enough tensile strength to be used to produce scaffolds with good mechanical performance. Osteoblasts directly cultured over chitosan fiber mesh scaffolds presented adequate morphology and proliferation. In the other bone tissue engineering application, Zhao et al.^[74] seeded osteoblasts on a 3-D hydroxyapatite/chitosan-gelatin network scaffold. Zhu et al.^[75] attached various amino acids (lysine, arginine, aspartic acid, phenylalanine) onto chitosan by using glutaraldehyde. These amino acid functionalized chitosan moieties were subsequently entrapped on PLA surfaces. The amino acid–chitosan–PLA membrane was shown to have a good cytocompatibility with chondrocytes.

(b) *Glycosaminoglycans*. Glycosaminoglycans (GAGs) are linear polymers of repeating disaccharide units of a uronic acid (e.g., glucuronic acid) and a hexosamine (e.g., N-acetyl-D-glucosamine).^[25] The major GAGs attached to the protein components of proteoglycans are chondroitin sulfate, hyaluronic acid, dermatan sulfate, keratan sulfate, and heparan sulfate. The most commonly used and the largest GAG is hyaluronic acid (hyaluronan), which is a linear, anionic polysaccharide with repeating N-acetylglucosamine and glucuronic acid units, and molecular weight in the range of 500 kDa to several thousand kDa. It can be isolated from natural sources (e.g., rooster combs) or produced by fermentation. Hyaluronic acid can be easily chemically modified, as by esterification of the carboxyl moieties or crosslinked to form hydrogels. The gels can be formed into sheaths, membranes, tubes, and particles of various shapes and sizes. No species variations have been found in the chemical and physical structure of hyaluronic acid. It is not antigenic, and elicits neither inflammatory nor foreign body reaction. Its main drawbacks in this respect are its residence time and the limited range of its mechanical properties.

Zavan et al.^[76] investigated whether an extracellular matrix obtained from fibroblasts cultured within scaffolds of HYAFF-11 (derived from the total esterification of hyaluronic acid with benzyl alcohol on the free carboxyl groups of glucuronic acid along the polymeric chain leading to an increase of the hydrophobic component of the polymer chain) could influence the proliferation rate and survival of hepatocytes. The hepatocytes exhibited a round morphology and re-established cell-to-cell contacts, and grew into aggregates of several cells along and/or among fibers in the fabric. Aigner et al.^[77] used benzyl ester of hyaluronic acid (HYAFF-11) as a scaffold for the culture of human nasoseptal chondrocytes for cartilage tissue engineering purposes. The scaffold allowed good viability and adhesivity of the cells. The cultured cells expressed cartilage-specific collagen type II, indicating

their ability to redifferentiate within the scaffold of HYAFF-11 and to retain a chondrocyte phenotype even after a long period under in vitro conditions.

Plant origin/polysaccharide-based polymers

(a) *Starch*. Starch is a plant-originated polysaccharide found in a variety of plants, including wheat, corn, rice, beans, and potatoes.^[78] It is a branched polymer formed by amylose as the linear portion (20% w/w) and the amylopectin branches. Granular starch is sometimes added to polyethylenes in order to make it biodegradable. Heating the starch in the presence of water during extrusion or injection molding causes the formation of a thermoplastic material that may be deformed during blending. This starch-based product is then blended with either natural or synthetic materials. Heating starch above its glass transition temperature breaks its molecular structure, allowing further bonding.^[79] Plastic materials from starch-based blends may be injection molded, extruded, blown, or compression molded.

Salgado et al.^[80] prepared 50:50 (wt%) blend of starch and cellulose acetate scaffolds to seed osteoblasts for bone tissue engineering. The scaffolds had adequate porosity and allowed the cells in the centre of the scaffolds to remain viable for more than 3 weeks. The maintenance of osteogenic phenotype and deposition of mineralized extracellular matrix showed the success of the study.

(b) *Alginate*. Alginate is a copolymer of β -D-mannuronic acid (M) and α -L-guluronic acid (G) isolated from seaweed. Gels are formed in the presence of divalent cations (eg. Ca^{+2}) and formed by covalently crosslinking alginate with adipic hydrazide and PEG using standard carbodiimide chemistry.^[51] It has advantages and disadvantages. It is widely available, relatively biocompatible and easily gels. However, its gels lose their integrity upon removal of the gelling cation by the biological medium. It is nondegradable in the human body and its composition and purity varies from batch to batch. The crosslinking density, and thus mechanical properties and pore size of the ionically crosslinked gels can be readily manipulated by varying the M to G ratio and molecular weight of the polymer chain.^[51]

Li et al.^[81] constructed a naturally derived chitosan and alginate polymers having significantly improved mechanical and biological properties as compared to its chitosan counterpart. They revealed that bone-forming osteoblasts readily attached to the chitosan-alginate scaffold, proliferated well, and deposited calcified matrix. The hybrid scaffold had a high degree of tissue compatibility in vivo and also promoted rapid vascularization and deposited connective tissue within the entire scaffold structure.

Polyesters of biological origin

Polyhydroxyalkanoates (PHAs) are thermoplastic, biodegradable, natural polyesters that are produced by numerous micro-organisms. They are intracellular storage polymers whose function is to provide a reserve of carbon and energy. The differences between various PHAs arise from the length of the pendant groups (Fig. 6). PHAs with short pendant groups are hard crystalline materials, whereas PHAs with longer pendant groups are elastomeric.^[82] Its high crystallinity (60%–90%) makes its hydrolysis by enzymes or physiological medium difficult.^[83] PHAs are combined or blended with other polymers and materials to improve properties, shape and/or performance.^[82] Research is mainly concentrated on two commercially available, more crystalline, more brittle poly(hydroxybutyrate) (PHB) (Fig. 6A) and the less crystalline, more flexible, more degradable copolymer of butyrate and valerate moieties, poly(3-hydroxybutyrate-co-3-hydroxyvalerate) (PHBV) (Fig. 6B). PHAs are fabricated in molded shapes, films, fibers (Fig. 7), woven and nonwoven materials, tubes, and composites.

PHB's degradation product, R-3-hydroxybutyric acid, is a normal constituent of blood at concentrations between 0.3 and 1.3 mM and is also found in the cell envelope of eukaryotes,^[83,84] and is therefore biocompatible. The polymer itself was not reported to be incompatible and a negative reaction cannot be expected due to the acidity of accumulated product because PHB has a rather low degradation rate in the body, extending into months and even years, depending on the crystallinity of the polymer. Thus, PHB can be accepted as a biocompatible material.

Fig. 6 Chemical structure of (A) PHB and (B) PHBV.

Fig. 7 Scanning electron micrograph of PHBV fibers.

Torun Kose et al.^[85,86] constructed macroporous PHBV matrices by solvent evaporation and solute leaching to cultivate osteoblasts for bone tissue engineering. It was revealed that the weight and density of the matrices were unchanged for a period of 120 days. Scanning electron microscopy results indicated that osteoblasts proliferated even in the inside of the matrices. In addition, growth of osteoblasts on matrices was observed after 60 days of incubation. Torun Kose et al.^[87] used PHBV matrices also for cartilage engineering and revealed that PHBV matrices show early cartilage formation resembling normal articular cartilage. In the late phase of the experiment, mature hyaline-like cartilage formation was observed in chondrocyte-seeded PHBV scaffolds. Sun et al.^[88] investigated a polymer scaffold system consisting of PHBV for possible application as a matrix for the three-dimensional growth of chondrocyte culture. PHBV scaffolds with *ca.* 80% porosity were constructed by compression molding, thermal processing, and salt leaching. They revealed that the proportion of chondrocytes in their natural round morphology increased and they could synthesize the type II collagen and cartilage-specific proteoglycans in the prolonged incubation time.

Modified Polymers of Natural and Synthetic Origin

When the polymer of choice has most of the properties needed, but is lacking in some others, one of the options is to modify the principal polymer by attaching functional groups or polymers via grafting through application of chemical compounds, with or without activation, with ionizing radiation, plasma, etc. The principal polymer defines the gross shape, size, and major mechanical properties of the final molecule, while the grafted component defines the chemistry and

mode of interaction with the biological interface. The synthetic macromolecules generally lack functional groups recognizable by the tissue, such as their lack of cell-recognition signals. In contrast, fibrinogen (Fb) or fibronectin (Fn) carry one of the many cell recognition sequences, such as RGD. Thus, the combination of the principal polymer, with the physical and mechanical properties required from a cell carrier, and the attachment of Fb or Fn, brings the advantage of cell recognition and thus creates a cell-adhering scaffold for use in tissue engineering.

Most approaches to tailored surface modification involves introduction of a specific adhesion peptide to the polymeric surface to enhance the degree of cell adhesion.^[15] A simple approach to this is attachment of a long hydrophobic peptide tail and spacer to the adhesion peptide. This, as well as some involving covalent linkage of peptides to the polymer backbone, introduces additional sites for adhesion allowing precise control over the surface properties. Cell migration and differentiation can be inhibited by strong adhesion of cells due to high ligand surface densities, and its control is of prime importance.

Besides protein- and peptide-attached synthetic polymers, sugar residue-bearing polymers offer a surface suitable for cell attachment and, thus, might be used to improve cell recognition in tissue engineering applications.^[89]

Modification of polymers to activate cell-material interface is very common in tissue engineering, and in order to give an idea a few examples are cited below. In the study of Grzesiak et al.^[90] collagen/glycosaminoglycan matrices modified with covalently-bonded RGD containing peptide were seeded with endothelial cells, keratinocytes, and fibroblasts. It was revealed that modification of the collagen/GAG matrices with RGD binding sites led to enhanced attachment of cells and was considered a potential structure for dermal regeneration. Santiago et al.^[91] modified poly (caprolactone) surfaces to promote the attachment and proliferation of adipose-derived stem cells (ASCs). The results showed that laminin-derived isoleucine-lysine-valine-alanine-valine (IKVAV) peptide sequences, covalently attached to an aminated polymer surface using carbodiimide chemistry, improved the attachment of ASCs to a tissue-engineered scaffold. For tissue-engineered vascular graft, He et al.^[92] designed a collagen-coated poly(l-lactic acid)-*co*-poly(ϵ -caprolactone) P(LLA-CL) (70:30) nanofiber mesh (NFM), which was fabricated using electrospinning, followed by plasma treatment and collagen coating. The collagen-coated P(LLA-CL) NFM enhanced the spreading, viability, and attachment of human coronary artery endothelial cells, and moreover, helped preserve their phenotype. Tezcaner et al.^[93] used PHBV film to serve as a temporary substrate for growing retinal pigment

epithelium (RPE) cells as an organized monolayer before their subretinal transplantation. The surface of the film was rendered hydrophilic by oxygen plasma treatment to increase the reattachment of D407 cells on the film surface. It was concluded that the oxygen plasma treated PHBV films were good substrates for use as temporary templates for subretinal transplantation of RPE cells.

Intelligent Polymers: Responsiveness Against T and pH

Intelligent materials are very useful in tissue engineering for a variety of reasons. They are known to help cell sheet removal from surfaces, control release of cell activating factors from microparticles, membranes, etc. or help load and unload cells and other support molecules onto the tissue engineering scaffold. Currently under development are anionic, cationic, and biomimetic hydrogels, controlled pore structures, and biodegradable polymers responding to specific biological conditions.^[23]

“Smart” or stimuli-sensitive materials can be either synthetic or natural and are generally polymer-based. Some smart polymers could undergo reversible gelation and some are covalently crosslinked to form irreversible hydrogels. Major examples of these kinds of polymers include poly(*N*-isopropylacrylamide) poly (NIPAAm), alginic acid and its univalent salts, chitosan, -carrageenan, and their combinations, such as collagen-acrylate and polyethylene glycol-peptides.^[94]

Smart polymeric materials are designed to respond to small changes in their environment with a considerable change in their properties.^[94] Smart systems change shape, surface characteristics, solubility, and form molecular self-assembly or sol-gel transition. Environmental stimuli include temperature, pH, chemicals, light, magnetic field and electric field.^[95]

The thermosensitive poly(NIPAAm) is one of the most commonly studied smart polymers, and various strategies for the synthesis of the hydrogel have been described.^[94] Efforts have been directed toward altering the swelling/shrinking behavior and preparing copolymers that also respond to other stimuli.

Poly(NIPAAm) and its copolymers are most often investigated for drug delivery^[96] and tissue engineering applications.^[97] An aqueous poly(NIPAAm) solution precipitates when the medium temperature is raised above 32°C, the phase transition temperature or the LCST below which favorable interactions via hydrogen bonding with water through the amide groups of the polymer, lead to dissolution of the polymer chains, and above the LCST, the hydrogen bonds are broken and water molecules are expelled from the polymer, resulting in the precipitation of the polymer.^[98] The

LCST of NIPAAm polymers can be controlled by copolymerizing it with other monomers with different hydrophobicities.^[99]

Hydrogels containing different LCST oligomer grafts show dual transitions with increasing temperature. Comb-type grafted hydrogels of crosslinked poly(NIPAAm), grafted with oligoNIPAAm^[100] or PEG,^[101] exhibited fast response to temperature changes. It was suggested that the grafted short chains of oligoNIPAAm contribute to fast dehydration, whereas the hydrophilic PEG chains provides a water channel for a fast deswelling mechanism.

Li et al.^[102] synthesized biocompatible, thermo-responsive ABA triblock copolymers where the A blocks were poly(NIPAAm) and the B blocks were poly(2-methacryloyloxyethyl phosphorylcholine) via atom transfer radical polymerization with a commercially available bifunctional initiator. These novel triblock copolymers are water-soluble in dilute aqueous solution at 20°C and pH 7.4, but form free-standing physical gels at 37°C. This gelation is reversible, and the gels are believed to contain nanosized micellar domains. It was suggested that the less viscous copolymer gels were worthy for tissue engineering applications such as cartilage regeneration. Au et al.^[103] studied the thermally reversible polymer gels poly(NIPAAm-*co*-AAc), as a scaffold for chondrocytic cells. The results indicated that chondrocytes propagated in the thermo-reversible polymers expressed enhanced or maintained expression of collagen type II and aggrecan. The results support that *N*-isopropylacrylamide and acrylic acid copolymer gel has potential use as a cell culture substrate and as a cell delivery vehicle. Cho et al.^[104] demonstrated that human mesenchymal stem cells (MSCs) could differentiate into chondrocytes in a thermosensitive chitosan-poly(NIPAAm) copolymer gel. They showed that the thermosensitive gel transition was optimal for in vivo applications because the LCST was 32°C. Thus, chondrogenic differentiated cells from MSCs with a thermosensitive polymer could be used as an injectable cell-polymer complex and the differentiation process was induced both in vitro and in vivo.

Besides temperature and pH responsive materials, bioresponsive polymers are developed in drug delivery and tissue engineering applications. Wang et al.^[105] constructed a bioresponsive, intelligent hydrogel based on a phosphoester-poly(ethylene glycol) polymer (PhosPEG) for application to marrow-derived mesenchymal stem cell (MSC) encapsulation and tissue engineering of bone. The degradation of the scaffold and the extend of calcification were controlled by alkaline phosphatase levels. It was revealed that phosphate-PEG-derived hydrogels, containing an intermediate concentration of phosphorus, promoted gene expression of bone-specific markers, secretion of

bone-related matrix, and mineralization and may have a potential impact on bone-engineering therapies.

Future Trends

Tissue engineering is in development along a number of avenues. One of these is nanotechnology, which is making a great impact. Through the use of nanotechnological approaches in the production of nanofibers or in the creation of nanomodified material surfaces, we are able to change the cell–material interface significantly. Already a number of studies involving the influence of nanofiber dimensions, and incorporated compounds such as hydroxyapatite and growth factors, have been published. Creation and examination of nanopatterned surfaces expand our knowledge of the nano-world but also bring up new questions to answer. Nanotechnology is also providing us nano-sized drug delivery systems, which are especially important in the delivery of growth factors to guide tissue regeneration.

Self-assembled monolayers, constructed using a variety of molecules, is another novel approach to surface modification as a “bottom-up approach.” This leads to both surfaces modified at a molecular level, as well as to intelligent, responsive surfaces.

Developments in stem cell biology and technology are also very important. Researchers use cell biology approaches to direct the stem cell differentiation routes and gain the ability to create a number of different tissue types from a few cell-scaffold constructs.

Finally, with the contribution of molecular biology and cell biology, we are able to identify and even to quantify the tissue regeneration level, thus decreasing the dependence on such qualitative techniques as histology. For example, identification and quantification of mRNA is one important step in this. When we learn more about the roles of individual growth factors, we measure their impact by determining their amounts in the tissue, determine their products (cell number, differentiation markers, etc.) and learn about the extent of regeneration. With all these developments in their infancy the future of tissue engineering appears very exciting.

CONCLUSION

Research on biomaterials is showing great advances especially in two directions: tissue engineering and nanobiomaterials. The polymers used in tissue engineering are playing their roles in this. Researchers are developing new polymers or copolymers using synthetics, biologicals, and synthetic analogs of biologicals, all designed to meet the new requirements of

tissue engineering such as responsiveness. Thus, this chapter could not be considered a complete review of the field; but rather just a glimpse to this rapidly expanding research area.

Polytetrafluoroethylene

Robert R. Pavlis

Department of Chemistry, Pittsburg State University, Pittsburg, Kansas, U.S.A.

HISTORY

Tetrafluoroethylene is a gas having a molar mass of 100.016 g/mol, a boiling point of -76.3°C , and a melting point of -142.5°C . The critical temperature is -33.3°C , and the critical pressure is 39.52 atmospheres. Tetrafluoroethylene will readily undergo radical polymerization, forming an extremely important polymer that is the topic of this work.

Fig. 1 shows the chemical structure of polytetrafluoroethylene and represents its actual conformation in crystal structures. The dark spheres represent carbon atoms; the white spheres represent fluorine atoms.

Like many important discoveries, the discovery of the polymerization of tetrafluoroethylene was an accident. In 1936, one of DuPont's research chemists, Roy J. Plunkett, was engaged in research to develop new refrigerants. He and his colleagues produced many kilograms of tetrafluoroethylene, which they stored in cylinders which they kept packed in dry ice.

On April 6, Dr. Plunkett's assistant, Jack Rebock, attempted to get some of the material from one of the storage cylinders when he found there was no pressure in the cylinder. They weighed the cylinder and discovered that there was still material inside. When they removed the cylinder valve, they discovered that the cylinder was filled with a white powder that was insoluble in every common laboratory solvent that they tried. It was also remarkably unreactive, showing no reactivity toward strong acids and oxidants. The material was also remarkably thermally stable.

One of its peculiar characteristics that the group immediately seemed to recognize as important was that it was amazingly slippery.

The next year they applied for a patent, which was granted in 1941. During World War II, PTFE was used for several military applications. Its extraordinary chemical inertness resulted in its being used for lining containers for the uranium hexafluoride diffusion process used to separate uranium isotopes.

The "Teflon" trademark was registered by DuPont in 1945, and commercial products using it appeared the following year.

Dr. Plunkett worked on tetraethyl lead for most of the rest of his career. He retired from Dupont in 1975. He died in 1994.^[1]

CHEMICAL PROPERTIES

Polytetrafluoroethylene owes its remarkable chemical and thermal stability to several different factors: (1) The C–F bond strength for secondary carbon atoms is about 450 kJ/mol, far higher than the C–H bond strength. (2) The C–C bond strength in fluorocarbons is unusually high, while the C=C bond strength in fluoroalkenes is fairly low, creating an enthalpy of polymerization of about -163 kJ/mol and making this an extremely exothermic polymerization. (The enthalpies of polymerization of most other alkenes are about half this value; styrene, for example, is 70 kJ/mol. Ethylene is above average at 109 kJ/mol.) (3) Because both the C–F and the C–C bonds in PTFE are so strong, almost any reaction that would convert this material into something else requires a substantial input of energy to disrupt these strong bonds.

The extraordinarily high enthalpy of polymerization results in an extremely high ceiling temperature—well above 1100°C ! The thermodynamic values at 25°C are ($\Delta H = -163$ kJ/mol, $\Delta S = 112$ J/deg-mol, and $\Delta G = -121$ kJ/mol).^[2] (ΔH is enthalpy change, ΔS is entropy change, and ΔG is the change in Gibbs Free Energy; $\Delta G = \Delta H - T\Delta S$. At the ceiling temperature, $\Delta G = 0.0$.)

Quantity	Value
ΔH	-163 kJ
ΔS	112 J/deg-mol
$\Delta G (25^{\circ}\text{C})$	-121 kJ

Polytetrafluoroethylene chains consist of nothing but perfluoromethylene groups. Because these are highly symmetrical, the material can crystallize, forming a highly solid state polymer with a very high crystal lattice energy. Its melting point is 327°C . Amorphous polymer has a density of 2.00 g/cm³, but 2.30 g/cm³ is the solid state density.^[3] PTFE is a peculiar material with several first-order transitions (19 , 30 , and 90°) and several second-order transitions (-90 , -30 , and 130). (When materials undergo a first order transition, there is an immediate change of a physical property; but when they undergo a second order transition, there is a change in the rate of change of a property.)

Tables can be obtained from Web sources that list the important physical properties of various forms of this

Fig. 1 Chemical structure of polytetrafluoroethylene

material. MatWeb Material Property Data has a particularly extensive set of tables of various commercial polytetrafluoroethylene products; in fact, they provide this data for over 100 different fluorinated polymers.^[4]

PRODUCTION OF THE MONOMER AND POLYMER

Tetrafluoroethylene is generally produced from chloroform. Two of its chlorine atoms are first exchanged by reacting it with a mixture of hydrogen fluoride and antimony pentafluoride, forming chlorodifluoromethane:

When chlorodifluoromethane is heated to about 950°C, it forms tetrafluoroethylene. The reaction mechanism for this process almost certainly involves first producing difluorocarbene, which immediately dimerizes to form tetrafluoroethylene:

The monomer is normally polymerized using emulsion polymerization under pressure in stainless steel vessels. Various water-soluble peroxides can be used as initiators for the radical polymerization process. It is, as mentioned above, highly exothermic. As the polymer forms, it separates. Because it is so extremely insoluble, it is easy to recover it completely:^[5]

PROBLEMS WITH TOXICITY

One of the most important commercial applications of this material is as a coating for cookware. Its thermal stability and its slippery nature make it possible to coat cooking surfaces with it, creating a “nonstick” coat.

Unfortunately, there have been some negative consequences to its use.

DuPont researchers and others have shown that high-temperature thermal degradation of PTFE in air produces a remarkably complex mixture of compounds that includes tetrafluoroethylene, hexafluoropropene, perfluorocyclobutane, perfluoroisobutene, carbonyl fluoride, perfluoromethane, trifluoroacetic acid, trifluoroacetyl fluoride, hydrogen fluoride, monofluoroacetic acid, and difluoroacetic acid, along with traces of other compounds. It also produces particulate matter. Several of these compounds are extraordinarily toxic—monofluoroacetic acid, for example, is far more toxic than hydrogen cyanide.

Polytetrafluoroethylene-coated cookware and household appliances are very popular. Occasionally, cooking accidents may result in these items being heated to temperatures at which at least some degradation begins to occur.

Birds have far more efficient respiratory systems than mammals.^[6] There have been many instances reported of birds being fatally injured by exposure to thermal degradation products from overheated PTFE. There have been similar problems in the poultry industry. When PTFE-coated heat lamps were used in poultry production,^[7] there were a massive number of deaths. These problems seem to occur when PTFE surfaces are heated to relatively low temperatures, perhaps only about 200°C. There is some evidence that the toxicity in birds is due to oligomers that are driven from the polymer mixture upon heating.^[8]

Because PTFE is produced by radical polymerization, typical samples contain a wide range of molecular weights. Fluorinated compounds tend to have unusually high vapor pressures compared to their molecular weights. The polymer molecules with lower molecular weights seem to distill out of the polymer mass when it is heated to relatively low temperatures. These molecules condense and produce a smoke with very fine particles. Strong heating may also cause rupture of a few of the polymer bonds, and thus produce even more polymer chains with low molecular weights.^[9]

Dr. Carl Johnson and coworkers^[10] reported that neither the smoke nor the other gases produced by heating PTFE are toxic enough to kill animals by themselves, but that the two together are extremely toxic. They suggested that toxic compounds become absorbed on the particles and are carried in this state to the lungs, where they cause severe tissue destruction. The particles need to be very small to be dangerous; those around 16 nm seem most toxic, and those larger than about 100 nm do not seem to be toxic to rats.

There have been many reports of human illness caused by breathing these fumes. One of the most famous incidents occurred when all the passengers and crew of a flight became ill. Not only did the passengers and crew become ill, but the four people who collected samples after the aircraft landed did as well. After ruling out other possible causes, the toxicity became linked to PTFE tape that was used to cover part of the exhaust manifold.^[11]

There have been many other incidences of what is often called "polymer fume fever." A paper by Zanen and Rietveld describes a case in which a woman became seriously ill after breathing fumes from a defective microwave oven.^[12]

Toxicity problems seem to become generally acute above the polymer melting point (327°C). In solid state PTFE, the high crystal lattice energy of the material reduces the vapor pressure and thus reduces the volatility of the lower-molecular-weight materials in the polymer.

It should be noted that pyrolysis of PTFE in vacuum results in its quantitative conversion to the monomer. It simply "unzips" to form it! The reactions that occur to form the complex and toxic mixture produced by overheating coated cookware only occur when the polymer is heated in air.^[13]

PERFLUOROCTANOIC ACID

In recent years, many news stories have appeared in various news media concerning possible environmental consequences that may result from the use of perfluorooctanoic acid, commonly called C-8 or PFOA.

Perfluorooctanoic acid is extremely stable, so its environmental life seems to be extremely long. It is used as a surfactant during the polymerization process. The U.S. Environmental Protection Agency Web site contains a risk assessment.^[14]

RELATED COMMERCIAL FLUORINATED POLYMERS

There are several other polymers similar to PTFE that have been developed and that are in current production. All are extremely chemically inert.

Polytetrafluoroethylene itself is a linear polymer with long chains of completely symmetrical difluoromethylene groups. This results in, as stated formerly, a high degree of crystallinity, a high crystal lattice energy, and an extremely high melting point. By introducing side chains or making copolymers, this symmetry can be reduced or destroyed.

Vinyl polymers with side chains can be isotactic, syndiotactic, or atactic. Atactic polymers are generally not solid state because they are not stereo regular. The polymers discussed below are produced in an atactic state, because the primary reason for using them rather than PTFE itself is to have a polymer without such a high degree of crystallinity.

Chlorotrifluoroethylene polymers have been produced commercially. The trade name of one such polymer is Kel-F 81. This material was formerly produced by 3M, but it was discontinued in the mid-1990s. Daikin currently produces this material under the trade name of Neoflon.

DuPont produces a copolymer of tetrafluoroethylene and ethylene. It is produced under the trade name Tefzel.

DuPont also produces a polymer called Teflon Fluoroethylene-propylene (FEP) that is a copolymer of hexafluoropropylene and tetrafluoroethylene. It can be processed using conventional thermoplastics processing equipment, because the trifluoromethyl side chains introduce asymmetric carbon atoms into the structure and thus prevent crystallization.

An essentially alternating 1:1 copolymer of ethylene and chlorotrifluoroethylene is produced by Ausimont under the trade name of Halar.

CONCLUSION

Polytetrafluoroethylene has become an extraordinarily important material since its discovery in 1936. Its chemical and thermal stability make it an ideal material for many applications.

Similar polymers with reduced stereo regularity are also used for many applications.

There has been concern in recent years about the toxic products that form when it is strongly overheated. This concern has been enhanced by the demonstrated toxicity toward birds. Many consumers try to avoid using products that use it. The author overheard a woman in a department store saying, "If these pans kill birds, they can't be good for my family either!"

Her concerns were probably an overreaction. Vast numbers of coated cookware has been produced, and the number of human illnesses reported is relatively small.

Polyurethane Biomaterials

Joanna D. Fromstein
Kimberly A. Woodhouse

Department of Chemical Engineering and Applied Chemistry, University of Toronto,
Toronto, Ontario, Canada

INTRODUCTION

Polyurethanes (PUs), a family of polymers containing the urethane linkage, were first used in medicine in the late 1950s to construct a composite PU foam breast prosthesis. By the early 1960s, catheters and pacemaker lead insulators were also being made out of PU. The popularity of PUs for use in medical applications has risen steadily ever since. Polyurethanes are generally considered to have good biocompatibility, and PU chemistry is so varied that it enables fine-tuning of the chemical properties for any given application. Polyurethane copolymers or segmented PUs represent an important subclass of thermoplastic polymers that is frequently used in biomedical devices. These materials tend to be elastomeric, making them particularly well suited for soft tissue engineering applications, where a matrix that can withstand local mechanical forces is needed. The construction of a cardiac patch is one such example.

In this review, the structure and chemistry of PUs will be introduced, as well as a brief description of synthesis techniques. Next, the wide array of medical applications in which PUs are used is provided. Following this, the biocompatibility of these polymers is described, including the mechanisms of degradation and the general host response to PU-based materials. Finally, the bulk of this review pertains to the PUs currently in use and in development.

SEGMENTED PUs

Segmented PUs or PU copolymers are phase-segregated polymers composed of alternating polydispersed blocks of “soft” and “hard” segments. Almost all segmented PUs are synthesized using three components: a diisocyanate, a polyol, and a chain extender, usually a diamine or diol. The availability of a wide array of reactants enables fine-tuning of the physical and chemical properties of the PU for a given application.

Polyurethanes can be synthesized using either a one-step or a two-step process. Most biomedical PUs are

made using the two-stage condensation process (Fig. 1).^[1] This technique provides good control over polymer architecture.^[2] The first step of this method involves the reaction of an isocyanate with a polyol to form a prepolymer. This prepolymer is then reacted with a chain extender, usually a diamine or a diol, to create the final PU. The use of an amine chain extender will lead to the formation of urea bonds, whereas a diol chain extender produces urethane linkages. Table 1 details the chemical components of some common commercial biomedical PUs.

Unlike polyols and chain extenders, there are only a handful of isocyanates that are readily available for use in PU synthesis. Traditionally, methyl diisocyanate (MDI) and, to a lesser extent, toluene diisocyanate (TDI) have been used extensively in the biomedical PU industry.^[2,5] These aromatic isocyanates have been used because they result in materials with high Young's modulus, ultimate strength, and elasticity. Concern was raised, however, about the potential for these aromatic diisocyanates to degrade into suspected carcinogens methylene diamine (MDA) and toluene diamine (TDA).^[5] As a result, many medical PUs, especially those designed to be intentionally degradable, are now synthesized using aliphatic diisocyanates despite the poorer mechanical properties and relatively low risk presented by the TDA or MDA degradation products of implants.^[5] Some of the more common aliphatic isocyanates currently being used in medical grade PUs include: hexamethylene diisocyanate (HMDI), 4,4-methylene dicyclohexyl diisocyanate (H12MDI), lysine diisocyanate (LDI), and *trans* cyclohexane-1,4-diisocyanate (CHDI).^[2,3]

In the formation of biomedical PUs, soft segments are almost always diols. Commercially, polytetramethylene oxide (PTMO) and polycarbonate (PCN) diol are the most commonly used. These soft segments have been associated with improved long-term stability *in vivo*. Other popular soft segments used in research include: polyethylene oxide (PEO), poly(ϵ -caprolactone) (PCL), and polypropylene oxide (PPO).

The primary purpose of the chain extender is to extend the length of the hard segment and increase the hydrogen-bond density of the PU.^[3] Commercially

Fig. 1 The two-step PU synthesis process.

available medical PUs are generally made with 1,4-butanediol (1,4-BD) or ethylene diamine (ED) in this role. Ethylene glycol or oxide can be used as a chain extender as well; glycol-extended PUs tend to have greater flexibility but less strength than amine-extended analogs.^[3]

A segmented PU is made up of two distinct moieties within the polymer: a hard segment, comprised of the isocyanate and chain extender, and a soft segment containing the diol. These two segments are thermodynamically incompatible, and the extent of phase segregation can be varied by altering the molecular weights, chemistry, and relative percentages of the reactants.^[4] The segmented nature of elastomeric PUs are responsible for their mechanical properties^[2] with interchain hydrogen bonding playing an important role.^[1,2]

The phase-segregated morphology allows for re-arrangement of the polymer's surface depending on the

surrounding environment.^[1] In the case of a medical device or implant, this translates into an ability to change the protein and cellular response to the PU by controlling the surface morphology of the PU under physiological conditions.

MEDICAL APPLICATIONS OF PUs

Polyurethanes are the most extensively used synthetic polymers in biomedical applications.^[6] This popularity is a result of the versatility and recognized "biocompatibility" of PUs. Current and proposed uses of PUs in medical devices are summarized in Table 2. In addition to these applications, degradable PUs have tremendous potential for use in drug delivery and tissue-engineered constructs.

Table 1 Commercially available biomedical PUs

	Soft segment diol	Isocyanate	Chain extender	Manufacturer
Pellethane	PTMO	MDI	BD	DOW Chemical
Biomer	PTMO	MDI	ED	Ethicon
Corethane	HMEC	MDI	BD	Corvita Corp.
Tecoflex	PTMO	HMDI	BD	Thermedics Inc
Estane	Varied	Varied	Varied	BF Goodrich
Medadhere	Aliphatic	HMDI	Aliphatic	Medtronic

PTMO, polytetramethylene oxide; HMEC, hexamethylene ethylene carbonate; MDI, diphenylmethane diisocyanate; HMDI, hexamethylene diisocyanate; BD, butane diol; and ED, ethylene diamine.

BIOCOMPATIBILITY AND TOXICITY

The adsorption of proteins from the blood or other biological fluids immediately following exposure is critical in determining the cellular interactions with the surface, including thrombus formation and bacterial infection.^[7] Bacterial infection represents one of the greatest risks in using biomaterials, with half of all hospital infections associated with implants and/or medical devices.^[9]

The term “biocompatibility” is used to assess the performance of a material in a given application. In the field of PUs, many investigators refer to PUs as simply being biocompatible. This is based on results that PUs perform relatively well *in vivo* under a wide variety of uses and that PUs generally have better blood and tissue compatibilities in comparison to numerous other synthetic polymers.

MECHANISMS OF PU BIODEGRADATION

It is widely acknowledged that traditional biomedical PU materials degrade in the biological environment.^[2] The ultimate biostability of PUs can be affected by the chemical structure, morphology, manufacturing, and processing conditions. The major mechanisms of degradation are hydrolysis and oxidation, both *in vitro* and *in vivo*.^[10] Environmental factors including biological fluids, proteins, cells, and mechanical forces, play an important role *in vivo* in the degradation of

PUs. Calcification can also play a role in the degradation of biomedical PUs.^[10]

Hydrolysis

The soft segment generally dominates the degradation characteristics of the PU and an increased soft segment content tends to be accompanied by higher degradation rates.^[5] Ninety percent of commercial PUs are polyester urethanes. These materials are commonly chosen for their low cost combined with high tensile strength, tear strength, and resilience (wear resistance). Unfortunately, polyester urethanes are highly susceptible to hydrolytic degradation.^[10] While polyether urethanes are less susceptible than their polyester counterparts, they too undergo hydrolysis when implanted long term.^[10]

Oxidation

While not as degradable by hydrolysis as polyester PUs, polyether-based PUs are particularly susceptible to oxidative degradation. Oxidation can be initiated by peroxides, free radicals, and enzymes, and can also be the result of metal-catalyzed oxidation (MO). Metal-catalyzed oxidation is most frequently associated with pacemaker leads, where the metallic components of the lead catalyze oxidative degradation of the PU. Metal ions are commonly released by reaction of the metal with radicals of hydrogen peroxide and superoxide produced by phagocytic cells during inflammation.^[3]

Environmental Stress Cracking

Environmental stress cracking (ESC) is an important problem with long-term PU implants.^[8] Fig. 2 is a scanning electron micrograph of a PU that has undergone ESC. The ESC manifests itself as crack lines that are usually found perpendicular to the direction of the stress being applied on the material.

Crack depths from ESC sometimes represent a significant portion of the material's thickness, and these cracks allow for tissue infiltration, often resulting in a well-integrated material.^[3] Some implanted PUs that are not under stress develop shallow cracks. In these cases, the cracking is considered to be the result of auto-oxidation, not ESC, and the cracking is generally limited to the surface. Although the mechanisms of ESC are still being elucidated, it has been determined that oxidation is the driving force behind the degradation. Of the PUs, PCN-based PUs are the least susceptible to ESC.^[8]

Fig. 2 A PU that has undergone ESC. (From Ref. [3].)

Enzyme and Cell-Mediated Degradation

Inflammation, one of the primary biological responses to implantation of a synthetic biomaterial, is characterized by the presence of leukocytes and macrophages.^[11] These cells have been shown to release a variety of hydrolytic enzymes. Within 48 hr of implantation, monocytes are the predominant cell type present at the PU interface.^[8] These cells change over time into monocyte-derived macrophages (MDMs), which remain present for the duration of the implant. Monocyte-derived macrophages are activated by adhesion to surfaces that are too large for them to engulf, leading to a process called frustrated phagocytosis, whereby oxidative species and hydrolytic enzymes are released in the vicinity of the PU.^[8] Substances released from phagocytes might include hydrogen ions, enzymes, and oxygen radicals.^[5] Activated MDMs also fuse to form multinucleated foreign body giant cells, the central mediators of the chronic inflammatory response to biomaterials. The adhesion and activation of MDMs can be altered by changing the chemistry of the biomaterial or by masking the PU with some other group, such as a protein layer.^[8] For more details on these methodologies, a discussion on surface modification will be presented later in this article.

Enzymatic cleavage is one of the main mechanisms by which both nondegradable and degradable PUs are degraded.^[5] Esterase, papain, bromelain, ficin, chymotrypsin, trypsin, and cathepsin C all have the ability to cleave some PUs, although the extent of degradation observed for stable PUs has been limited to date.^[5] The susceptibility to these enzymes appears to be related to soft segment chemistry and molecular weight. Trypsin has also been shown to degrade the ether linkages present in polyether soft segments.

Ratner, Gladhill, and Horbett^[12] subjected four PUs to enzymes and oxidizers to assess their biodegradation. The PUs investigated were Pellethane 2363, Estane 58409, and two materials synthesized using MDI, ED, and PPO (MW625 or 2000). The study involved two endopeptidases (papain and α -chymotrypsin), an exopeptidase (leucine aminopeptidase), and hydrogen peroxide. This study demonstrated that all three of the enzymes investigated degraded the test PUs to some extent. Of the PUs, the estane was found to degrade the least. In this study, the enzyme solutions contained 100 \times the amount necessary to cleave every bond in the PU backbone. Hence, although degradation was seen, the overall percentage of degradation was not very large, especially for such a high, nonphysiological presence of enzymes. The hydrogen peroxide degraded each of the PUs more significantly than any of the enzymes tested. Thus, the most important result of this study is the confirmation that PUs are susceptible to oxidation.

Tang, Labow, and Santerre^[13] investigated the effects of PU chemistry and morphology on degradation by cholesterol esterase. Results of this study indicated that, for PCN-based PUs, the hard segment content affects the hydrolytic stability of the material. Degradation of these urethanes is initiated at sites where there are low quantities of hydrogen-bonded carbonates and urethanes.

CURRENT TRENDS IN BIOMEDICAL PUs

Biostable PUs

Biodegradation is dependant in part on the degree of hydrogen bonding in the PU. Hence, the biostability of a PU can be improved by increasing the degree of hydrogen bonding. Gorna, Polowinski, and Gogolewski^[14] showed that the longer the diol chain, the lower the percentage of urethane linkages. The higher density of urethane linkages will enable increased hydrogen bonding. Consequently, using a lower molecular weight diol will result in a more biostable PU.

Polyurethanes based on aromatic isocyanates are more biostable than those synthesized using aliphatics.^[2,5] As a result, MDI has been the isocyanate of choice for biostable PU synthesis. Ester and ether groups have both been found to be susceptible to hydrolytic degradation. In addition, fewer ether linkages in the soft segment results in improved resistance to oxidation.^[2] Of the available diols, PTMO has been found to form PUs with the highest biostabilities.^[5]

Harder PUs have traditionally been found to be more stable *in vivo* than softer PUs.^[5] Tang, Labow, and Santerre^[13] have demonstrated that the higher the hard segment content, the more resistant the PU to

hydrolysis. It is suspected that the high degree of hydrogen bonding present within hard segments is responsible for this increased stability. Crystallinity of the soft segment may also improve the hydrolytic stability of PUs, for example, in polycaprolactone-containing PUs.^[13]

The PCN-based PUs appear to hold the most promise for use as biostable PUs. They have been shown to possess higher stability than traditional medical PUs, and there are already several PCN-PUs on the market, including: Corethane, Carbothane, Bionate, and Chronoflex.^[2,13] Carbonate linkages are more hydrolytically stable than esters because of the presence of oxygen molecules flanking both sides of the carbon.^[13] These oxygens form a quasi- π electron system, thereby stabilizing the central ketone group.^[13] In the short term, PCN-based PUs have demonstrated improved resistance to biodegradation and ESC as compared to PTMO-based PUs.^[8] The degradation of PCN urethanes appears to be the result of monocyte-derived macrophages and enzymes such as cholesterol esterase.^[2]

Other approaches explored include aliphatic PUs, polyether-based PUs, using higher macrodiols than PTMO, and siloxane-based PUs.^[2] Polyurethanes composed entirely of aliphatic components tend to be stiffer materials, and hence may not be appropriate for many biomedical applications. The polyether-based PUs developed by Gunatillake et al.^[2] were significantly more resistant to biodegradation than PTMO-based PUs. Siloxane-based PU elastomers are promising materials that incorporate many attractive properties of polydimethyl siloxane (PDMS) into the PU. These properties include: low toxicity, good hemocompatibility, good hydrolytic and oxidative stability, and low surface energy (nonadhesive).^[2] This means the siloxanes groups will migrate to the surface and help to prevent cell adhesion to the material. Both of these materials may become alternatives for PCN-based PUs.

Biodegradable PUs

Researchers have been working to develop PUs for use in drug delivery, tissue engineering, and regenerative medicine. For these applications, a biodegradable PU is desired. The ideal degradable PU scaffold would: be nontoxic (including the degradation products), have a degradation rate that correlates to tissue ingrowth, and have mechanical properties similar to that of the tissue it is replacing.

Guan et al.^[15,16] have developed a biodegradable poly(ester urethane) urea based on polycaprolactone or a copolymer of PCL and polyethylene glycol (PEO), and 1,4-diisocyanatobutane (BDI), and chain extended

with putrescine. These reactants were purposely chosen so that the PU would degrade into nontoxic degradation products, including putrescine, which is already present in vivo, and is a suspected mediator of cell growth and differentiation. The investigators have successfully synthesized materials with tensile strengths on the order of 1–2 MPa.^[15]

Skarja and Woodhouse designed a family of degradable PUs based on LDI, and L-phenylalanine-based diester chain extender and either PCL or PEO as the soft segment. The specially synthesized chain extender was added to incorporate enzymatic susceptibility into the hard segment. Chymotrypsin-like enzymes were found to successfully degrade the PU in a surface-limited fashion (Fig. 3). The PCL and PEO-based versions of these PUs were blended together, by Fromstein and Woodhouse, to create a range of PUs that are more susceptible to degradation, while maintaining the mechanical properties imparted by the PCL soft segment.^[17] By varying the soft segment molecular weight and chemistry, the degradation rates in vitro

Fig. 3 A scanning electron micrograph of one of Skarja and Woodhouse's degradable PUs following 28 days of exposure to chymotrypsin. Degradation was surface limited, and the amorphous regions were worn down first, leaving nubs of crystalline spherulites sticking out. (Courtesy of G. Skarja.)

ranged from a matter of days to several years. Investigation into the degradation products of this family of PUs indicated that the presence of phenylalanine in the hard segment led to the PU backbone being cleaved not only at the ester bonds, but also at the urea bonds neighboring the phenylalanine residues.^[18]

Zhang et al.^[19] have also designed a PU that will degrade into nontoxic products that the body will recognize. Their material is synthesized using LDI, glycerol, and ascorbic acid. Degradation products from this PU do not result in a change in pH, and initial cell culture results using osteoblastic precursor cells looked promising. One reason for the selection of ascorbic acid was its ability to promote osteoblast differentiation. Although this group is not the only group using PUs for orthopedic applications, the vast majority of PU research is focused on more flexible tissues.

Another attempt at using natural components to produce a degradable PU was made by Ganta et al.^[6] who reacted 2-methyl pentane-diisocyanate and sucrose. The polymerization reaction was stopped via the addition of water to create a porous three-dimensional PU foam. These foams were tested both *in vivo* and *in vitro*, and were found to be biocompatible, and did not appear to elicit a significant inflammatory response.

Covolan et al. fabricated a PU using HMDI, PEO (MW400), PCL (MW530), and chain extended with 1,4-BD.^[20] These materials demonstrated good cell compatibility as assessed by adhesion and spreading of mouse embryo fibroblasts, but the degradative properties have not yet been reported.

Polyurethanes can also be formed into hydrogel materials that may be useful for cell encapsulation, soft tissue engineering, and drug delivery applications.^[21] Petrini et al. synthesized a hydrogel using PEO, HMDI, and diazobicyclooctane. Although the resulting material was water insoluble, the hydrophilic nature of the PEO soft segment encouraged hydrolytic degradation of the PU hydrogel, making this material a candidate for shorter term implantations.

Processing Techniques

The processing methods used to create a medical product can have an effect on the biological response to the PU. This is a result of the ability of the segments within the PU to arrange themselves differently depending on their treatment during processing. As a significant amount of the research currently involving PUs has to do with tissue regeneration, many researchers have been investigating various methods of fabricating porous three-dimensional scaffolds that can serve as temporary matrices for seeded or growing cells. Common methods of making porous materials include: foaming, thermally induced phase

separation (TIPS), particulate leaching, and electrospinning.^[15,16,22–24] The TIPS (Fig. 4) is a popular processing method that requires very little equipment. Essentially, the PU is dissolved in an organic solvent such as dioxane and then the PU solution is frozen and then subsequently freeze dried. The resulting materials have an open pore structure, and depending on the freezing temperature, PU concentration, and size of container, the physical characteristics of the scaffold can be altered.

Electrospinning PUs for use in tissue engineering has become a popular method of scaffold formation. Unlike the other techniques used, electrospinning forms scaffolds with fiber thicknesses on the micro- and nanoscale. It is hypothesized that these electrospun meshes therefore appear a lot closer to natural tissue or extracellular matrix architecture (Fig. 5).

In a recent study, Kidoaki, Kwon, and Matsuda^[22] made scaffolds for use in tissue engineering by cospinning a PU and PEO into microfibers. The incorporation of PEO was intended as a leachable that would be hydrolyzed from the construct prior to implant. The microvoids formed by the elimination of PEO are hypothesized to provide pores via which cells can migrate into the construct. The merits of this approach have not yet been confirmed.

Fig. 5 An electrospun mat of a biodegradable PU developed by Skarja and Woodhouse. Matrices like these are being used to seed cardiomyocytes for use as a cardiac patch. (Photo courtesy of J. Fromstein and material electrospun by D. Rockwood and J. Rabolt, University of Delaware.)

The phase-segregated nature of segmented PUs can have a significant impact on the biological response to the material.^[25] Takahashi, Kita, and Kaibara were able to improve the blood compatibility of Pellethane, simply by thermally annealing the material. It is believed that the thermal annealing encourages the surface of the PU to become more hydrophobic and therefore prevents the activation of adhered platelets.^[25] This study also determined that there was a different biological reaction to a PU depending on whether the PU was in contact with air or with a solid surface during fabrication/molding. This reinforces the point that the processing method plays an important role in the compatibility of the PU.

Biomedical PU Modifications

Antibacterial PUs

One area that has received some attention over the past decade is the development of a PU that has antimicrobial agents incorporated into the material in an attempt to minimize the risk of implant-associated infection. Grapski and Cooper,^[9] for example, synthesized a series of nonleaching biocidal PUs containing quaternized pyridine residues in the chain

extender. Results from this study indicated that the PUs exhibited bactericidal activity against *Staphylococcus aureus* and bacteriostatic activity against *Escherichia coli*.

Woo, Mittleman, and Santerre^[26] used a similar strategy, incorporating the antimicrobial agent into the PU backbone. In their work, however, they designed a biodegradable polyester urethane that would intentionally release antimicrobial agents into the implant site. Their strategy relied on the inflammatory process to trigger degradation of the polymer and to control the magnitude of the response.

Improving biological response to PUs

Biocompatibility is a property that will change for a given application depending on what biological areas the material will be exposed to. The interfaces to which medical devices are exposed can be grouped into three categories: 1) direct contact with blood (e.g., a vascular graft or heart valve); 2) direct contact with solid tissue (e.g., fatty, connective, and muscle); and 3) contact with other bodily fluids (e.g., urine). When modifications of the PUs are performed, these biomaterial interfaces must be taken into account.

Blood–Material Interfaces. Blood-compatible surfaces are defined as materials that do not induce a large number of platelets and fibrinogen molecules to adhere, and do not activate platelets during blood contact.^[4] The segmented PUs have traditionally been considered to have relatively good blood compatibility. This property may be attributable in part to the phase-segregated nature of the PU, although there does not appear to be a direct effect of hard-to-soft segment ratio on blood compatibility.^[4] To improve blood–material interactions, a number of techniques have been investigated. Some of the more important findings are summarized below.

Grasel and Cooper^[4] showed that lower degrees of phase segregation in a PU system based on PTMO and PPO led to the formation of relatively large thrombi during blood contact. This study also showed that changing the degree of phase segregation by changing the ratio of PTMO to PPO was a primary determinant for blood compatibility. These results indicate that the segmented morphology of PUs may play a central role in hemocompatibility.

Many researchers have utilized PEO either as the soft segment incorporated in the polymer backbone or grafted onto the PU surface.^[4,10,27] These strategies result in surfaces that are hydrophilic in nature and have low interfacial surface energy, high chain mobility, and molecular chain conformation.^[27] Polyethylene oxide had been a popular choice for biomaterials because it is

resistant to protein adsorption, platelet adhesion, and bacterial adhesion.^[4,27] For example, Corneille et al.^[7] incorporated PEO into a standard PTMO-based PU, and found that the addition of PEO yielded a polymer that was nonadhesive for cells, but was relatively cyto-compatible. This PU holds promise for use in tissue engineering applications.

There remains a debate over the benefits of hydrophobicity. Some researchers have found that hydrophobic surfaces are hemocompatible.^[10] Others, however, feel that hydrophobic biomaterials initiate a foreign body reaction.^[23] Although a foreign body response will be initiated by any synthetic material, whether the extent of this response is greater than for hydrophilic surfaces is not known with any certainty.

A method of surface modification that has been popular for use with PUs is the use of surface-modifying additives (SMAs) also called surface-modifying macromolecules.^[28–31] These synthetic surface modifiers are designed to have chemistries similar to that of the PU they are being incorporated into. This similar chemistry enables hydrogen bonding between the PU and SMA to occur, thereby firmly anchoring the modifiers to the material. Surface-modifying additives make use of groups such as PEO or fluorine tails to ensure that the SMA is predominantly present at the surface of the biomaterial rather than in the bulk. The presence of these additives at the PU surface has been shown to improve blood compatibility.^[29,30]

Another method of ensuring good blood compatibility is to achieve a covering of endothelial cells (ECs) on the PU.^[32] Unmodified PUs do not tend to support endothelial cell adhesion and proliferation.^[25] An intact endothelial layer would mask the underlying PU from the blood, mimicking the natural lining of a blood vessel. The ECs are negatively charged, and release antiplatelet and antithromogenic factors into the vicinity.^[33] Zhu et al. published a study recently, in which porous PU (Estane) tubes were covalently coated with collagen, gelatin, or chitosan. The resulting materials were then seeded with human umbilical vein endothelial cells (HUVECs), and cultured for six days in vitro. The authors were able to achieve a viable intima on the luminal side of the PU scaffold, indicating that these modified PUs hold promise for use in vascular tissue engineering.

Tissue–PU Interactions. When it comes to material–tissue interactions, we are usually trying to encourage cells to adhere to and grow on the PU. In the case of a medical device such as a wound dressing a minimal foreign body response is desired. The response could be prevented most successfully by the formation of an endothelial cell layer along the surface of the implant. Similarly, for a tissue engineering construct, it is also important to encourage the growth and adhesion of

the cell type(s) native to the tissue being replaced. The second goal in tissue engineering can sometimes be overlooked, but is equally important to the long-term survival of an implanted construct, angiogenesis. To ensure that a newly populated construct will remain viable, scientists should consider adding angiogenic factors to their construct in an attempt to address this issue.

By controlling hydrophobicity of the polymer surface, the adherence of cells can also be controlled.^[6] A hydrophobic surface will encourage the absorption of a passive layer of proteins like albumin upon implantation.^[4] Sanders et al.^[23] have been charging the surface of PU scaffolds using plasma coatings in an attempt to affect cell adhesion, proliferation, and migration. To date they have not found conclusive evidence that they can reproducibly control the biological response using surface charge alone. Others have found that positively charged surfaces do enhance endothelial cell migration and spreading.^[33]

One of the most popular strategies for modulating cell and tissue response to foreign materials involves the use of natural materials to “mask” the surface or to mimic extracellular matrix. Researchers have used adsorption, grafting, and SMAs as methods of distributing the biological materials across the PU surface. They have tried using proteins, such as fibronectin, and peptides, such as RGD and YIGSR, that are known to affect cell adhesion.

In one study, Wang et al.^[33] used SMAs to coat their PU with RGD peptide and with the individual amino acids lysine, arginine, glycine, and aspartic acid. Results from this work showed that similar endothelial cell growth and adherence was achieved with both the peptides and the basic amino acids (lysine and arginine). Interestingly, they tried dispersing a 1:1:1 mixture of the individual amino acids making up the RGD across the surface of the PU. The response of the ECs to this mixed surface was significantly lower than to the RGD-covered PU, indicating that while basic coatings comprised a single amino acid may perform equally well to an RGD-covered surface, the RGD sequence is only effective as a sequence, and not as three separate amino acids.^[33]

Guan et al.^[16] found that cell adhesion to their degradable putrescine-based poly(ether ester urethane) ureas was low compared to tissue culture polystyrene. In an attempt to improve the biological response, they modified by immobilizing an adhesion peptide (RGDS) onto the surface using a spacer molecule and radio-frequency glow discharge. A marked improvement in cell adhesion was achieved.

Kidoaki, Kwon, and Matsuda.^[22] have recently published results of layering electrospun PU (micro-scale) with sheets of electrospun collagen and gelatin (nanoscale). In addition to the spinning of flat sheets,

tubular structures with an inner (luminal) coating of collagen and an outer layer of PU were produced.

Jun and West^[27] recently published results of a new PU synthesized using MDI, PEO as the soft segment, and a peptide chain extender containing the sequence YIGSR sequence. The incorporation of a bioactive peptide and PEO was expected to result in improved endothelial cell adhesion. Their results indicated that in addition to improved cell adhesion and spreading, the material also suppressed platelet adhesion. This improved blood response is attributed to the presence of PEO.

Van Wachem et al.^[34] investigated tissue integration into Pellethane that had collagen I immobilized on the surface using acrylic acid spacer arms. Collagen-immobilized PU was implanted subcutaneously in rats, using the acrylic acid-grafted Pellethane and original Pellethane as controls. Results indicated that the collagen-covered PU incited a far more intense foreign body reaction than the controls, as evidenced by increased fibrin deposition and accumulation of granulocytes and macrophages. At the end of six weeks, however, the collagen-immobilized samples had the thinnest capsule formed around them, and demonstrated the most adherence of connective tissue.^[34] It is important to note that the collagen used in this study was from a bovine source, and so there is an additional cross-species response that may have played a role in the elevated initial foreign body response.

Increased metabolite transport may occur in scaffolds with increased hydrophilicity.^[15] This could result not only in increased degradation, but also in a more viable environment for cells deeper within the construct. This could be a way to improve angiogenesis and cell infiltration within the center of the scaffold. The encouragement of angiogenesis and cellular penetration are primary goals in the design of any tissue-engineered construct.^[6]

Exposure to Biological Fluids. In some cases, an implant will be interfacing with tissue on one side and bodily fluid on the other. A good example of this would be a bladder patch. As the implant will be exposed to urine, it is important to select a material that will not degrade if a permanent implant is sought. In addition, the material should not induce calcification. A PU/PEO hybrid hydrogel, Aquavene, has been tested for degradation in artificial urine, and results indicated that degradation was not evident.^[35]

CONCLUSIONS

Although PUs have played an important part in biomedical applications since the 1960s, until recently

their use was restricted to nondegradable device applications including catheters, wound dressings, coatings on pacemaker leads, and ventricular assist devices. Researchers are now designing PUs specifically for a given application and are expanding the use of these polymers into the arena of tissue engineering. Features being incorporated through the flexible chemistry of these segmented PUs include: tunable degradation rates, bioactive degradation products, resistance to hydrolysis for permanent implants, and modification of surface charge and morphology to support cellular interactions. With their diverse mechanical, chemical, and physical properties, and relative ease of processing, PUs are likely to play a major role in medical implants into the future.

Positron Emission Tomography (PET)

Anna-Liisa Brownell

Department of Radiology, Massachusetts General Hospital, Boston, Massachusetts, U.S.A.

INTRODUCTION

The concept of positron emission-based imaging was developed in 1951^[1] and the first human studies were published in 1953.^[2] Since then, fundamental technical development has taken place in all scientific fields including electronics, computer science, biology, and biochemistry. These developments have also significantly advanced the development of positron emission-based imaging techniques. Even though positron imaging technology is more than 50 years old, its use in the clinical environment has been recognized only in the past 10 years. Interestingly, the earliest applications of positron imaging were tumor studies in the brain.^[2] The main clinical use, as well as a major research interest today, is also related to cancer. In the early applications long-lived positron emitters such as copper-64 and arsenium-72 were used for tumor detection, whereas today the most important positron ligand is a glucose analogue, fluorine-18 labeled 2-fluoro-2-deoxy-D-glucose. The limited availability of suitable positron ligands has been the biggest delay to clinical applications.

Technical development of positron emission imaging has gone through many steps after starting as two-dimensional imaging using one pair of single detectors.^[2] The major developments have been in detector design including crystal material, crystal size, light detection, photomultiplier development, and overall detection geometry. However, the most important aspect has been the development of mathematical algorithms. This development turned positron imaging into positron emission tomographic (PET) imaging.^[3–8] Further development of tomographic image reconstruction including filtering techniques has followed the advances in computer science.

Recently, PET imaging systems have also been developed for specific applications. In addition to self-standing, whole-body PET scanners, combined PET and X-ray computed tomographic (CT) systems are commercially available. These systems can combine high resolution anatomical information provided by CT to the functional information of PET. Also, organ-specific systems are developed along with many different designs for the imaging of small animal models.^[9,10]

Studies in the small animal models and advances in gene research have introduced a new level of biological molecular imaging and biomarker has become a magic

term in noninvasive imaging techniques. PET imaging techniques have high detection sensitivity; thus, only tracer amounts of radiolabeled ligand or drug is needed for imaging and the homeostasis of the biological system will not be changed. PET imaging techniques can be used to investigate physiological functions related to blood flow, metabolism, or receptor binding; to track cells or reporter genes; and to test drug candidates. Radiolabeled biomarkers have significantly enhanced the role of PET imaging, especially in drug development, as well as in developing new sensitive diagnostic methods and/or techniques to follow the response of therapeutic regimen.

TECHNICAL ASPECTS OF PET

Positron Emission and Annihilation

The nuclear origin of the positron is a proton. Under the influence of other nucleons the proton is converted into a neutron, a positron, and a neutrino. The immediate result of the breakdown is that the positron and the neutrino are ejected from the nucleus while the neutron remains (Fig. 1). The released positron carries kinetic energy depending on the binding energy in the nucleus and loses it while traveling in the surrounding media. The annihilation reaction is a result of a collision between the positron and a negatively charged electron. In annihilation the masses of the two particles completely turn into energy. The energy is divided equally between the two photons (each of 511 keV), traveling to the opposite directions ($180 \pm 0.25^\circ$) of each other. In PET imaging these two emitted photons are detected as a line between a detector pair (Fig. 1).

Light Detection

In the earliest applications (Fig. 2), sodium iodide (NaI) was used as a crystal material to absorb the emitted photon (released in annihilation) and turn it into light (Fig. 2). With thallium, enhanced NaI is still used as crystal material in instrument design. The drawbacks of NaI(Tl) are its hygroscopicity and low melting point. There are a number of other crystals that are better in these aspects and have better light production.

Fig. 1 Schematic diagram of the process where a positron is released from the nucleus of the radioactive marker. After that, the released positron travels in the surrounding media and loses its energy, finally colliding with a negatively charged electron. In this process, annihilation, the masses of the two particles completely turn into energy, which is divided between the two photons (each 511 KeV) traveling in opposite directions ($180 \pm 0.25^\circ$) of each other. This released photon pair can hit the scintillation crystals connected with coincidence logic and can be detected as a line between the crystals. This resultant information is used to generate images of activity distribution.

Characteristics of some crystals used in the PET imaging devices are presented in Table 1. Barium fluoride (BrF) is the fastest of the crystals listed in Table 1. It is used in PET designs based on time-of-flight detection. Bismuth-germanate (BGO) and lutetium oxyorthosilicate (LSO)^[11] are presently the most commonly used crystal materials in commercial PET devices. Of these two crystals, LSO is superior, having 5 times more light output than BGO and 7.5 times faster decay of light than BGO, resulting in a combined speed and light output improvement of 37.5 times over BGO.^[11]

Fig. 2 Coincidence scan (a) of a patient showing recurrence of tumor under the previous operation site, and an unbalance scan (b) showing asymmetry to the left. The site of the previous tumor is indicated by the indentation in the skull outline, which resulted from the absence of the bone flap. (Reproduction of a picture published in Ref. [2].)

Table 1 Characteristics of the most important scintillators used for detector material

Quantity	Unit	Na(Tl)	BGO	LSO	BaF

Melting point	°C	65	1,000	1,000	135

(From Ref. [11].)

Detector Design

To obtain optimal resolution and sensitivity, crystals are cut into different sizes and shapes and packed in different ways to enhance the special characteristics of PET imaging devices. In the earlier designs, the crystals were large. In PCI (Positron Camera I) and PCII (Positron Camera II) PET scanners, constructed at Massachusetts General Hospital, the diameter of the crystals was $\frac{3}{4}$ " and the thickness $2\frac{1}{4}$ ". In PCI the photomultiplier tubes (PMTs) were arranged in a square pattern and in PCII in a hexagonal pattern over the crystals. Since the system resolution correlates with the crystal size and is generally almost equal to it, the crystal size has been decreased significantly. In the present commercial scanners, the crystal pattern is typically rectangular or square. In the commercial human scanners, the size of the crystal surface is between 4 and 7 mm, while the thickness is between 20 and 30 mm (Table 2). In the animal scanners, the crystal size is smaller to obtain a higher resolution. In the commercial animal scanners, the crystal size is typically $2 \times 2 \times 10$ mm (Concord Microsystems; P4 and R4), and in some in-house built scanners, even as small as $1 \times 1 \times 5$ mm.^[10]

Because it was not possible to reduce the size of PMTs in the same scale as crystal size, the concept of analogue coding^[13] and block detector^[14] was developed. In the first PET device using analogue coding, crystals were placed on a circular light guide and one PM tube was looking for four crystals. Crystals were 20 mm long and 30 mm thick and the width varied from 4 mm at the front to 4.5 mm at the light guide, permitting the detectors to be assembled in a continuous ring.^[15] The position of the crystal, from where light was emitted, was determined by the ratio of the adjacent photomultiplier signals. The first block detector had 32 crystals for four PMTs.^[16] Photomultipliers are also of different shapes and sizes. In addition to the traditional

tube model there are flat area-sensitive PMTs. Table 2 summarizes detector designs of some commercial PET devices.^[12]

Gantry Assembly

The earliest PET cameras had a two-detector bank design and the camera heads rotated at 180° (Fig. 3).^[17–19] This first design was followed by several single-ring designs^[20–22] and hexagonal designs having six detector banks.^[23] After that, several multiring systems were developed, and finally separate rings have been replaced

with detector blocks. Also, a cylindrical design has been built.^[24] To obtain a large covering for the whole-body cameras, the two-detector bank design has been redesigned with large rectangular detector heads. Because of the large variation in the gantry design of the present PET devices, the standards to evaluate performance of the imaging systems have been changed accordingly.^[25]

Resolution

Resolution in positron imaging is limited by positron range, small angle deviation, sensitivity, count-rate

Fig. 3 Development of the PET designs at the Massachusetts General Hospital. On the left is PCI, the first positron emission tomograph with a two-detector bank design, built in 1968–1972. The spatial resolution of this device was 10 mm. In the middle is the first PET device that used analogue coding, built in 1983. The spatial resolution of this device was 4.5 mm. On the right, is a high resolution tomograph for rodent studies, built in 1999. The spatial resolution at the center is 1.16 mm.

capability, and sampling. Each of these factors must be considered in the optimization of an instrument design. Spatial resolution of the tomograph determines how small of a structure can be observed. Structures that are smaller than the spatial resolution cannot be perfectly distinguished from adjacent structures and are blurred by the activity from near-by structures. Spatial resolution is an important factor, especially in the quantification of radioactivity concentration. The size of the object should be at least two times the spatial resolution to avoid partial volume effects.^[26] If the object is smaller, there will be an underestimation in activity concentration. However, on the visualization point, partial volume effect may not be a problem if there is high activity or high contrast between the lesion and the background activity.

Spatial resolution is considered separately for in-plane (transverse) and out-of-plane (axial) directions. In-plane resolution is determined by the spread of the point or line source in the direction of a line from the center of the gantry to the position of the source (radial) and perpendicular to it (tangential). When the source is at the center of the gantry, radial and tangential resolution should be the same and would give the best value for the spatial resolution. Normally the spatial resolution is given at that point as a width of the half maximum.

Out-of-plane (axial) resolution refers to the slice thickness and ability to separate structures in the axial direction. According to the latest National Electrical Manufacturers Association (NEMA) recommendations,^[25] the spatial resolution should be measured with a point source in all three directions, rather than by a line source, to allow more comparable results between two-dimensional and three-dimensional imaging modes of PET. The spatial resolution of the positron imaging devices has improved from 30 mm in the early scanners^[2] to 4.5 mm in commercial whole-body scanners (Table 2). In commercial small-animal scanners, the resolution is 1.8 mm (primate microPET, P4, Concord Microsystems) and as good as 1.16 mm in the special in-house built rodent PET scanner.^[10]

Sensitivity

Sensitivity of the tomograph is determined as a ratio of the coincidence count rate and the radioactivity concentration. Annihilation photons are emitted in all directions, and only a small percent of photons can be detected in the tomograph. Depending on the width of the detector bank, fewer than 10% of the emitted photons are detected. If the efficiency of the scintillation crystal is 80%, the coincidence detection efficiency in two crystals is 64% and the PET device is able to detect about 6.4% of the annihilation events. If the radius of

the gantry is 50 cm, it can be calculated that only 1% of the emitted photons can be detected in a 1-cm-wide slice.

The sensitivity of the PET scanner is measured with a phantom, normally using ^{18}F as a positron emitter. Only a small amount of radioactivity is used in these measurements to minimize random coincidences and dead time losses. According to the latest NEMA recommendation,^[25] the sensitivity should be measured using a 70-cm long tube filled with radioactivity and surrounded by several sleeves to create stepwise differences in attenuation. The attenuation-corrected counting rate is mathematically calculated from the observed data and used to determine sensitivity. However, if the length of the field of view of the PET scanner is less than 19 cm, the sensitivity can be measured with a phantom of 20-cm diameter and 19-cm length.

Data Acquisition

Data acquisition is a compromise of the characteristics of the tomograph and the requirement of the biological application. Injected activity (radiation dose) and acquisition time are often limited by the biological system. The acquisition parameters in the system are adjusted with these guidelines. The old classical data acquisition method is two-dimensional, which means that the data are acquired in a plane. The recent technical development in detector design has enabled three-dimensional data acquisition, which means that data can be acquired both in the crossplane and in the axial direction. Three-dimensional data acquisition increases sensitivity, but internal scatter and random coincidences will also be higher than in two-dimensional acquisitions. Additional technical factors affecting data acquisition and final image quality are sampling, statistical noise, scatter, and attenuation.

Sampling

Sampling describes the density of coincidence lines in the field-of-view. The linear sampling distance (d) sets a resolution limit for any imaging system. This limit is known as Nyquist frequency ($d \leq (1/2v_{\text{max}})$) and means that the highest spatial frequency component to be recovered from the data has to be sampled with at least two points per cycle. Axial sampling can be improved by the motion of the detector head in the axial direction by half of the slice thickness.^[27] In-plane sampling can be enhanced by wobbling, the circular motion of the detector head by 1–2 cm off-center.^[28]

Statistical noise

During data acquisition, the collected counts are subject to the statistical noise, since radioactive disintegrations

occur at random and it is not possible to determine when a given atom will disintegrate. The detected counts (N) have a standard deviation \sqrt{N} and the statistical noise is determined as $1/\sqrt{N}$. Statistical uncertainty increases with low counts. However, obtaining high counts might be limited by radiation dose or imaging time. Long imaging times increase the possibility for motion-induced artifacts.

Scatter

The scattering of annihilation photons leads to falsely positioned coincidence events. They contribute to the noise and loss of the contrast in PET images. Scattered coincidences cannot be distinguished from true coincidences electronically, and there are no exact methods for correction of scatter in biological studies. However, there are several methods for partial correction.^[29,30] Internal scatter in biological systems is often a burden if some low activity areas are investigated near an area with a high accumulation of activity. An example of this problem is studies of glucose metabolism in the heart. After administration of the radiolabeled ligand ^{18}F -2-fluoro-2-deoxy-D-glucose (^{18}F -FDG), the high activity will be first in the blood pool inside the ventricles, but after 30 minutes the activity will be metabolized into the cardiac muscle and cleared off from the blood pool. In the image, the high scatter is first at the cardiac muscle because of the high activity inside the walls. After 30 minutes the high scatter will be in the lumen because of the high activity in the cardiac walls. In this special case, the scatter-created malfunction is called spillover.

Attenuation

Photons created through annihilation lose energy when passing through the tissue depending on the thickness and density of the tissue. Attenuation correction is necessary to obtain activity distribution, especially if surrounding tissues have asymmetrical bone structures. Measurement for attenuation correction can be done in two ways. The most accurate method is to perform a separate imaging for transmission and correct the sinograms with the transmission data. This is done in most commercial scanners by using rotating line or point sources. The other method is to use a mathematical approach based on determining the length of the photon range inside the surface contours. In combined PET-CT imaging systems, transmission image is conducted by CT.

Image Reconstruction

Data can be acquired both in two- and/ three-dimensional mode. However, independently of the data

acquisition mode, reconstruction is often done in a two-dimensional mode to obtain transverse, coronal, and/or sagittal slices with a variety of slice thicknesses depending on the statistical count distribution and biological questions. To reconstruct a data set in two-dimensional mode after three-dimensional acquisition requires the rebinning of the sinograms. The sinograms are corrected for uniformity, scatter, and attenuation before reconstruction of images. Also, corrections for acquisition time, decay, and injected radioactivity can be included with the corrections before reconstruction.

Reconstruction algorithms have been developed for both two- and three-dimensional approaches. The most commonly used algorithm is filtered backprojection. Also, convolution backprojection can be used to reconstruct two-dimensional data sets.^[4] Resolution in filtered backprojection, as well as in convolution backprojection, is affected mostly by the selection of the filter function and its cut-off value, which depends on the noise level of the data. Also, several arithmetic iterative reconstruction techniques are available in commercial PET scanners for two- and three-dimensional data analyses including the basic ordered-subsets expectation-maximization (OSEM) algorithm, attenuation-weighted OSEM (WA-OSEM) and segmented attenuation/weighted OSEM (WLS-OSEM) as well as Fourier binning OSEM (FORE). Even though the OSEM algorithm is used to suppress image noise and to make non-negative value images, it is not superior to the filtered backprojection in parametric images.^[31] Selection of the reconstruction algorithm depends mainly on the biological application.

Quantification

For accurate quantification, a good contrast is required to outline the borders of the different tissues. With the present multimodality imaging techniques it is possible to fuse PET images with anatomical magnetic resonance images and obtain the needed anatomical borderlines. A number of different biological models have been developed for quantification of PET imaging studies so that the final results can express biological function in metric units. There are generally approved models to quantify hemodynamics^[32] and glucose metabolism^[33] and several models for receptor binding, depending on binding mechanism.^[34-36] With the present PET imagers, the resolution is high enough to minimize partial volume effects.

BIOLOGICAL APPLICATION OF PET

The variety of biological applications of PET imaging is based on the superior sensitivity of detection of radioactivity. The obvious applications are studies of

Table 3 A summary of the most commonly used radioligands in PET imaging and their biological target

Physiological function	Radioligand	Disease or target	Reference
Hemodynamics			
Blood flow	C ¹⁵ O ₂ , H ₂ ¹⁵ O	Stroke, infarct, activation,	[32,37–41]
Blood volume	C ¹⁵ O, ¹¹ CO	cancer, myocardium	
Perfusion	¹³ NH ₃		
Metabolism			
Glucose metabolism	¹⁸ F-FDG	Cancer, stroke, infarct,	[33,42–44]
Oxygen metabolism	¹⁵ O ₂	Alzheimer's disease, Huntington's disease	
Amino acid metabolism	¹¹ C-methionine	Cancer	[45]
Fatty acid metabolism	¹¹ C-palmitic acid, ¹⁸ F-fluoro-6-thia-heptadecanoic acid	Myocardium	[46,47]
Receptor function			
Dopamine transporter	¹¹ C-CFT, ¹⁸ F-L-dopa	Parkinson's disease,	[34,48–50]
Dopamine D1 receptor	¹¹ C-SCH 23390	schizophrenia, drug addiction	
Dopamine D2 receptor	¹¹ C-raclopride		
5-HT (1A) receptor	¹¹ C-WAY 100635	Schizophrenia	[51]
Benzodiazepine receptor	¹¹ C-flumazenil	Epilepsy	[52]
Opioid receptor	¹¹ C-diprenorphine, ¹¹ C-carfentanil	Pain	[53,54]
Estrogen receptor	16 alpha-[¹⁸ F]fluoro-17beta-estradiol	Cancer	[55]
Molecular mechanism			
Proliferation potential	3-deoxy-3- ¹⁸ F-fluoro-thymidine	Cancer	[56]
DNA synthesis	¹¹ C-thymidine	Cancer	[57]
Herpes simplex virus type 1 thymidine kinase (HSV 1-tk)	¹⁸ F-5-fluorouracil, 8- ¹⁸ F-fluoroganciclovir, ¹⁸ F-acycloguanosine, ¹²⁴ I-FIAU	Cancer	[58–60]

functional mechanisms, where a tracer amount of radioactivity is introduced into the system without changing its physiological environment. Biological applications have developed together with radiopharmaceutical development, especially with the development of chemical synthesis and labeling techniques. Carbon-11 ($t_{1/2} = 20$ min) and fluorine-18 ($t_{1/2} = 110$ min) are the most commonly used positron emitters in these labeling procedures. Recently, there is also a trend to develop labeling techniques for small peptides using copper-64 ($t_{1/2} = 12.8$ hours) and iodine-124 ($t_{1/2} = 4.2$ days). The commonly used radiopharmaceuticals and their targeted applications are summarized in Table 3.

Imaging of Hemodynamics

Stroke

Detection of hemodynamic changes in brain blood flow has been one of the earliest clinical application of PET techniques.^[32,37] These techniques were used intensively in stroke studies to localize a site and extend, as well as

follow up, the recovery.^[38,39] Recently, magnetic resonance imaging (MRI) techniques have overcome many of these applications.^[61] When separate information is needed for blood flow or blood volume changes and the possible connection to oxygen consumption, only PET studies can provide information on all these hemodynamic aspects.^[62]

Activation studies

PET studies have been extensively used to evaluate hemodynamic changes induced by stimulations to evaluate the activation and connectivity in different brain circuitries. These stimulations can be introduced through all the senses, but visual stimulation is the most commonly used technique, combined with different tasks.^[40,63] Also, pure electrophysiological techniques can be used to activate specific brain areas.^[64]

Infarct

PET studies of hemodynamic changes in the heart are often combined with studies of glucose utilization to

obtain more clinically relevant information, especially differentiation of ischemic and infarcted tissue areas (Fig. 4).^[65] If only blood flow studies are done, it is necessary to repeat the studies during rest and exercise or combine blood flow studies with evaluation of wall motion in order to differentiate viable versus nonviable tissue areas.^[66]

Cancer detection

Most tumor tissues have an enhanced growth rate and they require a lot of energy, creating a need for an increased blood supply. This can be introduced by increased blood flow and/or blood volume. Blood flow is a sensitive indicator of changed hemodynamic requirements. PET studies of tumor blood flow and volume have been used as an indicator of efficacy of the treatment with antiangiogenic agents. A study of combretastatin, an antivascular agent, showed a 30–60% reduction in tumor blood flow in patients treated with a high dose of the drug.^[67] Similar studies were done to evaluate the antiangiogenic activity of endostatin.^[68] This type of assessment can be a new method to determine the efficacy and optimal dosage of antiangiogenic agents.

Imaging of Metabolism

The availability of fluorine-18-labeled 2-fluoro-2-deoxy-D-glucose (¹⁸F-FDG) has significantly enhanced PET

Fig. 4 Experimental studies of blood flow and glucose metabolism in the heart demonstrate the concept of matching information (infarct) and mismatching information (ischemia). In the ischemic process, the blood supply (flow) was decreased in the apical area (upper row, left), which shows an enhanced accumulation of ¹⁸F-2-fluoro-2-deoxy-D-glucose (upper row, right). In the infarct (lower row), both blood flow and glucose metabolism are similarly decreased.

Fig. 5 Studies conducted of glucose metabolism with ¹⁸F-2-fluoro-2-deoxy-D-glucose in normal human, primate, and mouse brain. The human study shows a transverse slice imaged with PCII (spatial resolution of 10 mm). The primate study shows a coronal slice imaged with PCR-I (spatial resolution of 4.5 mm) and the mouse study shows a coronal slice imaged by the rodent scanner (Fig. 3). These images demonstrate the effect of the instrumentation development on the biological outcome.

studies based on glucose metabolism, as well as instrumentation development to the level of the concept of FDG-PET. The most important application of FDG-PET is in cancer studies, especially in whole-body imaging in order to find metastases.

Glucose is the main source of energy in the brain (Fig. 5). Therefore, all the changes in functionality create some changes in regional glucose metabolism. Even though glucose metabolism is a sensitive indicator of changed metabolism, it is not a selective method. Thus, the clinical relevance has to be obtained with other additional bases.

The tracer kinetic model of glucose consists of intravascular tracer, a tissue precursor pool in exchange with blood, and a metabolic pool representing a tracer that has been chemically transformed.^[69] The compartments are interrelated by the transport constants so that k_1 and k_2 represent exchange between blood and tissue (in the blood-brain barrier) and k_3 and k_4 represent the rate of tracer phosphorylation by hexokinase and dephosphorylation by glucose-6-phosphatase, respectively. There is an additional parameter, a lumped constant, which correlates the steady-state rate of tracer (¹⁸F-FDG) phosphorylation to the rate of glucose phosphorylation.^[33] The lumped constant has different values in different organs and it can also be affected by disease-induced stress in the tissue.^[69–71]

Glucose metabolic rate can be used as an index of malignancy of brain tumors,^[42] as well as to predict the response of the therapy.^[72] A study of high-grade gliomas showed that a decrease in ¹⁸F-FDG accumulation after 7 days of treatment could predict radiological response seen at 2 months.^[73]

Using ¹⁸F-FDG, it is possible to obtain invaluable information on all other biological studies except those

that are based on specific receptor recognition mechanisms.

Imaging of Receptor Function

Imaging of the receptor function has significantly enhanced the understanding of underlying pathophysiological mechanisms, especially in many neurological disorders. There are a number of specific ligands to investigate dopaminergic and serotonergic receptor functions (Table 3). PET studies of dopaminergic function have enabled an early diagnosis of Parkinson's disease,^[48] as well as the development and testing of therapeutic regimens for repairing the function via either pharmacological or surgical methods, including deep brain stimulation^[74] or cell transplantation.^[75] Dopaminergic function is affected in neurodegenerative disorders, schizophrenia,^[76] drug addiction,^[77] and in many psychological conditions such as anger,^[78] anxiety, and hyperactivity.^[79]

PET imaging is also used to assess the kinetics of drug–receptor interaction to determine the presence and level of in-vivo expression of receptors in tumors without the necessity of biopsy and to aid in selection of the appropriate therapy. PET studies of breast tumors using ¹⁸F-estrogen (FES), a radioligand for the estrogen receptor, correlate well with estrogen receptor status obtained from pathological samples.^[80,81] This correlation allows longitudinal in-vivo follow up of hormone receptor status and aid in the choice of therapy.

Imaging of Molecular Mechanism

In molecular imaging, ¹⁸F-labeled compounds with high specific activity have a central role, since biological processes and incorporation of ligands into the cells, genes, or DNA may take hours. For example, ¹⁸F gas is used in the synthesis of ¹⁸F-labeled acycloguanosine analogues and other compounds used to image Herpes simplex virus 1 thymidine kinase to follow gene therapy,^[58,59] and in the production of ¹⁸F-labeled 3'-deoxy-3'-fluorothymidine (FLT) to image proliferation potential in the cell.^[56] DNA synthesis can be imaged by ¹¹C-labeled thymidine.^[57] PET studies with ¹¹C-thymidine showed in patients receiving a variety of chemotherapy regimens a 100% decrease in ¹¹C-thymidine flux constant among responders, compared to a 35% decrease in partial responders and an even smaller decrease in non-responders after 7 days of treatment.^[82] Thus PET studies can be used to evaluate cell-based responses in chemotherapy.

Drug Development

PET has the potential to be a powerful tool in drug discovery and development. PET imaging is able to noninvasively assess drug distribution and action at the molecular level. Positron emitters can be introduced to the drug candidates and used as radiolabeled ligands. It has been well established that substituting a stable atom with a radioisotope of the same element does not affect the physicochemical, pharmacokinetic, or biological properties of a drug.^[83] Preliminary studies indicate that dynamic PET imaging, using repeated images over time, can be a valuable technique for defining the time course of uptake and retention of radiolabeled anticancer drugs in tumors and in the surrounding normal tissue in patients.^[84] These drugs are designed to inhibit key processes in cancer initiation and progression: angiogenesis, proliferation, avoidance of cell death or apoptosis, invasion and metastasis, and transduction of signals that modulate these processes. Many of these drugs are inhibitors of cell surface receptors or inhibitors of intracellular enzymes that transmit signals from receptors to the nucleus.

The current generation of PET scanners provide whole-body imaging and good spatial resolution to evaluate drug effects in small targets, and only trace amounts (nano or picograms) of the labeled ligand (drug) will be administered into the patient.

CONCLUSION

Development of positron imaging instrumentation has been a challenging effort in the past 50 years. Now is the time to establish its biological use. The future technical development relies mainly on developing faster and more efficient light detection, as well as even faster electronics. These aspects would increase sensitivity and improve image quality. In the clinical environment, PET has established its power in cancer studies. However, these studies utilize only a fraction of the possibilities that can be obtained by PET imaging. In the future, the main challenge of PET imaging is in drug development based on different biological and functional mechanisms. The new ligands and drugs can be used in humans to enhance early diagnosis and predict and follow the progression of the therapy. The biggest challenge is to develop new radioactive ligands to investigate in vivo different receptor and enzyme functions. For example, the amino acid glutamate mediates most of the excitatory synaptic transmissions in the brain and the glutamatergic pathways are involved in diverse processes like epilepsy, ischemic brain disease, pain, learning, etc. However, there is no radioactive ligand available for human studies to investigate in vivo glutamate receptor functions. The potential applications of

PET imaging in drug development have just begun to be studied and the preliminary successes of these approaches are evidence of the future power of PET imaging.

ACKNOWLEDGMENT

I would like to acknowledge Dr. Gordon L. Brownell and Mr. Charles Burnham for the brief discussions about PET instrumentation development.

Protein Adsorption Modeling

Alan H. Goldstein
Alastair N. Cormack

New York State College of Ceramics at Alfred University, Alfred, New York, U.S.A.

INTRODUCTION

This article deals with theoretical aspects of the initial events underlying protein adsorption to the surface of materials used in the body (biomaterials). A wide range of approaches to simulate protein adsorption are currently under investigation. However, there is no *prima facie* reason to treat the forces controlling these interactions differently from *in-vivo* processes whereby proteins functionally adsorb to a wide range of naturally occurring surfaces, including the surfaces of other proteins. These processes would include: formation of protein quaternary structures, assembly of supramolecular complexes, and both peripheral and integral association with biological membranes, to name a few. In this article, we will consider the physicochemical bases of the initial adsorption process, briefly survey current strategies for computer simulation of adsorption, and then provide a specific example of the use of molecular mechanics and dynamics for atomistic simulation of protein adsorption to a materials surface in an aqueous environment.

OVERVIEW: THE PROPERTIES OF BIOMATERIALS ARE OFTEN THE PROPERTIES OF THEIR SURFACES

A Protein Is a Material

At this point in the biotechnology revolution, the time has come for biomaterials scientists and structural biochemists to work closely together to use existing atomistic/molecular computer modeling systems to develop a detailed understanding of the interface formed between a protein initially folded into its native tertiary structure and a biomaterials surface. Our database of known protein structures is growing dramatically, as is our ability to predict protein structures from genetic sequence data and atomic composition. The future of this branch of science is clearly targeted toward a comprehensive predictive capability based on primary protein sequence data. While reaching this goal may lie somewhat in the future, it is appropriate for biomaterials scientists to make a parallel effort to bring current materials computer modeling systems

into the mix so that we can begin to develop simulation capabilities with respect to the materials–protein interface. Such efforts must, of course, be paralleled by laboratory studies designed to test the output of such models.

Biomolecular–Materials Composites

It is interesting to ask this question: What engineering challenge do the following emerging technologies have in common?

- Fabrication of new biomimetic/bioreactive materials.
- Optimization of DNA and protein microarray density and sensitivity.
- Engineering of optimized microfluidics systems.
- Development of tissue engineering scaffolds, and hybrid devices such as stents or controlled drug release implants that include both biological and nonbiological materials.

One answer is that the optimized design and fabrication (engineering) of these systems require an understanding of the biomolecular–materials interface and, more specifically, an atomistic/molecular picture of the nanostructure of this interface. While this concept applies to any biomaterial that uses or interacts with biological macromolecules, this article will focus on proteins and their adsorption to surfaces of inorganic materials.

Both the fields of protein engineering and materials engineering have virtually unlimited potential to provide significant advances in science, medicine, and industry. It is logical to propose that, as our understanding of protein structure–function relationships continues to grow, the status of protein engineering will begin to approach that of the more mature fields of engineering where our knowledge of fundamental physicochemical properties permits precise structures to be created *de novo* with prescribed functions.^[1,2] A mature protein engineering capability will allow us to understand: 1) how proteins interact with nonbiological materials (classic biomaterials); and 2) how to optimize construction of hybrid materials comprised of proteins and nonbiological materials. A mature protein engineering

capability will also allow us to fabricate hybrid structures comprised of proteins and other materials such as polymers and glasses. Such composites will often be developed as biomaterials. However, one definition of a biomaterial endorsed by a consensus of experts is “a nonviable material used in a medical device intended to interact with biological systems.”^[3] This is really too broad a definition within the context of advanced materials science and biomedical engineering. We propose the name protein–material composite (or more generally biomolecular–material composite), to define a new class of materials based on emerging technologies that will allow researchers to fabricate entirely new compounds with unique or dramatically enhanced properties of great utility in science, medicine, and industry.

Examples of these biomolecular–materials composites already exist. The DNA microarray, usually a DNA–glass composite material, represents a dramatic example. Likewise, the line between microfluidic and nanofluidic systems will mainly be drawn based on interfacial phenomena that control the movement of biological macromolecules when the dimensions of the transport system are on the same scale as the molecules to be transported. From a bioengineering standpoint, an important first step in optimizing these types of systems is gaining the ability to understand and visualize what is occurring at the biomolecular–materials interface. This, in turn, requires the integration of existing atomistic computer simulation systems for materials and biopolymers (e.g., proteins, nucleic acids) to optimize our modeling and predictive capacity. Fabrication followed by micro- and nanostructural characterization will be required for validation of these models which, in turn, will finally result in production and use of these new biopolymer–material composites.

Molecular Modeling of Proteins

The numbers of proteins whose structures are known at the atomic–coordinate level is increasing at a dramatic rate (cf., Refs. [1,2], and <http://www.rcsb.org>). Of equal importance, structure–function analyses have revealed that the virtually unlimited range of protein functions results from permutations and combinations of a relatively limited set of structural motifs.^[1] Structural stability for a given protein is almost always imparted by some type of folding involving alpha-helices and beta-sheets packed together into a stable three-dimensional conformation based on energy minimization within the protein’s native environment. These folding motifs are well characterized for a large number of protein families and, in fact, are so common that we can now recognize superfamilies with over 200 members that use almost identical folding motifs to maintain structural stability (e.g., the globin superfamily). Atomistic and molecular

modeling of proteins has now reached the point where protein engineering is possible. Proteins with enhanced thermal stability or modified substrate specificity are now produced routinely. Catalytic antibody technology and other strategies make it possible to design protein surfaces to mimic nonbiological catalysts (cf., Ref. [2] and references therein).

Ab initio prediction of the native conformation of a protein remains one of the great challenges to modern biochemistry and molecular biology.^[2] Computer simulation is essential in our attempts to understand processes such as protein folding. There is reason to be optimistic with respect to the ultimate development of an ability to predict the native conformation of a protein from its amino acid sequence. Recently, Duan and Kollman^[4] have folded a 36 residue protein fragment by molecular dynamics simulation into a structure that resembles the native state. But even while significant barriers remain to the prediction of protein structure from calculations based on the primary amino acid sequence, X-ray crystal structure data (as well as NMR and other experimental techniques) currently provide the capability to produce accurate three-dimensional pictures of a wide variety of protein structures. It is reasonable to suggest that available high-resolution structures include all the spatial and electrochemical information necessary to predict how a protein will bind to a surface and/or the type of material surface required to retain, or even enhance, protein function. With the growing availability of these databases, it is proposed that the time is right for a concentrated effort aimed at modeling protein–materials interactions.

Is Protein Adsorption to a Material Surface Unique as a Physicochemical Phenomenon?

Whereas complex chemical reactions may occur between a biomolecule and other materials, there is no reason to assume that there are any unique forces governing the initial protein adsorption to a material’s surface. A protein is, after all, a polymeric material whose structure and properties are determined mainly by surface-mediated (interfacial) phenomena. From protein folding itself, to the binding of a substrate in the active site of an enzyme, to the polymerization of structural proteins such as actin to form microfilaments, standard noncovalent interactions play the roles of paramount importance. These interactions include all the usual suspects: hydrogen bonding, electrostatic bonding, and van der Waals interactions. A fourth category, often referred to as hydrophobic interactions, is really a manifestation of a balance between the previous three types of forces, an observation that is not meant to trivialize the importance of the hydrophobic effect in the aqueous environment of living systems.

When a protein approaches a materials surface the result is almost invariably adsorption.^[3] Adsorption literally means to gather on a surface in a condensed layer (be the condensate a gas, liquid, or dissolved substance). While undoubtedly practiced since antiquity, the term adsorption was first coined in the late 19th century, although the process itself was not widely appreciated until the 1940s and 1950s when activated carbon was first used for municipal water treatment. It is of interest to note that this term is not used with any degree of rigor and this lack of specificity has evolved, quite probably, from that early use of activated carbon as a common but nonspecific adsorbent. Like the famous quote by a Supreme Court justice about pornography, we know adsorption when we see it. However, what is actually occurring at the surface is usually a mystery. The related term chemisorption, often defined as adsorption involving a chemical linkage between adsorbent and adsorbate, is also notably lacking in mechanistic information. Like most of the biological processes involving proteins (catalysis itself being the major exception), the initial adsorption of a protein to a surface is assumed to be based on multiple weak noncovalent interactions. The number and types of such interactions will be a function of the protein, the materials surface, and the solvent (in addition to any effects of temperature and pressure).

SIMULATION MODELING OF PROTEIN ADSORPTION

General Considerations

In this section, we will review some characteristic examples of computer simulation strategies employed to model protein adsorption. Most molecular modeling studies involve three stages. In the first stage, methodology is selected within which to describe the intra- and intermolecular interactions in the system. The two methodologies used in molecular modeling are quantum mechanics and classical mechanics. These methodologies enable the energy of any arrangement of the atoms and molecules in the system to be calculated, and allow the modeler to determine how the energy of the system varies as the positions of the atoms and molecules change. The second stage of a molecular modeling study is the calculation itself, involving techniques such as energy minimization, molecular dynamics or Monte Carlo simulation, or a conformational search. The results of the calculation must be analyzed, not only to obtain properties, but also to check that it has been performed properly. Finally, experimental validation of the simulated output is required. This may, in fact, be the limiting factor in evaluating the utility of most theoretical studies.

As we will discuss, there are basically two approaches to the simulation of protein adsorption: the continuum and the atomistic. The continuum approach is based on solving Poisson's equation for a model of the electrostatic potential in and around a protein near a charged surface, using dielectric constants for both the protein and the electrolyte. The atomistic approach, as its name implies, treats the system atomistically. This strategy includes explicit atom-atom interactions, which are basically summed to provide the energy of the system, and include both Molecular Mechanics/Molecular Dynamics (MM/MD) and quantum mechanics. Usually, MM and MD are coupled iteratively in order to simulate molecular motion and energy minimization during the adsorption process. In general, the large size of the system (number of atoms) requires that quantum approaches are semiempirical and are reserved for small organics (e.g., amino acids or polypeptides) although larger systems are being explored, as will be discussed subsequently.

The Continuum Approach

In a classic example of the continuum approach, Yoon and Lenhoff^[5] attempted the computation of the electrostatic interaction energy between a protein and a charged surface. The interaction potential energy between the molecule and the surface was used to determine equilibrium states or to follow the dynamics by integration of the equation of motion for the molecule. The interactions were considered to be entirely electrostatic in nature, but were analyzed using continuum models in which the overall interaction was decomposed into parts, e.g., van der Waals (VDW) interaction, electrostatic double-layer interaction, hydrophobic interaction. The authors noted that these are usually treated as being independent and additive despite the fact that they might not be mutually exclusive, and alluded to the first successful example of this approach as being DLVO (Derjaguin-Landau-Verwey-Overbeek) theory, which is central to much of colloid science. In DLVO theory,^[5] the VDW and electrostatic double-layer interactions are combined. These authors made use of full three-dimensional protein structure to account for the anisotropy of the shape and function of the protein molecule in determining its electrostatic double layer interaction with a charged surface. Numerical results were presented for ribonuclease A, with and without the presence of a charged surface, and the potential field information was used to determine the electrostatic interaction energy. These authors used a continuum formulation that assumed the potential Φ^i in the interior B^i of the biomolecule to be governed by the Poisson equation with the dielectric constant taken to have a uniform value ϵ^i .

A set of n point charges q_k were placed at positions x_k inside the molecule and the linearized Poisson–Boltzmann equation was assumed to govern the potential Φ^e in the exterior region B^e .

Protein interactions with synthetic polymers have been extensively investigated by numerous techniques. The general consensus appears to be that, in most cases, binding results in monolayer formation and strong hydrophobic interactions are crucial for observed irreversibility. The most important question to be solved is that of the orientation and tertiary structure on the polymer surface. Waldman-Meyer and Knippel^[6] generated a surface charge density model for the structure and orientation of polymer-bound proteins. These workers used negatively charged polystyrene (PS) beads. Their model was based on a layer of maximal packing density able to cover the total polymer surface. They assigned 15 \AA^2 per sulfate group on PS, so that a typical $5 \mu\text{m}$ microsphere would have a $\sigma' = -38 \times 10^{-3} \text{ C/m}^2$ (where σ' = surface charge density). This, in turn, meant that the ionogenic part of the surface would be only 1.8%. The authors concluded that, to account for observed full coverage, interactions must be mainly entropy-driven. Measured adsorption values of approximately 1.8 mg/m^2 for human serum albumin (HSA, a classic aqueous protein), and approximately 12 mg/m^2 for immunoglobulin G (IgG, a much more hydrophobic protein), indicated close-packed monolayers of adjacent HSA or protruding IgG, respectively. Likewise, Lu and Park^[7] examined protein adsorption on polymer surfaces and calculated adsorption energies. These workers looked at the adsorption of hen eggwhite lysozyme (HEWL), trypsin, an immunoglobulin, Fab, and hemoglobin on five polymer surfaces: polystyrene, polyethylene, polypropylene, poly(hydroxyethyl methacrylate), and poly(vinyl alcohol). They used an approach (later modified by Noinville et al., which will be discussed subsequently) that calculated binding energies from -850 kJ mol^{-1} to $+600 \text{ kJ mol}^{-1}$ with an average interaction energy of -155 kJ mol^{-1} ($-36.89 \text{ kcal mol}^{-1}$). These workers also cited microcalorimetric experimental data that had shown a mean net heat of adsorption of approximately 7000 kJ mol^{-1} ($1666 \text{ kcal mol}^{-1}$) for human γ -(7s)-globulin adsorbed on glass. Noinville et al.^[8] extended this work by modeling protein adsorption on polymer surfaces through a large number of initial interaction states. Protein-poly(vinylimidazole) polymer interaction energies were calculated for 2592 configurations scanning (according to the authors) the whole space of possible orientations from the bulk down to the contact with the adsorbent. Their approach assumed that the total interaction potential energy was equal to the sum of the individual pair potentials between the atoms of the protein and those of the solid surface. The protein was treated as a rigid molecule and the effect of the electrolyte solution

was accounted for by a simple distance-dependent function. For hen eggwhite lysozyme (HEWL), minimum interaction energies ranged from $-7.39 \text{ kJ mol}^{-1}$ to $+69.97 \text{ kJ mol}^{-1}$ ($-1.76 \text{ kcal mol}^{-1}$ to $+16.65 \text{ kcal mol}^{-1}$). For calcium-depleted α -lactalbumin (ALC), minimum interaction energy ranged from $-133.8 \text{ kJ mol}^{-1}$ to $+12.06 \text{ kJ mol}^{-1}$ ($-31.84 \text{ kcal mol}^{-1}$ to $+2.9 \text{ kcal mol}^{-1}$). For comparison, the experimentally measured ΔG of adsorption for Ca-depleted ALC was $-0.85 \text{ kJ mol}^{-1}$ ($-0.2 \text{ kcal mol}^{-1}$).

Song and Forciniti^[9] used Monte Carlo simulations of peptide adsorption on solid surfaces, based on the assumption that hydrophobic interactions, electrostatic interactions, and van der Waals forces are the main driving forces for protein adsorption on solid surfaces. They recognized that one of major problems encountered in the simulation of biological systems is the large number of atomic pair interactions involved. To compensate for limited simulation capability, water was treated as a dielectric continuum, and proteins were represented by reduced atomic coordinates or lattice protein models. Proteins were further assumed to have a rigid structure in solution. Computer simulation studies of protein adsorption became even more complex with the inclusion of solid surfaces. The authors concluded that protein adsorption onto hydrophobic surfaces may be entropically driven with water playing the dominant role. The argument is that release of water of hydration from the hydrophobic surface upon adsorption increases the entropy of the system. This implies that the entropy gain by the solvent is greater than the entropy loss caused by protein localization at the surface. Using Monte Carlo methods, paired correlation function (PCF) analyses showed that the solvent must be considered when adsorption phenomena are simulated. Water molecules remained trapped, even when considering adsorption of a fully ionized aspartate residue to a surface of uniform positive charge. Our own results are in agreement with much of this argument (see the subsequent discussion).

The Importance of the Solvent

The problem of including water (or other electrolyte) in the simulation is not trivial. Daura et al.^[10] addressed the question of a solvent requirement for peptide folding per se. Their results clearly showed that the solvent cannot be ignored in folding simulations and that there are significant difficulties in implicitly modeling solvent effects in an atomic interaction function for the solute. Likewise, Andricioaei and Karplus^[11] conducted a calculation of entropy from covariance matrices of the atomic fluctuations during protein folding. These authors noted that the small free energy of protein

folding (on the order of 10 kcal mol^{-1} at 300 K for many proteins) involved a near cancellation between a large decrease in enthalpy and a large decrease in entropy. A corresponding balance occurs in ligand binding so that we may assume, at least *prima facie*, that a similar balance occurs in the initial adsorption of proteins to biomaterials surfaces.

Bujnowski and Pitt^[12] studied the water structure around enkephalin near a polyethylene (PE) surface using molecular dynamics. A molecular model was constructed simulating a pentapeptide protein, leucine enkephalin, near a crystalline PE surface surrounded by explicit water molecules. A molecular dynamics simulation of the model was performed to examine the forces exerted on the protein by the surface and the water molecules. These workers used the MD software packages of Insight II[®] and Discover[®], with a simulation temperature of 298 K. The system was relaxed during an energy minimization for 300 time steps, equilibrated for another 1000 time steps, and then allowed to run for 12,000 time steps, which simulated a real time of 18 ps (at 1.5 fs time step). However, the authors locked the α carbons in place to prevent the protein from making any gross translations or rotations. The results of the simulations showed that there is a relatively strong spatial and orientational structuring of the water directly adjacent to the PE surface, and a lesser amount of structuring near the surface. This triple layer effect is, of course, familiar to students of classical electrochemical theory,^[13] but does not appear explicitly in most computer simulations. As with Daura et al.,^[10] these authors concluded that solvent interactions in the system played a key role in the proteins' behavior near a surface. This conclusion is further strengthened by the data presented by Ben-Tal et al.^[14] These workers examined the theoretical and experimental aspects of a related problem involving binding of small basic peptides to membranes containing acidic lipids. They directly measured the binding of the polypeptides lys3, lys5, and lys7 to vesicles containing acidic phospholipids in a 100 mM monovalent aqueous electrolyte. The standard Gibbs free energy for the binding of these peptides was found to be 3, 5, and 7 kcal mol^{-1} , respectively. The electrostatic free energy of interaction was considered to arise from both long-range coulombic attraction between the positively charged peptide and the negatively charged lipid bilayer, and a short-range Born repulsion. These workers considered that, in this system, each basic residue contributes approximately 1 kcal mol^{-1} to the membrane binding energy under physiological conditions. An energy minimum was achieved when approximately 2.5 Å (i.e., one layer of water) existed between the van der Waals surfaces of the peptide and the lipid bilayer, reemphasizing the importance of a proper treatment of the solvent.

The Quantum Mechanics Approach to Modeling Protein Adsorption

An example of the semiempirical quantum mechanics approach may be seen in the work of West et al.^[15] The hypothesis for the development of the study was that, to understand and predict protein adsorption behavior, it was necessary first to understand the adsorptive behavior of each individual midchain amino acid segment making up the protein. By incrementally increasing the number of amino acid residues experimentally studied and numerically modeled, the authors conceived that protein adsorption behavior itself would be eventually understood. Their model predicted direct hydrogen bonding of lysine hydrogen to oxygen of the silica substrate (modeled as a ring structure) with an average adsorption value of $-3.6 \text{ kcal mol}^{-1}$. This is approximately $4 \times$ the accepted value for an H-bond in an aqueous environment. The authors then used molecular mechanics in order to show that the helical structure of the polylysine would allow only two active amine sites per polylysine 16mer. When the % silica was reduced to reflect actual composition (from 100% to 71–74%), a calculated theoretical value of approximately $-0.34 \text{ kcal mol}^{-1}$ was developed. This value was close to the measured adsorption isotherm values of $-0.23 \text{ kcal mol}^{-1}$ for a midchain lysine residue bound to silica spheres.

Because the experimental values were obtained with polymers of lysine and molecular mechanics predicted that only one in eight residues would be able to interact with the silica surface, the interaction of a single midchain L-Lysine with the silica surface was assumed by West et al.^[15] to be approximately $8 \times$ the average value of the experimentally measured value ($8 \times -0.23 \text{ kcal mol}^{-1}$) = $-1.84 \text{ kcal mol}^{-1}$. The experimental component of this study utilized 6-, 13-, 42-, and 120-mers of poly-L-lysine in PBS at pH 7.4.

A potential difficulty with the output of the QM simulation is that this particular work predicted direct contact between the amino acid residues (in this case poly-L-lysine) and the materials surface. Based on the work discussed in the preceding section, ignoring the contributions of the solvent may be a serious error, given the dominant role of water in both the native protein conformation and the biomaterials surface structure. The interested reader is referred to Latour, Jr.^[16] for further discussions of this strategy.

Forcefield-Based Molecular Mechanics and Molecular Dynamics to Simulate Protein Adsorption to Biomaterials Surfaces in Solvent

Heuristically, it is useful to consider protein adsorption as a specialized case of protein structure–function relationships. As noted earlier, surface-mediated interactions

hold the key to most protein functions, from binding of substrate prior to catalysis, to association with specific regions of the cell membrane *in vivo*. If we assume that protein adsorption to a biomaterials surface is a subset of this larger group of phenomena, then it is quite reasonable to apply many of the existing rules of protein structure and function to protein adsorption to a biomaterial. Of course, this does not mean that the problem is simple, but rather that no new (or hidden) variables require explicit treatment *a priori* in order to accurately simulate initial adsorption events. These are still treacherous waters, especially when one begins to validate the adsorption model, as shown by the study of Daggett and Levitt.^[17] These workers developed a model of the molten globule state of a protein from molecular dynamics simulations. Simulations proceeded with 2-fs time steps up to 550 ps with *T* up to 423 K. With *T* at 423 K, the average rms displacement of α carbon from the crystal structure coordinates increased to 5.1 Å. While disulfide bonds strongly constrained the protein at high *T* ($C\alpha$ rms deviation $\sim 50\%$ higher in the reduced protein at 423 K than in the oxidized protein), some simulated displacements still were as high as 18 Å. In spite of these large simulated displacements, experimental measurement and MD modeling were in agreement with respect to the amount of secondary structure retained, and even added, at these higher temperatures. Experimental measurements showed that secondary structure content ranged from 60%–200% when the native protein was thermally denatured to the molten globule state. This was seen in the MD simulations as well. As the authors pointed out, if the amount of secondary structure were used as a measure of unfolding, both simulations and experimental techniques such as circular dichroism (CD) could conceivably show almost no unfolding at 423 K (equivalent to 150°C).

These types of data should be taken as a warning to modelers with respect to validation of simulated protein adsorption to materials. Protein biochemists generally consider that folding to the molten globule state *in vivo* is very fast (milliseconds at most), whereas attainment of proper tertiary interactions is slow. One could assume that the reverse is true as well. This would indicate that it is highly unlikely that proteins will denature past the molten globule state on biomaterials surfaces, at least during the initial adsorption phase. In all probability, the protein will assume some slightly modified version of the native tertiary structure.

Protein Adsorption: A Standardized Simulation Strategy for Molecular Mechanics/Molecular Dynamics

One goal of our current work on protein adsorption to biomaterials has been to develop a generally applicable,

standardized approach to the simulation of protein adsorption. A prerequisite for this is the use of widely available software systems so that a relatively large number of workers may compare results within a unified theoretical framework. Toward this end, a step-by-step tutorial describing our entire algorithm has been made available at www.bmes.alfred.edu.

The essential problem associated with modeling the interaction between a protein and inorganic surface is the determination of suitable interatomic potentials. For the simulation of protein structure, a number of satisfactory and proven potential functions exist. We currently use the intermolecular and nonbonded potentials known as the consistent-valence forcefield, or CVFF.^[18] The magnesium oxide surface shown on our tutorial Web site is accurately modeled in a particularly simple manner wherein the atoms are considered completely nonpolarizable with integer atomic charges of +2.0 and –2.0 for the magnesium and oxygen ions, respectively.^[19]

The challenge is that well-established potentials are not available for describing the interactions between proteins and inorganic materials. One starting point is to consider all interactions between the protein and magnesium atoms to be purely coulombic, with the interactions between the atoms of the protein and the oxygen atoms of the inorganic surface represented by Lennard-Jones potentials^[18,20] with a single oxygen parameter that serves the various interactions through a combinatorial procedure. This tactic has been applied with some success in the case of organic molecules interacting with silica-related inorganic materials, such as zeolites.^[21–23] Unfortunately, with this approach, unreasonably close binding was found to occur between the magnesium atoms and the nitrogen, carboxylate oxygen, and carbonyl oxygen within the protein molecule since the coulombic interactions are, in these cases, attractive so that short-range potentials acting between the magnesium atoms of the surface, and nitrogen and oxygen atoms within the protein, cannot be neglected.

As discussed in preceding sections, we have concluded that proper treatment of the aqueous solvent is absolutely essential for a valid simulation. Another reason to choose MgO for our adsorption study was because a great deal of effort has been invested in the simulation of the interaction between water and magnesium oxide surfaces.^[24–26] For example, the work of McCarthy et al.^[25] provides highly tractable potential functions that are fully compatible with the CVFF forcefield as well as the surface model in use. However, these researchers represented the water molecule by a rigid SPC model,^[27] which we felt was too restrictive, so we chose to use the more flexible TIP3P model of water in our work. Details of the short-range potential parameters for the magnesium oxide surface as well as

for the adjusted surface–water interactions utilized in our present study are available by using the <Bio-materials Modeling> link at www.bmes.alfred.edu or by going directly to the modeling tutorial at: http://biot.alfred.edu/%7Elewis/BPTI_WEB_1/front_page.html.

The parameters apply to a simple Buckingham potential model,^[19] which means that it is only necessary to establish the interaction potentials between the surface and the remaining protein molecule atom types. Our first approximation was to use the potential parameters for the surface–water interaction for all other forms of hydrogen and oxygen within the protein. Also, interactions with nitrogen atoms were assumed to be equivalent to those with oxygen interactions, as has been done before.^[28] Finally, all other nonbonded interactions between magnesium and the protein molecule (i.e., carbon, sulfur, and phosphorus) were treated as purely coulombic while the single, CVFF oxygen potential type was used to represent nonbonded interactions with the surface oxygen atoms.

The goal is to simulate the interaction between a single small protein molecule and an (infinite) inorganic surface, within an aqueous environment. To this end, an eight-layer, magnesium oxide system, $67.3380 \text{ \AA} \times 67.3380 \text{ \AA}$ in surface dimensions, with periodic boundary conditions, was chosen to serve as the surface. The bottom three layers of the system were fixed at their bulk positions to more fully represent the effects of an infinite bulk away from the surface. Infinite space above the magnesium oxide was modeled by adjusting the *z*-direction boundary condition so as to leave the eventual surface–protein–water system effectively uncoupled from its periodic images. A *z*-dimension of 86.8 \AA was used for this purpose. The space above the surface is where the protein and its aqueous environment were placed.

The energy of interaction between protein molecule and the surface is usually evaluated as the difference between the energies of an interacting protein–surface system and a noninteracting system (in which the protein and surface are at, essentially, infinite separation) with both systems in aqueous environments. We and others (as per the previous discussion) have found that the interaction between protein and the inorganic surface is directly mediated by the intervening water molecules. Therefore, water is explicitly included as part of the system. In our work, all the energy calculations employed a group-based direct sum method with a 14.0 \AA cutoff. Therefore, rather than completely fill the space above the surface in the simulation box with water molecules, a 15.0 \AA layer of water was used to approximate an aqueous environment. Naturally, there remained a vacuum–water boundary at which some water molecules are not within an aqueous environment at all and we would expect the energy of these to deviate slightly from bulk values. However, considerable computational expense is saved in this way.

The usual method of evaluating the energy of the noninteracting system would involve calculating the energy of a single protein molecule encased within a 15.0 \AA layer of water and adding to that the energy, calculated separately, for the surface system covered with a 15.0 \AA layer of water. The interacting system energy would then be established by evaluating the energy of the combined protein–inorganic surface system collectively coated with a 15.0 \AA layer of water. The disadvantage of this approach may be seen when the energy of the water is evaluated. The numbers of water molecules within the noninteracting and interacting systems are not automatically equivalent. Even if they were deliberately made equal, the water–vacuum interface would not be the same in the two systems. Therefore, our noninteracting system was constructed within a single periodic system as will be described subsequently.

The BPTI (Bovine Pancreatic Trypsin Inhibitor) crystal structure 6PTI was downloaded in PDF format from the Protein Data Bank: <http://www.rcsb.org/pdb/>.

The BPTI file was modified as necessary (hydrogens added, capping, pH set to 7.0, etc.) and energy minimization and molecular dynamics on the hydrated molecule were conducted using the Accelrys Discover[®] software package with the CVFF forcefield function. The minimum energy structure was then inserted into the simulation box containing the magnesium oxide surface. To create the noninteracting system, the protein molecule was placed a minimum of 20 \AA away from the surface; the remainder of the simulation box was filled with water molecules to within a minimum of 10 \AA above the uppermost segments of the protein molecule. Figure 1 shows a postminimization visualization of the simulation box. The complete pre- and postminimization simulation boxes may be viewed at: http://biot.alfred.edu/%7Elewis/BPTI_WEB_1/system_set_up.html.

This resulted in a total of 7541 water molecules being included in the system. This system was then subject to energy minimization (coupled with MD as described subsequently) to find the minimum energy of the noninteracting system. The interacting system was constructed in an equivalent way, with the periodic system containing an equal number of water molecules, but in which the protein is much closer to the surface. This system was also subject to energy minimization (coupled with MD as described subsequently) to find the minimum energy of the noninteracting system. The resulting systems both contained a single, well-defined water–vacuum boundary that is nearly identical in each case and this fact allowed for a straightforward comparison of the two. The interaction energy is then quite simply the difference between the total energies of the interacting and noninteracting systems.

The amorphous nature of the protein and water molecules requires special handling for the energy calculations. Local minimization techniques alone are not sufficient to acquire a reasonable estimate of the minimum energy of such a system. For this purpose, an improved estimate was obtained by alternating 2.0 ps molecular dynamics simulations at 320.0 K with local minimization until consistent values were achieved. Consistency was typically obtained within five iterations and the lowest energy thus obtained over five additional iterations was taken as the minimum value. Detailed results of these investigations will be published elsewhere.^[29] However, Fig. 1 shows a characteristic output from our standardized protein adsorption modeling system. The protein bovine pancreatic trypsin inhibitor (BPTI) is adsorbed to the magnesium oxide surface in water with a binding energy of $-100.5 \text{ kcal mol}^{-1}$ for this starting orientation. This minimized structure is equivalent to System_2 at: http://biot.alfred.edu/%7EEllewis/BPTI_WEB_1/results.html.

There are several instructive aspects to the output of this simulation. First, it is significant to note that the simulation accurately produces double layer waters at the highly polar MgO surface. This aqueous double layer, in turn, mediates the initial adsorption of the BPTI. Tyrosine21 in the amino acid sequence of BPTI has been identified, to facilitate analysis of Fig. 2 versus Fig. 1. The orientation of Tyrosine21 also shows

Fig. 1 Visualization of initial adsorption of the protein BPTI to magnesium oxide in pure water. This output shows one of many possible orientations of the protein relative to the surface. We have chosen to designate this as orientation number 2, which is identical to System_2 at: http://biot.alfred.edu/%7EEllewis/BPTI_WEB_1/results.html. Full materials and methods used for the simulation may be found at the linked Web pages. The protein is adsorbed to the hydrated magnesium oxide surface with a free energy of binding of approximately $-100.5 \text{ kcal mol}^{-1}$.

Fig. 2 Close-up of System_2 showing the hydrogen bond formed by Tyrosine21 of BPTI with double-layer waters bound tightly to the magnesium oxide surface. As discussed in the text, it is useful to note the clustering of protein hydrogens around the aromatic ring of this R group (hydrophobic shielding) as well as the difference in orientation of secondary hydration waters in regions of the magnesium oxide covered by the adsorbed protein versus the part of the magnesium oxide surface in contact with bulk solvent.

that even the most tightly bound residues of the protein (those within 5 Å of the material surface) initially interact through the double layer. Fig. 2 is a close-up of the region from Tyrosine21 along the MgO:BPTI interface into bulk solution. Several structure–function components of the simulation are revealed. Note the clustering of BPTI hydrogens around the aromatic ring of the Tyrosine R group. This hydrophobic shielding, in turn, allows the OH group of this residue to directly interact, presumably by H-bonding with double layer water at the surface. Therefore, in our simulations, the double layer mediates the initial adsorption event. Following the interface from adsorbed protein into bulk solution (right to left), it may be seen that, as expected, the secondary waters begin to take up positions intermediate in orientation between the protein surface and the bulk solvent while the double-layer waters remain intact. We believe that this is the first forcefield-based biomaterials modeling system to consider adequately the solvent in generating an atomistic picture of initial adsorption events. Note the emphasis on the term initial. Dramatic postadsorption rearrangement of proteins are routinely reported in the literature. Such rearrangement may certainly include direct contact and/or covalent bond formation between the biomolecule and the material surface and even changes in the chemical nature of the entire interphase region, as is known to occur with Bioglass[®].^[14]

CONCLUSION

Characterization of the structure and functionality of biomolecular–materials composites will play a key role in the development of both next-generation materials for biomedical engineering and biotechnology systems including genomics- and proteomics-enabling instrumentation. Given the importance of the problem, it is essential that standardized computer simulation software be developed that, in turn, may be used as CAD tools for the engineering of these advanced biomaterials and other devices. Based on the theoretical considerations and calculations described here, it is concluded that, conceptually, protein adsorption will be governed by the same structure–function rules that are known to apply in other areas of protein physical biochemistry. What is lacking is a seamless integration of current highly sophisticated protein and materials modeling software systems that explicitly takes the solvent into account. A brief summary of several current approaches to simulating adsorption have been presented, including efforts in the authors' laboratory to use customized commercially available software suites to simulate initial protein adsorption events.

INTRODUCTION

This article traces the milestones of how the two fields—1) proteins and cell signaling and 2) surfactants and biomaterials—converge into the new field of roles of surfactants in protein and cell signaling with biomaterials. It highlights biomedical and bioengineering importance of naturally occurring surfactants and the more established industrial, biomedical, bioengineering, and pharmaceutical applications of surfactants. It discusses the key advances in roles of surfactants in protein and cell signaling and points out the need for simpler model systems to elucidate the roles of surfactants in protein and cell signaling to facilitate new biomaterials and tissue engineering research and development. It summarizes some of the exciting new data obtained using enzymes as model systems to elucidate the effects of surfactants on protein functions and looks to the future of advances in biomaterials, biomedical and tissue engineering, and pharmaceutical research and applications once the roles of surfactants in protein and cell signaling are better defined.

HISTORICAL PERSPECTIVE AND DEVELOPMENT

We briefly discuss the biomedical importance of naturally occurring surfactants in different, better characterized physiological and cellular systems and indicate how biomedical scientists and biomedical engineers have borrowed from nature in designing biomedical, industrial, and related applications. This historical perspective allows us to pinpoint some of the developmental milestones leading to the new field of surfactant roles in protein and cell signaling with biomaterials.

Naturally Occurring Surfactants (Endogenous Biological Surfactants)

Extracellular surfactants

The better known and physiologically important extracellular surfactants include 1) bile acids; 2) lung surfactants; 3) joint/tendon lubricants; 4) certain types and fractions of extracellular matrix; and 5) microbial surfactants.

Bile Acids. These complex organic acids are synthesized in the liver from cholesterol and can be conjugated with taurine or glycine to form secondary bile acids. Bile acids play important functions in lipid digestion and absorption. These functions are attributable to the ability of bile acids to form micelles.^[1]

Surfactants of Lungs and Other Tissues/organs. A lung surfactant is a complex mixture of phospholipids (~80%), cholesterol (~10%), and proteins (~10%). This surfactant is mainly synthesized and secreted by Type II alveolar cells of the lung. Because surfactants act to lower the surface tension, the lung surfactant helps the lungs to adjust dynamically to their rates of inflation and deflation during the breathing process.^[2] Additionally, other tissues/organs are recently known to secrete surfactants: The gastrointestinal surfactant secreted by the apical epithelial cells of the gastrointestinal tract may be involved in lubricating the gastrointestinal tract; eustachian tube contains a surface tension-lowering substance; and surfactants are also detected on the surface of peritoneal, pericardial, and pleural mesothelial cells.^[2]

Joint/tendon Lubricants. Surfactants play important lubricant roles in sites in the body where tissues slide over each other with ease (e.g., tendon/tendon sheath and joints).^[3,4]

Certain Types and Fractions of Extracellular Matrix. The complex extracellular matrix material secreted by many mammalian cell types forms an intricate scaffold onto which such cells congregate and form a three-dimensional matrix.^[5] Some of the “ground material” of this scaffold show surfactant properties.^[5,6]

Microbial Surfactants. Other than mammalian cells and tissues, diverse genera of bacteria also produce a host of biosurfactants, which can act as models for the design of biodegradable and environmentally friendly synthetic surfactants and related chemicals.^[7]

Intracellular surfactants

Cytomatrix. The intracellular syntheses, assembly, and ultimately the targeting of lung surfactants for release into the extracellular space constitute an excellent model system for understanding how secretory cells make and secrete surfactants. “Surfactant phospholipids are synthesized in the type II epithelial cells of the lung. The lipids and surfactant proteins are assembled in intracellular storage organelles, called lamellar bodies, and are subsequently secreted into the alveolar space. Within this extracellular space surfactants undergo several transformations. First, the lamellar bodies unravel to form a highly organized lattice-like lipid: protein structure tubular myelin. Second, the organized structures, in particular tubular myelin, adsorb to form a lipid at the air-liquid interface of the alveoli.”^[8]

Nuclear Matrix. Unlike the metabolism and trafficking of lung surfactants in the cytomatrix prior to its secretion into the extracellular space, localization and/or function of surfactants in the nuclear matrix have not been defined. However, surfactant protein A (SP-A) was found in the nuclei of type II alveolar cells^[9] even though the role of SP-A in alveolar nuclei was unknown.

Industrial Formulations and Applications of Surfactants

Industrial applications of surfactants are widespread and economically significant; many applications involve synthetic polymers. In addition to biomedical applications, surfactants are used for paint mixing, water and wastewater treatment, hazardous waste remediation (mostly to mobilize water insoluble substances), and food processing.

Biomedical and Bioengineering Use and Applications of Surfactants

Historically, the empirical applications of surfactants in the pharmaceutical and biotechnology industries are

among the best known industrial applications. However, the molecular mechanisms underlying these applications are either the proprietary information of the companies that hold the patents for such surfactant applications or not well understood.

Biomedical uses and applications

Drug Formulation and Drug Delivery. Surfactants have been extensively employed in drug formulation. Included as pharmaceutical ingredients, surfactants have been employed as emulsifying agents, surface active agents, tablet coating agents, and tablet lubricants.^[10] Surfactants are also employed as soft contact lens cleaners.^[10]

In addition to the formation of liposomes as drug delivery device, surfactants have also been used to deliver viral vaccines,^[11] to formulate lipid microspheres to target drugs to the liver,^[12] and to target immunoliposomes to brain glial tumors.^[13] These are just a few of the numerous current examples of applications of surfactants in drug delivery.

Bioengineering uses and applications of surfactants

Protein Engineering. The traditional and well-established applications of surfactants in protein engineering are the large-scale purification of cellular proteins and solubilization of membrane-bound proteins. There are several new and exciting applications of surfactants in protein engineering. One such application involves enzyme-mediated site-specific poly(ethylene-glycol) (PEG)ylation of proteins to improve the applicability of PEG-protein conjugates for clinical use.^[14] Another new development is the reverse micellar extraction for downstream processing of proteins/enzymes in purification of proteins/enzymes.^[15] The third exciting area is to exploit the catalytic capabilities of enzymes when enzymes are entrapped in reverse micelles so that water insoluble substrates can be metabolized by the elevated enzymatic activities.^[16]

CURRENT ADVANCES IN ROLES OF SURFACTANTS IN PROTEIN AND CELL SIGNALING

As discussed in detail in a related article, recent advances in cell and molecular biology as well as biotechnology have pointed to proteins having two important roles in cell signaling, namely intercellular and intracellular roles. Furthermore, recent developments in cell and tissue engineering research also exemplify the functional and biomedical engineering importance of these two roles of proteins in cell signaling.

Roles of Surfactants in Protein and Cell Signaling: The Intercellular or Extracellular Perspective

“Protein signaling is crucial to regulate cell phenotype and thus engineered tissue structure and function.”^[17] This assertion highlights the role of protein cell signaling in phenotypic expression of cells in culture or in engineered tissue. For example, proteins adsorbed onto substrates on which osteoblasts are cultured provide the integrins on cell membranes of osteoblasts with ligands for interactions, thereby facilitating the integrins’ control of cell behavior through bidirectional signaling pathways.^[18] Another example is the dependence of the phenotypic expression of human chondrocytes on the structure of the biomaterial substrate on which the chondrocytes are cultured.^[19] Thus, depending on the chemical nature of the biomaterial substrate and substrate interaction with focal adhesions on the chondrocytes, the chondrocytes can develop either differentiated or dedifferentiated phenotypic characteristics.^[19] Although protein–protein and protein–substrate interactions are instrumental in cell signaling, the roles of surfactants in mediating these signaling protein interactions have not been fully elucidated.

Even though the roles of surfactants in protein and cell signaling are at present poorly defined, one may use the example of the better-characterized lung surfactant to deduce such putative roles of surfactants. A lung surfactant is a macromolecular complex containing mainly phospholipids and proteins (~10% of lung surfactant weight). There are four main surfactant-associated proteins: SP-A and SP-D are hydrophilic proteins, whereas SP-B and SP-C are hydrophobic proteins.^[2,20] Lung surfactants are synthesized by type II epithelial cells lining the alveoli and stored in lamellar bodies (which are typical intracellular inclusion bodies). The secreted, alveolar form of the surfactant is a complex mixture of lamellar bodies, tubular myelin (which are very organized structures), and monolayered and multilayered, phospholipid-rich sheets and vesicles.^[20] “The multiplicity of these structural forms is influenced by the stoichiometry of lipids and specific proteins, by mechanical forces exerted on the material during the respiratory cycle, and by the uptake, recycling, and degradation of subgroups of particles by respiratory epithelial cells and alveolar macrophages. Alveolar macrophages regulate catabolism of both lipids and proteins—activities that are under strict control of the signaling of granulocyte-macrophage colony-stimulating factor (GM-CSF).”^[20]

As the preceding summary by Whitsett and Weaver^[20] clearly indicates that although the underlying cellular and molecular mechanisms are far from being fully characterized, the secreted lung surfactant phospholipid and protein components play vital signaling

roles in their interactions with each other in the respiratory cycle. Furthermore, the signaling of GM-CSF also regulates the metabolism of and interactions between the components of the lung surfactant (i.e., phospholipids and proteins).^[20] Thus, it is conceivable that other surfactants secreted into the extracellular space (e.g., the gastrointestinal surfactant and joint/tendon lubricants) may share protein and signaling mechanisms similar to those of the lung surfactant.

Roles of Surfactants in Protein and Cell Signaling: The Intracellular Perspective

Even though the evidence for the extracellular roles of surfactants in protein and cell signaling is scant, from the better characterized example of the lung surfactant one can at least derive some generalizable principles as to how surfactants may play roles in protein and cell signaling. In contrast with the extracellular roles of surfactants in protein and cell signaling, the evidence for the intracellular roles of surfactants in protein and cell signaling is even more tenuous. Nevertheless, one can again look to the better-characterized lung surfactant as an example for some mechanistic clues. Both SP-B and SP-C are synthesized in alveolar type II cells as much larger precursor proteins, transported from the endoplasmic reticulum to the Golgi apparatus, then incorporated into multivesicular bodies, and ultimately packaged in lamellar bodies where the active SP-B peptide is stored with SP-C and surfactant phospholipids.^[20] Subsequently, the contents of lamellar bodies are secreted into the extracellular air space, and they interact with SP-A to form tubular myelin.^[20] During the transit from multivesicular bodies to lamellar bodies, both precursor proteins are proteolytically cleaved to form the corresponding SP-B and SP-C.

It is important to note that SP-B is crucial to the proper proteolytic cleavage of the SP-C precursor to form SP-C, the organization of surfactant phospholipids in lamellar bodies, the formation of tubular myelin in the alveolus, and the production of surfactant films that are able to reduce surface tension.^[20] From our knowledge of the intracellular protein and phospholipid trafficking in secretory cells, it is evident that multiple signaling pathways/mechanisms are involved in the transfer of proteins and phospholipids from the endoplasmic reticulum to the Golgi apparatus prior to the exocytotic release of these macromolecular complexes. Consequently, although the signaling mechanisms for the SP-B and the SP-C trafficking from the endoplasmic reticulum to the Golgi apparatus per se have not been fully elucidated, one could reasonably infer the possibility that some signaling pathways/

mechanisms are likely to regulate such intracellular processes.

Need for Simpler Model Systems to Elucidate the Roles of Surfactants in Protein and Cell Signaling

As discussed in the previous sections, evidence is accumulating for the fact that surfactants likely play some roles in protein and cell signaling. However, it is important to emphasize that it is imperative to understand surfactant–protein interactions in molecular and biophysical terms prior to assigning which surfactant–protein interaction could lead to a particular form of cell signaling. Consequently, it is noteworthy that to elucidate the molecular details of surfactant–protein interactions, one needs to design more simplified model systems whereby one could systematically investigate surfactant–protein interactions under vigorously controlled experimental conditions. To address this need, we have employed enzymes as model proteins to systematically investigate surfactant–protein interactions (see the following section).

PROTEIN AND CELL SIGNALING WITH BIOMATERIALS: INFLUENCE OF SURFACTANTS

Surfactants can drastically affect the functions of many proteins, thereby directly or indirectly influence functions of membranes, cells, and organs. Numerous studies have purportedly elucidated the effects of surfactants on cells or membrane-bound proteins. Those studies employed heterogeneous or complex systems that contained many macromolecular structures and/or organelles. Consequently, it is difficult to extrapolate the results of such studies to delineate the effects of surfactants on single proteins. Thus, predicting how surfactants affect cellular protein functions (e.g., enzymatic activity or transport) with existing knowledge is nearly impossible.

Surfactant Effects on Protein Functions

Limitations of previous studies in this area

Historically, there have been many studies on surfactant effects on protein functions using enzymes as model proteins in the biochemical literature. However, most of such earlier studies focused on employing surfactants to release enzymes from their membrane-bound or membrane-associated sites or using surfactants to aid enzyme purification process. Thus, few, if any, of such studies were primarily aimed at a

systematic investigation of the effects of a variety of surfactants on protein functions.

Among model proteins, lactate dehydrogenase (LDH) has been extensively characterized. Many of its catalytic properties and kinetic constants are established. Thus, LDH is an excellent model protein for elucidating the effects of surfactants on protein functions.^[21] Although there have been several studies on the effects of cationic and anionic surfactants on the catalytic activity of purified LDH, most of these studies employed either comparatively narrow ranges of surfactant concentrations,^[22–24] or a very few surfactant concentrations but with a diverse group of cationic and anionic surfactants.^[25] Clearly, even for a well-characterized protein such as LDH, there is a need for systematic and comprehensive studies on the effects of surfactants on its function.

Need for comprehensive and systematic studies to elucidate surfactant effects on protein functions

A systematic understanding of how surfactants affect enzymes is important because many of our body functions or cell signaling are directly or indirectly modulated by naturally occurring surfactants. Our simplified approach of employing enzymes as model proteins allows us to systematically elucidate surfactant effects on protein functions.^[21] Through this approach we can monitor enzymatic activities when enzyme proteins are exposed to surfactants under different but more vigorously controlled conditions thereby permitting us to gain more insights into the dynamics of surfactants' interactions with functionally important enzymes and other proteins. Consequently, the results from studies employing this experimental approach will facilitate better designs of systems of enzyme reactors^[15,26,27] and have important practical implications and applications in protein and tissue engineering^[28,29] as well as drug targeting and delivery in pharmaceutical research and development.^[30,31]

We have selected three well-characterized and metabolically important enzymes—glutamate dehydrogenase (GDH), LDH, and malate dehydrogenase (MDH)—as model proteins to examine the effects of surfactants on protein functions (especially catalytic activity) and on protein transport (see section “Surfactant Effects on Protein Interfacial Transport Across a Semipermeable Membrane”). We have studied anionic surfactants with decreasing hydrophilicity (IB-45, MA-80-I, OT-75, and TR-70) and a small-molecular-weight cationic surfactant (c-573). As a “standard” for comparison with results obtained using these surfactants, we have conducted similar studies with the well-characterized nonionic surfactant, Triton X-100.

Effect of various surfactants and pH on LDH activity

When LDH is exposed to the anionic surfactants IB-45, MA-80-I, OT-75, and TR-70 (in increasing order of hydrophobicity) at pH 6.95, its activity exhibits bands of surfactant concentration dependence, with the most hydrophobic TR-70 exerting the most inhibitory effect (Fig. 1).

At concentrations below or near 1 ppm, Triton X-100 (a nonionic surfactant) exerts an inhibitory effect on LDH activity similar to those induced by the anionic surfactants investigated (Fig. 1). However, between 1 and 10 ppm, Triton X-100 slightly depresses LDH activity (from 15% to 4% depression). Between 50 and 500 ppm, Triton X-100 actually induces increases in LDH activity, with the maximum increase to 120% at 150 ppm (Fig. 1). Thus, the concentration-related effect of Triton X-100 on LDH activity at pH 6.95 is different from those induced by the anionic surfactants on LDH.

These results (Fig. 1) indicate that prediction of changes in enzymatic activities with respect to surfactant concentration is impossible without detailed experimental observations. Moreover, the direction of changes in enzymatic activity induced by a surfactant is just hard to predict even though most enzymatic activity fluctuations are noted with surfactant concentrations less than 10 ppm (Fig. 1).

In general, a systematic pH dependent pattern in LDH activity with various surfactant concentrations is not clearly evident (data not shown). Nevertheless, surfactant concentration-related LDH activity at pH 6.5 is generally lower than the corresponding values at the two higher pHs (6.95 and 7.4), especially at surfactant concentrations less than 10 ppm (data not shown).

Fig. 1 Effects of surfactants on LDH activities at pH 6.95. (From Ref. [21].)

Moreover, LDH activity is usually higher in the presence of the hydrophilic surfactant IB-45 than those in the presence of the hydrophobic surfactant TR-70. For the hydrophobic surfactant TR-70, the pattern of pH-related changes in LDH activity at various surfactant concentrations is quite different from those noted for IB-45 and Triton X-100 (data not shown).

Effects of hydrophilic and hydrophobic surfactants on enzymes of various molecular masses

For GDH, the enzyme with the largest molecular mass among the three enzymes examined, its activity is the most stable in the presence of the hydrophilic surfactant IB-45 (Fig. 2). Glutamate dehydrogenase activity varies between 84% and 104% of control values at IB-45 levels below 10 ppm (Fig. 2). When IB-45 levels increase, GDH activity exhibits surfactant-related decreases and is about 47% of the control activity at 5000 ppm of IB-45, at which IB-45 concentration, the LDH activity also shows about the same activity. Interestingly, as GDH activity commences to show surfactant concentration-related decreases, LDH and MDH (MDH, the enzyme with the lowest molecular mass among the three enzymes examined) activities show a “step up” when the IB-45 concentrations are higher than 10 ppm; LDH and MDH activities are 101% and 76%, respectively, of the corresponding control values at 50 ppm of IB-45. It appears that, MDH, the enzyme with the smallest molecular mass, exhibits more distinctive bands of activity changes with increasing concentration of IB-45 (Fig. 2). As the molecular mass of the enzyme increases, the enzymatic activity varies less unpredictably with increasing IB-45 concentrations.

Fig. 2 Effects of surfactants on different sizes of enzymes at pH 6.95 in IB-45 (hydrophilic surfactant). (From Ref. [21].)

Both smaller mass enzymes (i.e., LDH and MDH) behave similarly in the presence of the hydrophobic TR-70. At TR-70 levels lower than 10 ppm, LDH and MDH activities show almost linear decreases with logarithmic increases in the TR-70 concentration. Similar to the effect of IB-45 on GDH, GDH activity is not significantly affected by the hydrophobic TR-70 until the surfactant concentration is higher than 10 ppm, at which point GDH activity shows TR-70 concentration-dependent decreases and is drastically decreased at TR-70 levels higher than 1000 ppm.^[21]

The effects of the nonionic Triton X-100 on the three enzymes of different molecular masses are somewhat the reverse of those noted with the hydrophobic surfactant TR-70, especially at concentration above 10 ppm. Generally, the presence of Triton X-100 tends to enhance enzymatic activities; however, its effect on GDH activity is minimal. Although there are some decreases in activities of the enzymes at Triton X-100 levels less than 10 ppm, MDH and LDH activities are actually more than 100% at Triton X-100 concentrations between 50 and 1000 ppm.^[21]

As one might predict, the activity behavior of LDH (whose molecular mass is midway between those of MDH and GDH) is usually between that of the enzyme with the smallest molecular mass (i.e., MDH) and that of the enzyme with the largest molecular mass (i.e., GDH).^[21]

Time course of LDH activity in the presence of a hydrophilic, a hydrophobic, or a nonionic surfactant at pH 6.95

In the presence of the hydrophilic surfactant IB-45, LDH activity does not markedly change with time. In general, LDH activity tends to decrease in a surfactant concentration-dependent and a time-dependent manner although the decreases in activity beyond the first 60 min of exposure to IB-45 are modest.^[21]

The time course of LDH activity at pH 6.95 varies depending on the concentration of the hydrophobic surfactant TR-70 (Fig. 3). At TR-70 levels lower than 10 ppm, LDH activity does not markedly decrease after the first two hours. However, at TR-70 levels higher than 10 ppm, LDH activity shows a wider range of time-related decreases (Fig. 3), a range much bigger than that exhibited by LDH exposed to the hydrophilic IB-45.^[21] At TR-70 levels higher than 500 ppm, LDH becomes totally inactive.

In the presence of Triton X-100 (a nonionic surfactant), LDH activities show surfactant concentration-dependent and time-dependent variations that are similar to those observed with LDH exposed to the hydrophobic TR-70, with the largest range of 42%. However, unlike the effect of TR-70 on LDH activity, Triton X-100 tends to induce increases in LDH activity

Fig. 3 Lactate dehydrogenase activities with various surfactants over time at pH 6.95 in TR-70 (hydrophobic surfactant). (○) 0.05 ppm, (▽) 0.1 ppm, (◇) 0.5 ppm, (×) 1 ppm, (+) 5 ppm, (Δ) 7 ppm, (●) 10 ppm, (◆) 50 ppm, (—) 100 ppm, (□) 500 ppm, (◁) 1000 ppm, (▷) 5000 ppm. Average relative error of each datum was $<\pm 10\%$. (From Ref. [21].)

with exposure time.^[21] Thus, the findings summarized above suggest that hydrophilic and hydrophobic anionic as well as nonionic surfactants exert dissimilar concentration-related and time-dependent effects on LDH activity.

Effect of a low-molecular-weight cationic surfactant (c-573) on activities of enzymes of different molecular masses at pH 6.95

As discussed above, the generalization that surfactants tend to exert a stabilizing effect on enzymes with larger molecular mass (e.g., GDH) is also valid for depicting the effect of a low-molecular-weight cationic surfactant (c-573) on enzymes of different molecular masses (data not shown). At concentrations below 100 ppm, c-573 tends to induce an enhancement of GDH activity relative to this surfactant's effect on LDH and MDH whose molecular masses are lower than that of GDH. As c-573 concentration exceeds 100 ppm, GDH activity gradually becomes inhibited, similar to the inhibitory effect of this surfactant on LDH and MDH. In general, the smaller the enzyme protein molecule, the more the fluctuation of its activity for the range of surfactant concentration tested.

Comparison of effect of surfactants with different charges on LDH activity at pH 6.95

When LDH activity monitored in the presence of a hydrophilic anionic surfactant (i.e., IB-45) is compared

to that monitored in the presence of a low-molecular-weight cationic surfactant (c-573) at the same concentration range, it is evident that both types of surfactant show similar inhibitory effects on LDH activity except that at levels below 1 ppm the c-573-concentration-dependent variations in LDH activity are less marked compared to the corresponding variations in LDH activity in the presence of IB-45 (data not shown). At levels between 1 and 10 ppm, the inhibitory effect of c-573 on LDH is less pronounced compared to that of IB-45 (data not shown).

Surfactant Effects on Protein Interfacial Transport Across a Semipermeable Membrane

Surfactants can induce an increase or inhibit the permeation rate of proteins across semipermeable membranes, thereby directly or indirectly exert some control of cell signaling. We have employed a U-Tube separation cell to study the effects of surfactants with various hydrophilicities on LDH permeability across a 10- μm thick polycarbonate membrane with 1- μm pores.^[32] We summarize and discuss some of our findings as follows.

Effects of anionic and nonionic surfactants on permeation LDH through a semipermeable membrane at pH 6.5, 6.95, and 7.4

To simulate the intracellular conditions in which the functions of cells can occur with the two extremes of intracellular pH, namely between pH 6.5 and 7.4, we have carried out experiments at pH 6.5, 6.95, and 7.4. We monitored the appearance of LDH in the left half-cell at various times after the enzyme had been administered into the right half-cell.

At pH 6.5, the solution without any added surfactant allows the least amount of LDH to permeate the left half-cell, whereas the solution containing the most hydrophilic surfactant (namely, IB-45) allows most LDH to permeate but the solution containing the

Fig. 4 Permeation of LDH in the presence of various surfactants with 10 mM of phosphate buffer. Membrane pore size 1 μm , surfactant concentration at the right side is 0.1 ppm at pH 6.5.

nonionic surfactant (Triton X-100) is the least effective in promoting LDH permeation (Fig. 4). Interestingly, the results obtained at pH 7.4 are exactly in the reversed order: The solution without surfactant allows the highest amount of LDH permeation through the membrane; the solution containing IB-45 allows the least amount of LDH permeation; and among the solutions containing different surfactants, the solution containing Triton X-100 is the one that exerts the least “inhibition” of LDH permeation.

At pH 6.95, which is the normal intracellular pH for most mammalian cells, solutions containing surfactants allow higher LDH mass permeation than the solutions without surfactants do. At this pH, solutions containing hydrophilic or nonionic surfactants are more effective than other surfactant-containing solutions in enhancing LDH permeability. Table 1 lists the permeabilities of LDH determined in some of our experiments.

Table 1 Permeabilities (cm/sec) of LDH with various surfactants and pHs through the 10- μm thick polycarbonate membrane

	pH 6.5	pH 6.95	pH 7.4
IB-45	9.15E-05	1.89E-04	3.25E-05
MA-80-I	5.94E-05	1.66E-04	3.37E-05
OT-75	5.91E-05	7.02E-05	3.94E-05
TR-70	4.13E-05	7.63E-05	3.50E-05
Triton X-100	3.21E-05	1.01E-04	5.01E-05
No surfactant	1.03E-05	7.86E-05	5.44E-05

Surfactant concentration was 0.1 ppm.

CONCLUSIONS

This article traces the milestones of how the two fields—1) proteins and cell signaling and 2) surfactants and biomaterials—converge into the new field of roles of surfactants in protein and cell signaling with biomaterials. It highlights biomedical and bioengineering importance of naturally occurring surfactants and the more established industrial, biomedical, bioengineering, and pharmaceutical applications of surfactants. It discusses the key advances in roles of surfactants in protein and cell signaling and points out the need for simpler model systems to elucidate the roles of surfactants in protein and cell signaling to facilitate new biomaterials and tissue engineering research and development.

We have selected three well-characterized and metabolically important enzymes—GDH, LDH, and MDH—as model proteins to examine the effects of surfactants on protein functions (especially catalytic activity) and on protein transport.

There is no generalizing trend about the pH effect on the surfactant concentration dependence of the activity of enzymes of different molecular masses. Functional changes of enzymes (e.g., enzymatic activity) are dependent on time of exposure to the surfactant, surfactant concentration, and hydrophilicity of the surfactant. As a factor, pH modulates enzymatic activity only when enzymes are exposed to selected surfactants.

Surfactants appear to exert a “stabilizing effect” on enzymes of larger molecular mass (e.g., GDH). The activity of such an enzyme is less affected by pH, surfactant hydrophilicity, or surfactant concentration. Activity of enzymes of larger molecular mass is more predictable with variation of the concentration of surfactant employed. There are no sudden swifts of enzymatic activity with small changes of surfactant concentration. For an enzyme of smaller molecular mass (i.e., MDH), there are sudden swifts of enzymatic activity at low surfactant concentrations (less than 10 ppm). In general, enzymes are more active in hydrophilic than in hydrophobic surfactants. This difference in enzymatic activity is more prominent at high surfactant concentrations.

Triton X-100, a nonionic surfactant, generally induces increases in enzymatic activities, usually at a concentration higher than 10 ppm. The enhancement in enzymatic activity is less than 50%.

Surfactant effects in modulating activities of enzymes critically depend on contact time with surfactants. Thus, any comparisons of activity of enzymes exposed to a surfactant must take into account the time factor.

Caution must be exercised when using enzymatic activities to calculate mass balance for enzymes, especially in the presence of surfactants and when time is a variable during enzymatic assays. Thus, because of these other factors, changes in the activities of enzymes may become nonlinear with mass calculation.

Anionic and nonionic surfactants have definite effects on permeability of enzymes through semipermeable membranes. Their effects are dependent on surfactant hydrophilicity and are not linearly related to pH.

Until the structures of protein enzymes are known, it would be difficult to investigate the mechanisms of how these proteins interact with surfactants. However, we observed that increase of ionic surfactant concentrations exerted bands of activity suppressions to enzymes, and increase of nonionic surfactants at high concentrations slightly enhanced enzyme activities. We speculate that the enzyme active sites are charged; therefore, charged surfactants would tie up (bind with) the active sites and inhibit the catalytic reactions of enzymes. As the concentration of surfactants increases to certain level, surfactants reconfigure the orientation of enzymes thus create bands of activities of enzymes. For nonionic surfactants, we speculate that the surfactant actually “relaxes” the enzymes to expose more active sites, or it captures the reactive species (pyruvate, for example) and creates a high reactive site with enzymes, similar to the surfactant effect in photocatalytic reactions.^[33]

Results from ongoing studies on surfactant effects on protein functions employing enzymes as model proteins indicate that such simpler experimental systems allow us to investigate systematically the interactions between surfactants and proteins at the molecular level. Such studies will further our understanding of the surfactant–protein interactions, ultimately leading to the elucidation of the roles of surfactants in protein and cell signaling with biomaterials. Moreover, this type of fundamental studies will make significant contributions toward cell and tissue engineering, drug formulation and targeting, and water/waste water treatment.

INTRODUCTION

This article traces how the field of protein and cell signaling with biomaterials originated from the biomedical research on protein and cell signaling to the current advances in biomaterial design and its applications in cell and tissue engineering. Despite the paucity of relevant data in the literature on this subject, this entry identifies the importance of interfacial transport in protein and cell signaling and reports on some fundamental studies concerning interfacial protein transport. It discusses some of the key thermodynamic, kinetic, and molecular properties of a novel membrane system for protein transport. It highlights many application areas of interfacial protein transport, including, but not limited to, development of new techniques for drug separation; improved, more efficient apparatus design for dialysis; engineering applications in water and wastewater treatment; and applications in artificial organs and cell and tissue engineering.

HISTORICAL PERSPECTIVE AND DEVELOPMENT

This introductory section traces the origin of the field of protein and cell signaling with biomaterials from the biomedical research on protein and cell signaling to the current concepts in biomaterial design and their applications in tissue engineering. Ultimately, this historical perspective highlights how interfacial transport plays an important role in protein and cell signaling with biomaterials.

Protein and Cell Signaling

The development of cell and molecular biology has led to the elucidation of two roles of proteins in cell signaling—intercellular and intracellular. In intercellular signaling, the coupling of specialized proteins in membrane dynamics is involved in cell-to-cell recognition,

adhesion, and signaling; this intercellular protein signaling also plays an important role in apparently unrelated but physiologically significant cell fusion functions, such as phagocytosis, cell migration, axonal growth, and synaptogenesis.^[1] Among the key factors of the extracellular environment influencing these cell-to-cell protein signaling functions are pH, ionic strength, and extracellular matrix. On the other hand, intracellular signaling implicates plasma membrane-bound proteins (e.g., receptors, transporters, membrane-bound or membrane-associated enzymes), which transmit a series of signaling cascades within cells resulting in, for instance, intracellular protein trafficking and/or alterations in regulation of gene expression.^[2] This membrane mechanism highlights the importance of transmembrane events including, but not limited to, ligand–receptor interaction and interfacial transport (or transport through membrane pores and ion channels). This type of intracellular protein signaling can be influenced by changes in intracellular environment, such as the changes in intracellular pH and ionic milieu, resulting in alterations in binding capacities and other molecular properties of intracellular protein signals. Such changes in intracellular protein signals are ultimately responsible for controlling intracellular protein trafficking and gene expression.

Biomaterials scientists and biomedical engineers have exploited the understanding of the extracellular and intracellular roles of proteins in cell signaling in biomedical engineering research and development (see below). However, there has been a paucity of systematic studies to elucidate how extracellular and intracellular milieu exerts effects on protein signals at the molecular level (see below).

Protein and Cell Signaling with Biomaterials

Biomaterials and tissue engineering research and development

Advances in biomaterials have exploited different aspects of protein and cell signaling. An important area

where this knowledge is applied is in drug formulation and drug delivery. For example, a protein drug (e.g., trastuzumab) that targets to cancer cells recognizes surface receptors on cancer cells. As a result of this recognition of surface receptors on the cancer cells, the protein drug can interact with the cancer cells and leads to killing of the cancer cells (see Ref. [3] and references therein). Another example is artificial bone/joint design, in which the biologically competent and compatible integrins (i.e., cell adhesion proteins) are used as linker proteins between osteoblasts and bone replacing materials.^[4] This tissue engineering example is based on new knowledge of how the integrins control cell behavior through bidirectional signaling mechanisms/pathways.^[4] Similarly, other applications of protein-based signaling include, but are not limited to, the manipulation of cell signaling employing growth factors and peptides in tissue engineering, whereby the damaged tissues are replaced using either transplanted or host cells.^[5]

Despite significant advances in biomaterials and tissue engineering, there are methodological issues that preclude the design of new and fully biocompatible biomaterials employed in cell and tissue engineering. These methodological issues revolve around the central question of “biocompatibility.” To more adequately address the more global aspects of biocompatibility, researchers have focused their attention on enhancing their understanding of: 1) protein and cell interactions with biomaterials; 2) protein and cell signaling with biomaterials; and 3) more biocompatible biomimetic.^[6–8] (A detailed discussion of these topics is, however, beyond the scope of this entry.)

Protein and cell interactions with biomaterials

Earlier, biomaterial scientists, biochemists, and biomedical engineers had focused their attention on broad biocompatibility issues by addressing protein conformational considerations, as proteins interact with biomaterial surfaces. Even then, researchers conjectured that to really understand protein and cell signaling with biomaterials, one must get down to the more fundamental level of being able to understand what are the molecular interactions between a protein and the surface it adsorbs to, and the conformational changes of the protein as it adsorbs to the same surface.

As extensively discussed by Lu, Kadambi, and Lai, proteins in solution assume one of two different secondary structures, i.e., the α -helix or the β -sheet (or some combination of the two structures), depending on the number and the type of amino acids that constitute the proteins.^[9] For a protein in bulk solution, its conformation is determined by the internal

stabilization forces, including hydrogen bonding, hydrophobic interactions, electrostatic interactions, dispersion forces, and conformation entropy (see Ref. [9] for a detailed discussion). Molecular modeling of the interaction potential, hydrophobic interactions, and conformational changes has been employed to determine the conformational changes of a protein adsorbed onto a surface.^[9] Thus, molecular modeling and various experimental approaches have been used to elucidate how the conformational changes of a protein, as it adsorbs onto a surface, play a role in the protein's interaction with the surface, thereby imparting the signaling function of the protein (see Ref. [9] for a detailed discussion). The nature of the biomaterial surface (e.g., its hydrophobicity or hydrophilicity) determines how the protein, on adsorption onto the surface, interacts with the surface.^[9] From the results of these earlier studies emerges the notion that this protein–surface interaction determines the way the protein functions as a signaling molecule. Furthermore, these earlier studies pointed to the fact that there is a need for new mechanistic studies to further elucidate the binding characteristics and interactions of the adsorbed protein with cells at the solution–material interfaces.^[9]

Importance of interfacial transport in protein and cell signaling with biomaterials

As alluded to above, recent advances in protein and cell signaling with biomaterials have emphasized on functions of cell surface proteins but very few studies have addressed interfacial transport of proteins in this context.^[3–5] Nevertheless, earlier studies on interactions of adsorbed proteins with cells clearly suggested an important function for interfacial transport in protein and cell signaling with biomaterials.^[9] Consequently, any studies to elucidate mechanisms underlying interfacial transport of proteins will shed new light on protein and cell signaling with biomaterials.

INTERFACIAL TRANSPORT

Introduction

Biological interfacial transport must involve some kind of membrane barrier. Incidentally, membrane research and applications are technologies identified by the National Science Foundation (NSF) and the Department of Energy as the emerging technologies of the future.^[10] Recent developments in nanotechnologies broaden the applications of membrane science even faster. Armed with a better understanding of surface phenomena and science, membrane researchers are

exploring many applications that were overlooked previously, especially in biomedical fields. Thus, the newly formed biomedical research and engineering division at the National Institutes of Health (NIH) has targeted nanotechnology as one of its main programmatic emphases; evidently, this strategy was directed, in part, to address the gaps in membrane research applications in the biomedical engineering field. Because of the complex nature of membrane phenomena, both NSF and NIH have advocated that any research and applications of membrane sciences have to adopt an interdisciplinary approach and strategy.

As most of our bodily functions are dependent on the interactions of various membrane systems, a better understanding of how the selectivities and permeabilities of biomolecules and drugs across these membranes are controlled allows biomedical researchers and bioengineers to come up with improved designs of membrane systems, such as those in hemodialysis and detoxification of body fluids. Similarly, the pharmaceutical industry can greatly exploit this technology in varieties of chemical separations they routinely carry out.

Both the NSF and the NIH have recently emphasized the importance of membrane-associated phenomena and the underlying biophysical and molecular mechanisms. While most previous and current research directions in this field are concerned with the transport of chemicals across the membranes, very few studies address the transfer across membranes of macromolecules, such as enzymes and other proteins, because most studies have focused on the transfer of small molecules (e.g., sugars, amino acids, and small-molecular weight drugs).

Membrane research has been conducted by diverse investigators for some time, especially in the biomedical sciences.^[11-14] A substantial number of reports can be found in the literature about liquid membrane systems, mostly in the biological sciences.^[13-16] However, most of these observations were based on limited data employing biological systems, which are heterogeneous and contain multiple, complex experimental variables. Consequently, these reports are mainly statements of facts or qualitative descriptions of phenomena; few fundamental physical and thermodynamic properties and related principles can be deduced from such observations because of the complexity of their membrane systems, which invariably contained very heterogeneous biological membrane components.

On the other hand, most of the membrane research in the engineering domain in the past emphasized on industrial applications, such as purification of gaseous mixtures, desalination of brackish water, and food processing.^[17]

In the past, many research groups (e.g., those located at the University of Texas at Austin, McMaster University, University of Ottawa, and University of

Colorado at Boulder) concentrated their research efforts on membrane formulation and industrial applications. More recent development of nanotechnology expands the traditional membrane research to include more explorations in biomedical applications.

Up to now, the literature on surface phenomena and behavior and on thermodynamic properties of membranes is scant. The exceptions are the contributions of the group led by Martin and Mitchell, and Nishizawa, Menon, and Martin, who have pioneered the method of creating conductive membrane mesh by electrochemical deposition and have begun to quantify transport properties of the unique membrane(s) they designed.^[18-21] On the other hand, information on protein transport across semipermeable membranes is nearly nonexistent.^[22]

To understand how proteins are transported intercellularly and intracellularly, and how these transport mechanisms are functionally coupled to cell signaling, we must gain more fundamental insights into the thermodynamic properties that are the driving forces of these transport mechanisms. In general, because biological membrane systems usually contain a heterogeneous, multifunctional mixture of membrane components (e.g., membranes of different sizes, shapes, density, and chemical composition) and subsystems, it is impractical and methodologically difficult at this time to try to harness such multicomponent mechanisms all at once in a multicellular system design. Thus, it would be more realistic to investigate the thermodynamic properties of interfacial transport employing a simple, more homogeneous membrane system in which the experimental conditions can be much more vigorously controlled, and the environmental factors and other test parameters can be evaluated one at a time. Through the latter approach one can construct a comprehensive picture of the transport properties of biomaterials of interest.

Current Applications of Interfacial Transport

A comprehensive review of applications of interfacial transport in biomedical engineering, environmental engineering, and biotechnology is beyond the scope of this entry. Nevertheless, it is important to briefly point out some of the rapidly growing areas where applications of interfacial transport are making significant inroads and contributions.

Critical issues in applications of interfacial transport in artificial organs and tissue engineering

Although the idea of creating artificial organs dated back several decades, development of functionally competent artificial organs is still in its infancy except

for the development of the artificial kidney. As indicated above (in the section “Biomaterials and Tissue Engineering Research and Development”), the successes of a designed artificial organ and an engineered tissue critically depend on the ability to engineer biomaterial surfaces that specially target certain functionally important and biocompatible protein–ligand interactions and signaling cascades to achieve a strategy for optimizing cellular responses in biomaterials and tissue engineering applications.^[3–5] Furthermore, implicit in the latter assertion is the implication that success in artificial organ and tissue engineering design is equally contingent on a strategy to optimize interfacial transport of biomolecules. For example, from the functional point of view of designing and manufacturing artificial organs, it is imperative to have a fundamental understanding of the transport properties between the organ surface/membrane and the blood vessels that supply the organ with oxygen and nutrients.^[23] In other words, we must have a good understanding of the transport properties between the cell membranes of the organ and the blood vessels. Therefore, the development of artificial membranes (which allow the systematic investigation of such transport phenomena) becomes the forefront of research and development of artificial organs.

There are two important aspects of the development of artificial membranes we must resolve—the mechanistic and the functional aspect. In the last decade or so, several research groups have been working on the first aspect: the most advanced artificial membranes are currently made from polymer(s) and metal composite.^[24–26] However, the functional aspect of the development of artificial membranes is yet to be addressed.

What appears to hold up the advances in the functional aspect of the development of artificial membranes can be traced to two critical issues. First, the membrane properties of organs vary depending on their functions and there is no single artificial membrane—for that matter even a series of artificial membranes—that can represent all organ surfaces/membranes. Second, our body fluids are very complex heterogenous systems and contain multiple, chemically dissimilar components. Consequently, the transport of components in our body fluids across organ membrane systems is very complex and is very difficult to simulate employing artificial membranes. Hence, we must resolve these two critical issues before significant strides can be made in research and development of artificial organs and tissue engineering.

Applications of interfacial transport in water and wastewater treatment

There are discharges of industrial hormones from the dairy and poultry industries, excretions of vitamins and

enhancement hormones from humans in sewer systems, and discharges from the pharmaceutical industry. This new category of contaminants (which are quite unlike the traditional humic materials that perpetually exist in most of the surface waters and wastewaters) mainly comprises small molecular weight protein and other organic molecules. These organic contaminants eventually find their way into our water supply systems. As recycling of spent water for potable use is becoming a reality, the understanding of how these organic molecules affect our water treatment processes is becoming important, especially for the emerging contaminants, such as antibiotics and steroid hormones; treatment standards for these organic compounds are soon to be realized.^[27] As most of these molecules exist in rather low concentrations ($<10^{-6}$ M) and in soluble forms, treatment and removal of these molecules are more difficult than that of the suspended solids. Artificial membranes can be used to remove these soluble biomolecules. Thus, a better understanding of interfacial transport of biomaterials can help develop more efficient water and wastewater treatment systems.

Interfacial Transport Across a Membrane

Before examining how one can study interfacial transport across a membrane, one needs to be cognizant of some basic definitions and theoretical considerations in this field.

Some basic definitions and theoretical considerations

Flux of i component across a membrane can be defined by:

$$F_i^0 = L_{ii}^0 \phi(\Delta G_i) + \sum_j L_{ij}^0 \phi(\Delta G_j) \quad (1)$$

The first term represents the driving force of the i th component, which is a function of free-energy difference across the membrane and the phenomenological flux coefficient (L_{ii}^0) and includes the diffusion coefficient and others. The second term represents the coupled flow of component i with other components and their phenomenological flux coefficients.

From thermodynamics utilizing the Gibbs equation, the entropy production rate can be written as:^[28]

$$\phi = T \frac{d\Delta S}{dt} = J\Delta P + I\Delta E$$

where T is temperature, S is entropy, J is generalized flux of molecules, P is pressure, I is electric current, E is electrical potential, and t is time.

The linear equations corresponding to currents and fluxes can be written as:

$$I = L_{11}\Delta E + L_{12}\Delta P \quad (2)$$

$$J = L_{21}\Delta E + L_{22}\Delta P \quad (3)$$

where $L_{ij} = L_{ji}$, and they are phenomenological coefficients. Eq. (2) states that electrical potential and pressure gradient can cause electric current, and Eq. (3) states that both electric potential and pressure gradient are responsible for the flux or bulk volume flow.

Using Onsager relationship, Eqs (2) and (3) can be combined and simplified to:

$$\left(\frac{\Delta E}{\Delta P}\right)_{I=0} = -\left(\frac{J}{I}\right)_{\Delta P=0} \quad (4)$$

$$\left(\frac{\Delta P}{\Delta E}\right)_{J=0} = -\left(\frac{I}{J}\right)_{\Delta E=0} \quad (5)$$

Therefore, pressure, electrical current, and electrical potential can be manipulated to control fluxes of molecules going across both sides of a membrane.

Design of a separation cell to investigate interfacial transport

As indicated in the previous section, pressure, electrical current, and electrical potential are some of the critical variables that can determine the fluxes of molecules across a membrane. To evaluate how biomaterials behave thermodynamically during interfacial transport based on Eqs. (1), (4), and (5), one needs to design a comparatively simple artificial membrane system in which the experimental conditions can be vigorously controlled. (The importance and utility of such a membrane system have already been discussed earlier.) Thus, to address this experimental design need, we have developed a simple separation cell (Fig. 1) that allows us to systematically investigate interfacial transport of biomaterials. In the series of studies to be discussed below, we address several key parameters that may exert effects on the interfacial transport of proteins. We chose three well-characterized enzyme proteins as the surrogate biomaterials: L-glutamate dehydrogenase (GDH) [EC 1.4.1.3; G-2626; Sigma Chemical Co., St. Louis, Missouri, U.S.A.; from bovine liver, molecular mass (MM) = 2,200,000], L-lactate dehydrogenase (LDH) (EC 1.1.1.27; L-2518; Sigma Chemical Co.; from rabbit muscle, MM = 135,000), and L-malate dehydrogenase (MDH) (EC 1.1.1.37; M-2634; Sigma Chemical Co.; from porcine heart,

Fig. 1 The separation cell with a 1 μm semipermeable polycarbonate membrane.

MM = 70,000). These enzyme molecules were chosen as a representative of proteins with small (MDH), intermediate (LDH), or larger (GDH) MMs. Furthermore, these enzymes were selected because they are important in several key metabolic pathways in mammalian cells and, as already discussed above, systematic elucidation of interfacial transport of these enzyme proteins employing an interdisciplinary approach will shed new light on interfacial transport in protein and cell signaling with biomaterials.

Effect of protein concentrations on protein permeability through an artificial membrane

For this study, the surrogate protein is LDH. Fig. 2 is the atomic force microscopy (AFM) image of a polycarbonate membrane employed for this study. As shown in Fig. 3, when protein concentration is the sole driving force in the system, the amount of LDH protein that passes through the membrane increases with concentration, but not necessarily proportionally. Observation of the medium concentration curve ($1.00 \times 10^{-8} \text{ M}$) at 2 hr shows a decrease in concentration; we believe it was the effect of artifact(s). A parallel run at pH 6.9 of the same concentration shows that LDH concentration continues to increase at the 2 hr period.

Permeability Through an Artificial Membrane of Proteins Having Different MMs. For this study, the surrogate proteins employed are MDH (having the lowest MM of the three proteins), LDH (having the intermediate MM), and GDH (having the highest

Fig. 2 Atomic force microscopy of a 0.1 μm polycarbonate membrane in LDH solution with 10 mM phosphate buffer.

MM). As shown in Fig. 4, other than the concentration difference, the size of a protein molecule would also influence its effective permeation. If as the hydrodynamical theory predicts, the diffusivity is reversibly proportional to the molecular radius and directly proportional to permeability, then our results are the same as that predicted.^[29] L-Malate dehydrogenase, the smallest molecule among the three proteins studied, has the highest permeability. In addition, even when

Fig. 3 L-Lactate dehydrogenase permeation at various initial concentrations (low = 2.50×10^{-9} M, medium = 1.00×10^{-8} M, and high = 2.00×10^{-8} M) at pH 7.4 in 2 hr.

Fig. 4 Permeability of GDH (MM = 2,200,000), LDH (MM = 135,000), and MDH (MM = 70,000) at pH 6.95 in solution with 10 mM of phosphate buffer and 100 mM of KCl through a membrane with pore size of 0.1 μm . The initial concentration of GDH was 1.42×10^{-7} M, that of LDH was 2.86×10^{-8} M, and that of MDH was 1.82×10^{-7} M.

their concentrations are low, larger protein molecules tend to form multimeric molecular aggregates, which certainly hinder their microfluidic passage through the membrane. Furthermore, for biological protein molecules in general, their activities behave differently even at the same pH, thereby further complicating the separation process.

Effect of pH on Permeability Through an Artificial Membrane of Proteins Having Different MMs. For this study the surrogate proteins employed are MDH (having the lowest MM of the three proteins), LDH (having the intermediate MM of the three proteins), and GDH (having the highest MM of the three proteins). As mentioned previously, proteins, such as enzymes, behave differently at various pHs.^[30] Although the proteins used in this study are among the better-characterized ones, the exact molecular structure of these proteins in solution are not well defined and many molecular properties have not been elucidated. Therefore, we investigated the effect of pH on protein permeation through an artificial membrane that could eliminate many complications associated with biological membranes. As shown in Fig. 5A, permeation of MDH (the smallest) is more pronounced at a higher pH (7.4), and its permeation decreases at a lower pH (6.51). However, for LDH (the intermediate) (Fig. 5B), its permeation is highest at pH 6.95 and lowest at pH 7.4. Fig. 5C shows that GDH (the largest) has the highest permeation at pH 6.5 and the lowest at pH 6.95, although the membrane pore size for the GDH

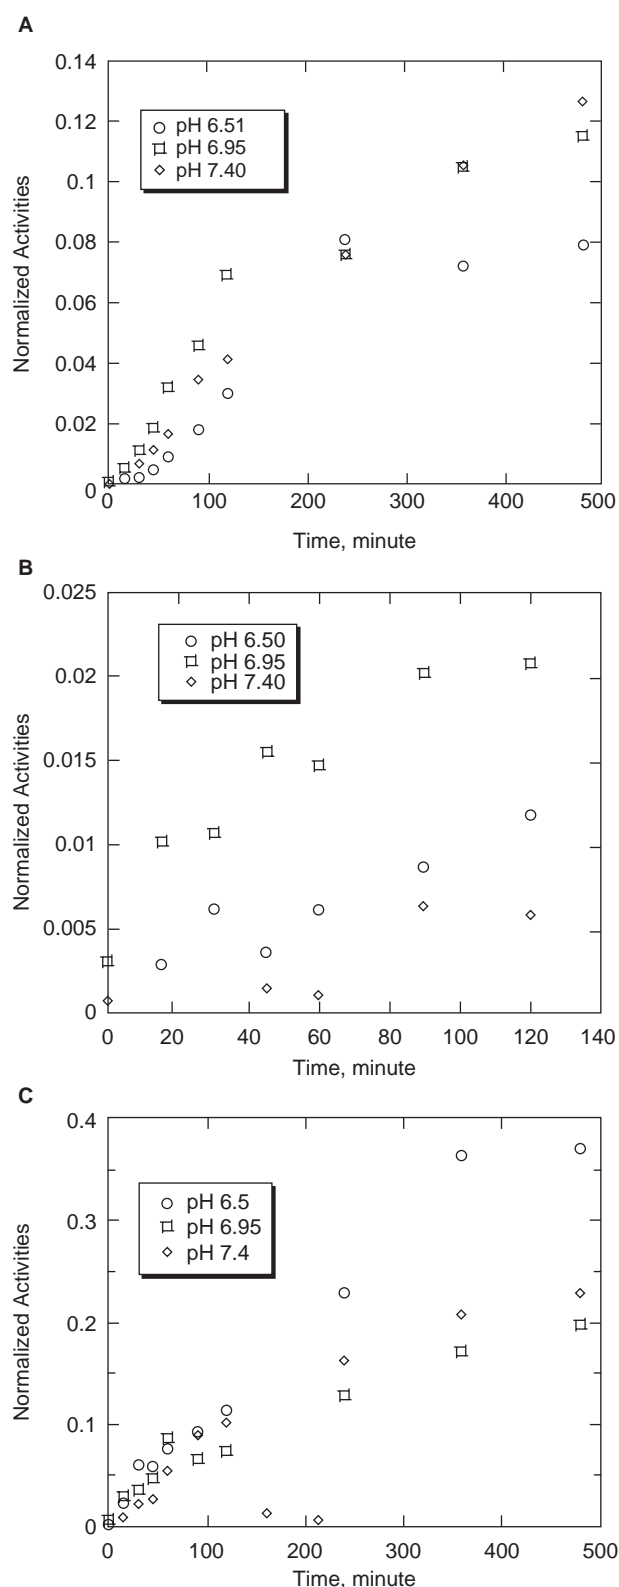

Fig. 5 (A) pH effect on permeability of MDH. All solutions started with same initial concentration (1.82×10^{-7} M). (B) pH effect on permeability of LDH. All solutions started with same initial concentration (2.86×10^{-7} M). (C) pH effect on permeability of GDH. All solutions started with same initial concentration (1.42×10^{-7} M).

Fig. 6 Effect of electrolyte on LDH permeability. Initial concentration of LDH for all solutions was 2.86×10^{-7} M. Concentrations of KCl were 0, 100, and 200 mM.

experiments was 10 times that employed in the experiments with LDH and MDH. Therefore, if a membrane is used to separate biological protein molecules, one must take into consideration how the pH will affect their permeabilities to obtain the optimal result. It should be noted that the pH effect on protein molecules is different from the pH effect caused by hydrolysis on membranes made from organic ester(s).^[31]

Some factors we are neglecting here in our observations are the effect of pH on the surface charge of the membrane and the surface charge (zeta potential) of the protein molecules.^[32] Since the size (MMs) of protein molecules can vary more than orders of magnitude, it is reasonable to expect that their pI's of zero potential are different. When viewed in conjunction with the potential of significant sorption of protein on the surface of the membrane, the effect of pH on interfacial transport of protein is complex. A complete understanding of the phenomenon requires a detailed study of multiple-surface phenomena (see above) and is thus beyond the scope of our discussion.

Effect of Electrolyte Concentration on Protein Permeability Through an Artificial Membrane.

For this study the surrogate protein is LDH. From the results of our limited number of observations, there is no obvious effect of KCl as an electrolyte on the permeability of LDH (Fig. 6). As the concentration of electrolytes in the solution increases, the electrostatic interactions between the electrolytes and LDH molecules also increase.^[33] Thus, mobility of LDH molecules will decrease as a consequence. Hence, one would expect that the solution with no KCl would allow for the highest permeation rate, but this was not

obvious from the results of our experimental conditions. On the contrary, the results of our experiments appear to indicate that the solution with no KCl allows for the highest increase of permeation rate with time.

Effect of Membrane Pore Size on Protein Permeability Through an Artificial Membrane.

For this study the surrogate proteins employed are MDH (having the lowest MM of the three proteins), LDH (having the intermediate MM), and GDH (having the highest MM). Fig. 7A shows the permeation rate of LDH through membranes with pore sizes of 0.1, 1, and 5 μm . Our results show that permeation rate increases with pore size, although the rate of increase is not linearly

proportional to the pore size. When the membrane pore size approaches the size of the molecule to be separated, other factors, such as surface potential and charge of electrolytes in the solution will become critical.^[34] As shown in Fig. 7A, the results suggest that when the pore size reaches a certain threshold, the increase in permeation rate with pore size is reduced significantly. This could be the consequence of two possible effects. First, accumulation of LDH molecules in the pore tunnels of the membrane blocks a certain amount of LDH going through in the case of the larger pore membranes, but LDH molecules would not accumulate in the pore tunnels of the smaller pore membrane because of higher mass flux going through

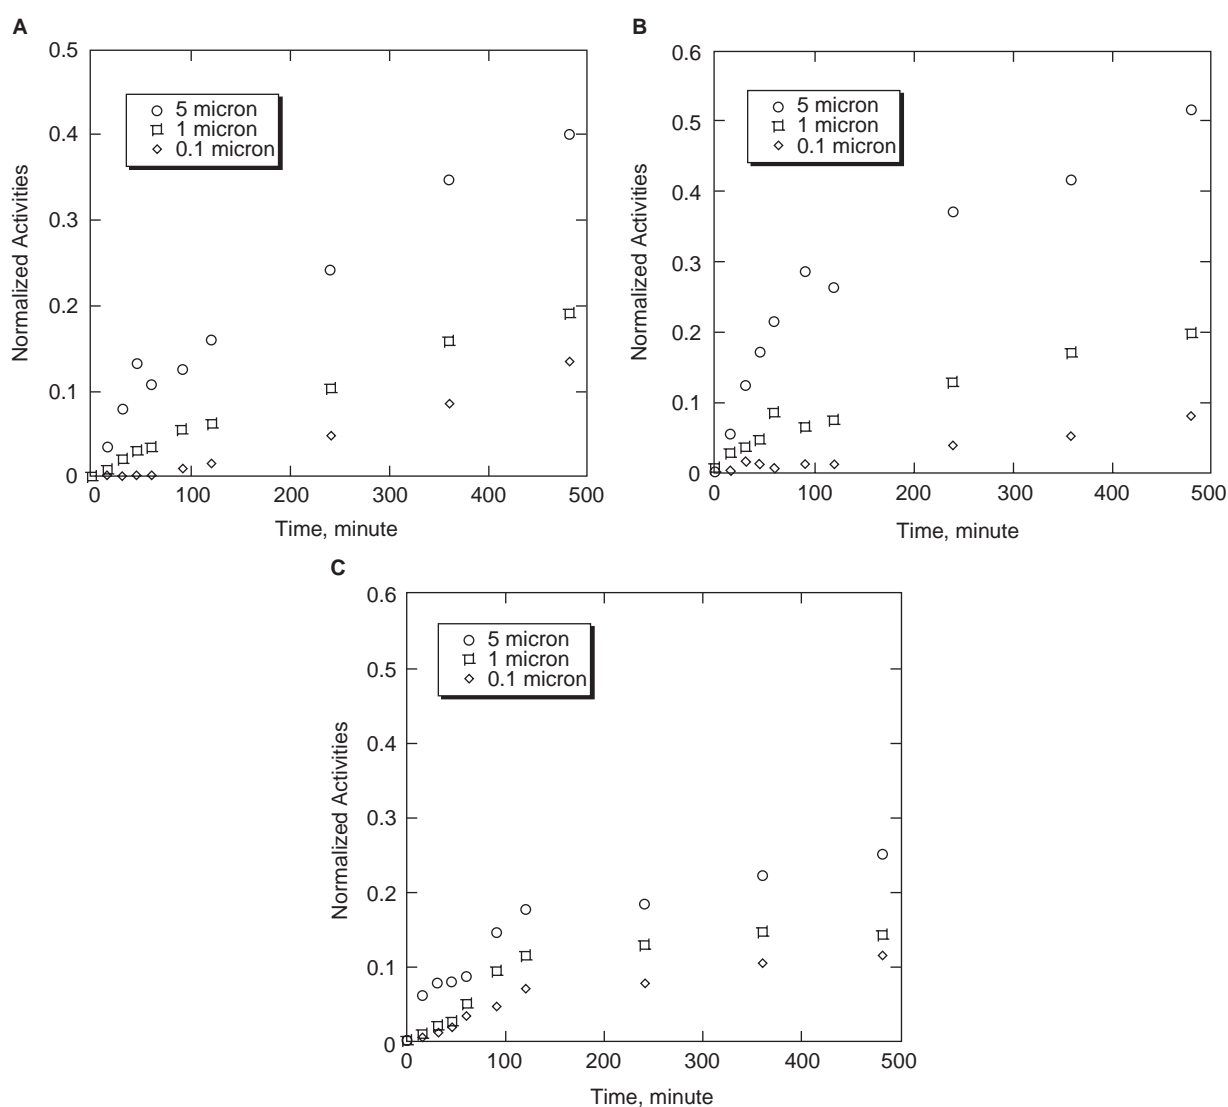

Fig. 7 (A) Permeability of LDH through different membrane pore sizes of 0.1, 1, and 5 μm . Initial concentration of LDH was 2.86×10^{-7} M in 10 mM of P-buffer with no KCl at pH 6.95. (B) Permeability of GDH through different membrane pore sizes of 0.1, 1, and 5 μm . Initial concentration of GDH was 1.42×10^{-7} M in 10 mM of P-buffer with no KCl at pH 6.95. (C) Permeability of MDH through different membrane pore sizes of 0.1, 1, and 5 μm . Initial concentration of MDH was 1.82×10^{-7} M in 10 mM of P-buffer with no KCl at pH 6.95.

the tunnels. Second, after enough LDH mass has been passed through the membrane from the concentrated side of the half-cell, the driving force of mass differential for the larger pore membrane is significantly less than that of the smaller pore membrane. Thus, slower permeation rate is the result. However, the first speculative mechanism cannot be verified until we can physically observe the LDH at the molecular level on the surface and pore tunnels of the membrane.

Observations on GDH (Fig. 7B) and MDH (Fig. 7C) show the same consistent results as those for LDH (Fig. 7A). It should be noted that the mass flux of MDH going through the membrane is much less than that of LDH or GDH, although MDH was the smallest of the three protein molecules. Evidently, membrane pore size is not the only controlling mechanism for mass permeation through the membrane. As technologies such as AFM, scanning electrochemical potential microscope, and other analytical instruments become more developed, verification of the permeation mechanism will soon be possible.

Effect of Gold-Palladium Alloy Coating of Membrane on Protein Permeability. The conditions of this set of experiments were essentially identical to those shown in Fig. 7A with LDH, except for the 0.1 nm of gold-palladium coating on the membranes. This set of experiments was included in this study to examine if a metal-coated membrane would behave differently from that of a noncoated one. Coating a membrane would alter the surface properties of the membrane drastically; thus, studies with a coated membrane can improve our understanding of ion transport in cells and organ surface. As shown in

Fig. 8 Effect of gold-palladium coating on LDH permeability. Conditions of solutions in this figure were the same as in Fig. 7 except the gold-palladium coating.

Fig. 8, the permeation rate through the membrane with 0.1 μm pore size supersedes that through the membrane with 1 μm pore size at the later stage of the experiment. It appears that the metallic coating has allowed an increase in the permeation rate through the 0.1 μm membrane. The coating has also allowed increases in the permeation rate through the membranes of pore sizes 1 and 5 μm for the first 120 min, and then the protein permeation slows down immensely, especially that through the 1 μm membrane. This latter phenomenon could be caused by several factors, such as sorption and surface charge, as indicated by the elegant studies of Nishizawa, Menon, and Martin.^[19] This metal-coated membrane is conductive; thus, the surface charge of the membrane can be changed according to the potential being applied. Therefore, one can exploit the electrokinetic effect on the transport properties of proteins with this “smart membrane.”

Permeabilities of Proteins Having Different MMs. For this study the surrogate proteins employed are MDH (having the lowest MM of the three proteins), LDH (having the intermediate MM), and GDH (having the highest MM). For solute flux through a membrane with concentration gradient being the sole driving force, the solute flux can be written as:^[35]

$$F_i^0 = D_i^0 K_d \frac{\Delta C_i}{\delta_m} = K_p \Delta C_i$$

where D_i^0 is effective diffusion coefficient of species i , K_d is distribution coefficient, δ_m is thickness of membrane, and ΔC_i is the concentration difference across the membrane for species i . K_p is the coefficient of permeability and usually a constant in the range of interest for the membrane. For the conditions given in Fig. 4, K_p of GDH, LDH, and MDH were calculated to be 1.81×10^{-4} cm/sec, 2.64×10^{-4} cm/sec, and 3.97×10^{-4} cm/sec, respectively. As expected, the permeability of these protein molecules decreases with the increase of their MMs.

CONCLUSIONS

The field, as depicted by the title of this entry, “Protein and Cell Signaling with Biomaterials: Interfacial Transport,” is so new that there are many aspects where the lack of fundamental data does not allow us to make generalizations. One major point we would like to make at this juncture is that significant advances in this field can only be made if current and future studies adopt an interdisciplinary approach. The multidisciplinary nature of this field demands that biomedical engineers, biomedical researchers, and

chemists, and other physical scientists work together synergistically to address the fundamental issues. After all, in membrane separation technology, many of the interfacial and surface phenomena have been overlooked and are not well understood. Moreover, of the two major aspects of artificial membrane research (namely, the mechanistic and functional aspects), only the mechanistic aspect has been investigated in the last decade or so. By contrast, the functional aspect of artificial membrane research has not been addressed until recently.

In this entry, we trace the origin of the field of protein and cell signaling with biomaterials from the biomedical research on protein and cell signaling to the current concepts in biomaterial design and their applications in tissue engineering. We emphasize how and why interfacial transport is important in protein and cell signaling with biomaterials. We further advocate that interfacial transport in biological systems is too complex and not easily understood. However, we can begin to unravel such complexity by designing a more simple artificial membrane system to simulate discrete paradigms of the biological membrane systems. The availability of such a simpler artificial membrane system allows us to systematically investigate, in an interdisciplinary manner, the fundamentals of interfacial transport under vigorously controlled experimental conditions.

We report herein some of the results of our ongoing studies employing a simple separation cell to investigate qualitatively and quantitatively how large proteins are separated by artificial membranes at low concentrations under well-defined controlled conditions. To date, our results indicate the following: permeation of proteins increases with protein concentration; increase of ionic strength under the experimental conditions (≤ 200 mM) does not seem to induce a decrease in protein permeability; and protein permeation in general increases with increase in membrane pore size and decreases with increase in molecular mass of the protein. For biological macromolecules, which possess multiple functional groups, surface interactions with membranes are complex; prediction of the trend of permeability with variation of pH is difficult because of variations of zeta potential and surface charge that are chemical species dependent, even under a restrictive controlled environment. Change of surface potential can alter the order of size effect when molecules are passing through the microchannels in membranes (permeabilities).

The study of permeabilities of macromolecules and other chemical species in solution are valuable in the development of a treatment system using membrane technology to reclaim spent water for potable use, as well as for the development of tissue engineering. While artificial organs constitute an imminent

development in the biotechnology forefront, behavior of protein transport across artificial membranes must be well understood for this development to be successful. Thus, the results of our ongoing studies employing simple artificial membranes are highly relevant to the development of bioengineering, tissue engineering, and water/wastewater treatment applications. Clearly, for the rapid advances of such applications, more systematic studies using artificial membranes are warranted.

ACKNOWLEDGMENTS

We thank Garnet Rivera, John Cleary, and Kurino Ashizawa for their assistance in some of the studies reported in this entry. Our studies were supported, in part, by NIH Grant #P20 RR16454 from the Idaho BRIN Program of the National Center for Research Resources at the National Institutes of Health, and an FRC grant and an URC grant from Idaho State University.

INTRODUCTION

More effective and tailored drug delivery systems (DDS) are continuously investigated, tested, and, eventually, marketed. In the last 30 yr, the pharmaceutical industry has made substantial steps in this direction. Drug products containing proteins and peptides, as therapeutic agents, are a perfect example of these two intimately correlated aspects: route of administration and quality of life. In the past 60 yr, hormones, serum proteins, and enzymes have been extensively used in therapy as active ingredients.^[1,2] But recently, molecular biology and, especially, recombinant deoxyribonucleic acid (DNA) technology have made tremendous progress resulting in the availability of a wide variety of peptide- and protein-based therapeutics for poorly controlled diseases. For this class of drugs, however, the parenteral route represents today the predominant route of administration, as the bioavailability of alternative routes is extremely low and variable.

The development of a successful non-parenteral delivery system for proteins implies challenges including the protection of the therapeutic agent from hostile physiological conditions, otherwise detrimental for the biological activity, and gentle manufacturing conditions to maintain the original molecular conformation of the protein. One such agent widely studied as model protein is insulin, a 51 amino acid polypeptide, used in therapy for the treatment of diabetes mellitus. Diabetes mellitus is a group of metabolic disorders characterized by hyperglycemia that affects a sizeable portion of the population worldwide, estimated to increase in the next 20 yr of more than 30% reaching the size of an epidemic.^[3] Furthermore, the complications coupled with it are debilitating and at times fatal. For these reasons, a chronic therapy is required. To maintain normal glucose levels in the blood and mimic the physiological profile of the secretion of the protein, frequent daily injections (up to four) of insulin are needed.

One of the most promising new methods of non-parenteral protein delivery is oral delivery. For this process, various types of specialized polymeric carriers are used. For example, hydrogels have been studied as suitable candidates for oral drug delivery of peptides.

Particularly the complexing hydrogels that respond to pH changes in the surrounding environment have been extensively studied. For example, we developed new cross-linked copolymers^[4] composed of poly(ethylene glycol) (PEG) grafted on poly(methacrylic acid) (PMAA) backbone, henceforth designated as P(MAA-g-EG), by UV-initiated bulk-free radical polymerization. They possess the unique characteristic to form interpolymer complexes in response to changes in pH of the environmental fluids. The interpolymer complexes are formed owing to hydrogen bonding between the protonated carboxylic acid group of PMAA and the ether group of the PEG chain. In particular, they remain in the collapsed state at low pH values, similar to those found in the stomach. Therefore, the release of the protein is impeded, and the protein entrapped in the network can be protected from the undesirable conditions found in the stomach. When the pH rises up to approximately 6, the network swells. This unusual behavior seems very promising for an oral formulation that would be able to release the labile therapeutic agent only in a more favorable environment such as that encountered in the upper small intestine. The expansion of the system would allow the polymeric chains to interact with the mucosal lining, causing the tight junctions to slightly separate, thus enhancing the transport of the protein into the systemic circulation.^[5]

PROTEIN STRUCTURE AND FORMULATION DESIGN

Proteins and Peptides: The Internal Architecture

Proteins are high molecular weight molecules, characterized by high-ordered, hierarchically organized structure. It is possible to describe their structure at four separate but interdependent levels: primary, secondary, tertiary, and quaternary structures, mainly stabilized by weak physical forces.^[6] The primary structure is essentially the amino acid sequence connected one by one via peptide bonds to form a polypeptide chain. This “linear” sequence is responsible for determining the higher levels of organization of the molecule.

A single change in the primary structure can have a profound outcome on the overall arrangement and function of the protein. For instance, hemoglobin, the oxygen carrier in the blood, is a tetramer consisting of two α chains and two β chains. A change in the sixth residue of a β chain from glutamic acid (glu) to valine (val) causes deformation of the red blood cells, an extremely serious condition called *sickle cell anemia*.

The second level in the protein organization hierarchy is known as secondary structure, where chains of amino acid residues are further organized in space forming regularly repeating patterns. The most common secondary structures in proteins are the α -helix, a rod-shaped structure wrapped around an imaginary cylinder and stabilized via hydrogen bonds mainly, and the β -pleats, where the backbone amino acids atoms form a zigzag pattern (the β sheet). The structure of many proteins consists mainly of α -helices, some others mainly of β sheets, and still others a combination of both, the random coils.

The global structure of a single polypeptide chain is known as tertiary structure. Groups of α helices or β sheets (domains) fold with one another to form a three-dimensional architecture. Hydrogen bonding involving groups from both the peptide backbone and the side chains is important in stabilizing the tertiary structure. In addition, an important role is also played by covalent bonding (disulfide bridges) and hydrophobic interactions between side chains. The polypeptide chain folds such that the side chains of non-polar residues are hidden within the structure and the ones carrying the polar moieties are exposed on the outer surface.

Finally, the quaternary structure refers to the arrangement of two or more polypeptide chains (tertiary structures) into a multisubunit structure. However, not all proteins exhibit quaternary structure. Usually, each polypeptide within a multisubunit protein folds quite independently into a stable tertiary structure, and the folded subunits associate with each other to form the final structure. Quaternary structures are stabilized mainly by non-covalent interactions such as hydrogen bonding, van der Waals interactions, and ionic bonding. The hierarchy described above generates a complex architecture that dictates the biological activity of the protein. Here lies the great difference between proteins and low molecular weight drugs. The large amount of functional groups and the complex and labile three-dimensional structure render them prone to a variety of degradation and inactivation pathways. In general, the biological activity can be lost because of chemical or physical alterations. Examples of chemical alterations that can be detrimental for the protein are reactions of deamidation. Glutamine and asparagine under certain condition can undergo the deamidation reaction that can strongly affect the activity of the protein. Oxidation and reduction can usually affect free cysteine.^[6,7]

Also, owing to the primary reactions of certain groups, reactions of aggregation and internal cross-linking can occur thus leading to significant loss of biological activity. A common example of cross-linking within the protein subunits is the formation of disulfide bridges or the rearrangement of the existing S-S bonds.^[8]

Another important chemical reaction in terms of loss of activity is proteolysis. This reaction is owing to the breakdown of the peptide bonds because of harsh conditions such as long exposure to extreme pHs or high temperature or, again, because of proteolytic enzymes. They may also undergo adsorption processes that can irreversibly denature them. A polypeptide chain generally folds into a sole three-dimensional conformation, unique in ensuring biological activity. Examples of physical alterations are conformational changes and non-covalent aggregation (self-association). Therefore, a wrong handling or manufacturing procedure may lead to irreversible changes in the arrangement of polypeptide chains, which become inactive.

For this reason, the formulation and drug delivery of such pharmaceuticals represent a tremendous challenge for the pharmaceutical scientist. The stringent interplay between the biological activity and the final conformation of such a complex structure is the crucial issue to be addressed in protein drug delivery. It is well known that environmental conditions such as temperature, moisture content, salinity, or pressure can have a profound, and, at times, detrimental reflection on the internal architecture of these macromolecules. The protein conformation, indeed, exhibits a marginal stability.

The protein stability has several definitions.^[8-10] Generally it can be described in terms of *thermodynamic stability* and *kinetic stability*. A protein unfolds and refolds following a two-state process, the equilibrium of which can be described as

where K_u is the equilibrium constant for unfolding. The rate of unfolding and the reversibility of the process reported in Eq. (1) are the key issues. In other words, a protein may be fully unfolded and inactive in certain conditions; yet, it will refold and fully recover its activity in the "original" or "ideal" condition. Hence, from a functional point of view, this may be all that is required for the molecule to be classified as thermostable. However, from a thermodynamic point of view it would be classified as thermally unstable.

Irreversible loss of protein folded structure is represented by

where k_i is the rate constant for some irreversible inactivation processes such as aggregation, disulphide exchange, proteolysis, irreversible subunits dissociation, chemical degradation, and so forth.

In light of the aforementioned features, protein stability must be investigated at molecular level, taking into consideration that all the inactivation processes described above can occur during preparation, storage, and release from the dosage form. Thus, the formulation has to be designed in such a way that these delicate structures are stable during preparation, purification, formulation, storage, and administration to the patient. The structure of the whole molecule should be preserved during all stages ensuring proper pharmacokinetic and pharmacodynamic profiles. Furthermore, therapeutic proteins may need special formulation procedures to protect them against the physiological conditions they have to face before reaching the target.

Protein Absorption and Formulation Issues

To understand the limiting step of administration of a protein as drug and, on the whole, of a therapeutic agent, one must understand the concept of drug kinetics. In short, pharmacokinetics refers to what human body does toward a medicine. It involves the processes of drug absorption into the body, distribution to various tissues, metabolism, and excretion.

Absorption can be defined as the process by which a drug passes from its site of administration into the bloodstream. When the therapeutic reaches the systemic circulation, the blood carries the drug to all the organs, including those on which the molecule acts. The rate, ease, and degree of absorption are all related to the route of administration, to the physicochemical properties of the drug itself, and to the formulation intended as the actual dosage form.

The routes of administration can be broadly classified as enteral and parenteral. The enteral route refers to those dosage forms wherein the drug is ultimately absorbed within the intestine such as oral and rectal. However, the term “enteral” is used more broadly to refer to any route of administration that involves absorption anywhere from the mouth to the rectum. Thus, sublingual administration is often categorized as an enteral route of administration.^[11]

Parenteral, on the other side, means introduced by way of other routes outside of the intestines and not by way of the alimentary tract. There are several sites of administration via this route. The three primary routes of parenteral administration are subcutaneous, intramuscular, and intravenous, although there are others such as intracardiac and intraspinal. In the intravenous administration, the drug is injected directly into the blood, most commonly into a peripheral vein. The

advantages of such a mean are the rapid achievement of concentration in the blood and precision in delivering the effective dosage. Among the disadvantages, however, are the high initial concentration that can fall into toxic levels, especially for drugs with a low therapeutic index, the fact that once the drug is injected there is no retreat, and, not least, the need of skilled personal.

Generally, the delivery of proteins is performed by parenteral administration (subcutaneous or intramuscular injections). The problem with this kind of administration is related to the short half-time of the protein, which results in the necessity of frequent administrations to obtain therapeutic effectiveness. Obviously, multiple injection regimens do not meet patient acceptance. To avoid lower compliance, one approach involves producing smart parenteral delivery systems that reduce the frequency of injection by providing a sustained release of the drug over time. Examples of this type of devices could be found in insulin pumps,^[12] which provide a continuous subcutaneous infusion of the protein trying to mimic the physiological circadian rhythm of the protein. A needle is inserted only every three or four days giving the patient a wide flexible lifetime. The use of genetically modified protein analogs can lead to an increase of the low availability of the injected protein. Again, implantable infusion devices could represent a reasonable intelligent system for delivering proteins without the need of multiple injections.

However, the development of non-parenteral protein delivery systems remains an intriguing challenge for many investigators in the pharmaceutical field as a reasonable alternative to the parenteral route.

A wide range of dosage forms have been proposed for the delivery of proteins via enteral routes such as nasal, pulmonary, buccal, rectal, vaginal, transdermal, and oral routes. Among these, the oral administration has always represented the “holy grail” for proteins and peptides delivery, especially in chronic treatment. Compared with others, enteral routes, oral administration has always been considered the most natural, convenient, and safe mean of administration. The advantage in terms of patient compliance is amplified by the potential cost saving to the health-care industry, as no skilled personnel or sterile processes are required.

So far, in despite of all efforts spent in reaching the target of safe and effective oral formulations for peptides and proteins, relatively small progress has been made.^[13] The main reason for the absence, to date, of a successful oral protein formulation can be ascribed to the characteristic of the drug molecule itself. To have adequate bioavailabilities, the protein should possess robustness toward the highly acidic environment of the stomach, should be able to pass across intestinal cell membranes, and it should have endurance to destruction by hepatic metabolism (first-pass effect). In most

Fig. 1 Types of transport across intestinal membrane.

cases, such drugs do not have intrinsic characteristics to withstand these conditions.

Proteins must bypass physical barrier, enzymatic digestion, chemical degradation, and intrinsic low stability.^[14] The former is represented by the single layer of intestinal epithelial cells that form the barrier between the lumen of the gastrointestinal (GI) tract and the body fluids. Generally, transport of molecules across the intestinal epithelium can be achieved by three transepithelial pathways: transcellular (across the cell membranes), carrier-mediated active or facilitated transport, and paracellular transport (i.e., through the intercellular spaces between adjacent cells) (Fig. 1).

For many drugs, the predominant route of transport across the intestinal epithelium is the transcellular route. The molecule diffuses through the cell from one side to the other. This usually happens for molecules such as oxygen and carbon dioxide. In the carrier-mediated transport, the molecule interacts with binders exposed on the surface of the cell membrane. A complex is formed and this crosses the lipid layer to the inside of the cell. The bound molecule complex then dissociates inside the cells, and the free molecule moves to the other side of the cell where the same mechanism takes place and allows the molecule to reach the outside environment.

Paracellular transport, on the other hand, occurs when the molecules move through the layer by passing between adjacent cells. Small hydrophilic compounds and charged molecules are mainly transported via paracellular route. Epithelial tissue is tightly bound together into sheets, called epithelia, and specialized junctions between the cells enable this tissue to form barriers to the movement of water, solutes, and cells from one lumen side to the systemic circulation. The presence of these “occluding” junctions, known as tight junctions, often hampers the paracellular path. Under various physiological conditions, material transport across tight junctions occurs in a regulated manner.

Absorption of glucose from the intestine, for instance, occurs via paracellular way, across tight junctions, particularly when luminal glucose concentrations are elevated, saturating the Na^+ -glucose cotransporter in the apical plasma membrane. However, under normal conditions, this way is restricted to molecules with molecular radii less than 11 \AA and therefore is not accessible to large compounds such as peptides and proteins.^[15]

The Role of Enzymes and Environmental pH in Protein Absorption

The intestinal absorption of drugs can be reduced by the presence of efflux proteins like P-glycoproteins and/or metabolism in the gut.

The proteolytic degradation in the GI tract is another important impediment that limits the effectiveness of peptide- and protein-based delivery systems. Enzymes located throughout this part of the body are capable of denaturing or destroying these fragile molecules. Proteases are the enzymes deputed for the digestion of proteins in the stomach and they represent the first enzymatic barrier that the protein has to face along the GI tract. Passing the pylorus and arriving in the small intestine, pancreatic enzymes such as trypsin, chymotrypsin, and carboxypeptidases are other enzymes responsible for degradation of ingested proteins. Finally, degradation also can take place on the brush-border membrane of the intestinal cells because of various peptidases. It is very unlikely that such a labile molecule can withstand all these possible degradation. A protection against proteolytic degradation, therefore, is necessary.

The sharp pH gradients that characterize the GI tract are another problem to bear in mind. The gastric pH has been measured to range from 1.4 up to 2.1 on an empty stomach. It can reach pH values around 4 or 5

when food is present.^[16] In such conditions, reactions of aggregation, deamidation, can easily occur and can be detrimental for the biological activity of the drug.

Another hurdle in developing an effective oral delivery formulation may be the harsh conditions of the manufacturing process. As described above, proteins have very large globular structure, a complex and fragile internal architecture that defines their unique biological activity, chemically weak bonds and numerous reactive groups on their side chains. All these aspects render these compounds difficult to handle, sensitive to the interactions with excipients. Any disruption in one of the levels of the molecule architecture (primary, secondary, or tertiary structure) can lead to inactivation, reversible or irreversible, of the protein. These disruptions may occur upon slight changes in the microenvironment. A rise in the temperature, a change of the pH, the presence of a particular solvent, and a change in the crystalline form of the protein represent a common scenario during the manufacturing process of a formulation. Therefore, it is clear that an accurate evaluation of the physicochemical characteristics of the protein, a careful analysis of the interaction between the drug molecule and the excipients, and the impact of the manufacturing processes on the protein structure are important issues in developing a new formulation.

Several strategies to improve oral absorption of peptides and proteins have been investigated to target both the low physiological permeability and the stability of these compounds.

The main approaches include the addition of penetration enhancers to increase the permeability across the epithelium, the use of proteolytic inhibitors within the final dosage form to surmount the enzymatic degradation, and gastroenteric coating to protect the drug against the acidic environment of the stomach.

A common approach to overcome the low epithelial permeability has been the use of permeation enhancers such as bile salts, fatty acids, calcium chelating agents, surfactants, and the like. These compounds apparently have the ability to loosen the intestinal tight junctions and therefore improve the paracellular transport.

Calcium chelators administered together with proteins improved significantly the absorption through the epithelium. The improvement observed was owing to subtraction of calcium ions from the tight junctions, resulting in the opening of water channels.^[17,18]

Bile salts and their derivatives have been also widely used to enhance the penetration through the cells membrane. They are amphiphilic compounds that above the critical micellar concentration tend to self-associate forming vesicles referred to as micelles, where the hydrophobic groups orientate themselves toward the inside creating a lipophilic core, whereas the hydrophilic groups are exposed to the medium rendering the whole structure water soluble.

The mechanism by which these compounds increase the absorption of proteins and peptides through the intestinal mucosa has not been fully understood. However, it appears to be a combination of mechanisms. The formation of aqueous channels in the cell membrane can be a reason for the increase in cell membrane permeability. Ion pairing between bile salts and proteins and peptides that become more lipophilic could be another effect.^[19] Also micellar solutions have shown the capability to increase the fluidity of the mucosal membrane and consequently enhance protein absorption.^[20] A variety of bile salts like taurocholate, cholate, and glycocholate have been tested through the years, and they have been found to be equally effective in enhancing protein absorption.

Surfactants are also used for improving penetration through physiological mucosa. These agents have the peculiarity to lower the surface tension of water and promote micelles formation. They modify the properties of biological membranes and alter their permeability and transport characteristics.^[21] Sodium lauryl sulphate, saponin, and Laureth-9 are some examples of surfactants used for improving absorption across biological membranes. They have all shown to have membrane-solubilizing effects toward membranes.

In any case, the ability of all these agents in enhancing epithelial penetration is related to serious and at times irreversible modifications or disruptions of the integrity of biological membranes. The potential toxicity of these compounds, therefore, has worried the scientific community. One big threat of such excipients is their ability in altering the membrane-barrier functions. Moreover, rendering the paracellular way pervious would mean exposing the systemic circulation indiscriminately to the intestinal tract content, including toxins and undesired compounds.^[22] Considering the gravity of the damages that this can cause (solubilize and therefore extract important components from the cell membrane and irreversibly lose pivotal barrier functions of the mucosa), the acceptance to these compounds as excipients in drug formulation is very much unlikely.

Other ways have been investigated to improve the epithelial penetration of proteins and peptides. A target widely tackled has been the opening of the tight junctions. Recently, zonula occludens toxin, designated as ZOT, a protein elaborated by *Vibrio cholerae*, has been discovered.^[23] The protein has shown the particular ability to interact with specific surface receptors present in the mature cells of the small intestine, but not in the colon. *In vitro* and *in vivo* studies have demonstrated that ZOT effects are reversible and that the compound is not cytotoxic. Therefore, it seems to be a promising alternative to other enhancers, but the studies on this direction are still in progress. Up to date, however, bioavailabilities reached using these expedients are still too low.

Enteric coating is another approach widely used in pharmaceuticals for providing protection of drug against the harsh environment of the GI tract. It has been successfully used for small drug molecules and it has been extensively investigated for proteins and peptides as well. The concept behind it is to encapsulate the protein in pH-sensitive materials and release it only in a more “friendly” environment. Polyacrylic polymers have been used for this purpose. Eudragit[®] polymers are a well-known example of enteric coatings used in pharmaceutical industry and it has been proposed also for a “site-specific” insulin release.^[24] However, the bioavailability obtained with this strategy was only around 0.1%.

Methods of Elimination of Proteolytic Activity

Numerous strategies have been attempted for inhibiting proteolytic enzymes responsible of the inactivation of proteins. For example, it has been shown that the use of protease inhibitors such as bacitracin, soybean trypsin inhibitor, and camostat mesilate could improve the intestinal absorption of these compounds.^[25] Increasing attention has been focused on methods of administering proteins and peptides continually for prolonged time periods and in a controlled manner. The primary method of accomplishing this controlled release has been through incorporating these bioactive agents into polymeric particles.

As a matter of fact, polymers are gaining increasing importance in pharmaceutical technology owing to their great versatility in applications. First introduced in the medical field such as suture means and the like, they have become quickly excipients widely used as drug encapsulants for protecting an active agent during its passage through the body until its release, as vehicles of drug delivery and as means for controlling the drug release. A conventional tablet usually releases the drug in regions of the body where it may not be at its most effective, typically reaching a maximum concentration, which then decays exponentially until the next administration. In some cases, this is not the best pharmacokinetic profile. This can be overcome to some extent by sustained/retarded release, and/or selective delivery of the drug to the targeted organs. The use of polymers in pharmaceutical formulation has paved the way for controlled release. One of the most remarkable features of these compounds is the possibility to tailor the characteristics of the final polymeric system upon need, combining different monomers or polymers.

There are several formulations containing microspheres loaded with proteins on the market.^[26] Lupron Depot was one of the first controlled-release delivery devices for the administration of leuproreline acetate,

an LH–RH analogue, and contained microspheres. De-Capeptyl SR is another example of a formulation containing microspheres of a lactide–glycolide copolymer loaded with triptorelin, belonging to the same pharmaceutical category of leuproline and so on. All these systems are nevertheless designed for injections or implantable devices.

Nowadays, polymeric matrices are receiving significant attention for the oral delivery of proteins. For example, Lowe and Temple^[27] studied nanoparticles of polyacrylamide (PAAm) and poly(isobutyl cyanoacrylate) for the oral delivery of human calcitonin and insulin. These two different polymers have shown the ability to reduce enzymatic degradation in the GI tract.

Yet, the most exciting systems in the controlled release area lie in the responsive delivery systems.^[28] The advantages over other controlled release systems include the release of the therapeutic agent only in response to an external stimulus such as change in pH, temperature, ionic strength, and electromagnetic radiation in the surrounding environment. This behavior can be of particular interest when a constant concentration of the drug in the blood is not desirable, while the release of the drug would be ideal if occurring as a response to a physiological change. The most used example is the delivery of insulin. In patients affected by diabetes mellitus, insulin has to be released in response to an increase in the blood glucose level, to mimic the physiological release from the pancreas.

Many other examples of such ideal disease treatment could be found in hormone administration. Hormones have usually a circadian release into the body. Hence, the ideal delivery of such compounds should be a stimuli-sensitive release, instead of a “conventional” controlled release. This kind of devices is also known as “smart” DDS. Hydrogels belongs to this category. Both cationic and anionic hydrogels are becoming very popular in this field.^[29] Structure and properties of these polymer networks can be manipulated to achieve the desired features. Permeability and swelling behavior are indeed strongly related to the chemical nature of the polymers composing the final network.

An example of such network is pH sensitive hydrogels. These polymeric materials contain ionizable side groups such as carboxylic acids or amine groups that provide them the peculiar characteristic of responding to pH changes.

The most studied include PAAm, poly(acrylic acid) (PAA), and PMAA.^[30] These copolymers exhibit pH-dependent swelling behavior and are able to release drugs depending on the pH of the environmental fluid. These systems seem to be promising for the formulation of protein- and peptide-based drugs.

pH-Responsive Complexing Hydrogels as Oral Delivery Systems for Peptides and Proteins Administration

The characteristic pH profile of the GI tract makes pH-sensitive polymeric systems promising candidates for the oral delivery of peptides and proteins, owing to their ability to respond to the surrounding environment. Hydrogels, in particular, have captured many consensuses among researchers because of their benign characteristics. They can be defined as three-dimensional networks physically or chemically cross-linked. In any case, their cross-linked nature renders them insoluble. Owing to their hydrophilicity, they can absorb large amounts of water.^[31] Hydrogel's structure can be designed according to the desired application. Reacting, for example, monomers with ionic functional groups will provide the final network with environmental sensitivity, whereas other functional groups could allow the carrier to target a specific area of the body and protect the therapeutic agent from otherwise detrimental physiological conditions.

Hydrogels contain hydrophilic functional groups such as $-\text{OH}$, $-\text{COOH}$, $-\text{CONH}_2$, $-\text{CONH}$, and $-\text{SO}_3\text{H}$,^[32] which allow large amounts of water to be incorporated in the polymer. However, the presence of cross-links, as already mentioned, renders the polymer networks water insoluble. According to the ionic nature of the pendant groups, hydrogels can be classified as anionic gels or cationic gels. Hydrogels containing pending groups such as $-\text{OH}$, $-\text{COOH}$, and $-\text{SO}_3\text{H}$ are classified as anionic, whereas cationic gels may contain amine groups.^[33]

Changes in the environment such as pH and ionic strength will turn the pendant functional groups in their unionized or ionized forms according to the ionic nature and this will affect their swelling behavior. For anionic hydrogels, the functional groups are weak acids and therefore are unionized below their $\text{p}K_a$. When the surrounding pH is increased above the $\text{p}K_a$, the functional moiety ionizes and the electrostatic repulsion causes the network to swell. The opposite occurs with cationic hydrogels. The characteristic equilibrium swelling behavior of the two types of hydrogels is shown in Fig. 2. This mechanism of swelling is often reversible. Many hydrogels can fully recover from deformation when the external stimulus terminates.

A promising class of stimuli-sensitive hydrogels is complexing hydrogels. Interpolymer complexes occur within the network owing to interactions between repeating units in the side chains. The resulting tie points act as additional physical cross-links.

These systems can be used to protect therapeutic agents such as proteins from the harmful physiological conditions that could degrade such agents before they produce their therapeutic effects.^[31,34]

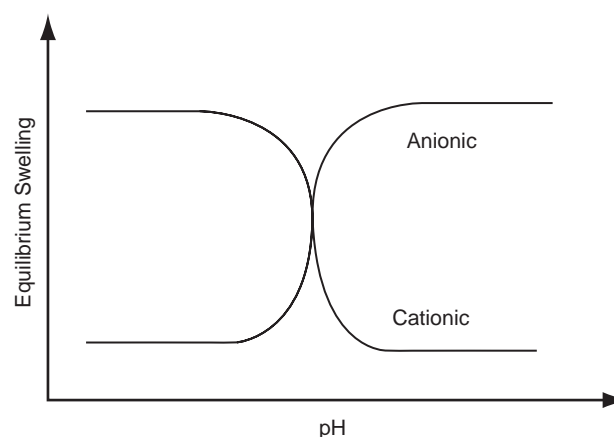

Fig. 2 Equilibrium swelling of anionic and cationic hydrogels as a function of pH.

PAA hydrogels that show pH-sensitivity have been utilized as stimuli-sensitive mucoadhesive carriers. We have studied these systems in detail^[35] and we have examined the effect of incorporation of PEG grafts into a PAA network. The polymeric network was prepared by free-radical solution polymerization. Different methacrylates with pendent PEG chains of various lengths were used as monomers in addition to the acrylic acid. Infrared spectroscopy was used to investigate the presence of hydrogen bonding in the networks. It is the sensitivity of this bond to the external environment that provides the pH-dependent swelling behavior to it and, in general, to all the hydrogen-bonding interpolymer complexes. The copolymer networks of poly(acrylic acid-g-polyethylene glycol) showed a pH-sensitive swelling behavior related to the length of the PEG graft. Networks with the largest PEG grafts showed the highest sensitivity to external signals.

Other pH-sensitive complexation hydrogels studied in our group, which have been used as DDS are the hydrogels of poly(methacrylic acid-g-ethylene glycol), henceforth designated as P(MAA-g-EG).^[3,36–38] Interpolymer complexes in this system are formed owing to hydrogen bonding between the etheric oxygen of the graft PEG chain and the acidic groups of MAA.

Furthermore, we confirmed^[39] that at low pH, the network is collapsed because of the formation of temporary physical cross-links. In Fig. 3 the effect of pH is reported on complexation–decomplexation mechanism of the polymer network. P(MAA-g-EG) hydrogels showed reversible, pH-dependent swelling behavior. This is owing to hydrogen bonding between the hydrogen in the carboxylic acid groups of the PMAA and the oxygen in the grafted PEG chains. At low pH values, which are lower than $\text{p}K_a$ of the carboxylic acid, the carboxylic acid groups of the PMAA protonate and hydrogen bonding can occur resulting in collapsed hydrogels. At higher pH values, these acid groups

Fig. 3 Network structural changes because of variations on environmental pH. At low pH (A) interactions between the tethered grafts with the protonized ionic moieties increase. The formation of interpolymer complexes occurs and the system is in the collapsed state. Higher pH (B) disrupts the interpolymer complexes and ionic moieties deprotonize leading to extensive swelling.

become ionized and then the hydrogen bonding breaks down. As a result, the hydrogels swell to a high degree because of electrostatic repulsion within the copolymers (Fig. 3) and water is allowed to enter.

Our group studied in detail the properties and stability of the polymer complexes formed in the P(MAA-g-EG) system. We investigated the equilibrium swelling behavior of the P(MAA-g-EG) hydrogels as a function of pH.^[40] The equilibrium swelling ratio, q , of the samples was calculated as a ratio of the equilibrium weight to the weight of the dry sample. At low pH values, when complexation occurs, the polymer networks were collapsed and the swelling ratio was low, while at high pH values, *circa* 8, the swelling ratio increased and reached its maximum value.

We were able to produce microspheres^[41] of poly(methacrylic acid-g-ethylene oxide) [P(MAA-g-EO)] network by using a suspension polymerization reaction. The reaction was carried out in silicone oil at high temperature and led to the formation of copolymer microspheres. The system showed the same pH-dependent swelling behavior as before. The aforementioned systems have been studied as possible intelligent carriers for the administration of peptides and proteins. These pH-sensitive hydrogels can provide protection to the drug loaded into the system and they can target the release of it into a more suitable environment such as the upper intestine.

In the work of Drummond et al.^[42] the uptake and release kinetics of budesonide from P(MAA-g-EG) systems in vitro as well as the pharmacokinetics following nasal administration were investigated. The loading efficiencies of budesonide into the polymers were examined as a function of concentration of ethanol in water. Ethanol was necessary to help the solubility of budesonide but hindered hydrogel swelling at pH 7.2. It was found out that the maximum loading was obtained using a 25% ethanol solution. A constant

plasma concentration was attainable for 45 min after nasal administration of the system.

We also investigated^[43] the use of P(MAA-g-EG) hydrogels as oral delivery vehicles for insulin. P(MAA-g-EG) microparticles were obtained by crushing films of copolymers and, subsequently, loading them with insulin by imbibition. The polymeric microspheres were then administered orally to healthy and diabetic Wistar rats. In the acidic environment of the stomach, the gels were unswollen. The insulin remained in the gel and was protected from proteolytic degradation. In the basic and neutral environments of the intestine, the complexed network dissociated and this resulted in rapid gel swelling and insulin release. Within 2 hr of administration of the insulin-containing polymers, strong dose-dependent hypoglycemic effects were observed in both healthy and diabetic. These effects lasted for up to 8 hr following administration.

In another work from Lowman,^[44] it was concluded that the addition of PEG grafted to the gels was crucial for the in vivo delivery of the protein. PEG chains participate actively in forming the interpolymer complexes, but also act as peptide stabilizers and enhance the mucoadhesive characteristics of the polymer network when in the swollen state. This is owing to the fact that when the network is in the relaxed state, PEG chains could reach out and act as anchors, thus promoting adhesion. On the other hand, in the complexed state, the grafts cannot fully extend, impeding to penetrate the mucosa.

We examined the feasibility^[45] of using the P(MAA-g-EG) as a carrier for the oral administration of salmon calcitonin. They found out that the loading efficiency of the system was highly affected by the amount of solvent used during hydrogel preparation. They explained the transport mechanism as relaxation controlled. The diffusion coefficient was estimated using a heuristic Fickian/relaxational model.

In addition, we conducted studies^[46] to investigate the P(MAA-g-PEG) hydrogel ability to inhibit proteolytic enzymes. It was found that the calcium-binding properties of the copolymer inhibited the enzymatic activities of digestive enzymes. This study was crucial in showing that the material was also capable of protecting the insulin inside by deactivating some of the digestive enzymes in the stomach.

Insulin: Oral Delivery Challenges

Insulin is a suitable example of all the efforts spent in finding a successful way for the development of an oral delivery system.^[24,44,47–51] An oral formulation of this protein, indeed, has been a challenging and hard-to-pin-down goal since the initial discovery in 1922. Since then, the protein has been administered by injections; yet,

there has always been a strong tendency to move toward more patient-friendly administrations. The emerging insulin delivery technologies are focusing on achieving similar efficacy to injectable insulin formulations, yet offering a higher degree of convenience and quality lifestyle to the patient. Although many alternative routes of insulin delivery are being developed or undergoing clinical trials, none of them have been commercialized yet owing to efficacy, safety, and cost considerations.

The human insulin gene is expressed in the β cells of the pancreas.^[52] The secretion and excretion of this hormone is triggered by glucose concentration to maintain normal glucose levels in the body. Insulin is synthesized from the β cells of the pancreas from a single chain precursor known as preproinsulin that is cleavage of the prepeptide sequence to generate proinsulin and eventually in the Golgi apparatus cut off of C-peptide and transformed into insulin. This protein comprises two peptide chains (A and B) connected to each other via disulfide bridges. In addition, the A chain contains another disulfide bridge within the chain.

Both the final form of the protein and the C-peptide are stored in secretory granules of the β cells and released after physiological stimulus.

As mentioned before, the trigger stimulus for insulin synthesis and secretion is represented by glucose. In detail, release of the hormone occurs in a biphasic fashion. When the glucose concentration outside the cell increases, the sugar molecules are transported inside the cell via an insulin-dependent glucose transporter, GLUT-2. This produces an immediate release of insulin stored in the secretory granules. If the physiological stimulus persists, a delayed response occurs and insulin is hence synthesized.

Insulin is an anabolic hormone indispensable for glucose transport across the membrane, formation of glycogen in the liver and in the skeletal muscles, and conversion of glucose into triglycerides.

Insulin of different animal species has similar biologic activity and differs only in the sequence of three amino acids in the A chain-source. Insulin is obtained from beef or pork pancreas. Human insulin is a product of recombinant DNA technology or chemical modification of pork insulin and is structurally identical to human insulin.

Insulin is the mainstay of treatment for diabetes mellitus, a group of metabolic disorders characterized by prejudiced glucose utilization, ensuing in hyperglycemia.^[53,54] Diabetes affects more than 150 million of people worldwide. It is in fact one of the most widespread and serious chronic diseases. Each year, approximately 800,000 people are diagnosed with diabetes, and its occurrence has been increasing steadily over the last half of this century.^[3] Incidence is expected to continue rising with the aging US

population and the increasing prevalence of obesity among Americans.

The disease is characterized by abnormalities in the metabolism of carbohydrates, proteins, and lipids as a consequence of deficiency in the synthesis, secretion, or function of insulin. All these anomalies lead to increased glucose levels, coupled with both macrovascular and microvascular complications during chronic treatments including coronary artery disease, peripheral vascular disease, nephropathy, neuropathy, and retinopathy. There are multiple causes for this disease. Each can be categorized under different forms of diabetes. A first gross classification distinguishes between primary or idiopathic diabetes mellitus, the most common, and secondary diabetes. The latter one includes forms of hyperglycemia associated with identifiable primary causes such as pancreatitis, pancreatectomy, and hormonal tumors that result in destruction of pancreatic islets.

Primary diabetes, on the other hand, has been further divided by the National Diabetes Data Group of the National Institute of Health into two variants: Type 1 and Type 2. Type 1 diabetes, formerly called insulin-dependent diabetes mellitus (IDDM) or juvenile-onset diabetes, is an autoimmune disease that results when the body's immune system attacks and destroys its own insulin-producing β cells in the pancreas. People with Type 1 diabetes need daily injections of insulin to survive. Type 1 diabetes develops most often in children and young adults and accounts for 5–10% of diagnosed diabetes in U.S.A. Type 2 diabetes, also called non-IDDM (NIDDM) or adult-onset diabetes, is characterized by non-responsiveness to insulin. It occurs when the β islet cells of the pancreas secrete too little insulin and/or the body cannot utilize insulin effectively. About 90% of people with diabetes have Type 2 disease. It is more common among people who are over 40 yr old, obese, or have a family history of diabetes.

Gestational diabetes develops or is discovered during pregnancy and usually disappears following pregnancy. Women who have had gestational diabetes are at greater risk for developing Type 2 diabetes later in their lives.^[3] Insulin is indispensable for Type 1 patients that do need to take exogenous insulin on a regular basis to control their blood glucose levels. Patients affected by Type 2 can delay the intake of the protein in the first stage of the disease, when they can control glucose levels with hypoglycemic agents, exercise, and diet. However, owing to progressive nature of the disease, they eventually require insulin administration to manage hyperglycemia owing to exhaustion of the pancreas. Insulin, therefore, is the indispensable treatment for diabetes mellitus.

Insulin was discovered in 1921 by Best and Banting at the University of Toronto, Canada. On January 23rd 1922, Leonard Thompson, only 13 yr old, was the

first patient saved by insulin injection. For more than a decade, after its discovery, unmodified ordinary insulin obtained from pancreatic extracts was the only preparation available.^[55] An attempt of administering the protein orally was performed. Nevertheless, no improvements in the diabetes symptoms were noticed. Since then, insulin has been administered by injections. At the present time, the available options to diabetic patients range between insulin syringes, insulin pens, insulin pumps, and jet injectors. Each of the available technologies appeals to a section of the insulin-dependent diabetics; however, the associated discomfort and inconvenience has raised the dissatisfaction among the users. The reduced compliance leads to poor glucose control and increase in diabetes-associated complications. This is a cause for concern because of the high incidence of diabetes worldwide. Recent research findings suggest that in the year 2000, over 20 million people were diabetics in U.S.A. As stated before, insulin syringes were introduced 75 yr ago and are still the most popular insulin delivery option.

Alternate Routes of Insulin Delivery

There are three main routes for insulin delivery being developed by researchers. The first is insulin via injection. It assures that insulin reaches the blood stream in an active form and in quick dosage patterns.

A few variations of the injection technique have been developed, most notably the insulin pump and insulin pens.^[56–58] Insulin pumps are mechanical pumps attached to a catheter. The flow of insulin into the body can be directly controlled by the pump speed and concentration of the insulin solution. They have been shown to accurately deliver insulin in its active form. The problem with this system is the size of the pump. Also, the catheter needs to be continually cleaned and sterilized when the pump is disconnected to avoid infection. The insulin pen is a small pen-shaped device with a small needle that can administer exact amounts of insulin into the body. While it is easier to use than standard needles, it still relies on injection for insulin delivery into the body.

The second route of insulin delivery system being developed is through transdermal systems.^[59] The use of ultrasound enhancement has led to the development of this system. Transdermal transport is usually limited to small weight compounds, but low-frequency ultrasound shows a several orders of magnitude increase in the insulin transport across the skin. Researchers continue to improve this process, but it is currently not efficient enough for clinical use.

The third process is transmucosal delivery of insulin into the blood stream. There are a number of mucosal

surfaces possible for transport: nasal, buccal, pulmonary, oral, vaginal, and rectal.^[58] Nasal, pulmonary, and oral are the leading candidates for transmucosal delivery.

Numerous researchers have developed delivery devices for insulin via the nasal route.^[19,60–62] A significant amount of insulin reaches systemic circulation through the nasal cavity. Researchers were able to monitor a response in the glucose levels of the body after dosage. Nonetheless the insulin bioavailability was too low. Further research into enhancement of insulin transport via the nasal passage has shown an increase in blood serum insulin when chemical enhancers were used over more traditional nasal administration.^[63]

The first method of oral insulin delivery was with the addition of proteolytic inhibitors such as diisopropyl-fluorophosphate^[64] or naturally occurring aprotinin.^[65] While some decrease in blood glucose levels was obtained, these reductions were far short of the decrease required.

Research on encapsulating insulin into liposomes^[66] showed large decreases in the blood glucose level, but the results were inconsistent.

Touitou and Rubinstein^[24] developed a polyacrylate coating designed to dissolve at the pH of the colon. The particles were able to decrease blood glucose concentrations for 3 to 4 hr in rats. This study was of historical importance as it was the first use of polyacrylate for oral protein delivery. However, as already mentioned, the bioavailability achievable with this system was still too low to be considered for a marketed product.

A wide range of biodegradable and conventional polymers have been investigated as possible oral insulin delivery devices.^[14,51] These systems must protect the insulin as it passes through the stomach, and were designed to release their insulin and successfully transport it across the GI lining. Most systems developed to this point either protected the insulin while in transit or aided in the transport of insulin across the cell layer of the upper small intestine, none have accomplished both. Not designing the system to deal with both challenges caused failure and resulted in little active insulin getting from the device into the blood stream.

Nagai and coworkers^[50] added a protease inhibitor to aid in protecting the insulin while in transit. They found an increase of nearly four times the insulin reaching the blood stream compared to the system without the protease inhibitor. The bioavailability of the insulin their system delivered was near zero. This study proved that adding proteolytic inhibitors alone would not protect the insulin. Thus, protecting the insulin from proteolytic degradation was not the only important concern of insulin degradation en route to the blood stream.

CONCLUSIONS

In conclusion from these studies it is clear that the oral (transmucosal) delivery of proteins has been a leading problem in drug delivery, yet one that has not had any significant solutions up to now. We believe that development of new oral protein delivery devices based on pH-sensitive or hydrogen bonding-complexing and pH-responsive gel carriers interspersed with bioactive protein is a promising solution. Insulin, calcitonin or other proteins can be loaded into polymeric microspheres or microparticles. In these systems, in the acidic environment of the stomach, the gels are unswollen due to the formation of polymer complexes.^[67-74] The protein remains in the gel and is protected from proteolytic degradation. In the basic and neutral environments of the intestine, the complexes dissociate resulting in rapid gel swelling and protein release^[75-80]. These system exhibit significant mucoadhesion in the upper small intestine and show inhibitory properties on the proteolytic activity of enzymes in the GI tract.

INTRODUCTION

Pyrolytic carbon (PyC), a material for long-term blood-contacting implants, has enjoyed great success. Over the past three decades, the use of PyC heart valve implants has become commonplace. The total number of components used in heart valve replacements alone is estimated to exceed 4 million with a total clinical experience of about 20 million patient years.

More recently, the successful use of PyC in small joint replacements over the past 20 years has led to the approval of such devices by the U.S. Food and Drug Administration. This event, in addition to recent improvements in PyC technology, has placed a critical focus on PyC as a candidate material for other implant applications. Although materials-related issues involving strength and durability have limited possibilities for many devices such as spinal prostheses and other joint replacements, the increased strength and toughness of recently developed PyC materials expands the horizon for new applications. The superior wear and fatigue properties of PyC and its stiffness match with bone further entice its increased use in load-bearing orthopedic implants.

PyC is formed by the high-temperature pyrolysis, or thermal decomposition, of source hydrocarbons and the subsequent recrystallization of elemental carbon. PyC is characterized by high temperature stability, high mechanical strength, and high chemical resistance. Furthermore, PyC exhibits excellent stability, wear resistance, fatigue resistance, and compatibility in the highly aggressive biological environment. Alloying elements such as silicon or boron may be added to the source hydrocarbon to produce carbide inclusions within the carbon matrix. Unlike other pyrolytic materials that tend to be highly anisotropic, the biomedical-grade PyC materials are deliberately prepared as isotropic materials.

Critical information needed for implant design using PyC is given in this text including physicochemical and

mechanical properties, manufacturing methods, and microstructural details. The intent is to provide the background, tools, and references for prospective designers and to spark their imaginations for new applications.

HISTORY

In 1964, abstract number 84—"The Anticlot Properties of Graphite Coatings on Artificial Heart Valves"—appeared in the journal *Carbon*, Volume 1, No. 3, April 1964. This abstract by Vincent L. Gott, James D. Whifler, Robert C. Dutton, Donald E. Koepke, Ronald L. Daggett, and William P. Young, all of the Department of Surgery at the University of Wisconsin, had been presented at the Sixth American Carbon Conference in Pittsburgh, PA, in June 1963. At the time, 95 percent of all heart valve implants in animals failed within two weeks following implant because of blood clotting (thrombosis). Their approach to the problem was to evaluate various plastics and coatings as candidates for use in artificial hearts and artificial valves in the hopes of finding a satisfactory clot-repelling material. Of all the materials tested, a colloidal graphite coating gave overwhelmingly better results than any of the others tested.

Another researcher, Jack C. Bokros at General Atomic Company in San Diego, happened to read this abstract. Bokros, a metallurgist by training, was working with PyC as coatings for nuclear fuel particles used in gas-cooled fission reactors. He was intrigued by Gott's work and contacted him to suggest trying PyC in the anticlot testing. This was the beginning of a collaboration that was to revolutionize heart valve technology and ultimately make the prospect of clinical heart valve implantation the commonplace event that it is today.

Development and Utilization

In the 1960s the study of biomaterials was in its infancy, and the only approach to solving materials problems for implants was by trial and error. There were designs for prosthetic heart valves and methods for implantation, but the effective lifetime of the implants was severely limited. Blood clots would form on the implants that interfered with function, or the materials would fail due to fatigue, by distortion due to sterilization, or by degradation due to exposure to the body fluids. Heart valve replacement lifetime was much shorter than the patient's expected lifetime.

Gott tested the PyC materials provided by Bokros and found excellent thromboresistance,^[1] prompting the collaborators to set out to optimize the material for heart valve applications. Their initial technical problem was to increase the PyC coating thickness from the micrometer thicknesses that Bokros had been using at General Atomic Company to levels on the order of 0.5 mm needed for the structural requirements for heart valves. To attain the thicker coatings, the coating reaction needed to be prolonged.

Pyrolytic carbons are prepared by heating a hydrocarbon such as propane to approximately 1200 to 1400°C in the absence of oxygen. At high temperature, the hydrocarbon breaks down to free radicals, which then "polymerize" into a solid. In order to produce isotropic PyC, a vertical fluidized bed reactor is needed.^[2] The reactor consists of a vertical tube containing a fine dispersion of refractory material particles, which are levitated using an inert carrier gas, such as nitrogen or helium, fed into the bottom of the tube. Induction coils on the outside of the tube heat the contents. At temperature, a hydrocarbon gas is added to the mixture and the pyrolysis reaction takes place. See Fig. 1.

This process can be described as a chemical vapor deposition because all of the particles within the bed become coated with PyC. Specific components are manufactured by placing preformed substrates within the fluidized bed that subsequently become coated with PyC during the reaction. The resulting components are composites consisting of an outer shell of PyC encasing and bonded to an inner refractory substrate such as fine-grained graphite. See Fig. 2.

The reactor depicted in Fig. 1 is a simple fluidized bed reactor. With prolonged coating reaction time, the bed surface area grows as additional carbon is deposited until fluidization ceases and the bed collapses. Bed collapse limited the coating thickness that could be applied in the simple bed reactor to micrometer levels. It was found that the coating reaction could be prolonged to give the needed thickness by simultaneously adding new bed particles and by withdrawing coated bed particles to maintain the reaction in a quasi steady

Fig. 1 A schematic diagram of a simple fluidized bed reactor. Components are levitated in the fluidized bed and coated with PyC as the source hydrocarbon is pyrolyzed. The reactor is heated using induction coils.

state.^[3] Because it was not possible to dynamically measure the bed surface area, the addition of new and removal coated bed particles was based on best guesses; consequently, there could be considerable variation in the properties of the resulting coatings. A quasi-steady-state reactor is depicted in Fig. 3.

The second technical problem was to ensure consistent production of pyrolytic carbon with the desired hardness and strength. Coating properties are dictated by several variables: bed temperature, gas composition, total gas flow rate, and bed surface area. See Fig. 3. With the reaction controls available in the 1960s, it was possible to control all of the variables except for the surface area of the fluidized bed of particles. Bed area

Fig. 2 Composite structure of PyC components. The PyC coating encases and is bonded to an inner substrate such as fine-grained graphite.

Fig. 3 A quasi-steady-state fluidized bed reactor. Bed particles are added and withdrawn in a semiempirical fashion to prolong the coating reaction. Silane gas is added to produce silicon carbide inclusions in the PyC coating.

was critical because it determined the resulting coating microstructure, strength, and hardness. Lack of bed area control was compensated for by the addition of methyl trichlorosilane gas. The silane gas decomposed during the pyrolysis reaction and formed fine silicon carbide inclusions dispersed within the pyrolytic carbon matrix. Silicon carbide inclusions increased coating hardness as needed for the consistent manufacture of heart valve structural components.^[3]

From Gott's tests, pure carbon displayed the best biocompatibility, whereas pure silicon carbide was thrombogenic, but silicon carbide in small amounts codeposited with PyC was found to be tolerated.^[1] A practical compromise between thrombogenicity and consistent mechanical properties was reached with a 4- to 12-weight-percent silicon-pyrolytic carbon alloy. This material was patented and given the trade name Pyrolite carbon.

Late-1960s state-of-the-art valve designs consisted of three major variations of a metallic cage with a single polymeric occluder, e.g., either a ball or disk poppet or a tilting disk^[4] as shown in Fig. 4. Typical heart valve occluder geometries consisted of spherical balls, lenticular poppets, or circular disks. Occluders were mounted in ringlike metallic cages or valve orifices, with struts that captured and guided the occluder during the opening and closing motions. Metals used for orifices were principally titanium or cobalt chrome alloys.

The use of Pyrolite carbon increased rapidly in existing mechanical heart valve designs as a replacement for the polymeric occluders beginning with the ball-in-cage DeBakey Surgitool design first implanted

Fig. 4 Different heart valve design types: (top left) Starr-Edwards silicone rubber ball in metallic cage (1964); (top right) Cross Jones polymeric lenticular poppet in metallic cage (1967); (bottom left) Bjork Shiley tilting disk, originally a polyacetyl disk in a metallic cage (1969), shown here with a PyC disk (1975); (bottom right) On-X prosthetic heart valve, all-carbon bileaflet valve (1996).

clinically in 1968. The superior durability, stability, and biocompatibility of Pyrolite carbon eliminated the causes of early valve failure, thus allowing valves to endure for the patient's lifetime.^[5] Utilization of PyC as a material for mechanical heart valves was declared an "exceptional event."^[6]

In order to meet the demand for heart valve components, General Atomic Company formed the Medical Products Division, which in 1979 was sold to Intermedics, Inc. The new entity, renamed Carbomedics, was the sole source of Pyrolite carbon in the United States and a number of other countries worldwide until the original patent expired in the early 1990s.

The General Atomic/Carbomedics Pyrolite component manufacturing process consisted of several steps:

1. Fine-grained graphite substrate preforms were machined and included in the fluidized bed reactor to be coated with carbon. The substrates had the desired component shape but were under-sized to accommodate the added coating thickness.
2. The substrates were coated with silicon-alloyed Pyrolite carbon in the reactor to an excess coating thickness to compensate for the poor control of coating thickness.

3. Excess coating was removed by abrasive grinding.
4. The components were polished to a fine surface finish.

Because of the problems of wear and durability experienced with polymeric valve components, valves were designed with freely rotating circular disks to distribute the wear circumferentially rather than being concentrated at fixed contact points. Evaluations of PyC for use in the replacement of polymeric disks revealed that although the wear rate of PyC caused by metal was much less than that observed for polymers, it was still necessary to use the rotating circular disk concepts for the existing Lillehie–Kaster and Bjork–Shiley designs.

It was recognized in the 1970s that ball-in-cage and poppet designs produced lateral flow and tilting disk designs produced skewed asymmetric flow.^[7] In order to improve the flow, the obstructive designs that used poppets or tilting disk were rejected, and conceptualization was redirected toward bileaflet designs that centralized the flow. But bileaflet designs required fixed pivots and hence resulted in localized wear. Extensive testing using a variety of materials in contact with PyC indicated that PyC wearing against itself produced low wear rates,^[5] whereas metals wearing on PyC caused the PyC to wear much more rapidly. Consequently, efforts were directed to adapt the early Lillehie–Kalke bileaflet design, previously made using titanium, to an all-PyC design. The culmination of this effort resulted in the Saint Jude Medical (SJM) valve. The bileaflet SJM valve was implanted in 1976 and became the de facto standard mechanical valve during the 1980s.

During the 1980s several other mechanical valves that used PyC were developed. Sorin Biomedica in Italy produced a monoleaflet valve^[8] and a bileaflet valve^[9] using their own PyC (the Pyrolite carbon patents held by Carbomedics were not enforceable in Italy). The Sorin bileaflet valve was not all carbon; it had PyC leaflets and a titanium orifice. To improve blood compatibility, the Sorin titanium orifice was coated with a very thin layer of vapor-deposited carbon.^[10]

In the United States, two other bileaflet designs, the Duromedics and the Carbomedics valves, were introduced. These valves were designed using cylindrical orifices without upstream protrusions (like the SJM pivot guards) that included the pivot recesses. The protrusions were required in the SJM design because there was, at the time, no way to machine the pivot recesses on the inside of a straight cylinder and then grind them to final size after coating. Accordingly, a new manufacturing process was devised in which the configuration required to be on the inside surface of an orifice was machined as a negative on the outside of a graphite mandrel. After the PyC was deposited on the

mandrel, the mandrel was removed^[11] leaving a free-standing, all-PyC orifice. The shortcoming of the mandrel process was that during the initial moments of coating when the PyC layer is very thin (and in tension), the impacts of the mandrels with one another during the levitation causes impact defects that are exposed on the inside surface of the orifice once the mandrel is removed. These defects potentially reduce the strength and surface quality of orifices produced on a mandrel.

In the early 1990s the original General Atomic Company patents for Pyrolite carbon expired. Heart valve manufacturers that had relied upon Carbomedics as the sole source for Pyrolite valve components developed their own facilities to produce Pyrolite-like carbon. The FDA responded with guidance for demonstrating equivalence given in Appendix B of the Replacement Heart Valve Guidance—Draft document, Oct. 14, 1994. This document may be downloaded from the FDA Web site: <http://www.fda.gov/cdrh/ode/3751.html>.

During the early 1990s, Bokros and members of his original team from General Atomic left Carbomedics and formed a new company, Carbon Implants Incorporated (CII). At CII they reviewed the PyC reaction process, applying 1990s-level technological advances in transducers and computerized process control and were able to devise a method for dynamically measuring bed surface area. The bed surface area was the poorly controlled variable in the original General Atomic process that required the addition of silicon to maintain hardness and prevented the possibility of coating a substrate precisely to size, thus eliminating the final grinding operations.

With the new process controls, they attained a true steady-state reactor (Fig. 5), which made it possible to produce pure pyrolytic carbon. The resulting pure carbon PyC was stronger, tougher, and more deformable than the silicon-alloyed PyC. The improved PyC was patented and named On-X carbon.^[12]

In 1994, a new company was formed, Medical Carbon Research Institute, to design and produce a new bileaflet valve that took full advantage of the breakthrough in process technology. With the exception of Medical Carbon Research Institute's On-X heart valve, the original 1960s technology developed at General Atomic continues to be used in the manufacture of prosthetic heart valves, using the silicon-alloyed Pyrolite or Pyrolite-like carbon.

The new technology that allowed precise control of the deposition process provided a number of technological advances in the design of heart valve replacement.

First, the precise control allowed the consistent and reproducible production of a pure carbon that was

Fig. 5 True steady-state fluidized bed reactor. The coating reaction rate and bed surface area are analytically controlled by addition and withdrawal of bed particles. Such controls improved the quality of the PyC, which eliminated the need for the silicon carbide additive.

stronger and tougher than the silicon-containing material and with the hardness required to attain the wear resistance needed for use in heart valve replacements.

Second, the precision of the process allowed for the coating of pivot configurations inside of an orifice to produce finished dimensions that required no final grinding or otherwise shaping. This coat-to-size ability resulted in a surface quality not attainable with the older technology.

Third, the elimination of the silicon carbide addition to the PyC improved the toughness so that the design of heart valve replacement orifices was not restricted to straight cylinders (which are hemodynamically deficient) and allowed for the realization of orifices that are shaped more like the natural ones with a flared inlet.

Orthopedic Applications

The potential for PyC in orthopedic applications was recognized early on because of PyC's advantages over metallic alloys and polymers.^[13,14]

1. A modulus of elasticity similar to bone
2. Excellent wear characteristics
3. Excellent fatigue endurance
4. Excellent biocompatibility with bone and hard tissue
5. Fixation by direct bone apposition

Studies by Cook et al.^[15] of hemijoint implants of a PyC femoral head in the canine hip observed a greater

potential for acetabular cartilage survival in PyC than for cobalt-chromium-molybdenum alloy and titanium alloy femoral heads. PyC demonstrated significantly lower levels of gross acetabular wear, fibrillation, eburnation, glycosaminoglycan loss, and subchondral bone change than the metallic alloys.

In-vitro and clinical in-vivo PyC orthopedic implant studies during the 1970s through the early 1990s were summarized by Tian et al.,^[14] with the conclusion that PyC demonstrates both good biocompatibility and good function in clinical applications.

Between 1979 and 1987, 151 PyC metacarpophalangeal (MCP) finger joint replacements were implanted in 53 patients at the Mayo Clinic, Rochester, Minnesota.^[16] Follow-up after 10 years demonstrated excellent performance. These results were used in part to justify the FDA premarket approval (PMA) for the Ascension Orthopedics semiconstrained, uncemented MCP finger joint replacement, PMA P000057, Nov. 2001. The Ascension PMA summary of safety and effectiveness may be downloaded from the FDA Web site: <http://www.fda.gov/cdrh/pdf/p000057b.pdf>.

Although the potential for PyC in orthopedic applications is excellent, it can be more expensive than metals or polymers, so an economic prejudice exists against its use when less expensive materials were available and performed adequately at least in the near term. However, the recent demonstrations of long-term success with PyC MCP joint replacements, in combination with persistent materials-related lifetime limitations in metallic and polymeric devices, counter this economic prejudice. The cost of redo surgery to replace failed devices well exceeds the initial cost of

materials. New devices are currently being considered in which metals or polymers may be inappropriate.

PYC DESIGN CONSIDERATIONS

Materials selection for an implant is a complex issue that involves biocompatibility together with mechanical and physical compatibility. Data that a designer needs in order to consider PyC for an implant are summarized as follows.

Biocompatibility

Preclinical biocompatibility tests currently required by the FDA and European Community (International Standards Organization ISO 10993) for rigid material implants are given in Table 1 along with results for PyC. No significant reactions were observed.^[12] These tests do not detect a difference between silicon-alloyed and pure carbon PyC.

For long-term critical implants, a preclinical animal implant evaluation of a device is required. The animal tests model the implants and materials in the intended application as closely as possible. Examples may be found in FDA PMA Summaries of Safety and Effectiveness (SSE). See the Ascension MCP SSE, <http://www.fda.gov/cdrh/pdf/p000057b.pdf>, and the On-X valve SSE, <http://www.fda.gov/cdrh/pdf/p000037.html>, for examples. The FDA Web site has a searchable database that provides guidance documents and SSEs for a variety of devices: <http://www.fda.gov/cdrh/devadvice/pma/index.html>.

For any device, it is highly recommended to obtain regulatory agency guidance documents that may exist as a means of determining design testing and performance requirements. The International Standards Organization (ISO) also publishes guidance for devices. In many cases, a guidance document may not yet exist, but a review of one for a related device provides a good idea of the information needed. An excellent

review of theory and observations of PyC biocompatibility is given in *Cells and Materials* 1996;6(4):271–356, which is a special issue on “Pyrolytic Carbon: Biomedical Uses and Biocompatibility.”

Physical and Mechanical Properties

Carbon has an allotropic crystallographic structure and occurs as a spectrum of ordered or disordered (turbostratic) structures varying from tetrahedral covalent bonded diamond to layered hexagonal covalent in-plane and Van der Waals interplane bonded graphite. Each carbon allotrope has unique structure-dependent physical and mechanical properties. Carbon, rather than being a single material, is actually an entire family of materials: coal, charcoal, fullerenes, diamond, glassy carbon, etc. Thus, PyC biocompatible and mechanical properties that support implant applications are unique and cannot be assumed to apply for another carbon form just because it happens to be of the carbon family.

Pyrolytic carbon is a hard, rigid linear-elastic material and exhibits no appreciable plastic deformation. As most brittle materials, PyC has scatter in the value of its tensile strength. Strength scales with effective stressed volume or effective stressed area according to the Weibull relationship:

$$\sigma_2/\sigma_1 = (K_1 V_1/K_2 V_2)^{1/m}$$

where σ and KV are the strength and effective stressed volume of specimens 1 and 2 and m is the Weibull modulus of approximately 10 for PyC.^[17] Strain to failure also scales according to the Weibull relation. Elastic properties given in Table 1 are from four-point-bend, third-point-loading substrated specimens of dimensions 25 mm by 6 mm by 0.4 mm and effective stressed volume of 1.93 mm³. Thus, strength is determined by the specific device component design. For a new device, static and dynamic strength testing is required by regulatory agencies.

Table 1 Biological testing of pure PyC

Test description	Protocol	Results
Klingman maximization	ISO/CD 10993-10	Grade 1; not significant
Rabbit pyrogen	ISO/ DIS 10993-11	Nonpyrogenic
Intracutaneous injection	ISO 10993-10	Negligible irritant
Systemic injection	ANSI/AAMI/ISO 10993-11	Negative—same as controls
Salmonella typhimurium reverse mutation assay	ISO 10993-3	Nonmutagenic
Physicochemical	USP XXIII, 1995	Exceeds standards
Hemolysis—rabbit blood	ISO 10993-4/NIH 77-1294	Nonhemolytic
Elution test (L929 mammalian cell culture)	ISO 10993-5, USP XXIII, 1995	Noncytotoxic

The value of Young's modulus approximates that of cortical bone (~ 17 GPa). The similarity in modulus allows a much greater degree of stiffness matching between implants and bone. Interfacial stress concentrations that can contribute to implant loosening and bone reabsorption are minimized.^[13,14] Strain-to-failure values of 1.58% for the pure PyC are large relative to the strain-to-failure values of approximately 0.2% typical of ceramics.

Hardness is determined using a diamond penetrant indenter with a 500 g load. An interesting property of PyC is that it fully recovers the indentation, so hardness readings are made using a "record" of the indentation in a formvar coating over the test part surface. Density is low; therefore, valve moving components approach neutral buoyancy so component mass does not interfere with actuation by blood flow.

Fracture mechanics values cited were determined using miniature compact tension specimens and will be discussed subsequently in more detail. The graphite substrates were removed for the worst-case fracture mechanics value estimates using monolithic PyC. The friction coefficient for PyC bearing against PyC in blood plasma is low; the value of 0.15 given in Table 2

is a conservative overestimate. Wear resistance is given as the wear volume produced per linear distance using a rotating disk (PyC) pressed under load into a stationary PyC flat. However, it is important to note that wear and endurance are device design-specific tests. For example, heart valve designs are tested to 600 million cycles—full opening and closing under worst-case physiological flow conditions. Other devices must be tested in a manner simulating conservative end-use conditions. The Ascension MCP, for example, was cycled between 8 and 80 pounds load for 10 million cycles in a joint simulator.

Contemporary Long-Term Implant Design Criteria

The metallic strut failures in the convexo-concave Björk–Shiley heart valve during the late 1980s (see <http://www.me.utexas.edu/~uer/heartvalves/summary.html>) led to more stringent design evaluation criteria being required for long-term implants. In particular fracture mechanics, damage-tolerant design methods were strongly recommended in addition to the traditional stress-life (S–N) techniques.^[18] The first example of a damage-tolerant analysis for a heart valve was given in 1986 by Ritchie and Lubbock,^[19] but for metallic, not PyC, components. The late-1980s failure of PyC components in the Baxter–Edwards Duro-medics valve^[20] drove the development of methodology for measuring fracture mechanics properties of PyC.^[21] More recently, circa 2000, the FDA and ISO 5840 standards are requiring risk analyses also, but these are of a broader scope than damage-tolerant analyses.

Damage-tolerant life analyses for PyC long-term implant components have some unique aspects that merit discussion. Because PyC heart valve components and PyC layer thicknesses tend to be small, typical nondestructive evaluation techniques lack sufficient resolution and thus are not particularly helpful. Rather, a proof test approach has been taken. In this approach, every component is proof tested. Components survive the proof test provided that all flaws in the material are beneath the critical value (as defined by the fracture toughness K_{Ic}). Subsequently, flaws of the critical value are assumed to exist in the proof-tested components and to propagate under the worst-case service loads using the fatigue crack velocity, and the time-to-failure or lifetime is calculated. The existence of a fatigue threshold is disallowed, which requires that very small cracks behave in the same way as large cracks. This distinction will be discussed shortly, and it will be demonstrated that small cracks indeed behave as large cracks. Finally, an example of a damage-tolerant analysis will be given.

Table 2 Mechanical properties of biomedical carbons

Property	Pure PyC	Typical Si-Alloyed PyC
Flexural strength (MPa)	493.7 ± 12	407.7 ± 14.1
Young's modulus (GPa)	29.4 ± 0.4	30.5 ± 0.65
Strain-to-failure (%)	1.58 ± 0.03	1.28 ± 0.03
Hardness (DPH, 500 g load)	235.9 ± 3.3	287 ± 10
Density (g/cm ³)	1.93 ± 0.01	2.12 ± 0.01
Poisson's ratio	0.28 ± 0.04	0.22 ± 0.01
Fracture toughness (MPa m ^{1/2})	1.68 ± 0.05	1.17 ± 0.17
Fatigue threshold (MPa m ^{1/2})	1.11	0.7
Fatigue crack velocity (m/cycle)	$4.0 \times 10^{-15} \Delta K^{70.3}$	$4.15 \times 10^3 \Delta K^{88.9}$
Coefficient of friction	0.15	0.15
Wear resistance	$< 1.23 \times 10^{-6}$ mm ³ /km	
Residual stress (MPa)	18.2	28.6

(From Ref. [9].)

Fracture Mechanics

The primary role of fracture mechanics is to calculate the strength of a component containing a flaw with the basic assumption that all engineering structures are damaged and contain flaws or cracks. A “stress intensity factor” K describes the interaction of applied stress, σ_a , with a crack of a given size, a , and geometry, Q , and is defined in combined stress and flaw size units as $\text{MPa m}^{0.5}$ or $\text{ksi in.}^{0.5}$:

$$K = Q\sigma_a(\pi a)^{0.5}$$

The stress intensity factor K_I for mode-I tensile crack has a critical value K_{Ic} at which the component fractures in a single loading cycle, somewhat analogous to a fracture strength.

Stress intensities are defined for a given crack geometry and size relative to the component geometry and stress field. Many geometry factors have been determined and may be found in handbook tables or calculated analytically.^[22] For a through thickness transverse crack of length $2a$ oriented perpendicular to the stress direction in a tensile stress field, σ , where w is the specimen width, the critical stress intensity is given as

$$K_{Ic} = \sigma(\pi a \sec(\pi a/w))^{0.5}$$

A somewhat different formula is used for the edge crack of the compact disk tensile specimen. The K_{Ic} obtained using the appropriate formula for a compact disk, which had values ranging from 10 to 11 mm,^[12] gave an average value of $K_{Ic} = 1.67 \text{ MPa m}^{1/2}$. The question arises whether this behavior would extend down to the size of a flaw that might exist in a leaflet of a heart valve. Crack lengths of 10 to 11 mm are large relative to PyC coating thicknesses and heart valve components.

One way to make a crack in carbon is to apply a load to it by a Vickers diamond indenter. This gives a four-sided pyramidal indentation, and if the material is brittle, cracks extend from the four corners of the indentation. It was found that the smallest crack length that could be obtained by the Vickers indenter in PyC was 0.5 mm.

To make a shorter crack, it was necessary to use an indenter with a sharper edge and a more acute angle. The Berkovich diamond indenter proved satisfactory. It induced projected crack lengths from 138 to 169 micrometers, which were reasonable relative to coating thicknesses and component sizes. The Berkovich cracks were about 1/3 the length of the smallest Vickers crack and about 1/150 the size used in the compact tensile specimen. The pure carbon PyC specimens were loaded to failure to determine K_{Ic} . Averaged over five

tests, the K_{Ic} value was $1.76 \text{ MPa}\sqrt{\text{m}}$ with a standard deviation of 0.152. This is only slightly higher than the value of 1.67 obtained for the much larger cracks of the compact tension specimen.

Fatigue Tests

Three early studies—Schoen, Shim, and Kepner et al.^[23–25]—showed that the S–N curves for silicon-alloyed PyC were almost horizontal and within the scatter band of the static strength for up to 10^7 cycles and for Kepner et al. up to 10^8 cycles. The S–N curves appear to be horizontal, but it is our opinion that the cyclic stresses did not initiate the fractures. Rather, inadvertent stress excursions due to machine wear, machine vibration, and accidental shock initiated the fractures.

In the study of silicon-alloyed PyC, a specimen was tested at a strain of $10,000 \mu\epsilon$, $R = 0.05$, for 1.66×10^9 cycles without any indication of failure. (R is the ratio of the minimum stress of a cycle to the maximum.) The $10,000 \mu\epsilon$ strain is 94% of its average static fracture strain. For one lot of the silicon-alloyed carbon, the average static fracture strain was $10,610 \mu\epsilon$ with a std. dev. of $603 \mu\epsilon$. An unalloyed PyC specimen was cycled for 6.73×10^8 cycles without any sign of failure at $13,700 \mu\epsilon$, $R = 0.5$, which was 90% of the static fracture strength. It had survived an initial stress excursion of $14,200 \mu\epsilon$. (For this lot, the average strength was $15,200 \mu\epsilon$ with a std. dev. of $2400 \mu\epsilon$.)

Stepped Fatigue Test

From the three early tests cited previously, it appears that the fatigue strength, even at high cycles, is equal to the static strength. In order to demonstrate this more clearly, a novel testing procedure was developed. Tests on silicon-alloyed and unalloyed PyC are presented in detail in Ref. [26]. Static tests on 10 unalloyed specimens gave an average of $14,600 \mu\epsilon$ with a std. dev. of $2000 \mu\epsilon$; lowest value = $11,200$, highest value = $18,100$. It was found that cyclic stressing for 10^6 cycles in the scatter band of the static strength did not affect the subsequent distribution of the static strength.

Propagation and Non-Propagation from Microcracks

The average critical stress intensity factor for brittle fracture from microcracks in unalloyed PyC was $1.76 \text{ MPa}\sqrt{\text{m}}$. A reference level, σ_{ref} , for the threshold value for cyclic crack growth was taken to be 90% of this, i.e., $1.58 \text{ MPa}\sqrt{\text{m}}$. This value corresponds to an elastic strain of $4300 \mu\epsilon$ (133 MPa) and a crack length of $138 \mu\text{m}$. Considering the statistical variation of the

Table 3 Threshold study for cyclic crack growth

Interval	Cycles	% of σ_{ref}	Crack length (μm)		Growth?
			Initial	Final	
1	10^6	90	169	223	Yes
2	10^6	80	223	223	No
3	10^6	90	223	223	No
4	10^6	103	223	223	No
5	10^6	117	223	240	Yes (slightly)
6	10^6	107	240	240	No

properties, it is likely that this value might be in the range of the threshold value for crack growth under cyclic stress. Five specimens had cracks with lengths from 136 to 170 μm induced by the Berkovich indenter. This study is discussed in detail in Ref. [26]. The results on one of the specimens, given in Table 3, illustrate the behavior.

The test procedure was to subject the specimen to intervals of 10^6 cycles at different amplitudes of stress intensity factor near the reference value of $1.58 \text{ MPa}\sqrt{\text{m}}$ and see whether the crack grew or did not grow. For this particular sample, the following tests were performed and results obtained.

Notice that for the crack to grow in interval 5, the stress had to be raised to 117% of the reference value, thus making for this specimen the value for crack growth 105% above the value for brittle, fast fracture. Of course, it should have failed in fast fracture if there had not been a statistical variation of both the threshold value for growth and the critical value for fracture. In interval 6, the crack did not grow. The threshold value for crack growth is above this value. The value of the stress intensity amplitude for interval 6 was $1.69 \text{ MPa}\sqrt{\text{m}}$. The threshold for this specimen is above this value, but below $1.76 \text{ MPa}\sqrt{\text{m}}$.

The question that must be answered is, why did the crack grow in interval 1? It is known that there is a residual tangential stress field around an indentation and that it rapidly diminishes the farther the region is from the indentation. In the first interval, the crack grew under both the applied stress and this residual stress until it left the residual stress field.

This portion of the study answered two questions.

1. Is the crack tip made by the Berkovich indenter as sharp as the crack tip grown under cyclic stress? In this study, one might conclude that the indenter-induced crack tip is even sharper, but we believe this is the effect caused by the local residual tensile stress around the indentation.
2. Is linear elastic fracture mechanics valid over the range of crack sizes investigated in this series of studies from 11 mm down to 100 μm ? Based on the

values obtained, the answer is yes. In Ref. [27], a study with a transmission electron microscope at ultrahigh magnification showed that the structure of the carbon was in the nanometer range, thus indicating that, compared to the structure, 100 μm is also a large crack.

Structure

The structure was studied by transmission electron microscopy in the phase contrast mode at magnification ranging from 800,000 X to 4.5 million X. At the lower magnification, microbeads with an average diameter of 0.5 μm could be discerned. The pattern within the beads resembles that of a sliced onion.^[24] The beads might also be the tops of cones observed by Kaae.^[28] At a magnification of 1 million X, a spot pattern appears with all the spots having an average diameter of about 40 Å.^[29] See Fig. 6. This is about the size of the microdomains measured by X-ray diffractometry. The fact that the fatigue strength at high cycles could not be distinguished from the static strength leads us to believe that the isotropic PyC is

Fig. 6 Transmission electron microscope micrograph of unalloyed PyC (1,119,300 \times magnification). The spots are turbostratic carbon crystallites with an average size of 40 angstroms.

not subject to fatigue. Most theories of cyclic fatigue depend on the action of mobile dislocations. No dislocations were observed, and if they did exist, the extremely small size of the microdomains (4 nanometers) would make them immobile.

SUMMARY

The elastic strain at fracture for the unalloyed, isotropic PyC fatigue specimens was 1.46% at a stress of 448 MPa. The Young's modulus was 30.57 GPa and Poisson's ratio 0.28.

It was found that cyclic stressing within the scatter band of the static strength did not initiate cracks; induced cracks did not grow under cyclic stressing if below a threshold stress intensity factor, and this threshold stress intensity factor was valid over a wide range of crack lengths. Cyclic stressing did not reduce the static strength. No failures occurred when batches of 29 specimens were tested above the service stress at 6×10^8 cycles. The service stress is a small fraction of the fracture strength, thus a very high probability of survival can be ensured by a proof test of the assembly.

DESIGN ANALYSES EXAMPLES

Long-term implant devices in the United States require FDA premarket approval (PMA); a summary of safety and effectiveness (SSE) for each new device is prepared and made available to the public through the Freedom of Information Act. Many are directly available for download on the FDA Web site, <http://www.fda.gov/cdrh/>. While these documents typically give the results of analytic design evaluations, the exact details of the analyses may not be available because they are often considered proprietary information. However, for heart valves, several informative studies have been published in a special issue of the *Journal of Heart Valve Disease* 1996;5 Supplement I, which focused on fatigue and wear in mechanical heart valves. The best example from this issue, because it is the closest approximation of actual analyses used for a PMA, is given by Ryder and Cao.^[30]

Critical input information for Ryder and Cao's analysis includes estimates of the worst-case in-service loads (300 mm Hg pressure), which are used in finite element analyses to determine worst-case in-service stresses, σ_a , on the components. A proof test is then designed to apply a proof stress, σ_p , that defines an initial flaw size, a_i , in the component.

$$a_i \leq 1/\pi(K_{1c}/Q\sigma_p)^{0.5}$$

The initial flaw is then assumed to propagate with each loading cycle N by Paris law fatigue crack propagation,

$$da/dN = C\Delta K^m$$

where C is the fatigue constant and m the fatigue exponent. The crack grows until it reaches the final size, a_f , that satisfies the K_{1c} fracture criteria at the worst-case in-service stress:

$$a_f \geq 1/\pi(K_{1c}/Q\sigma_a)^{0.5}$$

The number of cycles to fracture, N_f , is the component lifetime and is found by integrating the Paris law crack growth rate:

$$N_f = 2/(C(m-2)a_i^{(m-2)/2})(K_{1c}/Q\sigma_a\pi^{0.5})^m$$

Cao's form of the Paris law fatigue crack velocity equation as given above is a simplification that recognizes that the initial flaw is much smaller than the final flaw size, and that stresses in heart valves range from zero to a maximum tensile value, without compression. For these reasons, Cao's fracture mechanics parameters as cited in Ref. [30] have slightly different values than those given in Table 2.

A heart is assumed to beat 40 million times a year, so the number of cycles divided by 40 million gives the damage-tolerant life in years. A summary of Cao and Ryders' results are given below in Table 4.

The calculated lifetimes are striking by their magnitude compared with an expected human lifetime. However, the small crack and stepped fatigue crack propagation results presented above demonstrate that crack propagation occurs only within the scatter band for the single cycle strength. Furthermore, the existence of a fatigue threshold has been ignored. Stresses may seem high relative to the values given in Table 2, but the effective stressed volumes are very different from those of the standard flexural stress test specimen and failure stresses scale by the effective stressed volume Weibull relationship. The Carbomedics valve design also survived the 600 million cycle accelerated test in severe loading conditions. Stress corrosion cracking has not been mentioned because the stress corrosion cracking rates for PyC are well below those for fatigue crack propagation.

Safe margins from fatigue failure demand good component design and require that no external damage is induced while handling the components during manufacture or implant. Fatigue crack propagation has been observed only when a crack has been deliberately induced in a component, as is done in the preparation of fracture mechanics specimens, or because of damage induced by an external mechanism,

Table 4 Carbomedics valve damage-tolerant lifetimes

Component and location	Proof stress (MPa)	Initial flaw size (μm)	Design stress (MPa)	Final flaw size (μm)	Lifetime (years)
Leaflet B-datum	167	21.5	47	250	1.8×10^{30}
Leaflet ear shoulder	64	143	33	431	4.6×10^{16}
Leaflet tip	157	24.3	40	325	5.2×10^{32}
Leaflet ear	530	2.67	310	7.8	7.8×10^{11}
Orifice pivot	530	2.67	310	7.8	7.8×10^{11}
Orifice groove	67	163	30	565	1.1×10^{20}
Orifice rim	78	98	34	414	3.0×10^{20}

such as cavitation, as occurred in the Baxter-Edwards failures. PyC does not have a known intrinsic damage generation or accumulation mechanism, such as dislocation pileup as occurs in metallic materials.

Other devices such as the Ascension MCP that are not considered life-sustaining do not necessarily require the rigorous damage-tolerant design analysis. For orthopedic devices, a conservative strength-and endurance-based evaluation can be sufficient. However, the individual designer must rationalize and defend the worst-case in-service loads chosen to define strength and endurance tests.

CONCLUSION

PyC has enjoyed considerable success as a material for long-term critical implants over the past three decades. Clearly, substantial progress has been made recently in PyC manufacturing technology and in the understanding of its behavior in complex, long-term implant biomedical applications. Factors such as PyC biocompatibility, successful clinical experience, improved mechanical strength, stiffness approximating that of bone, durability, and fatigue resistance support the use of PyC in new devices for long-term implants. The variability of carbon structures together with the dependence of properties on structure suggests that the pursuit of new, yet-to-be-discovered carbon structures also offers a viable means to provide further advances in many diverse areas, including implant design.

Rapid Prototyping

Department of Mechanical Engineering, University of Texas at Austin, Austin, Texas, U.S.A.

INTRODUCTION

The term rapid prototyping (RP) refers to a broad category of techniques that can automatically construct physical prototypes from computer-aided design (CAD) models. Rapid prototyping provides the unique opportunity to quickly create functional prototypes of highly complex designs in an additive fashion. This layered manufacturing is also known as solid freeform fabrication (SFF), desktop manufacturing, and computer-aided manufacturing (CAM). There are several methods of RP, but universal to all of them is the basic approach they use, which can be described in three phases:^[1,2]

1. A geometric model is constructed on a CAD/CAM system. Because the manufacturing technique relies on a layer-by-layer additive process, the model must be represented as closed surfaces, which define an enclosed volume.
2. Next, the CAD model is converted into an STL (STereoLithography) file format, which approximates the surfaces of the model by polygons. The more complex the geometry of the model, the larger the number of polygons needed to characterize the surface. Curved surfaces usually require more polygons to fit and in turn produce larger files.
3. A computer program reads the generated STL file and “slices” the model into a finite set of layered cross sections. Each layer is created individually from liquid, powder, or solid material and stacked onto the previous layer with each layer joined to its neighboring surfaces. The created three-dimensional (3-D) model resembles the geometry of the CAD structure.

There are a variety of methods that involve SFF, but several approaches have found frequent use in the biomedical arena. In this entry, the RP fabrication techniques are categorized by virtue of their state of material. The methods can be classified into three categories: 1) liquid-based systems; 2) powder-based systems; and 3) solid-based systems (see Fig. 1). The

liquid-based systems cure liquid material into a solid state through interaction with a laser beam. The most popular liquid-based technique used for biomedical applications is stereolithography (SL). The powder-based systems rely on a laser beam to melt and fuse powder grains or selectively bind powder particles using liquid binders. Frequently used powder-based techniques in biomedical applications are selective laser sintering (SLS) and 3-D printing. The solid-based systems extrude melted material in filament form and build 3-D shapes by layering filament in predesigned patterns. A popular solid-based method, fused deposition modeling (FDM), has gained interest recently for several biomedical engineering uses. Each of the aforementioned techniques will be discussed in further detail in the subsequent sections.

There are several advantages of RP systems, and the most prevalent is the ability to rapidly produce functional prototypes in small quantities.^[3] This benefit has greatly improved the efficacy of surgical planning and education by providing a convenient platform for rapidly creating anatomical models.^[4] An excellent example of this is demonstrated in a recent study, where a patient was involved in a car accident and suffered from a serious bone fracture of the upper and lateral orbital rim in the skull.^[5] As the first reconstructive surgery had proven unsuccessful, it was necessary to perform subsequent surgery to transplant an artificial bone into the hole. This would require the surgeons to carve an artificial bone during the operation and try and fit it into the hole. Given that the operation would be very time-consuming because of the fitting and refitting of the artificial implant, RP was applied to create a prototype of the patient’s skull. The model was then used to prepare an artificial bone that would fit the hole properly. The use of RP model not only greatly reduced the surgery time and risk of infection but also improved its accuracy. In another example of successful surgical planning using RP, a patient was diagnosed with a cancerous bone tumor in his temple area. Initially, the surgery plan was to access the tumor through the frontal, highly functional area of the brain. As a consequence of the surgery, the patient would lose vision in one eye and several motor

Fig. 1 Rapid prototyping systems.

functions would be impaired.^[6] Using RP technology, a replica of the patient's skull was manufactured from a series of 2-D computed tomography (CT) scans of the patient's skull. With the model, the surgeon was able to recognize that the tumor could be treated by entering through the patient's jawbone and that an alternative approach could be used for treatment. Using the alternative method, the risk of harming the eye and motor functions could be avoided. Other case studies relating to bone tumors have been reported with similar successful results.^[7,8]

The uses of RP for biomedical applications are extended beyond surgical planning and education. The single-operative RP processes also offer an excellent tool to aid in the development of new medical devices such as targeted drug delivery devices. An excellent example of this is illustrated in a recent study, where RP was used to manufacture morphologically detailed human tracheobronchial airway models in various disease states based on high-resolution anatomical imaging data.^[9] These anatomical detailed casts of respiratory tract structures that corresponded to diseased states from exposure to toxic or pathogenic aerosols were then used to explore new methods of targeted drug delivery via inhaled aerosols. These case studies are exceptional examples of the potential impact of RP for biomedical applications. Rapid prototyping processes also provide avenues to develop custom implants and prostheses, new scaffolds for the guided development of highly structured tissues, organs, and bones, next-generation in vivo controlled-release vehicles, and multilayer microfluidic networks. In the following sections, we will further explain several RP techniques and several examples of how RP can play an effective role in the biomedical industry.

STEREOLITHOGRAPHY

Stereolithography is perhaps the most widely used RP technique. It was commercialized by 3D Systems of Valencia, California, U.S.A.

Stereolithography is a liquid-based method that allows 3-D microfabrication in a room-temperature environment.^[1,10,11] This method relies on a photosensitive monomer resin or a photocrosslinkable polymer resin, which solidifies when exposed to ultraviolet

(UV) or visible light. The photosensitive monomers cure via photopolymerization, while the photocrosslinkable polymers become solids or hydrogels by forming cross-linking networks.

A typical SL system consists of a container filled with liquid photopolymer resin, a computer-controlled stage immersed in the resin, and a laser scanner, as shown in Fig. 2. The process begins with a 3-D solid model designed in CAD. The model is numerically sliced into a series of 2-D layers with an equal thickness in an STL file format.^[12] The code generated from each sliced 2-D file is then executed to scan a UV laser beam in the X-Y plane on the surface of the resin. The interaction with the laser beam causes the liquid to solidify in areas where the laser strikes. After the layer is completely traced and cured by the laser beam, the stage is lowered into the vat a distance equal to the thickness of a layer. However, as the resin is generally quite viscous, tools were developed to increase the speed of the process. Early SL systems drew a knife-edge over the surface to smoothen it. More recently, pump-driven recoating systems have been utilized. The scanning and recoating steps are repeated until the object is completely fabricated.

Fig. 2 Principle of stereolithography. (A) CAD model design. (B) STL file generation. (C) Laser scanning to photopolymerize the first layer of the 3-D structure. (D) The stage was lowered to produce the second layer of the 3-D structure. (E) Layer-by-layer selective photopolymerization to produce the entire 3-D structure.

The resolution of the conventional SL is limited by the spot size of the laser beam to approximately 25 μm . To fabricate smaller and more complicated geometries, such as tissue engineering scaffolds, minor modifications are made. The laser beam must be focused into a 1–2 μm spot by an objective lens. As it is relatively difficult to scan the objective lens, a 3-D stage is employed to move in the X – Y – Z directions instead. A line width of roughly smaller than 5 μm has been achieved using this approach.^[13]

This layer-by-layer liquid micromanufacturing system enables the fabrication of complex internal features, such as intricate passageways for microfluidic devices and curved surfaces, to be accurately produced.^[14] Furthermore, the approach can easily incorporate different proteins and microparticles containing polymer solutions for each layer (or even for partial layers). This allows SL the unique ability to rapidly create a precise spatial distribution of biochemical microenvironments within a single scaffold or system.

There are several factors that influence the quality of the SL generated products, and the photocurable polymer resin is the most sensitive to processing. Additionally, as the products are used for biomedical scaffold purposes, the demands of the resin are as follows: 1) biocompatibility and, in some cases, biodegradability; 2) low viscosity; 3) stability under visible light; 4) fast cross-linking kinetics; 5) compatibility with 3-D polymerization; and 6) reasonably good accuracy and mechanical strength in the cured state.

Several systems that meet the above demands have been investigated recently and include, poly(ethylene glycol) (PEG)-modified systems cross-linked with a photoinitiator, typically acetophenone (UV light) or eosin Y, and triethanolamine (visible blue light).^[15] Another system, comprising poly(ethylene glycol) dimethacrylate (PEGDMA) hydrogel polymer, has been used in a variety of *in vitro* and *in vivo* applications and has been proven to have no adverse effect on cells for a sufficient period of time. The polymer PEG, which is hydrophilic, highly wettable, and cell-adhesion resistant, can be modified with proteins [i.e., arginine-glycine-aspartic acid (RGD)] to enhance cell adhesion. Ten percent (w/v) resin of PEG has a viscosity close to that of water. Increasing the concentration leads to higher viscosity. The resin is stable under the normal experimental conditions, though sunlight should be minimized because it carries UV light. The curing speed depends on the UV sensitivity of the resin. High sensitivity indicates that a fast processing speed could be achieved. The resin can be cured only at the laser focal point and the uncured resin is reasonably stable under scattered or reflected UV light. Typical lateral resolution ranges from tens to hundreds of micrometers for PEGDMA systems. Though the resulting scaffold is relatively soft and fragile in aqueous environment, it has good tensile strength when water is extracted.

The successful fabrication of scaffolds using PEGDMA (MW 1000) along with cyto-compatible photoinitiator, 1-[4-(2-hydroxyethoxy)-phenyl]-2-hydroxy-2-methyl-1-propane-1-one, Darocure 2959, initiated by a frequency tripled Nd:YAG laser (355 nm in wavelength) was demonstrated recently.^[16] Poly(ethylene glycol) acrylates, covalently modified with the cell adhesive peptide RGD or the ECM component heparin sulfate, was incorporated within the scaffolds to facilitate cell attachment and to allow spatial sequestration of heparin-binding growth factors. Fluorescently labeled polymer microparticles and basic fibroblast growth factor (FGF-2) were chosen to illustrate the capability of SL to spatio-temporally pattern scaffolds. The results demonstrated a precise, predesigned distribution of single or multiple factors within the single 3-D structure with specific internal architectures. Functionalization of these scaffolds with RGD and heparan sulfate allowed efficient cell attachment and spatial localization of growth factors. Such patterned scaffolds might provide effective systems to study cell behavior in complex microenvironments and could eventually lead to engineering of complex, hybrid tissue structures through predesigned, multilineage differentiation of a single stem cell population.

The unique advantages of SL as a suitable technique for scaffolding lie in the following bases. First of all, the inherent photochemical process is attractive for the production of tissue engineering scaffolds because it has a controlled reaction initiation and termination, a relative short reaction time, and spatial control. Second, SL can be performed at mild conditions, such as room temperature and under physiologic pH, which allow incorporation of biologically active molecules and *in situ* cell seeding. Third, photopolymers can be modified with various peptides and copolymers, for instance, to promote or inhibit cell adhesion.

While SL does offer advantages for scaffolding, several issues must be addressed for subsequent use. First, as *in situ* cell seeding or *in vivo* scaffolding requires nontoxic precursors, initiators, and residues, a low concentration of initiators is essential. The inclusion of initiators frequently results in prolonged fabrication times and reduced control over resolution and composition of the scaffold. In addition, prolonged exposure to UV lasers may cause degradation in some bioactive molecules and reduce the capacity of the scaffolds to promote cell proliferation.

Selective Laser Sintering

Selective laser sintering is a popular RP powder-based technique. It was developed and patented at the University of Texas at Austin and commercialized by the DTM Corporation (now 3D Systems) in 1987.

The SLS process is similar to SL in that it creates 3-D objects layer by layer. However, SLS utilizes materials in powder form instead of liquid and uses heat generated from a CO₂ laser. The method begins by depositing a thin layer of material in powder form into a container. The layer of powder is then selectively irradiated by a CO₂ laser to the point of melting, fusing the powder particles to form a solid mass, as shown in Fig. 3 below. The intensity of the laser beam is modulated to melt the powder only in areas defined by the part's geometry, while the rest of the material remains in its original powder form. When the cross-sectional layer is solidified, sequential layers of powder are deposited via a roller mechanism on top of the previously scanned layer. The steps are repeated with each layer fusing to the layer below it until the 3-D model is completely built. As the material used in the SLS process is in powder form, the powder not melted or fused during the processing serves as a customized, built-in support structure. Therefore, there is no need to create support structures within the design phase or during processing and no support structure to remove when the part is complete. There is a broad range of materials that can be processed using SLS and no postprocessing or postcuring is required.

Much like SL, SLS provides an economical and efficient method to construct scaffolds for guided development of human tissues and organs. As SLS is also a layer-by-layer additive process, the design and fabrication of anatomically shaped scaffolds with varying internal and external architectures is possible.^[17] Additionally, as SLS uses materials in powder form, the precise control over pore interconnectivity, permeability, and stiffness of the scaffold can be achieved. The control of porosity arises from space between the individual granules of powder. The manipulation of these properties may optimize cell infiltration and adhesion, as well as mass transport of nutrients and metabolic waste throughout the scaffold. The SLS technique was recently

Fig. 3 Principle of selective laser sintering.

exhibited to engineer bone tissue scaffolds using the common biodegradable polymer, poly(ϵ -caprolactone) (PCL).^[18] Scaffolds were manufactured in a variety of designs and the biological properties of each were evaluated by seeding each with bone morphogenetic protein-7 (BMP-7) transduced human fibroblasts. The generated tissues were then studied using micro-computed tomography (μ CT) scans and histology. The results showed that PCL scaffolds fabricated via SLS possessed similar mechanical properties to trabecular bone and enhanced tissue in-growth in vivo.

Recently, it was demonstrated that a derivative of the SLS approach could be used to fabricate bioactive scaffolds using a layer of carbon, a strong absorber of laser radiation, deposited on a biodegradable polymer, poly(D,L-lactic) acid (DLPLA).^[19] In this experiment, near-infrared ($\lambda = 970$ nm) laser radiation, which DLPLA polymer particles do not absorb, was used to initiate the sintering process between a small quantity of carbon microparticles that were homogeneously distributed on the surface of the DLPLA particles. This limited the melting process to the surfaces of each particle and possibly opens up the SLS process to a range of polymers that could not previously be processed by conventional SLS. Furthermore, as the laser melts only the surface of the particles, delicate bioactive species such as enzymes or growth factors trapped within each particle can retain their activity throughout the processing.

The SLS technique has also been realized to fabricate controlled-release drug-delivery devices.^[20] A device composed of nylon was fabricated by selectively controlling the position and composition of the material. The drug model used for infiltrating the sample matrix was Fluka methylene blue dye. The results showed a gradient release profile and indicated that the release mechanism can be tailored to fit the specific application by controlling the device wall composition, anisotropy, and microstructure.

The SLS process also provides the ability to design and optimize subject-specific prototypes of orthotic devices that serve to compensate for a variety of injuries, disorders, and diseases. This was exhibited recently, where a patient suffered from a large frontal cranium defect after complications from a previous meningioma tumor surgery.^[2] The surgery left the patient with a missing cranial section, which caused the patient's head to look slightly deformed. A corrective surgery would have required a titanium-mesh plate to be hand-formed by the surgeon during the operation using trial and error. Using a CT scan of the affected area, a 3-D CAD generated model could be made, and fabricated using SLS. The SLS mold could then be used to mechanically press the titanium-mesh plate to the anatomical profile of the missing cranium section. The SLS technique improved the fit of the implant and significantly reduced the operation time.

Some disadvantages of the SLS technique are surface roughness, which can influence the cellular behavior in a scaffold, and trapped powder, which can affect the scaffold stiffness. Another disadvantage of the SLS process is the smallest attainable feature size, which is primarily governed by powder particle size, focused laser beam diameter, and heat transfer in the powder bed.

3-D Printing

Three-dimensional printing (3-DP) was invented and patented at the Massachusetts Institute of Technology. It was subsequently licensed and further developed by Z Corporation (Massachusetts, U.S.A.).

Three-dimensional printing has demonstrated the capability of fabricating microstructures and controlling local composition with a high resolution in the interior of the component.^[21] Similar to SL and SLS, a computer model (CAD) of the desired part is generated and a slicing algorithm draws detailed information for every layer. Just as in SLS, the process begins with a thin distribution of powder spread over the surface of a powder bed. Using a technology similar to ink-jet printing, a binder material selectively joins particles where the object is to be formed. A piston that supports the powder bed and the part-in-progress lowers so that the next powder layer can be spread and selectively joined. This layer-by-layer process is repeated until the part is completed (Fig. 4). The local microstructure within the component can be controlled either by changing the binder, which is printed, or by changing the printing parameters during the component construction. Although the system was initially designed for metallic or ceramic particles, powders of various polymeric biomaterials can be used directly. To print tissue engineering scaffolds, liquid solvent binder can be printed onto a powder bed of porogens (dissolvable particles that creates pores in a polymer matrix) and polymer particles. The solvent will dissolve the polymer and evaporate, and the polymer will reprecipitate to

form solid structures. The final porosity is achieved after particulate leaching and solvent removal.

A large combination of natural and synthetic biomaterials can be selectively bound using organic or water-based binders. Synthetic polymers include poly(lactic-co-glycolic acid) (PLGA), PCL, PLA, polyethylene oxide (PEO), with common organic binders such as chloroform, dichloromethane. Cornstarch, dextran, and gelatin have also been used in conjunction with water-based binders. Fine biomaterial powders are usually made by cryogenic milling with liquid nitrogen. The powders are then vacuum dried and sieved to obtain a uniform size.

Devices consisting of PCL and PEO were fabricated to demonstrate control of drug delivery profiles by controlling the position, composition, and microstructure.^[21] The top and bottom layers of the device were constructed by binding PCL powder into thin solid layers. A cellular-type pattern was printed with PEO, which has a faster degradation rate, in the intermediate layers. Dyes, which represent drugs, were selectively placed within the cells manually.

The fabrication sequence is described as follows: first, a bead of PCL powder (45–75 μm) is spread in a thin layer on the piston. Droplets of 20% acid-modified PCL LPS-60HP (PCL-LPS)/chloroform binder solution are deposited on the PCL powder layer through a 45 μm orifice plate to form a solid PCL sheet. Poly(ϵ -caprolactone) particles bind to each other according to the pattern of the printhead motion as the binder contacts the PCL layer. Lines of PCL are formed by moving the printhead in a linear motion. A dense PCL sheet is formed by repeatedly printing lines directly adjacent to each other. The piston is then lowered and ready for the next layer of powder. The second layer begins by spreading PEO powders (75–150 μm) on the top of the solid PCL sheet. A square grid pattern of 5 cells by 5 cells can be made by printing six parallel lines at 3 mm interline spacing, and then repeating another set of six lines at 90° to the first set by rotating the piston. Twenty-five cells, which serve as drug reservoirs, are

Fig. 4 Principle of 3-D printing.

formed by 20 layers of PEO grid pattern. Different dyes are selectively dropped into the unbound PEO powder before a top layer of dense PCL sheet is printed to seal the cells. Different release mechanisms can be achieved by controlling device wall composition, anisotropy, and microstructure with this technique.

Recently, a unique, heterogenous, osteochondral scaffold, which could be an effective tool for treating articular defects, was developed using the 3-DP process. The scaffold consisted of two distinctive regions that differed in material composition, porosity, macro-architecture, and mechanical properties. The cartilage region was 90% porous and composed of D,L-PLGA/L-PLA, with macroscopic staggered channels to facilitate homogenous cell seeding. The cloverleaf-shaped bone portion was 55% porous and consisted of a L-PLGA/calcium phosphate tribasic composite, designed to maximize bone ingrowth while maintaining critical mechanical properties. The transition region between these two sections contained a gradient of materials and porosity to prevent delamination. It was shown that chondrocytes preferentially attached to the cartilage portion of the device and cartilage formed during a 6-week in vitro culture period. The tensile strength of the bone region was similar in magnitude to fresh cancellous human bone, suggesting that these scaffolds have desirable mechanical properties for in vivo applications, including full joint replacement.

The fabrication of complex-shaped scaffolds has also been demonstrated using an indirect approach of the 3-DP process, where molds are printed and the final materials are cast into the mold cavity.^[22] To demonstrate the ability of this approach to build complex-shaped scaffolds from common biodegradable polymers with large pore size directly from medical imaging data, a zygomatic arch defect was fabricated. To evaluate the resolution that is possible with the indirect approach, scaffolds with small villi architecture were constructed. As the indirect approach involves the use of molding and mold release materials, the study addressed the removal of these additional materials by evaluating cell proliferation in the demolded scaffolds. To demonstrate the benefits of printing small features, cell attachment and proliferation in various regions of the scaffolds were also studied and showed cell growth in culture. This technique may be a useful adjunct for the fabrication of complex scaffolds for tissue engineering.

Postprocessing is necessary to remove the residual solvents and porogens, enhance the strength of the structures, or absorb functional molecules. Chlorinated solvents are undesirable because they may bring potential health risks. Those solvents are difficult to extract completely. An extraction method based on liquid CO₂ has been developed.^[23] Using water as a solvent eliminates the extraction procedure.

The as-solidified structures are vacuum dried at an elevated temperature to enhance the structural rigidity. Chemical modification may be performed, for instance, by infiltrating polymer structures with functional molecules to adjust the hydrophilicity.

In general, 3-DP is a fast and accurate process. It has precise control over composition, anisotropy, and microstructure. A wide range of materials can be used, provided they can be processed into powder form. It is possible to incorporate biomolecules, which may be carried by the binders, in the structures. However, the surface of the structures is usually powdery and the trapped powder is hard to completely remove.

Fused Deposition Molding

Fused deposition modeling is a widely used RP process that was developed by Scott Crump and commercialized by Stratasys (Minnesota, U.S.A.).

In this method (see Fig. 5) a spool of material is heated into a semiliquid state and dispensed into an extrusion head. The semiliquid material is extruded through the head and deposited into the desired shape. The platform, onto which the material is deposited, is maintained at a lower temperature so that the material cures immediately on contact after exiting the heated chamber. After the completion of each layer, the platform lowers, and the extrusion head deposits the next layer on top of the previous one until the 3-D model is completed. In newer FDM machines, two materials are fed through the extrusion head. One is used to produce the geometric model and the other is used to construct support structures. The second material forms a bond with the primary model material and is washed away when the 3-D model is processed. The advantages of using FDM include the speed and safety of the machine.

Fused deposition modeling has been demonstrated as a viable method for manufacturing functional

Fig. 5 Principle of fused deposition molding.

Table 1 Comparison of different rapid prototyping technologies in biomedical applications

RP system	Resolution (μm)	Material	Strength	Weakness	Reference
Stereolithography	100	PEG-acrylate	Biofriendly liquid environment; control over reaction; high resolution; can incorporate biomolecules and cells in situ	Relatively slow processing; UV exposure may cause degradation	[10–17]
Selective laser sintering	400	PCL, PEEK–HA	Fast processing; control over porosity; no postprocessing	High temperature; material must be in powder form; rough surface finish; trapped powder	[17–21]
Three-dimensional printing	100	PLGA, PEO, starch-based polymer	Fast processing; nonorganic binder is possible; no supporting structure needed; control over porosity	Material must be in powder form; rough surface finish; trapped powder	[17, 22]
Fused deposition molding	250	PCL, PCL–TCP	Can be operated in office-type environment; good mechanical strength	High temperature; simple geometry can be obtained	[23–26]

PEEK, polyetheretherketone.

scaffolds for tissue engineering. Tissue-engineering scaffolds with fully interconnected pore networks based on PCL were fabricated using FDM.^[24] The scaffolds were then seeded with human fibroblasts from the anterior cruciate ligament of a 34-year-old male. The 3-D structures showed excellent cell proliferation, differentiation, and extracellular matrix production. An adapted FDM method was recently applied in a similar fashion to create scaffolds. This method used a microsyringe to expel a dissolved polymer under constant pressure to form a desired pattern. Using this microextrusion approach, resolution down to 20 μm can be achieved.^[25] A modified FDM method produced PLGA scaffolds with a lateral resolution of up to 5 μm . The layer-by-layer fabrication method allows the design of a pore morphology that varies across the structure.^[26] Researchers have also used FDM to manufacture composite scaffolds of PCL, PCL–Tricalcium phosphate (TCP) and PCL–hydroxyapatite (HA). The scaffolds were seeded with human mesenchymal progenitor cells and proliferation toward and onto the surfaces were detected.

Another version of FDM uses a microsyringe to construct 3-D heterogenous multilayer tissue-like structures inside microchannels.^[27] The process involves a

three-step approach: 1) immobilization of a cell–matrix assembly; 2) cell–matrix contraction; and 3) pressure-driven microfluidic delivery using a syringe. Using this approach, patterning of biological microstructures can be used to form “neotissue” from different types of cells and biopolymer components in one single system. Thus, the approach provides a novel solution to fabricate hybrid biopolymers and hierarchical tissue structures for tissue engineering and basic cell biology.

Fused deposition modeling provides the unique ability to use almost any material but is limited by its narrow processing window, shrinkage, and high operating temperature, which could prevent the inclusion of biomolecules into the material. The approach also requires the input material in a particular size and geometry. (For a comparison of different rapid prototyping technologies in biomedical applications see Table 1.)

CONCLUSIONS

In addition to the aforementioned techniques, other plausible approaches for developing medical devices are available. One such method was recently developed as a means to create biodegradable microfluidic devices, using

a rational scaffold design.^[28] The novel approach used a thermal fusion bonding technique to rapidly fabricate 3-D monolithic microdevices with various internal geometries. The researchers stacked micropatterned thin films of the common biodegradable polymer PLGA, to create multilayer, microfluidic networks with extruded inlets and outlets without leaks and occlusions. The method also presents a viable platform for generating drug delivery vehicles with microscale cavities, capsules and microchannels for controlled-release locations, species and kinetics in complex biomolecular environments.

Another excellent study developed a technique derived from conventional integrated circuit technologies to photopattern hydrogels.^[29] The method began with a polytetrafluoroethylene (Teflon) base filled with polymer solution loaded with cells. Ultraviolet light was then shone through a patterned template atop the thin film, curing the exposed polymer that was seeded with cells. Using this layer-by-layer method, the construction of complex networks of cells and materials can be built by using various templates and depositing different layers atop one another.

Ultimately, RP platforms serve as an invaluable tool to achieve exciting new functionality in the fields of microfluidics, cell-support scaffold development, and controlled drug-release devices. The techniques are rapid, versatile, and low-cost approaches to precision manufacturing, thus making them ideal for large-scale engineering of complex, high-performance medical devices.

INTRODUCTION

Medical imaging modalities are important clinical and diagnostic tools in medicine. Ultrasound, computerized tomography (CT), and magnetic resonance imaging (MRI) provide images that can be used to localize structure and function in the human body; thus, they provide physicians the ability to determine patient abnormalities. However, conventional methods of displaying these imaging modalities are limited since they only allow for viewing images independent from the patient.

OVERVIEW

While this may not be an issue during non-invasive diagnostic imaging, it becomes one when these images are being used for guidance of surgical procedures. During these situations, the doctor is not able to use direct hand-eye coordination. Instead, the doctor must look at a display without obvious relation to the position and orientation of his surgical instruments in the operating field. This leads to difficulty in the surgeon's ability to utilize medical image guidance.

In order to allow surgeons a more natural feel during image-guided surgical procedures, there has been a recent push to develop augmented reality systems that seamlessly merge medical images with the direct vision of the surgeon. It is hoped that such systems will enable doctors to employ a more direct form of hand-eye coordination. In essence, medical augmented reality strives to give the surgeon a sort of X-ray vision in order to see directly inside the patient.

While many forms of augmented reality require a head-mounted or tracking apparatus, this article describes a particularly simple method called Real Time Tomographic Reflection (RTTR). A specific implementation of RTTR is called the sonic flashlight™. The sonic flashlight can project a virtual image of an ultrasound scan into its proper visual location within the patient and does not require any tracking or head-mounted apparatus. This system permits the operator to guide a needle through the skin by aiming directly at the ultrasound image and using natural

hand-eye coordination rather than looking away from the patient at a screen. It provides an intuitive merger of the visual exterior of the patient with the ultrasound image in situ, which can be shared by others standing next to the operator. The sonic flashlight may increase accuracy, safety, and speed for a wide variety of diagnostic and invasive procedures and enable them to be performed by an operator with less training.

REAL TIME TOMOGRAPHIC REFLECTION

Augmented Reality and Head-Mounted Displays

The main approach to fusing images with a direct view of the patient derives from research in augmented reality, so named to differentiate it from the more widely known virtual reality. After all, there is nothing virtual about real image data from real patients. Fuchs, Sauer, and others have developed augmented reality systems based on a head-mounted display (HMD), a type of device that generally replaces direct human vision with miniature video cameras and display screens mounted in front of each eye.^[1-5] The HMD permits the merger of a video view of the patient with image data, such as an ultrasound scan, that is rendered from an appropriate perspective. That perspective is determined by tracking both the HMD and the ultrasound transducer, which is generally held by the wearer of the HMD. Primarily because of their complexity, these systems have not been widely accepted. Significant problems remain unresolved, such as limited peripheral vision, resolution lower than human vision, and latency in the image registration. The weight, isolation, and need for a tether have also discouraged clinical use. Some of these problems will undoubtedly be addressed in time, but the HMD system remains inherently a complex and challenging approach.

Image Overlay

To reduce the apparatus that the operator must wear, DiGioia and his group at the Carnegie Mellon

Robotics Institute have developed a system called image overlay.^[6,7] They place the patient beneath a large, half-silvered mirror. Above the mirror, a flat panel monitor is mounted displaying 3-D renderings of computerized tomography (CT) data. The operator looks down through the mirror at the patient and sees the reflected CT rendering superimposed on the patient. The operator wears only a small, head-tracking optical transmitter, which is required to determine the proper perspective from which the CT data must be rendered for his/her particular viewpoint. A second tracking device must be attached to the patient in order to achieve proper registration between the patient and the CT data that was previously acquired. Special liquid crystal display (LCD) shutter glasses are needed if stereoscopic visualization is desired.

Real Time Tomographic Reflection (RTTR)

Real Time Tomographic Reflection (RTTR) represents a further simplification to DiGioia's image overlay. With restriction to a single tomographic slice (e.g., ultrasound) and by strategically positioning the transducer, half-silvered mirror, and display, RTTR eliminates the need for tracking the operator. This is possible because RTTR produces a virtual image. The word virtual is used here in its classical sense: the reflected image is optically indistinguishable from light-emitting voxels suspended in space. A virtual image is stable and independent of viewer location. Furthermore, it produces natural stereoscopic cues without requiring LCD shutter glasses. The operator does not wear any special apparatus, and several viewers can experience the same illusion simultaneously.

This approach is shown in Fig. 1. An ultrasound transducer acquires a tomographic slice representing a set of 3-D voxels in a plane. The image of that slice, which is displayed at its correct size on a flat-panel display, is reflected to occupy the same physical space within the patient. The patient is viewed through the half-silvered mirror. The reflected image is correctly located and independent of viewer location. Since the ultrasound transducer is an integral part of the apparatus, the merger is independent of patient location as well. The image will change during an invasive procedure in order to show the results of the procedure.^[8-14]

Masamune et al. have used a similar approach, which they call slice display, on CT data.^[15] In their first apparatus, the CT scanner was not an integral part; thus, independent registration of patient location was still required. They have since produced a real-time version in which the mirror and monitor are located within the CT scanner.^[16] Similar systems have been proposed previously, though, not for image-guided

Fig. 1 Geometric relationships for Real Time Tomographic Reflection (RTTR). The mirror must bisect the angle between the slice and the monitor. On the monitor, the image must be correctly scaled, translated, and rotated so that each point in the image is paired with its corresponding point in the slice to define a line segment perpendicular to and bisected by the mirror. By fundamental laws of optics, the ultrasound image will appear at its physical location— independent of viewer position.

intervention, including an ultrasound-based system by Hofstein.^[17]

Figure 2 shows an implementation of RTTR in which a human hand is seen with an ultrasound transducer pressed against the soft tissue between the thumb and index finger. While not a common target for clinical ultrasound, the hand was chosen for this example because it clearly demonstrates successful alignment. The external surfaces of the hand are consistently located with structures in the ultrasound image. The photograph cannot convey the strong sense, which is derived from stereoscopic vision, that the reflected image is located within the hand. This sense is intensified by head motion because the image remains properly aligned from different viewpoints. To one experiencing the technique in person, ultrasound targets within the hand are clearly accessible to direct percutaneous injection, biopsy, or excision. The device was named the sonic flashlight because the transducer appears to illuminate the interior of the hand with the ultrasound data. A U.S. Patent (6599247) on RTTR was issued in 2004.

Geometric Transform for Calibration

Clearly, an accurate method for calibration is required. Without it, the sonic flashlight would be unable

Fig. 2 View of a hand through the half-silvered mirror of the sonic flashlight.

to guide interventional procedures.^[14] Calibration requires careful consideration of the degrees of freedom in the registration process. The challenge is to make each pixel in the virtual image occupy and, therefore, appear to emanate from its actual 3-D location in the slice. We first only consider the geometric transform of a rigid body, i.e., we assume that the ultrasound slice is displayed without distortion at its correct scale on a perfectly flat monitor. The geometric transform that would be required to superimpose the virtual image onto the slice can be represented as two sets of translations and rotations. Each of which has three degrees of freedom (Fig. 3). The first (two rotations and one translation) allows the

Fig. 3 Geometric transforms for (A) physically moving the display and (B) moving the image on the screen.

flat-panel display to be moved into its correct plane, which makes the virtual image coplanar with the actual ultrasound slice. We can achieve this by physically moving the display, the ultrasound transducer, or the mirror. The second (two translations and one rotation) can be achieved simply by adjusting the image of the ultrasound slice on the flat-panel monitor.

Affine Transform for Calibration

The assumption that both the ultrasound slice and the flat-panel monitor are truly flat is a safe one and makes a rigid-body (geometric) transform sufficient to move the monitor into the correct plane. However, correctly adjusting the image on the screen actually requires more degrees of freedom than those provided by the geometric transform—if only because the image must be scaled to its proper size. Extending the geometric transform to an affine transform allows us to scale the ultrasound slice to its correct size, adjust its aspect ratio, and correct for skewing. The calibration process becomes a matter of finding the optimal parameters for that affine transform. Mapping location (x,y) to (x',y') with an affine transform is accomplished by multiplying the homogeneous form of (x,y) by a 3×3 matrix \mathbf{A} .

$$\begin{bmatrix} x'_1 & x'_2 & x'_3 \\ y'_1 & y'_2 & y'_3 \\ 1 & 1 & 1 \end{bmatrix} = \begin{bmatrix} a_{1,1} & a_{1,2} & a_{1,3} \\ a_{2,1} & a_{2,2} & a_{2,3} \\ 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} x_1 & x_2 & x_3 \\ y_1 & y_2 & y_3 \\ 1 & 1 & 1 \end{bmatrix}$$

An affine transform is capable of mapping any triangle onto any other triangle. If the apices of both triangles are known (and not colinear), we can find an explicit solution for the six unknown elements of the matrix \mathbf{A} . Calibration can thus be achieved by visually aligning three point targets with their appearances in the virtual ultrasound image.

CONCLUSION

Superimposing ultrasound images on human vision using Real Time Tomographic Reflection (RTTR) may improve an operator's ability to find targets while avoiding damage to neighboring structures and while generally facilitating interpretation of tomographic images by relating them spatially to external anatomy. As such, it holds promise for increasing accuracy, ease, and safety during percutaneous biopsy of suspected tumors, amniocentesis, fetal surgery, brain surgery, insertion of catheters, and many other interventional procedures.

Reconstructive Biomaterials

Mutaz B. Habal

Tampa Bay Craniofacial Center, Tampa, Florida, U.S.A.

R

INTRODUCTION

Today, the application and utility of biomaterials are essential for standard-of-care treatment of patients with extensive craniofacial trauma and reconstructive surgery. It is, therefore, imperative that surgeons using biomaterials have a comprehensive knowledge and understanding of the implications, applications, and effects of these materials when used in the living biologic systems. The biochemistry and composition vary from system to system, so that the details of the variables become as important as the mechanics of application. By definition, most biomaterials in use today are inert. They do not initiate any major inflammatory response or reaction and are easy for the practicing surgeon treating facial trauma.

In the past, controversy arose regarding the nature of the application of biomaterials in patients with acute trauma because of the high degree of contamination found in these traumatic wounds and limited the use to elective and clean wounds. The difference in the use of biomaterials in elective craniofacial surgery and its application in traumatic injuries are related to considerations of clean vs. clean/contaminated or grossly contaminated wounds of the facial skeleton. It was thought that the use of biomaterials in clean/contaminated (type II) or grossly contaminated (type III) wounds should be delayed, and immediate application limited to the clean conditions such as type I wounds. Other issues involving the use of biomaterials in facial surgery were related to open vs. closed wounds and the situation of internal contamination from the para nasal sinuses. These concerns compelled surgeons to defer the use of all biomaterials in craniofacial surgery related to primary trauma, and it had become a major principle that such biomaterials should only be used in the former type wounds rather than the latter two types. These concerns were alleviated as early as the 1970s when more relaxed views were applied owing to the understanding of the nature of the increased blood flow in the craniofacial region in contrast to that of other parts of the body. The presence of a good blood supply to the head and neck area may be the factor that differentiates trauma surgery in the craniofacial region from that in other regions of the body.

Biomaterials used today in facial trauma are divided into two categories: biomaterials used in immediate

trauma repair and those used for delayed reconstruction. Biomaterials are also used operatively for immediate skeletal fixation after reduction of the traumatized bone and placing them in their anatomic locations, as well as for delayed recreation and reconstruction of facial skeletal structures. In secondary reconstruction of traumatic defects, biomaterials are used as contour-fitting materials, and these procedures are most often deferred until after immediate surgical repair is done. Fixation of the craniofacial skeleton has undergone a major evolution in the past 30 years. However, our search continues for the ideal fixation device. The future of all skeletal fixation devices lies in the use of new biomaterials and new combinations of these materials to maximize the utility. In addition, the use of contour-fitting biomaterial will eventually follow the same process as in the past—that of the time element involved in the body's ability to incorporate these materials as a component that is not easily differentiated from adjacent tissue.

The last important concept that we need to go over in this entry is that of regeneration, as it affects the use of biomaterials in the craniofacial region. Multifunctional biomaterial implants have the ability to allow the surrounding bone to regenerate new bone, while using the applied material as a scaffold. A knowledge of the longevity of all the applied biomaterials is essential, as well as an understanding of the processes that are involved in total elimination by hydrolysis, incorporation, or regeneration.^[1,2]

SAFETY CONSIDERATIONS

The applications and the use of the biomaterials in any biologic system are always associated with a major question: Are those biomaterials safe to use or are they capable of causing harm? It is also of importance to know if there are any by-products that will be, under any circumstances, harmful. Safety issues are the fundamental focus of the Food and Drug Administration (FDA) and its European equivalents. These agencies study all biomaterials that are to be used for medical purposes, their efficacy, and the animal studies required before the premarket studies are designed to collect data from clinical applications. Data are then analyzed, and if the biomaterial is found to be safe and

efficacious, it is then released for marketing to doctors' offices and the hospitals for use in human patients. If there is any controversy regarding the applications clinically or any public concerns, the FDA will name a panel of experts to conduct a hearing before the application is allowed. All the biomaterials referred for discussion in this article have passed through this process and their final applications are dependent on the ability of the agencies to allow such a system to be used.

FIXATION OF THE FACIAL SKELETON

A review of the history of skeletal fixation is helpful to the understanding of the situations in which we work today. Skeletal fixation in the craniofacial region has gone through many advances in the past few decades. Most of these advances have followed major international conflicts involving the complex treatment of large numbers of casualties.

Initially, fractures of the craniofacial skeleton were treated without fixation by allowing the bones to heal in open soft tissue, then performing the repair at a later time. Fractures were also treated with closed reduction after manipulation. The next development was the use of an external apparatus for fixation. This method was useful until the external fixation was removed and the repaired structures collapsed again; these are referred to as relapsed segments.

Internal fixation then came into practice and required the use of rigid fixation. Use of the plating system began at the turn of the century, with the use of stainless steel plates. The use of vitalium and titanium plating followed. In the latter part of the last century, the use of resorbable plating systems evolved and has advanced to their present status today. Resorbable plating systems remain the state-of-the-art for skeletal fixation. The evolution of biocompatible resorbable polymers offers surgeons of today a new array of options for craniofacial skeletal fixation. Some of the potential benefits of resorbable polymers include greater ease and accuracy of contour adaptation, clear radiographic presentation owing to the absence of x-ray scatter, elimination of the need for secondary surgeries for device removal, and reduced risk of stress shielding of the underlying bone. Known as polyesters, these copolymers have chemical, physical, material, mechanical, and biologic properties different from those of metal fixation devices. Knowledge of these differences will facilitate the utilization of resorbable implants in fixation for craniofacial trauma.

Among the bioresorbable polyester facial fixation devices approved for clinical use by the FDA, copolymers of lactides and glycolides are available. The first copolymer of L-lactide and glycolide

(LactoSorb™, W. Lorenz, Jacksonville, Florida, U.S.A.) was approved by the FDA in 1996. The lactide in LactoSorb is a homopolymer of the levo form. The ratio of the L-lactide monomer to the glycolide monomer is 82:18 in poly(L-lactide-co-glycolide), to take advantage of glycolide's rapid degradation time. Strength declines to approximately 70% by six to nine weeks and resorption is complete by 12 months. The final resorption is dependant on the purity of the active form supplied by the manufacturer and is still slightly variable between the batches used.

Approved more recently in 1998 is a copolymer produced from a mixture of 70% L-lactide monomer and 30% D,L-lactide monomer (MacroPore®, MacroPore Biosurgery, Inc., San Diego, California, U.S.A.). This 70:30 ratio in poly(L-lactide-co-D,L-lactide) (PDLA) retains approximately 70% of its initial strength after nine months, and approximately 50% after 12 months, with resorption completed by 24–36 months. Additional resorbable polyesters from Bionx, Leibinger (Delta System and the New Delta System); Synthes (Resorbable System); KLS Martin (Resorb-X); and Inion (two systems) are all FDA approved and available for surgeons' to use. The differences among these systems are the ratios of the copolymers used in the compositions, which affect their longevity, a consideration of importance to surgeons. The deciding factor in which system to use is the individual surgeon's preference and ease in clinical application as well as the results obtained.

In view of these considerations, the primary focus in this article will be on the use of PDLA for skeletal repair and fixation, owing to the extensive clinical experience of the authors and to the commonalities this system shares with other systems that use similar materials in different compositions. The acronym PDLA, L-La/D,L-La copolymer, will also be utilized to designate a copolymer of the two monomers, L-lactide and D,L-lactide. In the interest of brevity, the copolymers are referred to as PDLA with the ratio given as well for accuracy.

PHYSICAL PROPERTIES

Poly(L-lactide), which has a high degree of crystallinity, is characterized by its strength and long degradation time. Conversely, a polymer created from D,L-lactide has little strength and degrades rapidly. Combining L-lactide and D-lactide polymers results in a copolymer with the intermediate characteristics of strength for 6–9 months and resorption in 24–36 months. In addition, the copolymer is optically clear and non-crystalline, resulting in minimal foreign body reactions by tissue. It is well noted that, even within a given copolymer, strength and degradation characteristics

can vary according to the degree of polymerization and purity within the copolymers. Therefore, the manufacturer must maintain this within the desired range. A common measure of the degree of polymerization is called intrinsic viscosity (IV) and, for any given polymer, the IV correlates with molecular weight. To measure IV, the polymer is dissolved in a standardized, known amount of chloroform and then passed through a viscometer. The length of time that it takes for passage is used to calculate the IV.

At sufficiently high temperatures, all materials change from hard to soft and finally to liquid. The temperature at which a material changes from hard to soft is known as the glass transition temperature (T_g). For 70:30 PDLLA, the T_g is 55°C (131°F), thus allowing heat to be utilized for contouring these implants.

Contouring an orbital floor liner illustrates this property. After making a template of the orbital floor, the template is held against the orbital floor liner (Fig. 1), then placed in a water bath and heated above T_g . The floor liner becomes soft in a few seconds and simply drapes over the template when lifted from the water bath. In a few more seconds, the floor liner cools below T_g and can be removed from the template. The liner is then ready to be placed in the patient. It is useful to note that 70:30 poly (L-lactide-co-D,L-lactide) has shape memory, and if placed back in the water bath it will return to its original contour thus enabling additional opportunities to recontour it. If only a portion of an implant needs to be recontoured, only that portion needs to be placed back in the water bath. Cyclic heating of 70:30 PDLLA to 70°C can be performed multiple times with no change in material strength or IV (Fig. 2).

R

CHEMICAL PROPERTIES

When lactic acid undergoes polymerization, ester bonds are formed and H_2O is released. Therefore, lactide copolymers are also known as polyesters. Resorption of lactide copolymers takes place as a reversal of this process, with sorption of H_2O and scission of the ester linkages. This bulk hydrolysis of lactide copolymer implants continues until single lactic acid molecules are released, which are then metabolized into glucose or into CO_2 and H_2O via the Krebs tricarboxylic acid cycle.

A variety of factors are known to affect the rate of lactide copolymer resorption, such as temperature and the internal chemical environment. A higher IV or molecular weight means that there are more ester linkages that undergo scission, and this process results in a longer resorption time. A larger implant size or volume will also require more scission before implant resorption can be completed. If the polymer is packed more tightly in an orderly crystalline pattern, there is less space for H_2O access, and resorption will take longer than for non-crystalline implants. As hydrolysis occurs both on the implant surface and within its interior, implant-increased porosity will increase surface area, facilitate H_2O access, and decrease resorption time. The molecular configuration of copolymers may alter resorption time. Greater vascularity of the implant host site as well as flexural bending from functional loading appears to be associated with an increased rate of hydrolysis.

TOXICOLOGY

The toxicology of lactides has been of minimal concern, owing to the relatively small volumes of implant

material, slow degradation rates, and short serum half-lives. The serum half-life of the levo form is 15 min; for the D,L form it is 22 min. The normal resting blood lactate level is 1.1–2.8 mM/L. After muscular activity, it will rise 10-fold to 10–23 mM/L. If the assumption is made that degradation occurs over two months, with first order kinetics and a half-life of 74 hr, a 100 g implant would release 0.18 mM/L of lactide acid in the first minute, far less than the changes resulting from muscular activity. Two of the largest sheets of 70:30 L-La/D,L-La copolymer weigh only 18 g, and degradation actually takes place over a much longer 18- to 36-month time interval. Even with first order kinetics starting instantly, the 18 g of lactide copolymer would result in an increase in blood lactate levels of only 1.1%.

HISTOLOGY

The histological responses to 70:30 L-La/D,L-La copolymer have been well studied. There is an initial acute inflammatory response following implantation. By 72 hr, there is a narrow zone of fibrinous exudate, edematous granulation tissue, and a modest degree of fibroblast proliferation. By 7–14 days, the granulation tissue has matured into a thin, cellular, fibrovascular capsule.^[3,4] Measurements of *in vivo* tissue pH adjacent to 70:30 L-La/D,L-La copolymer implants have detected no change during degradation.^[5,6]

MECHANICAL PROPERTIES

Comparing some of the mechanical properties of 70:30 L-La/D,L-La copolymer, bone, and steel, the tensile strength of lactide is approximately 30% of the strength of bone. With a tensile strength of 70 MPa, lactide materials can readily be designed to accommodate the failure loads for non-weight-bearing bones. When designed as 1.0 mm thick plates, the tensile strength is approximately 190 N or 45 lbs. When metal screws are over torque, the threads strip the bone. When lactide screws are overtorqued, the heads shear off. The shear strength of 2.0-mm screws is approximately 85 N or 20 lbs. As the 70:30 L-La/D,L-La copolymer undergoes hydrolysis, its mechanical strength will decrease. At three months, strength remains near 100%, decreasing to 90% at six months, 70% at nine months, 50% at 12 months, and 0% by 18 months.

PLATE SELECTION FOR FRACTURE FIXATION

As with all fixation systems, clinical experience eventually determines the choice of implant design that

is most likely to produce a successful outcome. As a starting point, it is recommended that the surgeon select a copolymer design one size larger than the titanium system currently employed. An example from the authors' experience is the substitution of titanium with polylactide (PLA) for genioplasty, when the anterior part of the mandible needs configuration change. A traditional metal plate with two holes on each side and 2.0 mm screws would normally have been used; however, this patient insisted on resorbable over metal fixation. To ensure adequate stability, the 70:30 L-La/D,L-La copolymer plate was contoured from a piece of 1.0 mm thick mesh with four holes on each side and attached with 2.4 mm screws. While this design may be excessive in strength, it is appropriate to be conservative until clinical experience is acquired (Fig. 3).

CLINICAL EXPERIENCE

The following comprises a review of the authors' clinical experience with biomaterial use in craniofacial fixation.

Resorbable Fixation

Zygomatic and midface fractures

The natural extension of surgical experience with metal plates is to use resorbable plates of similar designs, such as in malar fracture fixation. The principles of exposure and reduction of fractures remain unchanged when resorbable plates are employed. The holes for lactide screws require tapping and maximal screw insertion torque. The plates can be precontoured by dipping in a hot water bath and, after inserting one or two screws, be further contoured by using a flat heat applier (Fig. 3A), a gauze sponge dipped in the warm water bath, or by dripping warm water onto the plate. Resorbable plates are easily trimmed *in situ* using a cautery tip attachment (Fig. 3B). Resorbable mesh may be used in place of metal mesh, such as in an orbital floor fracture (Fig. 3C). Resorbable mesh is easily trimmed with scissors. It is helpful to leave the leading edge of the mesh uncut, so that it can be inserted with less likelihood of engaging adjacent soft tissues. Fragments of bone can be incorporated into either resorbable plates or meshes.

With increased experience, it became apparent to the authors that resorbable mesh offered more sites for fixation and provided greater strength when contoured in three dimensions. By allowing custom shapes to be cut with multiple mesh spaces for screw or tack fixation, the surgeon is freed from the geometric restrictions of limited selection for metal plate designs.

Fig. 3 Orbital fracture treated with bioresorbable plating system, a new biomaterial PLA. (A) Patient with a fractured orbit; (B) PLA panel shaped to inserted in the orbit via transconjunctival; (C) PLA inside the orbit; and (D) PLA fixation transpalpebral.

Combined with the speed and ease of adapting mesh to three-dimensional contours using warm water, it is not surprising that the use of resorbable mesh with screw or tack fixation has become even more prevalent than resorbable plates in our craniofacial and mid-facial reconstructions.

R

Fronto-orbital fractures

The properties of resorption and the ease of contouring have enabled complex fixation requirements of fronto-orbital fractures to be readily accomplished. By using the resorbable mesh as a template, accuracy of bone fragment fixation can be facilitated. In a two-year-old girl kicked in the forehead by a horse, the neurosurgeon outlined the planned craniotomy. Prior to making the bone cuts, a sheet of resorbable mesh was contoured over the fracture site to match the normal right forehead. The fragments were then reduced into this template on the back table, fixated with tacks, and then returned to the patient after completion of the neurosurgical repair. Additional tacks placed around the mesh periphery secured the reduction, restoring this girl's forehead symmetry.

When trauma results in boney defects, easily contoured resorbable mesh can be shaped into a template for the bone graft reconstruction. In a 11-year-old girl, anterior cranial base fractures were sustained in a motor vehicle accident. Following acute debridement she was transferred for definitive care of her cerebrospinal fluid leaks and fronto-orbital bone defects. To provide neurosurgical access to the anterior cranial base, the remaining frontal bone flap and orbital rim were removed. Contoured resorbable meshes were then used to rebuild the fronto-orbital construct from split cranial bone grafts from the flap, along with the portions of the orbital rim that had been removed. A nice fronto-orbital contour was achieved after the construct was fixated around its periphery.

Fixation of secondary craniofacial trauma during reconstruction

Perhaps no area of secondary craniofacial trauma reconstruction has been as challenging as the cranio-orbital fractures of the complex curvatures and multiple planes involved in the frontal bone, the orbital rims, and orbital roof. The availability of easily contoured, large resorbable sheets makes it possible to form templates using in situ anatomy for ex vivo back table assembly of the bone graft reconstruction. In a 59-year-old man, kicked in the right fronto-orbital area by a horse, osseous debridement was carried out at the time of initial neurosurgical repair. Three months later, he underwent reconstruction of his defect, which

included absence of the frontal bone; supraorbital, lateral, and medial orbital rims; and orbital roof. A full thickness bone flap from the right parietal skull was split, and the inner table was replaced and fixated with a resorbable mesh that was contoured before the craniotomy. A template of the desired cranio-orbital defect was formed using a sheet of 0.75 mm thick resorbable mesh, and the cranial bone graft was then cut to fit into the mesh template and fixated with tacks. The construct was fitted into the defect and secured around the periphery with additional tacks. Three months later, the cranio-orbital contour was excellent, the patient's preoperative diplopia completely resolved, and a ptosis correction was scheduled to complete the reconstruction.

EVOLUTION

Our experience is primarily with a pediatric craniofacial population in a practice that stresses treatment of the traumatic injuries of the craniofacial skeleton. However, our application of the techniques of fixation is similar to controlled osteotomies, non-controlled osteotomies, as well as multiple craniofacial fractures. Over time, our initial utilization of preformed plate design has been replaced by the use of sheets of mesh, which are easily cut to fit the requirements of repair for a given fracture. This choice is a matter of preference. With complex reconstructions, we have found that easily contoured resorbable mesh permits quick creation of templates that guide bone graft assembly to a precise and accurate reconstruction. We anticipate that techniques will continue to evolve, as more experience is gained with the properties of resorbable copolymers used for craniofacial fracture fixation and reconstruction.

OTHER BIOMATERIALS UTILITY

The above descriptions of biomaterials reflect those that are used most often in clinical practice. Today there are many surgeons who prefer the use of metallic implants, particularly titanium, for the correction of the facial fractures. Two points, however, must be stressed. First, in children, it is the standard-of-care to use bioresorbable plates and screws to mechanically stabilize the craniofacial skeleton, and it is impermissible to do otherwise. These patients have a higher possibility of screw migration, growth disturbances, and a need for unnecessary secondary operations. Second, for the adult population, repeated surgeries may also be avoided with the use of bioresorbable plating systems.

Other biomaterials are used to a lesser extent in the patients with craniofacial trauma for immediate repair and for reconstruction. However, their use is mostly limited to delayed reconstruction and, very rarely, such biomaterials are applied in the primary care of patients with multiple facial injuries. Fixation of the skeleton in the correction of facial fractures is the primary use for bioresorbable copolymers. When a defect in the craniofacial areas must to be reconstructed, the use of bone grafting is the treatment of choice for those patients. However, if that treatment is not an option or will precipitate a major disability for the patient, the surgeon should be knowledgeable in the applications of those biomaterials in use and familiar with the indications and contraindications of all such biomaterials.

Poly-Methyl Methacrylate

The use of methyl methacrylate was popular after World War II. However, analyzing that experience, we have learned that such biomaterial should not be used in type II wounds or in any contaminated areas of the craniofacial skeleton. Infection and fistulization often result, even when the biomaterial utilized for the repair has been present for over 30 years. The utility of the application of methylmethacrylate is in covering large defects in the skull. It is also used to protect the brain when skull defects are present. The reported incidence of infection varies owing to the longevity of use and because of the transient nature of the population in this country. The lack of standardized records, continuity of care, and information reporting contribute to the inaccuracy of existing data. Methyl-methacrylate is also used to correct contour abnormalities in the patients with trauma. The same principles apply for the avoidance of use in contaminated areas and type II and III wounds. This biomaterial application should always follow a list of strict indications and contraindications to achieve the best possible outcome for trauma patients. The last aspect that should be noted is that reconstruction of large defects in the skull may achieve the immediate purpose for the desired result, but the patient will end up with a shatter effect if the area is subjected to other blunt trauma. Reinforcement with metallic mesh did not alleviate that issue.

Silicones

Silicone rubber in the form of room-temperature vulcanizing silicone or prefabricated silicone components was used in skull repair, but was found to have no added value. Use of silicone was very popular in the early 1970s, and served in reconstruction to fill defects in areas of traumatic injury or for contour

abnormalities. The applications for silicone today are limited. This material is capable of causing major complications in dynamic sites owing to its ability to erode the underlying bone.

Polyether-Urethan Terephthalate and Med Pore

Both materials are used in a fashion similar to silicone but have less utility in trauma patients. We have extensive experience in the use of the polyurethane mesh as a contour and enhancer for bone regeneration for large defects in the skull. However, large sheets of bioresorbable biomaterial have replaced its use by obviating the need for a secondary surgery to remove the implant.^[7]

Bone Substitutes

To complete this discussion, we must also note the various bone substitutes that are in use today and available in most operating rooms. Bone substitutes react with the surrounding tissues to make the application more appropriate. Their main use is for filling defects that need a scaffold. These biomaterials do not stand sheer force, even after they consolidate, and are mechanically unstable. A second, more useful, application is for contour abnormalities.

We are not going to put a recommendation on any one of these biomaterials, but we will list them in a systematic way that will help those interested to know the difference between each component.

Biomaterials as bone substitutes

1. Osteo Inductive: Demineralized bone implants vary from 17% to 99%. Use should be species specific, so that there is no crossing of species boundaries (Dyna-graft 17%-).
2. Osteo Conductive: Calcium sulfate, calcium phosphate, and calcium carbonate combinations (Norian, Mimex, Bonepaste).
3. Bioactive and Interactive: Composition is changed when in contact with the biological system (Bioglas).
4. Tissue Engineering: Active cells and active scaffold will be needed in this unit of tissue repair. Scaffolds used vary from hydroxy appetite to collagen

to most of the degradable carriers. The stem cells used must be autologous in nature. Such uses in the trauma patients are under study today and have limited applications.

Rotary Cell Culture Systems

Stephen S. Navran

Synthecon, Inc., Houston, Texas, U.S.A.

INTRODUCTION

The original concept of the rotary cell culture system (RCCS) was developed at NASA's Johnson Space Center in 1996. It was conceived as a means of carrying cultured cells into space on Space Shuttle flights to study the effects of microgravity at the cellular level. At the time, it was becoming apparent that microgravity had a variety of negative physiological consequences for the astronauts as the duration of space flights increased. By studying the effects of microgravity on cultured cells aboard the Space Shuttle, NASA hoped to gain insight into the molecular mechanisms of the effects of microgravity on the astronauts, and to devise countermeasures.

The designers of the original RCCS (often referred to as the Rotating Wall Vessel, RWV, U.S. Patent 5,026,650)^[1] envisioned the RWV as a device to protect delicate cell cultures from the mechanical forces generated during launch and landing of the Space Shuttle. To accomplish this task, the designers attempted to create an artificial microgravity-like environment. They placed cells in a cylindrical, zero-headspace culture vessel and rotated the vessel at speed sufficient to maintain the cells in a suspended state, in the absence of large shear forces such as those found in spinner flasks. By randomizing the gravitational vector, cells can be cultured in a near free fall environment, simulating, in some respects, the microgravity environment of space. Oxygenation was accomplished by adding a coaxial tubular core covered with a silicon membrane, through which an oxygen/carbon dioxide mixture was pumped to allow bubble-free diffusion of gas into the culture media.

During initial ground-based testing of the bioreactor at NASA, it was noted that when dispersed anchorage-dependent cells were introduced into the RCCS, cells were observed to aggregate and form larger, three-dimensional structures resembling tissues.^[2] It was at this stage that NASA investigators recognized that the RCCS could be an entirely new approach to cell culture. Since 1992, NASA has devoted significant resources to promoting ground-based applications of the RCCS. NASA currently funds approximately 40 investigator-initiated projects per year based on the RCCS. This article will briefly summarize the theoretical background of the RCCS, which has

recently been reviewed in depth;^[3] describe the operation of the bioreactor; and provide specific examples of cell culture applications performed in the RCCS.

THEORETICAL BACKGROUND

In the first analysis of particle motion in the RCCS done at NASA, the simplifying assumption was made that cells cultured in the device would behave as small, spherical particles.^[4] As we will see below, cells often aggregate to form larger, tissuelike structures that may deviate from the theoretical ideal. Nevertheless, this analysis is a reasonable starting point for understanding the principles of cell culture in the rotating bioreactor vessel.

In designing the bioreactor, the overall goal was to minimize the shear forces that were known to cause cellular damage in conventional stirred or sparged suspension bioreactors.^[5,6] The RCCS was designed with several features intended to minimize fluid shear.^[3]

1. The fluid flow within the vessel is near-laminar, or solid-body, under most conditions, preventing the shear produced by turbulent flow.
2. The culture medium is mixed by the rotation of the vessel, avoiding the need for mechanical stirring.
3. The vessel is completely filled with media to prevent bubble formation.
4. A coaxial silicon membrane core, rotating at the same speed as the vessel, is used to oxygenate the media.

The primary determinants of fluid flows producing shear across the surface of cultured cells are gravitational, centrifugal, and Coriolis forces.^[4] Figure 1 shows a particle, P, rotating in a fluid medium at an angular velocity, ω . The gravity-induced sedimentation vector, V_s , is resolved into radial and tangential components, V_{sr} and V_{st} . The Coriolis force, V_{ct} , is tangential to the particle, whereas the centrifugal force, V_{cr} , is radial and outwardly directed. As the particle is rotated in the RCCS, it accelerates until it reaches its terminal velocity, V_s , where the force of gravity is opposed by centrifugal, Coriolis, and shear forces. The Stokes equation for a particle falling in a fluid

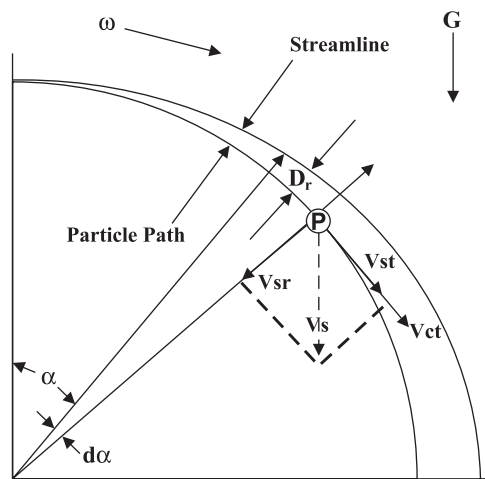

Fig. 1 Vector velocity diagram. The forces acting on a particle rotating in a fluid are shown. Gravity-induced sedimentation V_s is resolved into radial V_{sr} and tangential V_{st} components. Centrifugal force results in an outwardly directed particle velocity, V_{cr} . The Coriolis motion V_{ct} is tangential to the particle.

medium is

$$V_s = \frac{2\Delta dgr^2}{9\nu}$$

where V_s is the terminal velocity of the particle, Δd is the difference in density between the particle and the culture medium, g is the acceleration of gravity, r is the radius of the particle and ν is the viscosity of the medium. Therefore, the major determinants of the sedimentation rate, which is directly proportional to shear force, are gravity and the radius of the particle.

In practice, the rotational speed of the bioreactor vessel is set so that the sedimentation rate of the particle in the cell culture medium is minimized. The viscosity and density of the cell culture medium are not usually varied. As the particles increase in size, the rotational speed must be increased to keep the particles in suspension. Centrifugal force is then increased, causing particle impacts on the vessel wall. The increased rotation also causes an increase in shear. These two factors produce cell damage and effectively limit the size of cell aggregates to less than 1 cm in diameter.^[7] These limitations notwithstanding, the RCCS is a unique tool for constructing macroscopic, three-dimensional tissuelike aggregates that have proven highly useful in a variety of research applications, as detailed below.

Another important factor to be considered is mass transport of nutrients. In other types of suspension culture systems, such as spinner flasks or bubble sparged vessels, the extreme turbulence created to keep the cells in suspension ensures that the cells obtain

adequate nutrients and oxygen mostly by convective bulk flow, but at the expense of cellular injury from the fluid shear forces and bubbles. In true microgravity, where the terminal velocity of the cells is near zero, mass transport is accomplished primarily by diffusion. In ground-based applications of the RCCS, mass transport is accomplished by a combination of bulk flow and diffusion, without the damaging influences of fluid shear stress.

THE RCCS IN CELL BIOLOGY AND TISSUE ENGINEERING

The original purpose of the RCCS was to maintain cell cultures on the Space Shuttle before and during lift off. Once in orbit, the culture chamber served only as a containment vessel. Later, as the utility of the technology became apparent in ground-based experiments, the RCCS began to be thought of as a “microgravity simulator” that could be used to study the effects of microgravity on human physiology, as it impacted the astronauts. The immunosuppression experienced by astronauts on the Space Shuttle is an example. Studies on the ground using the RCCS have shown deficits in T-lymphocyte function similar to those found in the astronauts when subjected to simulated microgravity.^[8,9] More recent studies have used the bioreactor to devise a potential countermeasure for this immune dysfunction.^[10,11] However, a study comparing gene expression in the RCCS at normal gravity with that in the true microgravity of space demonstrated that there are considerable differences,^[12] suggesting that the RCCS may not be a good model of microgravity.

Most of the applications for the RCCS involve the ability of the bioreactor to assemble and maintain three-dimensional cell aggregates that closely resemble native tissue. When considering the utility of the RCCS as a tool to generate in-vitro models, an important question is whether the 3-D constructs produced are sufficiently differentiated. While the answer to this question is not complete, there are a number of studies which suggest that 3-D tissue aggregates grown in the RCCS are more differentiated than 2-D cultures.^[13-17] In general, these studies have dealt with a limited number of markers of differentiation. Ideally, the 3-D tissue constructs made in the RCCS should be compared to the native tissue. Such a study has recently been performed by Nakamura et al.,^[17] comparing a 3-D carcinoma model grown in the RCCS with actual tumor tissue, as well as with 2-D cultured tumor cells. The results showed that the 3-D construct was very similar to tumor tissue in those markers that were examined. The limitation of all the aforementioned studies is that they looked at only a few markers at

most. With the emergence of genomic and proteomic tools to study global gene and protein expression, it is now possible to compare large numbers of markers simultaneously. These technologies will undoubtedly be applied to the question of the degree of differentiation of 3-D culture in the RCCS.

The fact that the RCCS is capable of producing differentiated 3-D tissuelike constructs suggests that this technology will have widespread use in tissue engineering, including replacements for injured organs, drug development, and toxicity testing. A number of investigators have undertaken studies aimed at developing such applications (see examples in the following sections).

Methods of Cell Culture in the RCCS

The RCCS bioreactors were designed in two basic formats. One is the Slow Turning Lateral Vessel (STLV), illustrated in Fig. 2. This vessel has a cylindrical shape with a central core covered by a silicon membrane. The unit is placed in a humidified incubator with the appropriate gas mixture. The incubator gas is pumped through the core and diffuses through the silicon membrane without producing cell-damaging bubbles. Cells can be introduced into the vessel through a large fill port on one end cap. There are also two luer lock syringe ports on the end cap, through which bubbles removed and samples withdrawn. When feeding is required, the vessel is placed on its end under a laminar flow hood, and the cells or cell aggregates are allowed to settle to the bottom. The media can then be removed through the large fill port without disturbing the cells, and fresh media can be added.

The other basic RCCS bioreactor format is the High Aspect Ratio Vessel (HARV), as shown in Fig. 3. As its name implies, the HARV is a disk-shaped vessel.

Fig. 2 The STLV. The vessel is cylindrical and has a central core covered with a silicon membrane. The gas mixture is pumped through the core and diffuses into the vessel.

Fig. 3 The HARV. The vessel is disc-shaped and has a silicon membrane on the back. The gas mixture is pumped into the back of the vessel.

The gas-permeable silicon membrane is on the back of the vessel, and the fill port and syringe ports are located on the front face. The choice of which vessel to use is often not obvious, depending on unknown characteristics of the cell type being cultured. One general principal that seems to hold true is that non-adherent cells seem to grow better in the HARV.

In addition to the two basic configurations, the RCCS was also designed as a perfusion bioreactor (Fig. 4). With a rotating coupling placed on each end cap, the vessel can be continuously perfused with media. This type of reactor requires a filter to be placed on the effluent side of the vessel to prevent the cells from passing into the flow loop.

The RCCS can culture both suspension-dependent and anchorage-dependent cells, as well as tissue explants. Suspension cells that do not aggregate can be grown in the RCCS at very low rotational speeds

Fig. 4 The perfused RCCS. The medium is circulated through the vessel from a feed bottle. The media can be perfused into a collection bottle or recirculated. Gas exchange occurs in a section of coiled silicon tubing in the flow loop.

(<10 rpm), because their sedimentation velocity is minimal compared to three-dimensional cell aggregates. This type of culture allows for the lowest shear force possible in ground-based rotary bioreactors. Anchorage-dependent cells may be cultured in two ways. One way is to introduce them into the bioreactor vessel as individual, dispersed cells. During the initial phase of culture, some cell types may readily adhere to each other, forming three-dimensional aggregates. In other cases, substrates such as microcarriers or biocompatible polymers are required for initial cell attachment. Once attached, the cells proliferate and often adhere to cells on other microcarriers, forming large, three-dimensional aggregates of microcarriers and cells. As the aggregates grow and become visible to the naked eye, the rotational speed must be adjusted to maintain the aggregates in suspension. There are no absolute guidelines for determining whether anchorage-dependent cells will self-assemble or will require a substrate. The behavior of each cell type must be determined empirically. However, increasing the initial seeding density tends to favor self-assembly, due to the increased probability of cell-to-cell contacts.

More recently, the RCCS has found a new use: the culture of tissue explants. When explants are cultured in two-dimensional systems such as flasks or dishes, the integrity of the tissue is not maintained. Some cells migrate out of the explant onto the surface and proliferate, while most remain within the solid tissue mass and readily die off. The result is not representative of the original cell population. In the RCCS, however, small explants up to 2–3 mm in thickness can survive intact for extended periods of time, up to months in some cases (see Refs. [23] and [27]). Furthermore, new growth can often be observed. Explant culture has been shown to provide an excellent model for the study of complex cell interactions while maintaining the normal extracellular environment.

Coculture of multiple cell types is another area where the RCCS offers some unique advantages. Dispersed cells of two or more types can be introduced into the RCCS and assembled into a three-dimensional aggregate that closely approximates the native tissue cytoarchitecture. An example is shown in Fig. 5. In this study, done in collaboration with Dr. Arun Rajan at Baylor College of Medicine, two cell lines derived from pancreatic islets of Langerhans were assembled into artificial islets in the RCCS. The cell lines, alpha-TC6 and HIT (alpha and beta cells, respectively), make up the majority of the normal islet. When seeded into the RCCS, the cells assemble into spherical aggregates 200–300 microns in diameter and then remodel, so that the central core of the aggregate contains the beta cells surrounded by a layer of alpha cells, as in the normal islet. Functional studies have shown that these isletlike structures were capable of secreting insulin and

Fig. 5 Artificial islet assembled in the RCCS. A beta cell line, HIT, and an alpha cell line, alpha TC 6, were introduced simultaneously into the RCCS. After 2–3 days aggregates of 200–300 microns were assembled (left). Immunostaining (left) of these aggregates showed that the beta cells were in the center of the aggregates (bright staining) while the alpha cells were on the periphery (fainter staining).

glucagon when stimulated with the appropriate secretagogues.^[18]

Selected Applications

For a cell culture technology with such a short history, the RCCS has proven remarkably versatile. The following examples, in addition to those already mentioned, are chosen to illustrate the diverse areas in which the RCCS has been used. A complete bibliography is available at www.synthecon.com.

Cartilage

Chondrocytes, when cultured in two dimensional monolayers, dedifferentiate into a fibroblastlike phenotype and lose the ability to express cartilage-specific extracellular matrix proteins. However, when these cells are transferred to the RCCS, they spontaneously aggregate and re-express cartilage-specific proteins.^[19] Other investigators^[20,21] have used artificial polymer scaffolding such as polyglycolic acid to grow chondrocytes. Compared to static culture or spinner flasks, the RCCS produced constructs with more rapid tissue growth and higher levels of glycosaminoglycans and total collagen. The mechanical properties of the RCCS-cultured cartilage constructs more closely resembled the mechanical properties of native cartilage than did those of the other culture systems.

Cancer

Three-dimensional cultures of carcinomas in the RCCS have been shown to be superior models for the study of prostate cancer and have been used in the development

of therapies.^[22] Explants of human melanoma cultured in the RCCS maintain their structure and function for weeks, providing a unique model of human melanoma that mimics the *in vivo* environment more closely than conventional culture methods.^[23] Cocultures of cervical cancer and endothelial cells have been grown in the RCCS to study tumor angiogenesis.^[24]

Insect cells

Insect cells grown in the RCCS were maintained in the stationary phase two to three times longer than cells grown in shaker flasks.^[25] Cell death was reduced 20- to 90-fold in the RCCS. The differences were attributed to the reduction of hydrodynamic shear forces in the RCCS compared to the shaker flask.

Infectious disease (bacterial and viral)

A 3-D model of intestinal epithelium was developed in the RCCS to study the pathogenesis of *Salmonella*.^[26] Compared to static, 2-D culture, the RCCS produced a more differentiated tissue model. *Salmonella* was observed to infect the 3-D culture in a different way than it infected monolayer cells. There were marked differences in cytokine expression in the two models. The results showed that the RCCS provided a better means of studying microbial infectivity from the point of view of host–pathogen interaction.

Human lymphoid tissue explants (tonsil) maintained in the RCCS have been used to study the pathogenesis of HIV infection.^[27] Blocks of excised lymphoid tissue maintained viability and cytoarchitecture for more than three weeks in the RCCS. Both B and T lymphocytes were able to move freely between the lymphoid tissue and the growth media. The lymphoid tissue in the RCCS could be infected by several strains of HIV-1. It was suggested that such a model system could be used to study HIV pathogenesis as well as potential therapies.

Liver

Primary human liver cells have been cultured in the RCCS, forming 3-D spheroids up to 1.0 cm in diameter.^[28] The constructs were composed of hepatocytes and biliary epithelial cells arranged as bile duct-like structures. Scanning electron microscopy showed clusters of hepatocytes surrounded by extracellular matrix. When hepatocytes were cultured with endothelial cells, albumin mRNA expression was induced. Metabolic studies on porcine hepatocytes cultured in the RCCS demonstrated that the cells maintained normal metabolism for 21 days.^[29]

Conventional culture systems usually cannot maintain hepatocytes for that length of time. Development is currently underway to use RCCS technology for extracorporeal liver assist devices to treat liver failure.

Neural tissue

Murine neural precursor cells cultured in the RCCS formed macroscopic three-dimensional structures that were many times larger than those formed in static culture.^[30] The structures consisted of a surface layer of proliferating cells (nestin- and pcna-positive) and an inner core of more differentiated cells (beta tubulin III- and glial fibrillary acidic protein-positive). The results suggested that the RCCS may be a useful tool for production of transplantable neural tissue.

Pancreatic islets

The failure of islet transplants is the result of both poor initial condition of islets after isolation from the pancreas and rejection by the recipient's immune system. A period of *in vitro* culture markedly improves the success rate of islet transplantation. Islets cultured in the RCCS were shown to be superior—in terms of survival after transplantation—to those maintained in static culture.^[31] Furthermore, these studies showed that diabetic animals were immunotolerant to islets cultured in the RCCS, but not to static cultured islets. Other investigators have utilized the RCCS for coculturing islets and sertoli cells,^[32] which can confer immunotolerance to the sertoli-islet construct. Currently, studies are underway to test the feasibility of using the RCCS to enhance the success of human islet transplantation. Because of the shortage of donor islets, new sources of islets are being explored, including xenotransplants and islets assembled from stem cells. The RCCS can clearly be useful in both of these applications.

SUMMARY

The rotary cell culture system is a relatively new cell culture technology utilizing a zero-headspace, horizontally rotating vessel to grow cells in a low shear, free-fall environment. Under these conditions, anchorage-dependent cells will form three-dimensional aggregates either with themselves or on microcarriers or scaffolding. The aggregates can produce extracellular matrix and remodel into tissue-like structures that have differentiated functions similar to the native tissue. Until recently, the RCCS has been used primarily for basic science applications. However, in the emerging field of tissue engineering, several

applications utilizing tissues generated in the RCCS are approaching the stage of human testing.

The future of the RCCS will almost certainly co-evolve with tissue engineering technology for therapeutic applications. The exciting work now going on in stem cell biology will undoubtedly have a great impact on this area, providing virtually unlimited numbers of cells for production of almost any tissue. The RCCS is ideally suited to play an important role in the development of this technology because it can grow, assemble, and differentiate tissues originated from stem cells.

Self-Assembled Monolayers

Koichi Kato

Institute for Frontier Medical Sciences, Kyoto University, Sakyo-ku, Kyoto, Japan

INTRODUCTION

A self-assembled monolayer (SAM) is a thin, organic film that is formed spontaneously by adsorption of pre-designed organic precursors from the solution or vapor phase to the surface of an appropriate solid substrate. The process starts with chemisorption of headgroup possessed by precursor molecules and eventually produces a two-dimensional, highly ordered, thin layer. Many different combinations of a headgroup and substrate have been employed, such as organosilicons on hydroxylated surfaces (e.g., silica on silicon, alumina on aluminum, glass, etc.); alkanethiols on gold, silver, and copper; dialkyl sulfides and dialkyl disulfides on gold; amines on platinum; and carboxylic acids on aluminum oxide and silver. Among these combinations, alkanethiols on gold and organosilicons on glass have been studied most extensively in the field of biomaterials research.

The processes to obtain SAMs have many characteristic features and advantages over other methods of surface preparation for basic and applied studies on biomaterial surfaces. First of all, one can easily obtain a well-defined planar surface. Such a surface can be used as a simple, rigid model of organic biomaterials. As described subsequently, it is easy to prepare SAMs with various functionalities at the topmost surface in a well-controlled density and distribution by selecting a type of self-assembling molecules and compositions in the case of mixed SAMs. Other important advantage is the possibility of applying a wide variety of techniques for the characterization of SAM surfaces, such as infrared spectroscopy (IR), second harmonic generation (SHG), sum frequency generation (SFG), surface enhanced-Raman scattering (SERS), high-resolution electron energy loss spectroscopy (HREELS), near-edge X-ray absorption fine structure (NEXAFS), X-ray photoelectron spectroscopy (XPS), surface plasmon resonance spectroscopy (SPR), and scanning probe microscopy (SPM). As can be seen in recent publications, SAM surfaces have found many applications in the two-dimensional micropatterning of chemicals, biomolecules, and live cells.

The following deals with fundamental aspects of SAM formation and its supramolecular structure. It focuses on two representative cases of SAM systems: alkanethiol and organosilicon monolayers. The overview

of the biotechnological applications of SAMs will be given in the last section. Langmuir–Blodgett films of amphiphiles and monolayers consisting of fatty acids are also classical issues in surface engineering, but they are not dealt with in this article.

SAM FORMATION

As mentioned in the preceding section, various combinations of self-assembling molecules and substrates have been employed for the preparation of SAMs.^[1,2] Table 1 shows the example of various SAM systems appearing in literature. The critical steps of SAM formation involve: 1) chemisorption of headgroup to the substrate surface and 2) two-dimensional organization through the lateral interchain interactions. Both steps are an exothermic process, and the former serves to initiate the short-range, dispersive, London-type, van der Waals interactions between self-assembling molecules.^[2] Fig. 1 simply depicts a self-assembling building block that consists sequentially of a surface-active headgroup chemisorbed at the substrate surface, an alkyl or derivatized alkyl chain that is capable of lateral interactions with the neighboring counterparts, and a terminal group exposed to the outer phase. Another important backbone for SAM molecules can be a chain that contains aromatic rings. The physicochemical properties of the three components as well as a type of substrate and medium used, e.g., solvents in the case of chemisorption from solution, have synergic effects on the entire process of SAM formation and the properties of resulting monolayers.

The following two sections are devoted to the formation of alkanethiol monolayers on noble metal surfaces and organosilicon monolayers on hydroxylated surfaces.

Alkanethiol on Metal

SAMs made of organosulfur compounds, including alkanethiol, dialkyl disulfide, dialkyl sulfide, aromatic thiol, alkyl xanthate, and dialkylthiocarbamate, have been studied extensively.^[37] The key step of monolayer formation is the coordination of sulfur to the surface of metals such as gold, silver, copper, platinum, mercury, iron, γ -Fe₂O₃, GaAs, and InP. An amine-terminated

alkyl chain, even though this does not contain sulfur, forms a SAM on a platinum surface, which is similar to the case with alkanethiols. The surface of gold is the most frequently studied as a substrate for SAMs constructed with alkanethiols due to ease of preparation, well-defined structure, and absence of an oxidized layer.

The surface of gold can be prepared by vapor-phase evaporation of polycrystalline gold onto a glass plate properly cleaned by, e.g., treatment with piranha solution (7:3 concentrated H₂SO₄/30% H₂O₂). Since adhesion at the interface between glass and gold is poor, a thin layer of titanium or chromium is coated prior to evaporation of the gold to avoid delamination of the gold. Annealing or a simple flame treatment of a thin film of gold formed by evaporation is performed to obtain the Au(111) surface with a well-defined lattice structure.

So far, there are many types of alkanethiol used in the study of basic and applied research on SAMs on

gold. Some of them are commercially available, and others must be synthesized in-house. One can use both the oxidized (disulfide) and reduced (thiol) forms with similar results with respect to the structure of SAMs formed. An intermitting chain is an *n*-alkyl chain with a carbon number of, in practice, 1–20 or derivatized alkyl chains containing an aromatic ring, unsaturated alkene, etc. The length of *n*-alkyl chain has great effect on the kinetics of SAM formation and the order and stability of the formed monolayers. An alkanethiol with a longer alkyl chain forms a SAM more rapidly than that with a shorter chain. It is known that the presence of a polar group in the chain has a great effect on the second step of SAM formation, i.e., ordering of chemisorbed alkanethiol, due to attractive interchain forces. Depending on the research interests, many different functional groups can be incorporated to the terminal of *n*-alkanethiol. Proper functional groups, such as carboxylic acids, provide the possibility to derivatize the SAM surface for further applications. The example is modification with poly(ethylene glycol) chains; cell-binding peptides such as RGD (Arg-Gly-Asp); biotin, which strongly binds to avidin and streptavidin; histidine-tag chelating groups; porphyrin; etc.

The procedure employed for SAM preparation is very simple. In a typical case, a plate coated with a thin layer of gold is just immersed in a dilute solution of alkanethiol to initiate SAM formation. The plate is then washed with solvent to remove weakly adsorbed alkanethiol. Usually, the reaction is carried out under ambient conditions. The concentration of alkanethiol solution has an effect on the kinetics of SAM formation. As shown in Fig. 2,^[22] depending on the

Fig. 1 A self-assembling precursor molecule consisting of a headgroup, a long alkyl chain, and a terminal group.

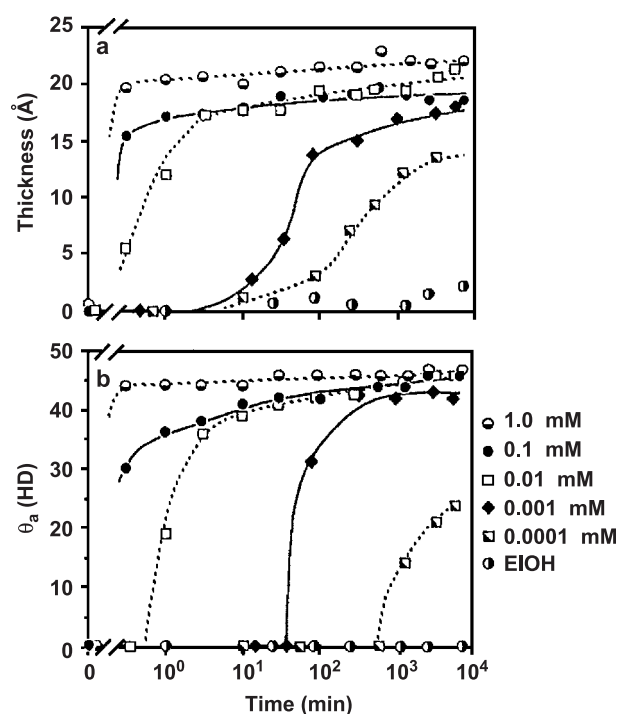

Fig. 2 Kinetics of adsorption of octadecanethiol from ethanol as a function of concentration: a) ellipsometric thickness and b) advancing contact angles. (Reprinted with permission from *J. Am. Chem. Soc.* **1989**, *111*, 321–335. Copyright (1989) American Chemical Society.^[22])

concentration of alkanethiol solution, time dependence of the ellipsometric thickness and the advancing contact angle is largely altered. These measurements represent the surface coverage and also the order of alkanethiol molecules. It can be seen that higher concentration gives rise to the rapid formation of SAM. The most popular solvent used in alkanethiol monolayer preparation is ethanol. Other organic solvents can also be used if they give an isotropic solution and have no specific interactions to the alkanethiol and the substrate. In case of formation of mixed SAM, by which different alkanethiols simultaneously form SAM from the mixed solution, small difference in the solubility power may produce a mixed SAM with an enriched single component compared to the other.

When the bare surface of gold is brought into contact with an alkanethiol solution, thiol is considered to react with gold through the oxidative addition of the S–H bond followed by reductive elimination of the hydrogen, which results in the formation of thiolate.^[2]

The energy associated with the sulfur–gold bond formation is estimated to be 40 kcal/mol^[2] while that with

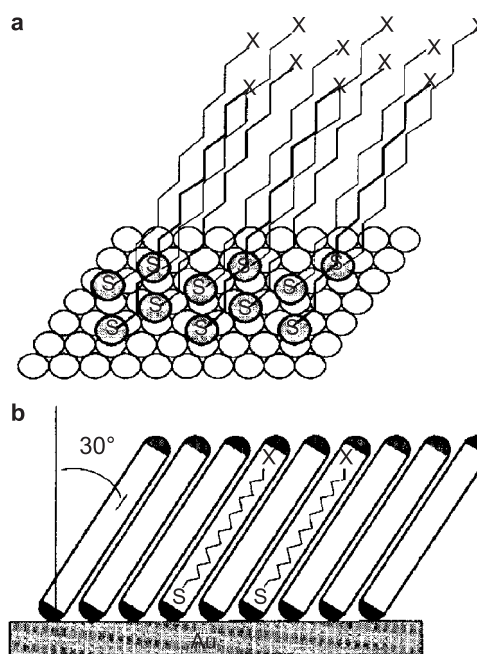

Fig. 3 Representation of a self-assembled monolayer (SAM) of alkanethiolates on the surface of Au(111). (Reprinted with permission from *Trends in Biotechnology* **1995**, *13*, 228–235. Copyright (1995) Elsevier.^[38])

interchain van der Waals interactions of alkyl chains is at the order of few (< 10) kcal/mol.^[2] The sulfur–gold bond is robust enough to fix alkanethiol molecules to the surface of gold, but the bonding energy is not necessarily high compared to other covalent bonds, which, in turn, gives the opportunity to be cleaved by site-restricted oxidation via, e.g., UV radiation through a photomask with a negative pattern that leaves a patterned SAM.

The structure of SAM that is organized on the surface of Au(111) has been extensively studied by means of electron diffraction, helium diffraction, atomic force microscopy, and ultrahigh vacuum scanning tunneling microscopy. As shown in Fig. 3,^[38] the sulfur atoms of alkanethiol coordinate to the hollow three-fold sites of the Au(111) surface on which the gold atoms are arranged in a hexagonal packing. The alkyl chains of alkanethiol are closely packed by interchain interactions and tilted approximately 30° from the normal to the surface. Readers should see Refs. [1,2,37] for more comprehensive consideration on the equilibrium and nonequilibrium structure of alkanethiol monolayers.

SAM of Organosilicon Derivatives on Hydroxylated Surface

Another SAM system important in the biotechnological application is a monolayer built up by the class of

organosilicon derivatives, R_nSiX_{3-n} ($n=1-3$). X is chloride or alkoxy, and R is an aliphatic or an aromatic hydrocarbon chain terminated with a functional group. The formation of SAM with organosilicon derivatives is primarily based on the chemisorption of a chloride or alkoxy terminal, which forms a covalent linkage of Si–O at the hydroxylated surface that has –OH groups, such as SiO_2 , SnO_2 , and TiO_2 . A glass is one of the most practical substrates. The Si–O linkage is also formed between neighboring organosilicons to form a two-dimensional layered, cross-linked network. Compared to other systems, e.g., a monolayer formed by fatty acid molecules by self-assembly, such a network is considered to provide a durable surface modification.

In the case of SAMs of organosilicon derivatives, the formation of an ordered, closely packed monolayer relies upon two steps: 1) chemisorption of self-assembling molecules associated with chemical bonding and cross-linking and 2) reorganization of pre-adsorbed molecules through lateral van der Waals interactions between hydrocarbon chains. Typically, a substrate having a hydroxylated surface, such as a properly cleaned glass, is immersed in a solution of organosilicon, such as alkyltrichlorosilane, in an organic solvent to obtain organosilicon SAMs.

It is often assumed that the chlorine or alkoxy are split off and the molecules are bound to the surface and each other by a Si–O–Si linkage. However, reality seems to be much more complicated. The process is reported to take place through two pathways: 1) direct chemisorption of a monomeric organosilicon and 2) adsorption of pre-formed oligomeric derivatives formed by Si–O–Si condensation in bulk solution. Such two different processes have implications in the structure of SAM formed, and it is often argued that organosilicon SAM is inherently disordered than, e.g., alkanethiol monolayers, in which molecules have more freedom to establish long-range order. Assuming that a monolayer completely covers the substrate surface and forms in situ Si–O bonds, there would not be enough space for all-trans hydrocarbon chains to organize a closely packed, ordered structure. According to Schreiber,^[1] octadecyltrichlorosilane (OTS; $CH_3-(CH_2)_{17}-SiCl_3$) forms a SAM on oxidized silicon with a thickness of circa 2.5 nm with a very limited correlation length. The alkyl chains are packed mostly in the all-trans conformation with a tilt angle of at most 20° normal to the surface, which exposes the terminal methyl group.

BIOTECHNOLOGICAL APPLICATIONS

As described in the preceding discussion, SAMs can be prepared by relatively simple processes and provide well-characterized, durable, organic thin layers on the surface of a variety of substrates. These advantages make SAMs

versatile modification techniques that have a potential to be utilized in various applications, such as coatings for the control of corrosion, wetting, friction, lubrication, and adhesion. Functionalized SAMs can also be used for graft-polymerization of organic monomers from the surfaces. The reactions and reactivity in SAMs were reviewed in Checik et al.,^[39] which discusses the growth of surface-attached polymers, intrafilm reactions, chemistry, photochemistry, and reactivity issues. Primarily due to the following two reasons, SAM is important in biotechnological applications. The surface of SAMs provides the model system in which very complex biological events taking place under in vivo and other quasiphysiological conditions can be simply simulated in vitro. The other advantage of using SAMs is concerned with much more practical applications as a component of biosensors and biochips.

It is often in biomaterials research that a detailed study on biomolecular interactions at the surface of artificial devices is affected by several intrinsic factors, such as surface roughness, dynamic property of surface molecules, and less controllable surface chemistry. Using SAM as a model surface can potentially circumvent these problems. In addition, various analytical methodologies are available for the precise study on surface events at a high resolution and sensitivity. They include quartz crystal microbalance, ellipsometry, and internal reflectance fluorescence. Besides them, scanning probe microscopy (SPM) has received considerable attention due to its potential to analyze in situ a broad range of biological objects. This is mostly owing to the specific feature that the SPM can be operated in aqueous media in contrast to other conventional techniques such as scanning electron microscopy (SEM). Currently, the SPM operated in aqueous media provides molecular-level images with a high signal-to-noise ratio that is comparable to those obtained by electron microscopy. Another powerful technique is surface plasmon resonance (SPR) spectroscopy, which takes advantage of a physical phenomenon of SPR to detect tiny changes in the refractive index of a medium near a thin metal film.^[40] The alkanethiol monolayer formed on gold is frequently employed because it is well suited for the configuration of SPR spectroscopy. Protein adsorption, protein–protein interactions, and DNA–DNA hybridization have been studied by many research groups using this technique.^[41]

Figure 4^[42] shows the example of SPR measurements in which interactions of serum complement fragment C3b were analyzed on mixed alkanethiol SAMs to investigate the effect of the surface density of hydroxyl group on the binding of complement fragment C3b to the surface as a result of complement activation. Information on the complement activation by biomaterial surfaces has important implications in various clinical settings, such as open heart surgery, blood transfusion

Fig. 4 a) Time curve of serum protein adsorption onto a SAM terminated with hydroxyl groups and anti-human C3b antibody binding to the protein adlayer formed on the SAM. medicine, and extracorporeal immunotherapy. The alkanethiols used for preparation of mixed SAMs were 11-mercapto-1-undecanol (HO-(CH₂)₁₁-SH), *n*-nonanethiol (CH₃-(CH₂)₈-SH), *n*-dodecanethiol (CH₃-(CH₂)₁₁-SH), and *n*-hexadecanethiol (CH₃-(CH₂)₁₅-SH). A series of mixed SAMs with different molar ratios was prepared using the hydroxyl-terminated alkanethiol and one of the alkanethiols with a methyl end group. For SPR measurement, a p-polarized He-Ne laser beam ($\lambda = 632.8$ nm) was illuminated to the backside of the glass plate through a glass prism (the Kretschmann configuration) at an incident angle near the SPR angle while a protein solution was allowed to pass through a flow cell. The intensity of a reflected light was determined by a PMT detector. The immobilization of C3b on the SAMs was assessed from specific binding of an anti-C3b antibody. As can be seen in Fig. 4a, a small amount of protein interacting with the surface could be detected in real time under the physiological condition. The results show that an increase in the hydroxyl content gave rise to an enhanced deposition of serum proteins (Fig. 4b). As is evident from Fig. 4c, the enhancement is likely due to binding of C3b upon complement activation at the surface through the alternative pathway.

Currently, the SPR technique is widely used in biomolecular interaction analysis at SAM surfaces. The next generation of the SPR measurement involves a biochip analysis by which multiple biomolecular interactions are analyzed in parallel using a microarray format or microfluidics prepared by utilizing SAM techniques. To realize such a high-throughput analysis, an imaging apparatus was developed^[43] by taking advantage of the SPR induced by a collimated, expanded, and p-polarized light source and a CCD camera as a detector. Surface-plasmon field-enhanced fluorescence

microscopy^[44] was also reported for the parallel multipot detection of biomolecules bound to SAM-based microarrays.

A key step to analyze biomolecular interactions is the immobilization of biomolecules (ligand) onto the surface of SAMs.^[45] A variety of chemistries has been applied to protein immobilization onto SAM surfaces. A frequently used method for efficient protein immobilization is to activate carboxylic acid with the use of carbodiimide. First, a carboxylic acid-terminated alkanethiol monolayer is prepared and then activated by carbodiimide. Water-soluble and -insoluble carbodiimides, *N*-3-dimethyl-aminopropyl-*N'*-ethylcarbodiimide (EDC) and dicyclohexylcarbodiimide (DCC), can be used in an aqueous media and organic solvent, respectively. It is known that carbodiimide-mediated coupling reactions are much more efficient with the concomitant use of *N*-hydroxysuccinimide (NHS) or *N*-hydroxysulfosuccinimide (sulfo-NHS). Figure 5 represents the reaction scheme for the activation of carboxylate by using EDC plus NHS and the subsequent coupling of an amine-containing ligand. The advantage of this modification lies in the long half life of the intermediate active NHS-ester formed during activation with EDC, which, in turn, gives rise to a substantially increased coupling yield. Since the remaining activity of proteins should be kept as high as possible after their immobilization on the SAM surface, several new methods have been proposed. A biotin-terminated alkanethiol can be used to prepare the molecular assembly of a streptavidin layer. Biotinylated proteins and nucleic acids can then be coupled to the immobilized streptavidin, which makes use of a highly specific biotin-streptavidin interaction.^[46] However, chemical modification may lead to inactivation of proteins, and the orientation of protein molecules cannot be controlled

Fig. 5 Reaction scheme for the immobilization of protein to the surface of a carboxylate-terminated SAM through an active *N*-hydroxysuccinimide ester intermediate.

during immobilization reaction. The sophisticated way to overcome these problems may be to use an alkanethiol that is terminated with a Ni(II)-chelating nitrilotriacetic acid, which selectively binds proteins with a histidine tag.^[47] This method takes advantage of the fact that recombinant fusion proteins tagged with a peptide of six histidines interact with two vacant sites on Ni(II) ions.

Recently, there are many publications on the micro-contact printing (μCP) method.^[38] This method is an attractive way to create a micropatterned monolayer of alkanethiols on gold and has found a variety of biotechnological applications. An alkanethiol solution is inked and dried on an elastomeric polydimethylsiloxane stamp with a micropattern that is prepared using a rigid, master template. Then, the stamp is pressed onto the gold-coated surface to transfer the alkanethiol to the gold surface. A SAM of the second alkanethiol with chemical properties different from the stamped one is then formed from solution to the surrounding region, which produces a micropatterned SAM in which two distinct regions are located, e.g., lines, dots, and any other shapes. With the μCP , one can easily obtain a micropatterned SAM with a feature of sizes ranging down to $1\ \mu\text{m}$. It is claimed that the method can be performed at a lower cost and with higher resolution than other processes such as UV lithography in which a restricted area of a pre-formed homogeneous SAM is oxidized with a UV light that is radiated through a patterned mask.^[38] Recently, a patterned protein nanostructure was fabricated on a SAM using dip-pen nanolithography (DPN).^[48] The method involves the fabrication of chemically reactive nanoscale feature by patterning a SAM of a COOH-terminated alkanethiol on a gold substrate by DPN, which is followed by covalent immobilization of a high-affinity, small-molecule ligand on the nanopatterned SAM and subsequent molecular recognition of its protein-binding partner from solution.

The patterned SAMs containing reactive regions can be further utilized to create the pattern of live cells. Figure 6 shows photographs of acute lymphoblastic

Fig. 6 a) Acute lymphoblastic leukemia cells (CCRF-CEM) attached to the patterned SAM. The homogeneous SAM of *n*-hexadecanethiol ($\text{CH}_3(\text{CH}_2)_{15}\text{SH}$) formed on a gold-coated glass plate was firstly patterned by UV lithography and then a SAM of carboxylic acid-terminated alkanethiol ($\text{HOOC}(\text{CH}_2)_{10}\text{SH}$) was formed in the irradiated regions. The carboxylic acid present in discrete regions was activated with DCC and NHS, and a monoclonal antibody to T-cell antigen, CD5, was covalently immobilized to the activated regions. After blocking the surrounding methyl-presenting SAM with bovine serum albumin, cells were plated to the SAM surface with patterned antibody. Cells are attached to 5×5 circular spots (1 mm diameter) with immobilized antibody. b) High-magnification image of a single spot (1 mm diameter) with mouse stromal cells, PA6. A patterned SAM was prepared by the same fashion as for leukemia cells, but fibronectin was immobilized to activated spots instead of antibody. Bar: (a) 1 mm, (b) $200\ \mu\text{m}$.

leukemia cells and mouse stromal cells that are attached to the patterned SAM surface. Specific interactions between cells and immobilized biomolecules are used to achieve regionally restricted cell attachment while cell adhesion is prevented on the surrounding regions by blocking with nonspecific molecules such as albumin and polymeric or oligomeric ethylene glycol. For the specific interactions, extracellular matrix proteins, e.g., collagen, fibronectin, and laminin; cell adhesion peptides, e.g., RGD peptide; and antibodies are immobilized to the reactive regions in order to capture cells expressing integrins and surface antigens. Using the techniques for preparing patterns of live cells, many attempts have been made to manipulate cell growth and axonal extension. The coculture system of two different cell types can be also established by making use of a patterned SAM, which provides a simple model for mechanistic studies of heterotypic cell-cell signaling in two-dimensional cellular organization.^[49] The highly integrated cell arrays prepared by patterning SAM will also provide promising platforms for the cell-based, high-throughput, functional analysis in which live cells are used to massively screen thousands of drugs, proteins, and genes in parallel.

CONCLUSION

Self-assembled monolayers are a thin organic film that are spontaneously formed by chemisorption and ordering of precursor molecules at the solid surface. Two important SAM systems, including the monolayers of alkanethiol on gold and organosilicon monolayers on hydroxylated surfaces, have been extensively studied. The kinetics of film formation and structural aspects are now well understood for these two systems. SAM is one of the best systems to establish a model mimicking biomolecular interactions at surfaces. Further modification of SAM terminals as well as patterning provides a broad range of platforms for biotechnological applications such as biomaterials, biosensors, and biochips.

Biomaterials and Bioengineering Laboratory, Laval University, Quebec City, Quebec, Canada

INTRODUCTION

Shape Memory Metals (SMM) have certain original properties, particularly an ability to return to a memorized shape in response to a simple change in temperature. The shape-memory effect was first observed in copper–zinc and copper–tin alloys by Greninger and Mooradian in 1938, but it was only in the early 1960s that Buehler and his colleagues discovered and patented Nitinol (N*ickel* T*itanium* N*aval* O*rdnance* L*aboratory*), a nickel–titanium alloy created in the Naval Ordnance Laboratory. Buehler suggested using SMMs in dentistry to make implants that would return to a pre-set shape. Much work has since been done to exploit the high potential of these materials for biomedical applications. They currently seem to hold the most promise in radiology, cardiovascular applications, urology, and other medical applications for use as prostheses, tissue connectors, and endovascular stents. In fact, SMMs have come into wide use because of their exceptional superelasticity, their shape memory, their good resistance to fatigue and wear, and their relatively good biocompatibility.

For biomedical applications, the most attractive SMM is Nitinol, an almost equiatomic nickel–titanium alloy. This SMM, however, is 55% nickel by weight and may thus have allergic, toxic, or carcinogenic effects. For short-term implantation, in-vitro and clinical data strongly support Nitinol as a safe biomaterial, at least as good as stainless steel or titanium alloys, such as Ti₆Al₄V. For long-term implantation, Nitinol's performance has yet to be proven and most of its interactions with living tissues and their effects when implanted have yet to be elucidated. Thus, the biocompatibility of SMMs is still doubtful. Biocompatibility is mainly surface-related, the surface being the part of the material to come into contact with cells, tissues, and body fluids. Many different processes have been developed to modify the surface in order to control the host's reaction to the material and to keep it from degrading in the body's inner environment. The main modifications involve insulating the material from the body by altering the nature of the surface while inducing or not inducing a specific response from

surrounding cells in the body. The metallic surface is treated to modify its topography, porosity, and chemical composition or it is coated with thin layers of polymer, ceramic, or other biocompatible and bioactive materials such as hydroxyapatite.

In the following sections, we will briefly explain the main actions and specific properties of SMMs, we will introduce some medical applications for SMMs, and, finally, we will review the importance of modifying the interfacial properties of SMMs for long-term implantation in humans.

PROPERTIES

The principal properties of SMMs are governed by phase transitions between the austenite (high-temperature phase) and the martensite (low-temperature phase). These properties are explained by a solid-state transition called the martensitic thermoelastic transformation (from the austenitic phase to the martensitic phase and vice versa). Four temperatures characterize this transition:

- Martensite start (M_s): the temperature at which the martensite layer spontaneously appears.
- Martensite finish (M_f): the temperature at which the entire specimen is transformed into martensite.
- Austenite start (A_s): the temperature at which the austenite layer spontaneously appears.
- Austenite finish (A_f): the temperature at which the entire specimen is transformed into austenite.

The behavior of the material is dictated by three parameters: stress (σ), strain (ϵ , or length (L)), and temperature (T) (Table 1). Changes in these parameters reflect changes in a class of thermomechanical cycles that are responsible for the specific characteristics of SMMs. The three parameters interrelate in a complex manner: It is thus difficult to predict the behavior of SMMs for any specific application. Most of the current applications use alloys that allow two of the three parameters to be varied, with the third one held

Table 1 Parameters that control the behavior of SMMs

Parameters	Definitions	Abbreviations
Stress (σ) (on the material)	Ratio between the force F and the surface S on which the force is applied: $\sigma = F/S$	F = Force
Strain (ε)	Observed relative displacement, for example, lengthening: $\Delta L = L - L_0$; $\varepsilon = \Delta L/L_0 = (L - L_0)/L_0$	L = Length
Temperature (T)	Temperature of the material's environment	T = Temperature

S

constant by a specific mix of alloy elements and thermomechanical treatment.

The relationship between phase transitions and temperature must be understood if we wish to control the properties of SMMs. Figure 1 presents an overview of SMM behavior when stress, strain, and temperature are varied:

- A one-way shape-memory effect (depicted in (1) and (2)), where changes in shape ($L \downarrow$) are regulated by the martensite-to-austenite transition.
- A two-way shape-memory effect, with a learning process by mechanical cycles in (1) and a memory effect apparent in (2), where changes in shape ($L \downarrow$ then \uparrow) are regulated by phase transitions (first, martensite-austenite; then, austenite-martensite).
- A superelastic effect (3), where the deformations ($L \downarrow$ then \uparrow) are regulated by phase transitions

Fig. 1 Review of principal properties of SMMs: One-way memory (outer line of (1) and (2)); two-way memory with learning (1) and the memory effect itself (2); pseudoelastic effect (3); superthermic effect, shifted (2) toward non-zero force values; rubber-like effect (learning cycle loops (1)).

(first, austenite-martensite; then, martensite-austenite).

- A superthermic effect, which is seen when the curve (2) is displaced from the zero plane ($L, T, F = 0$) to non-zero values of force. In this case, external constraints replace the internal constraints accumulated during the learning process.
- A rubber-like effect is seen in the repeated mechanical learning cycles (1).

It has to be noted that under certain conditions (aging temperature, time and cold working) an R-phase can appear upon cooling and heating and prior to the martensitic and austenitic phase transformation, respectively. The presence of this phase is determined by a sharp increase in the material electrical resistance, essentially due to a distortion of the austenitic cubic lattice.^[1] The R-phase transition behaves much like the martensitic transition, i.e., it exhibits superelasticity and shape-memory effects, but much lower recoverable strain.

The observed effects are quite noticeable when the SMM is in a single phase (pure austenite or pure martensite). These effects require the presence of a specific phase, so that when the state is biphasal (austenite + martensite), the same effects occur but are less significant. A more detailed discussion of how SMMs work is provided in another review article.^[2]

BIOMEDICAL APPLICATIONS

Because SMMs can exhibit one-way or two-way shape memory and display a superelastic effect, they are particularly well suited for the design of surgical devices.^[3] In fact, devices with shape memory very often make surgery easier, shorter, and safer for both the patient and the surgeon. Extensive reviews of SMM biomedical applications have already been published.^[2,3] We will review only the latest devices and applications.

Atherosclerosis involves localized narrowing of blood vessels and, in extreme cases, blockage of blood flow to the artery. Atherosclerosis may affect any

artery, including the carotid, coronary, renal, abdominal aorta, iliac, femoral, and lower arteries. Traditionally, treatment would require by-passes and endarterectomies, but nowadays these medical interventions are no longer the only ones available. Dilations with or without arterectomy are frequently performed when the lesions are localized. Inserting a stent maintains the artery diameter and prevents blockage from recurring in the same area and/or prevents fibrous hyperplasia at the site of an anastomosis. Such stents are deployed up to their functional diameter by expanding a balloon made of stainless steel, tantalum, titanium, or SMMs. If SMMs are used, the heat of the bloodstream can expand the stent to its functional diameter, thus preventing any initial mechanical damage. Such stents are called self-expandable. However, it has to be underlined that the elastic recovery in blood contact does not necessarily require 37 degrees for final shape, and that most stent applications use SMMs' superelastic properties. Use of self-expandable stents in vascular endosurgery has increased exponentially over the last 10 years, despite a lack of scientific consensus over their long-term safety.^[4,5] Although their clinical effectiveness is well established, further study is needed to explain the superiority of shape-memory alloys over other materials.^[6] In particular, the effect of disturbances in blood flow, the compatibility of these materials with blood and their long-term biostability, their bio-functionality, the possible need for anti-coagulant treatments, and the patient's biological and immunological responses must be studied. SMMs hold considerable potential, especially in the manufacture of stents, for treating cardiovascular diseases. Moreover, self-expanding metallic stents have also proven to be effective in noncardiovascular procedures, such as palliation of nonoperable malignant dysphagia and esophagus obstruction,^[7] although tumor overgrowth and incomplete initial expansion have been observed in some cases.^[8]

A recently developed SMM device displays interesting properties for scoliosis correction.^[9] It is a rod that was initially engineered to bring about a gradual three-dimensional correction of a scoliotic deformity. In the martensitic phase, it can easily be twisted into the shape of the scoliotic spine and attached to the spine. After heating (austenitic phase), it will regain its original shape and rigidity. The desired shape can be pre-set by bending the rod beyond its reversible limit after heating. This design induces a bending moment and a torque that correct the lateral curvature and the axial rotation, respectively. A comparable study on monkeys found that a Nitinol rod could completely correct scoliosis with a Cobb angle of 43 degrees after four weeks.^[10] There were, however, significantly higher nickel concentrations in the urine (ten-fold increase).

In surgical correction of maxillofacial fractures, shape-memorizing devices are simple to implant and effective in stabilizing fracture surfaces. Memory materials not only simplify the surgical operation but also shorten the time of rehabilitation and promote rapid bone healing, as shown by Itró et al.^[11] The main advantage lies in their complete functional independence. They need no energy source for operation, unlike conventional medical materials. This property makes them much easier to monitor during implantation. Moreover, the superelastic properties are much more common than thermally induced shape recovery for *in vivo* devices such as maxillofacial fracture reduction or stabilization.

SMMs have found widespread use in various dental and orthodontic applications.^[12] Nitinol is ideal for a new form of intermittent orthodontic treatment because of its ability to exert a mild recovery force within a normal range of oral temperatures. This recovery force is reversible, durable, and reproducible.^[13]

SMMs are increasingly being used in traumatology, dentistry, and pharmacology as surgical tools, orthodontic arch wires, implantable delivery systems and other applications, according to a review by Moorleghem et al.^[14] In the area of managing ureteral obstruction due to malignancy or a recurrent benign disease, Kulkarni et al. have tested a Nitinol device for four years and have shown it to be significantly better than devices made from conventional materials.^[15]

Despite their interesting mechanical properties, SMMs may not be completely safe over a long period of time. The long-term implications of implanting them should be methodically assessed and tested with a view to getting unequivocal answers. Since certain elements and their compounds, such as nickel and chromium, increase tissue reactivity and sensitivity and may induce cytotoxic, carcinogenic, or mutagenic effects, we should develop new techniques to modify the SMM surface and make implantation safer by enhancing compatibility and by minimizing the possibility of nickel leaching into the human body. In the next section, we will review the major techniques for modifying the surface of SMMs. We will focus on Nitinol, the most widely used SMM.

SURFACE MODIFICATIONS

The state of a material's surface depends not so much on the phase state of the material as a whole, but rather on the way its surface has been treated. It is well known that the natural surface of Nitinol consists mainly of carbon contaminants, stable titanium oxides (TiO₂), and smaller amounts of nickel oxides (NiO and Ni₂O₃).^[16] Nitinol's resistance to corrosion is mainly due to a TiO₂-based surface layer and its specific

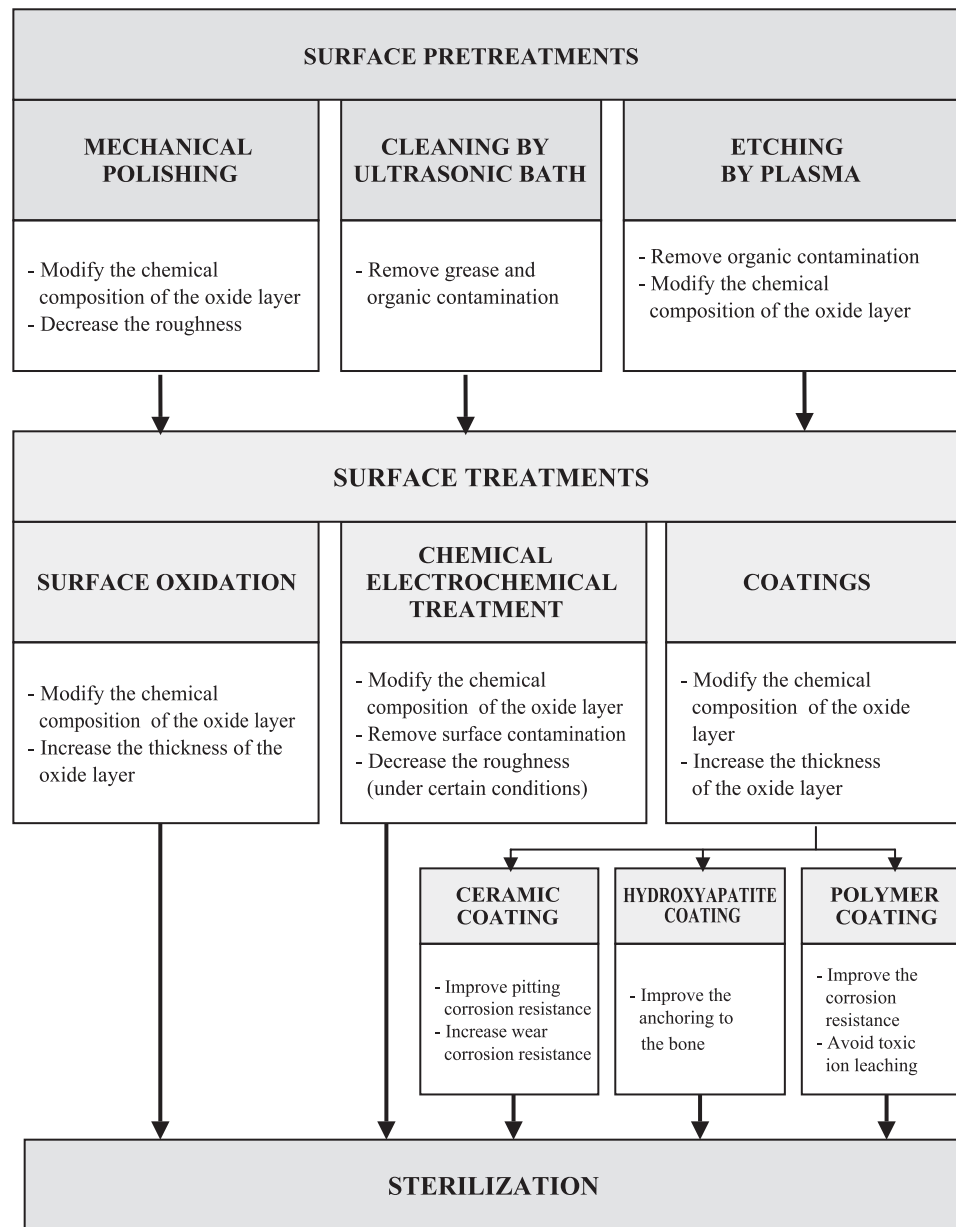

Fig. 2 Procedures for SMM surface modification before implantation: from pretreatment to sterilization.

properties, including its ability to form a calcium-phosphate layer when the device is implanted in living tissues.^[17] The surface chemistry and the amount of Ni may vary over a wide range depending on the preparation method.^[18]

For biomedical applications, a wide variety of Nitinol surface treatments are usually performed to improve corrosion resistance (and thereby prevent release of Ni ions), and/or to improve wear resistance or host-cell response. These treatments include (Fig. 2):

1. Preliminary treatments, including polishing, ultrasonic bath, and physical etching.

2. Surface oxidation.
3. Chemical and electrochemical treatments.
4. Surface coating (with ceramics, hydroxyapatite, or polymers).
5. Sterilization.

Preliminary Treatments: Polishing, Ultrasonic Bath, and Physical Etching

Surface chemistry and surface topography depend strongly on the way the material has been treated and this treatment will determine all of the interactions

between the implanted material and the body. In particular, corrosion resistance is reduced by a poor surface finish. The passive layer is affected by surface imperfections and impurities, which increase the rate of local corrosion.^[19] Consequently, for the most common applications, Nitinol surfaces are pretreated before any further surface treatment. Three preliminary treatments are commonly used: (mechanical or electrochemical) polishing, cleaning in an ultrasonic bath,^[20,21] and physical etching by argon plasma.^[21] For simple (i.e., flat) geometries, the surfaces are usually mechanically polished through a standard metallographic procedure by using a series of increasingly less abrasive SiC papers, followed by a micron alumina polishing powder to obtain a mirror finish.^[22] Roughness is reduced to an average vertical variation of around 10 nm after mechanical polishing, with typical Ti and Ni surface concentrations being around 10% and 25%, respectively, (or less).^[23] However, most of the commercially available implants are electrochemically polished, the geometries being more complexes. By this treatment, surface roughness results are decreased and the surface chemical composition modified. This point will be further discussed in a later section. After polishing, the surfaces are usually cleaned ultrasonically in cleaning reagents such as acetone, ethanol, and isopropanol to remove grease, organic contamination, and debris. Usually, this procedure is followed by rinsing with deionized water and finally drying with compressed air. The last pretreatment is argon plasma etching, to clean the surface before any further vacuum treatment, such as plasma polymerization.^[21]

Surface Oxidation

The formation of a passive TiO₂ film is responsible for the good corrosion resistance of Nitinol. Therefore, to improve Nitinol's corrosion resistance, an initial strategy is to optimize the quality of the oxide layer, e.g., by increasing or altering its chemical composition or by making it more uniform. The surface can be oxidized in various media. Some techniques promote the formation of highly adhesive passive films that should not crack as the device expands at body temperature. These techniques have been admirably reviewed by Shabalovskaya.^[24]

Oxidation processes may be dry or wet. In dry processes, the oxide layer is formed in an oxidative or steam atmosphere. Such Nitinol oxide films are essentially made of the dominant oxide TiO₂, although other Ti and Ni oxides, and elemental Ni, are present as well. At room temperature, the oxide layers are incomplete. At high temperatures, the surface is heterogeneous and composed of various oxides that make it more

vulnerable to corrosion. When oxide film coatings are produced by heat treatment of Nitinol in a low vacuum, they display better corrosion resistance and a higher potential for biocompatibility, and cracks do not appear after shape-memory deformation.^[25] At high temperatures, however, oxidation leads to an increase in elemental Ni at the surface, which could become a source of potential toxicity.^[23] Steam-treated surfaces have a higher Ni concentration than surfaces oxidized in boiling water, because Ni accumulates in the surface sublayers during the autoclaving procedure. The quality of treated surfaces is directly related to the conditions of steam treatment because high Ni concentrations and humidity will lead to the formation of Ni hydroxides during the steam process. This technique does not seem to improve surface biocompatibility (because of the presence of Ni compounds), and the high temperatures may also impair shape memory and superelasticity. Oxidation in boiling water, with preliminary chemical etching in an HF/HNO₃ solution, results in surfaces with a very low Ni concentration.^[24] The Ni concentration and the Ti/Ni ratio will strongly depend on how long the treatment lasts. The longer the boiling, the higher the Ni concentration at the surface. The boiling procedure includes selective Ni etching in a chemical solution, and the leaching of Ni into the water with simultaneous oxidation of the titanium results in a completely disordered surface. This amorphous surface state contributes to excellent corrosion resistance and biological response.

Chemical and Electrochemical Treatments

Chemical etching is generally used to remove surface contamination. One of the most popular solutions is a mixture of various ratios of HF, HNO₃, and H₂O. Shabalovskaya et al. have shown that this treatment produces a surface especially rich in elemental Ni, an inappropriate result if one wishes to increase biocompatibility.^[22] Another popular way to passivate Nitinol surfaces is to use nitric acid. Surfaces of polished Nitinol wires have been studied after heat treatment and passivation in a nitric acid solution.^[26] Improved corrosion resistance is obtained after heat treatment alone and heat treatment followed by passivation. The oxide composition seems to be more important than its thickness alone in improving corrosion resistance. The layer on both heat-treated and passivated wires consists primarily of TiO₂ with some NiO, but the passivated wires are enriched with Ni and NiO at their oxide-metal interface and with Ni at their outer layer. When the wires are immersed in a solution for a long period, the quantity of nickel released is lower for passivated samples and decreases over time.

Electropolishing represents a valid alternative to passivate Nitinol surfaces because it is already used

and well controlled for other materials, such as stainless steel. Electropolishing removes the native oxide layer and induces the formation of a new, more uniform, and smoother, almost nickel-free surface that greatly improves the implant's biocompatibility.^[18,27,28] Electropolished surfaces are extremely smooth and have better mechanical properties than surfaces chemically treated by an HF/HNO₃ solution or mechanically polished.^[29] Although electropolishing and nitric passivation have many advantages over other methods and hold much promise for commercial applications, the improvement they bring about is rather limited. At most, electropolishing lowers the passive current density by 1 order of magnitude.^[20]

Ceramic Coatings

Coating surfaces with a thin ceramic layer not only enhances resistance to pitting and crevice corrosion but also increases wear resistance as well. One of the most popular ways to deposit thin ceramic films, such as TiN and TiCN, on Nitinol surfaces is chemical vapor deposition.^[25] Although thin ceramic films exhibit better corrosion and wear resistance, they are less uniform and cohesive as a result of cracks that form during the extensive deformations induced by the shape-memory effect. Nitinol's shape-memory effect may produce a recoverable strain as high as 8%, which is much higher than the elastic strain possible with ceramic coatings. Several other techniques that form a thin hard layer on the alloy surface, such as ion implantation or laser treatment, are under investigation.

Ion nitriding at high temperatures can improve the surface properties of Nitinol. The treatment involves amorphization of the surface. Two layers are formed, an outer layer of TiN and an inner one of Ti₂Ni. Together, the two adjacent layers markedly increase surface hardness and surface wear-induced corrosion resistance.^[30] The coating is hard and strongly adherent to the substrate, but no tests involving substantial deformations have yet been performed. The shot-peening process can also improve the mechanical properties at the surface of SMMs.^[31] This technique and N⁺ ion implantation have been compared to surface microhardness and the coefficient of friction, because both techniques aim to produce an amorphous surface. The two treatments produce similar improvements in surface properties, with no direct effects on bulk properties. The presence of TiN precipitates within the surface oxide layer tends to make the ion-implanted layer harder, and less than 3 atomic percent of Ni is detectable at the surface after these treatments. The downside of ion implantation is that geometrically complex implants soon become a very complicated challenge.

A more recent technique is the Laser Melting Surface (LMS). It has the advantage of being very simple, allowing surface modification without affecting bulk properties. It forms a highly adhesive corrosion-resistant layer by immediately transferring the laser energy to the lattice and thereby quickly melting the near-surface regions. With this technique, the magnitude of the corrosion and the passivation current densities is reduced by an order of 2. LMS also induces thickening of the TiO₂-based oxide layer and, concurrently, nitrogen incorporation and surface homogenization. Nevertheless, it is very expensive and poorly suited for geometrically complex devices.^[32]

S

Hydroxyapatite Coatings

A smart Nitinol-based composite biomaterial has been developed with a hydroxyapatite coating.^[33] It allows the surrounding bone to colonize and encapsulate the implant. The main problem is the metal-hydroxyapatite interface rather than the bone-hydroxyapatite one. Although several treatments have been investigated, such as dip coating, electrophoretic deposition, and hot isostatic pressure, no significant solution has been found to date. Plasma spray coating greatly increases adhesion, probably by forming chemical bonds at the hydroxyapatite-Nitinol interface and by dissipating strain energy through stress-induced martensite formation and/or martensite reorientation.^[32] Despite having the appropriate mechanical properties, hydroxyapatite tends to dissolve when in contact with body fluids, probably due to its relative miscibility with them.^[23]

Polymer Coatings

To provide a protective barrier that will contain potential release of Ni and so protect the implant from corrosion and the patient from toxic contamination, the SMM can be evenly coated with a thin polymer film. Polymers seem to make a good coating for shape-memory material for three main reasons. First, they are more biocompatible than metals and therefore better suited for being in contact with living tissues. Second, they tolerate a wide range of elastic deformation and can bend with the shape-memory deformation without cracking. Finally, it is possible to create a plasma-deposited polymer layer that is uniform and adheres well to the metal substrate. Thus, an evenly deposited polymer film may provide implants with outstanding corrosion resistance.

Villiermaux et al. have studied the improvement in the corrosion resistance of Nitinol staples by applying an RF plasma polymerized-polytetrafluoroethylene

(PPTFE) coating.^[21] This coating had very good adhesion but lacked cohesiveness. It did, however, efficiently protect the substrate from pitting and decreased the corrosion rate. A PPTFE film can lower the current corrosion density by 1 order of magnitude although it cannot reduce the passive current density. The deposited film must be uniform. When damaged, its corrosion resistance can easily decrease in comparison to that of untreated samples. Moreover, the coating can bend with the bending of a substantial shape-memory deformation without cracking. Finally, plasma treatment is appropriate for geometrically complex implants. In contrast to fluorine-containing monomers, organosilicon is more environmentally suitable and less corrosive for vacuum equipment. Yang et al. have studied DC plasma polymerized hexamethyldisilazane (PHMDSN) coatings with a view to improving the corrosion resistance of Nitinol.^[20] At DC voltages higher than 1000 volts, PHMDSN coatings protect against corrosion in Ringer's solution and can be deformed by up to 2%. The corrosion current density of Nitinol can be lowered by 4 orders of magnitude—four times more than with an RF PPTFE coating.^[21] It is worth noting that before each plasma deposition, for both PPTFE and PHMDSN coatings, the samples were pretreated with successive mechanical polishing, degreasing in an ultrasonic bath, rinsing with distilled water, and drying with a stream of compressed air, and finally cleaning with argon plasma under vacuum. Plasma coatings for shape-memory alloys seem to be a promising and efficient way to protect implants from the severe environment of living human tissues.

Sterilization

Sterilization is the stage that all materials must undergo before being implanted into the human body. It affects the surface finish and corrosion resistance of metallic devices and, as with any surface treatment, we need to investigate effects and assess potential consequences. Tabrizian et al.^[27] and Thierry et al.^[28] have studied the effects of sterilization on Nitinol surfaces that had been mechanically polished prior to electropolishing. After sterilization by ethylene oxide, a common technique for sterilizing metallic implants, no changes were observed in the corrosion behavior of electropolished samples. The improvement in corrosion resistance due to electropolishing still remained even after sterilization by ethylene oxide. But some surface modifications were reported. After sterilization, the oxide layer was thicker and its nickel content higher and not uniform. Other sterilization processes, such as steam autoclave and peracetic acid sterilization, have been tested and shown to modify the corrosion resistance of Nitinol.

Other Treatments

Some other treatments can provide a Nitinol surface with very specific and biomedically useful properties. Phosphorus-ion implantation can be used to make radioactive stents.^[34] The purpose is to prevent cells from dividing, forming tissue hyperplasia, and thereby inducing restenosis. Phosphorus-ion implantation can be used to improve the hemocompatibility of Nitinol.

Gold coating can be used to improve the radiopacity of Nitinol medical devices, such as filters and stents. A thick gold layer adheres well to the substrate, and should be no thicker than around 4 microns to allow elastic deformation of the material. An electropolishing pretreatment before gold coating is recommended. The downside is that hydrogen uptake must be controlled to avoid Nitinol embrittlement.^[35]

CONCLUSIONS

Because conventional materials do not exhibit memory-related and superelastic properties, SMMs have attracted much interest. They offer new possibilities in the designing of new devices for unconventional purposes. Many applications have already been developed and we strongly believe that many more are on the way. With their unconventional properties, these alloys have made possible some of the boldest applications since the 1970s while clearing the way for further technological advances. All potential applications, however, must meet the social requirements of our age. First, they must be inexpensive, especially for medical/surgical uses. Second, they must be safe for human implantation. All implants must be biocompatible, biofunctional, and biodurable over the short, medium, and long term, depending on the application. Until now, no study has unequivocally proven that Nitinol devices will be completely safe for the human body and still functional after long-term implantation.^[36] If we wish to go on using SMMs because of their special mechanical properties, we will have to be sure of their safeness for the patient's health. We will probably have to focus on understanding their surface nature, tailoring their properties, and developing specific surface treatments or coatings that will protect the human body from any potential toxic contamination.

Silicones

Kenneth J. Wynne

Department of Chemical Engineering, Virginia Commonwealth University, Richmond, Virginia, U.S.A.

SiTech, LLC, Richmond, Virginia, U.S.A.

INTRODUCTION

Silicones, or properly poly(diorganosiloxane)s, describe a class of polymeric materials with high chemical stability that are widely used in biomedical applications. The chemistry, properties, surface science, and processing of silicone materials used in these applications are summarized herein. References within provide the reader access to the vast literature of poly(diorganosiloxane) materials.

BACKGROUND

It is important initially to distinguish the terms silicone and silicon^[1] and to note that silicones (polymers) contain the element silicon. The silicone designation comes from Kipping, who in the early part of the 20th century knew of the -O-Si- chain structure but anticipated facile conversion to structures analogous to ketones.^[2] This supposition proved incorrect, but the term silicones remains. In the context of similar terminology, silica (silicon dioxide, SiO_2) is used as a reinforcing filler for silicones. Amorphous, high-surface-area fumed silica is often the filler of choice.

The chemistry and materials science of silicones is a relatively mature area. For the basic chemistry of silicones, the chapter by Barry in the 1962 Stone and Graham text *Inorganic Polymers* is still worthwhile reading.^[2] Another *Inorganic Polymers* contains a chapter on silicones referencing many review articles,^[3] and a recent symposium volume on silicones and silicone-modified materials is available.^[4] The LaVier review^[1] is a useful introduction, as is the article by Arkles.^[5] Chapter 2 (Silicone Chemistry) in the NAS report *Safety of Silicone Breast Implants* gives good insight into the evolution of chemistry and processing for silicone materials.^[6] For implant medical devices, biocompatibility and biodurability are determined by chemistry, processing, and fabrication. Chapter 3 (Implant Catalog) in the NAS report just cited presents detailed information on the evolution of implant construction and the rationale for many changes.

PDMS STRUCTURE

The most commonly encountered poly(diorganosiloxane) structure is poly(dimethylsiloxane) (PDMS), which contains the $\text{-Me}_2\text{SiO-}$ repeat unit (Fig. 1).

The space-filling model of a PDMS chain with 12 repeat units (Fig. 2) was generated using Chem3DTM and partly energy-minimized with an MM2 calculation. This representation allows visualization of the effect of lack of substituents on oxygen and of the larger size of Si in the main chain compared to carbon chain polymers. In addition, the Si–O–Si bond angle is larger (143°) than the tetrahedral (109°) C–O–C or C–C–C bond angle.^[7] This combination of larger Si–O bond distance and Si–O–Si bond angle accounts for the lack of restriction of rotation about the Si–O–Si bond and the extremely low glass transition temperature (T_g) of PDMS elastomers (-120°C). The low T_g , nonpolar character (due to the masking of polar Si–O bonds by the methyl groups), and high thermal stability are hallmarks of the PDMS structure.

NOMENCLATURE

The nomenclature and shorthand notation used to describe silicones have been historically useful, if not highly rigorous. For the purposes of this article, the frequently employed M, D, T, Q notation will be used to denote Si bound to 1, 2, 3, and 4 oxygens, respectively. It can be assumed that methyl groups are present on the silicon atom unless indicated otherwise by superscript notation. Thus, a D silicon that has two Si–O bonds and methyl and vinyl groups is denoted D^{Vi} . Further examples are octamethyltrisiloxane and octamethylcyclotetrasiloxane, written as MDM and D_4 , respectively. Table 1 provides shorthand for some common silicones encountered as biomaterials.

MACROMONOMERS AND LOW-MOLECULAR-WEIGHT FLUIDS: SYNTHESIS

Equilibration reactions are used industrially to make liquid polymer precursors or macromonomers, or for

Fig. 1 A representation of the $-\text{Me}_2\text{SiO}-$ repeat unit in poly(dimethylsiloxane).

thermosetting elastomeric materials.^[2] Equilibration reactions are also used to make low-molecular-weight (MW) fluids such as trimethylsilyl-terminated PDMS (TMS-PDMS), known as silicone oil. Macromonomers and low-MW fluids are both useful in medical applications, but in completely different ways.

Macromonomers

A macromonomer is an oligomer or higher-MW polymer that has at least two functional groups. The term telechelic is also used for large (tele) difunctional (chelice) oligomers or low-molecular-weight polymers.^[8,9] Common telechelic functional groups include silanol ($\text{Si}-\text{OH}$), acetoxy ($\text{Si}-\text{O}-\text{C}(\text{O})\text{CH}_3$), vinyl ($\text{Si}-\text{CH}=\text{CH}_2$), and aminopropyl ($\text{Si}-\text{CH}_2\text{CH}_2\text{CH}_2\text{NH}_2$). An example of equilibration for the synthesis of terminally functionalized vinyl polymer, $\text{M}^{\text{Vi}}\text{D}_n\text{M}^{\text{Vi}}$, is shown in Scheme 1.

In this example, 1,3-divinyltetramethyldisiloxane is used as a chain stopper, so that vinyl groups occur as end groups in the macromonomer. The ratio of D_4 to functional disiloxane controls the molecular weight of the macromonomer. Reports on the synthesis and characterization of hydrosilation- and condensation-cured elastomers sometimes utilize macromonomers of low (2K–20K) MW.^[10] Macromonomers used in the formation of elastomers for biomedical applications generally have average molecular weights in the range of 25,000 to 400,000 or higher. Fluid viscosities are often cited by composition formulators as a measure of molecular weight.^[11]

The use of D_4^{Vi} , D_4 , and hexamethyldisiloxane gives D^{Vi} , or side-chain vinyl groups substituted randomly

Fig. 2 Space-filling model of a PDMS chain with 12 silicon groups. The chain ends with a trimethylsilyl moiety.

Table 1 Functional groups commonly encountered in silicones used for biomaterials

Moiety	R	Symbol
$\text{R}(\text{CH}_3)_2\text{SiO}-$	H, Vi, OH, OAc	M^{R}
$\begin{array}{c} \text{CH}_3 \\ \\ -\text{O}-\text{Si}-\text{O}- \\ \\ \text{R} \end{array}$	H, Vi	D^{R}
$\begin{array}{c} \text{CH}_3 \\ \\ -\text{O}-\text{Si}-\text{O}- \\ \\ \text{R} \end{array}$	$-\text{CH}_2\text{CH}_2\text{CF}_3$	D^{f}
$\begin{array}{c} \text{C}_6\text{H}_5 \\ \\ -\text{O}-\text{Si}-\text{O}- \\ \\ \text{R} \end{array}$	CH_3	D^{MePh}
$\begin{array}{c} \text{C}_6\text{H}_5 \\ \\ -\text{O}-\text{Si}-\text{O}- \\ \\ \text{R} \end{array}$	C_6H_5	D^{Ph}

along the main chain (Scheme 2). The average degree of functionalization is controlled by the mole ratio of D_4^{Vi} to D_4 . Side-chain vinyl may be used to change the crosslinking architecture or to obtain higher network crosslink density.

The small backward arrow in Schemes 1 and 2 indicates that there is always a significant concentration of lower-molecular-mass linear and cyclic species present.^[12] Numerous studies of these cyclic and linear species have been conducted. One recent review provides a summary of this work and a number of references for further reading.^[13] Low-molar-mass linears and cyclics are usually removed by distillation. The weight percent of low-molar-mass species varies considerably depending on the particular commercial resin involved. Polydimethylsiloxane species are very soluble in liquid and supercritical CO_2 .^[14] An innovative way to fractionate and purify PDMS macromonomers is by supercritical CO_2 extraction.^[15] For biomedical applications, the special purification methods used to reduce volatile constituents will be discussed later. Depending on the application, the presence of cyclics (nonfunctional oils) can be troublesome.

Macromonomers made by equilibration reactions have broad molecular weight distributions. Several methods may be used to make narrow-MW distribution macromonomers. Disilanol-terminated PDMS macromonomers can be prepared from hexamethylcyclotrisiloxane using a modification of Lee's method.^[16] This method utilizes a benzyltrimethylammonium bis(o-phenylenedioxy)phenylsiliconate catalyst, with dimethyl sulfoxide (DMSO) and water as cocatalysts. Disilanol-terminated PDMS macromonomers are converted to divinyl analogs by reaction with vinyltrimethylchlorosilane in toluene, using pyridine as an HCl acceptor. PDMS macromonomer polydispersities (PDs) of about 1.1 are obtained, compared to PDs of 2.0 or greater for commercially available macromonomers.^[17] Combining low- and high-MW macromonomers improves the mechanical properties of silicone elastomers.^[10]

Scheme 1

Another class of macromonomers made via equilibration reactions incorporates (trifluoropropyl) methylsiloxane $[-(\text{CF}_3\text{CH}_2\text{CH}_2)(\text{CH}_3)\text{SiO}-]$ groups. With increased fluoro-organo content, elastomers derived from these macromonomers become increasingly oleophobic. The starting material for $-(\text{CF}_3\text{CH}_2\text{CH}_2)(\text{CH}_3)\text{SiO}-$ containing macromonomers is the cyclic trimer D_3^f , $[(\text{CF}_3\text{CH}_2\text{CH}_2)(\text{CH}_3)\text{SiO}]_3$. A variety of polymerization catalysts may be used,^[18] some of which differ from those employed in dimethylsiloxane polymerizations. The choice of catalyst and reaction conditions is important to obtaining the desired polymer.^[19] Brown and Carmichael reported that in the case of reactions carried out between 333K and 423K using 100% methyltrifluoropropyl siloxane cyclic trimer and potassium hydroxide catalyst, the concentration of linear polymer was only approximately 14% in the bulk equilibrate, with cyclic oligomers making up the remaining 86%.

Low-Molecular-Weight Fluids

Equilibration reactions are also used to make low-MW fluids such as silicone oil, that is, trimethylsilyl-terminated

poly(dimethylsiloxane), $(\text{Me}_3\text{SiO}(\text{Me}_2\text{SiO})_n\text{SiMe}_3)$. Because of high thermal and chemical stability, silicone oil finds applications in numerous mechanical, electrical and chemical processing applications. TMS-PDMSs are chemically nonfunctional macromolecules that are used as swelling agents in silicone gels. In the same way that water is absorbed by hydrophilic polymers to generate soft hydrogels, lightly crosslinked PDMS (addition cure, *vide infra*) absorbs TMS-PDMSs to form a soft PDMS-gel.

Another class of low-MW fluids used in biomedical applications incorporates (trifluoropropyl) methylsiloxane $[-(\text{CF}_3\text{CH}_2\text{CH}_2)(\text{CH}_3)\text{SiO}-]$ groups. These fluids are similar in nature to the trifluoropropyl-containing macromonomers described above, except that they typically incorporate trimethylsilyl chain ends. The mole fraction of (trifluoropropyl)methylsiloxane groups can range from as low as a few percent to 100%, depending upon application requirements. For certain applications, many properties of fluoro-silicone fluids are superior to PDMS fluids in particular lubricity, solvent resistance, and performance across a wide range of temperatures.^[20]

Scheme 2 Synthesis of the co-dimethyl-methylvinyl macromonomer with trimethylsilyl terminal groups.

THERMOSETTING ELASTOMERS

The term thermoset is used to describe polymer chain network structures formed by covalent bonds through chemical reactions.^[21] Thermosets may have one or two components depending on the crosslinking chemistry. For thermosetting elastomers, at least one starting component must have a low glass-transition temperature, typically below -50°C . For PDMS elastomers, a filler is incorporated to improve mechanical properties. For convenient mixing, starting components must be flowable liquids, despite the presence of added filler. These considerations set the MW range of PDMS macromonomers produced by the equilibration reactions discussed earlier. For thermosetting PDMS elastomers, macromonomer molecular weights are usually in the range of 25,000 to 400,000 amu or higher.

Because of the extraordinary flexibility of the PDMS chain, even 10,000,000-centipoise macromonomers with degrees of polymerization of 5,000 or higher are flowable liquids (but slow!). Such high-molecular-weight macromonomers are employed in elastomers prepared by hydrosilation and peroxide cures discussed in the next sections. A wide range of macromonomer molecular weights is commercially available. Different macromonomer molecular weights may be employed in thermosets (and the thermoplastics that will be discussed later) to study surface properties or control mechanical properties.^[10,22]

Hydrosilation Cure

Vinyl functionalized telechelics are important in hydrosilation-cured (addition-cured) thermosetting elastomers for biomedical applications. There are several ways that network formation can be accomplished utilizing hydrosilation, which is the addition of a hydrosilane, i.e., a Si-H-containing species, to the vinyl group. One approach is shown in Scheme 3, where the Si-H functionalities are pendant to the main chain. Permutations on this approach, using functionality that is present as both end and pendant groups, are readily envisaged. Because the crosslinking reaction involves the formation of Si-C and C-H bonds, networks generated by hydrosilation cure are extremely chemically stable, particularly to hydrolysis, and well-suited to many biomedical applications. It has been reported that hydrosilation-cured coatings show no drop in receding contact angle or measurable mass loss after two months of immersion in water.^[23,24]

In carrying out addition cure, close attention must be paid to the Si-H-to-vinyl ratio. For a given catalyst concentration, the optimum Si-H-to-vinyl ratio is determined empirically, due to broad molecular weight distributions and side reactions. One approach to

determining the optimum ratios is minimization of soluble sol.^[17] Such a procedure minimizes non-network species that could leach.

Often, a divinyl(tetramethyldisiloxane) complex of platinum is used for hydrosilation.^[25] At ambient temperature or above, solutions of this catalyst may be unstable with respect to Pt(0) colloid formation. Cold storage or periodic replacement are two ways to keep the catalyst active. The catalyst remains in the network structure, though at a very low level. A recent study indicated that there is no evidence that residual Pt causes enhanced allergic reactions in women with breast implants.^[26]

A new platinum(0)-carbene complex reported by Markó et al. reduces the tendency to form platinum colloids and gives improved isomer selectivity.^[27] However, the authors report that the reactivity of this catalyst is lower relative to the vinyl-platinum complex. There have as yet been no specific reports of the use of this platinum(0)-carbene catalyst in biomedical silicone applications.

Peroxide Cure

Silicone elastomer networks can also be formed via free radical crosslinking processes catalyzed by organic peroxides. This was the first method invented for silicone elastomer synthesis, and it is still in use today for certain biomedical applications. As shown in Scheme 4, the process involves cleaving the oxygen-oxygen bond of an aryl peroxide catalyst at elevated temperatures to produce a free radical (Ar-O^{\bullet}). This free radical reacts with an organic group in the silicone polymer to produce a carbon-centered free radical (Si-R^{\bullet}), which then reacts further to yield a crosslink with another silicone polymer chain via carbon-carbon bond formation. A detailed description of the mechanism(s) of this process can be found elsewhere.^[28] The vast majority of peroxide-cured elastomers for medical applications utilize high-molecular-weight PDMS with a small amount of vinyl functionality (usually at the chain termini) and the peroxide catalyst bis-2,4-dichlorobenzoyl peroxide. The cure temperatures for this system are somewhat lower than for those employing other peroxide catalysts or with PDMS containing no vinyl functional groups. However, the product of bis-2,4-dichlorobenzoyl peroxide catalyst decomposition is 2,4-dichlorobenzoic acid, which must be removed in a high temperature postbaking procedure to avoid "blooming" of the material on the surface of the elastomer over time. This is responsible, in part, for the trend toward use of silicones that employ other cure systems.

Although the physical properties of silica-filled peroxide-cured elastomers differ in some respects from hydrosilation-or condensation-cured elastomers,^[29] they

Scheme 3 Network formation through the reaction of a terminal vinyl group with a side-chain Si-H group. The depiction shows a chain-end/side-chain reaction, which leads to network formation.

offer unique processing benefits.^[12] Uncured, silica-filled, catalyzed pre-elastomer stock, known in industry as high-consistency elastomer, can be stored as a stable mixture for months prior to use. The combination of filler loading, filler treatment (hydrophobization), and extremely high-molecular-weight polymer yields high green strength that, coupled with rapid cure rates, allows complex shapes and profiles formed from the material to retain their physical dimensions throughout the molding and curing processes. This dimensional stability during cure is especially beneficial for continuous extrusion and curing processes employed in the manufacture of high-volume products such as silicone tubing.

Condensation Cure

Condensation cure means that a volatile product (condensate) is formed. Water is always a product in the presence of moisture, whereas the organic product depends on the condensation precursor. Scheme 5 shows acetic acid as the cocondensation product stemming from the reaction of an alkyl triacetoxysilane, $\text{RSi}[(\text{OC}(\text{O})\text{CH}_3)_3]$

Scheme 4 General mechanism of the peroxide-catalyzed silicone elastomer cure.

or $\text{RSi}[\text{OAc}]_3$, with hydroxy-terminated PDMS. Ethanol is another common condensation product when silicon ethoxides are employed.

In contrast to the stoichiometric hydrosilation cure (one Si-H reacts with one Si-CH=CH₂), condensation cure is nonstoichiometric. Thus, it is important to note that the examples in Scheme 5 are ideal, or illustrative, because the composition of the hybrid product is determined by the experimental ratio of $\text{RSi}[(\text{OC}(\text{O})\text{CH}_3)_3]$ to Si-OH groups in the macromonomer. The term hybrid product indicates that the elastomer consists of a PDMS network and a siliceous domain (SD). In Scheme 5, the alkyl triacetoxysilane is both crosslinker and SD precursor. That is, $\text{RSi}[(\text{OC}(\text{O})\text{CH}_3)_3]$ is trifunctional and crosslinks the PDMS network by reaction with Si-OH, as well as undergoing self-condensation to form an SD.

The amount of crosslinker/siliceous domain precursor (C-SD-P) used is arbitrary but limited to certain bounds, as will be discussed further. C-SD-P in excess of that required by the macromonomer forms increasing volume fractions of SD. Care must be used in selection of the C-SD-P precursor. For example, tetraethoxysilane (TEOS) is volatile under these non-solvent reaction conditions. Under open conditions, product stoichiometry reflects up to 90% TEOS loss by volatilization.^[30] The absence of quantitative evaluation of composition confounds the significance of morphological studies on TEOS-cured materials.^[31] Condensation cure of PDMS at ambient temperature by the relatively involatile C-SD-P poly(diethoxysiloxane) produces materials of reproducible and predictable composition whose stability to mass loss in

A

B

Scheme 5 Examples of typical condensation-cure reactions.

water is highly dependent on the C–SD–P concentration.^[32] Information on stability to water is not available for other C–SD–Ps, but is an important issue for practical biomedical applications.

In Scheme 5, the composition of the siliceous domain (SD) is shown as $\text{RSiO}_{1.5}$. Equations for condensation cure are often represented in a way that indicates complete condensation, for example TEOS to SiO_2 .^[4] However, with the polydiethoxysiloxane C–SD–P precursor and ambient temperature cure conditions,²⁹Si solid-state NMR spectroscopy showed that the SD composition is approximately $\text{SiO}_{1.5}(\text{OH})$.^[32] Although the organic condensate ethanol is completely evolved within 24 hours, the crosslinked network formed by condensation cure at ambient temperature creates a kinetic barrier to the formation of water. The presence of the SD adds an element of compositional complexity to condensation cure that is not present in hydrosilation cure.

Condensation-cure systems for biomedical applications often use trifunctional crosslinkers, such as the alkyltriacetoxysilanes ($\text{RSi}(\text{OC}(\text{O})\text{CH}_3)_3$) illustrated in Scheme 5. Methyltri(acetoxy)silane (MTA) has a molecular weight of 220 g/mol, a melting point of 40°C, and boils at 95°C at 9 mm pressure. Given its relative low volatility, loss of MTA by volatilization during cure certainly does not occur to the extent observed for TEOS.^[30] Whether some small amount of volatilization occurs is not known. One notable example of the use of alkyltriacetoxysilane cure in medical devices is the silicone elastomer envelopes used in some saline-filled breast implants.^[33] Dramatic improvements have been reported in abrasion resistance and bi durability of these acetoxy condensation-cured shells, compared to those produced by hydrosilation cure. The improvement is specific to the saline implant envelopes and stems from envelope-to-envelope self-abrasion (such as at folds).

This wear mechanism is not operative for envelopes in silicone gel-filled implants, because the silicone gel acts as a lubricant.^[6,34,35]

In the presence of excess alkyltriacetoxysilane (ATAS), Si–OH macromonomer endgroups react to form alkyl(diacetoxy) siloxy-terminated chains (Scheme 5e). Upon exposure to moisture, Si-acetoxy groups in structures such as **A** are replaced by Si–OH (Scheme 5f). In the course of crosslinking and SD formation, Si–OH either condenses with another Si–OH group, **B**, or reacts with another Si-acetoxy (ATAS, **A**). A catalyst may be used to accelerate cure.

Each acetoxy group is liberated as acetic acid, which volatilizes under the ambient cure conditions driving condensation. This system is sufficiently reactive to cure sections with a thickness of approximately 1 cm or less. Above this thickness, the inability of moisture and acetic acid to diffuse in and out of the material on a practical time scale limits cure effectiveness. Excellent thick-section cure is a significant advantage of hydrosilation cure over acetoxy cure.

The ratio of ATAS to Si–OH is determined empirically for specific end-use applications, with the aim of optimizing physical properties and cure rate. Too low a ratio results in a crosslinked gel even in a sealed storage container, but too high a ratio results in slow cure rates under normal “moisture cure” conditions. Experience has led to a ratio of at least 10:1, as discussed further in the following text. Hydrolysis and condensation of excess ATAS lead to crosslinking and the formation of a siliceous phase. In contrast to the TEOS and poly(diethoxysiloxane) cure, the siliceous phase from ATAS contains T silicons.

Mallam, et al., have elegantly described the nature of the siliceous component for a hydroxy-terminated PDMS (M_n , 40K)–ethyltriacetoxysilane (4 wt%)

system.^[36] The mole ratio of acetoxy groups to Si–OH for this composition was approximately 10:1. Using light and neutron scattering, condensed ETAS aggregates with a mean radius of approximately 80 nm were found. Only about one-third of the ETAS was accounted for by these aggregates, with the remainder composed of oligomers and monomers. One can readily imagine the presence of a dispersed ethylsiliceous phase, composed of all manner of $\text{RSi}(\text{O}-\text{X})_3$ species, with $\text{X} = \text{H}, -\text{O}-\text{Si}(\text{C}_2\text{H}_5)(\text{O}-)_2, -\text{O}-[\text{Si}(\text{CH}_3)_2\text{O}]_n, \text{Si}(\text{CH}_3)_2\text{O}-$. In industrial formulations, the ratio of acetoxy groups to Si–OH may be considerably higher than 10:1. However, with PDMS macromonomers having extremely high MW, the weight fraction of the siliceous phase in the final material is low (ca. 3–5%).

Fillers

Hydrosilation-cured or condensation-cured (3–4 wt% siliceous phase) polysiloxane networks are inherently weak materials. To achieve the desired properties for most applications, silicone elastomers must be reinforced with fillers.^[37] The customary filler for biomedical silicone elastomers is noncrystalline (amorphous) fumed silica,^[6] but, reinforcing silica fillers may also be formed in situ.^[38,39] Fumed silica (SiO_2) consists of nanoscale-sized particles and particle clusters,^[40] the surfaces of which are usually treated with a hydrophobizing agent to moderate reinforcing properties. Commonly used silica treating agents include hexamethyldisilazane (HMDZ), octamethylcyclotetrasiloxane (D_4), dimethyldichlorosilane (DDS), and various polydimethylsiloxane oligomers, either with or without functional groups such as Si–OH. During these treatments, surface Si–OH groups are converted to siloxane groups, rendering the surface nominally hydrophobic. There is a large amount of information about these treated silicas available in refereed publications,^[37,40–44] the patent literature^[45–47] and manufacturers' product literature.^[48–58]

Treatment of fumed silica with HMDZ leads to a hydrophobic surface on which the majority of the surface Si–OH groups have been replaced by Si–O–SiMe₃ groups.^[41] This process can be conducted either in a separate pretreatment step prior to the compounding of the silica with siloxane polymer or in situ during the compounding process. Pretreatment is

employed when functional groups in the siloxane polymer may be reactive toward the HMDZ, as in the case of –Si–OH–terminated PDMS.^[12]

Treatment of fumed silica with difunctional agents also produces a hydrophobic surface, but in these cases the majority of the surface Si–OH groups are replaced by dimethylsiloxane oligomers. Again, the silica treatment can be carried out either in a pretreatment step prior to mixing with polymer or during the compounding step. Treating agents include dimethyldichlorosilane,^[53,54] dimethylsiloxane cyclics^[49–51] (e.g., D_4 or mixed cyclics), and PDMS.^[55–58] In situ treatment processes generally employ low-molecular-weight functionalized linear siloxane oligomers such as $(\text{RO})\text{Me}_2\text{Si}-(\text{Me}_2\text{SiO}-)_x-\text{SiMe}_2(\text{OR})$, where $\text{R} = \text{H}, \text{CH}_3$, etc., and $x =$ approximately 3–10.^[12]

An interesting alternative to fumed silica is the recent employment of nanoclays to provide nanocomposite hybrids. An example is the work of Giannelis, who reported that the addition of only a few percent nanoclays dramatically improves mechanical properties. A few percent nanoclay filler gives mechanical properties equivalent to the usual 25–30% addition of fumed silica.^[59] This is a promising result that may find medical materials applications.

POLYURETHANES AND UREAS

Copolymerization utilizing siloxane monomers and macromonomers (telechelics) and other modifications has led to a wide variety of polymer structures for biomedical applications that incorporate a silicone segment.^[60,61] Silicone polyurethanes have been increasingly investigated because of their durability, improved chemical stability, and good biocompatibility.^[62,63] Silicone polyurethanes (PUs) are readily prepared from precursors to hard and soft segments^[64] and are often referred to as segmented copolymers. Siloxane polyurethane ureas (PUUr) are prepared similarly, for example by using an α,ω -aminopropyl-dimethylsilyl substituted macromonomer (Fig. 3). Silicone polyurea ureas (PUrUrs) utilize an amine chain extender (instead of a diol), as well as the alkylamine-terminated silicone macromonomer. With the incorporation of urea functionality, better phase separation is observed due to

Fig. 3 General structure for a polyurethane urea derived from α,ω -bis-(3-aminopropyl) poly(dimethylsiloxane) (soft block) and methylene bis-p-phenyl isocyanate (MDI) and butane diol (BD).

Fig. 4 PDMS-PU heart valve on a poly(etheretherketone) frame, sewing ring attached, explanted after six months, in the mitral position. (From Ref. [68].)

enhanced hard-block hydrogen bonding.^[65,66] Therefore, for a given hard-block concentration, mechanical properties are better in the order $UrUr > UUr > UU$.

Because of their toughness and biostability, silicone polyurethane ureas have been used to fabricate heart valve leaflets.^[67] A mechanical and morphological study of biostable polyurethane urea heart valve leaflets explanted from sheep was reported by Bernacca.^[68] The valve was explanted after six months in the mitral position and there was “no sign of significant lipid uptake over this time.” SEM images on an unimplanted control were identical to the explanted leaflet. Figure 4 shows a picture of the explanted leaflet valve. These results are important, because some studies of silicone-polyurethane ureas, with regard to platelet deposition, and silicone-polyurethanes, with respect to lipophilicity, were not encouraging.^[69,70]

Instead of using the pure PDMS PU, various PDMS-containing segmented copolymers may be added in small amounts to conventional polymers as “surface modifying additives.”^[71,72] The SMA approach may be useful in large-volume applications such as tubing, where cost is an issue.

SURFACE SCIENCE

The surface science of poly(dimethylsiloxane)-containing materials is fundamental to the understanding of interfacial interactions relevant to biocompatibility. The poly(dimethylsiloxane) moiety, even when present in small amounts as an additive,^[72,73] dominates the surface and interfacial science. New experimental methods such as sum frequency generation (SFG) infrared spectroscopy^[71,74] provide in situ measurements that

promise better information on the chemical interface between polymers and biological systems. Better understanding of the chemical and morphological nature of this interface will lead to rational chemical and processing approaches to improve desired properties.

Contact angles have been used extensively to characterize PDMS implants or implant analogues.^[75–77] Water contact angles were used by Kennan et al. to estimate the degradation of medical-grade silicones under oxidizing conditions.^[78,79]

Recently, a method for measuring intrinsic advancing (θ_{adv}) and receding (θ_{rec}) water contact angles was reported by Uilk for hydrosilation-cured PDMS coatings that are analogues of biomedical materials.^[17] Static and dynamic contact angle (DCA) methods were used to evaluate coatings prepared from commercial divinyl-terminated PDMS (C-DVPDMS) and synthesized low-polydispersity divinyl-terminated PDMS (N-DVPDMS). DCA measurements showed that coatings prepared with both C-DVPDMS and N-DVPDMS contaminated the water surface during analysis. For ambient temperature cure, the rate of contamination was C-DVPDMS > N-DVPDMS. Methods for acquiring intrinsic contact angles on the PDMS coatings include using a large-surface-area reservoir or changing the water reservoir between DCA cycles. Intrinsic contact angles for hydrosilation-cured PDMS coatings are θ_{adv} , 118° and θ_{rec} , 83° . After contamination of the water surface, the contact angles change to θ_{adv} , 108° and θ_{rec} , 87° .

Changes in wetting behavior due to water contamination stand in contrast to changes in wetting behavior that occur due to surface structure reorganization. Surface reorganization in water is usually characterized by decreasing θ_{adv} and θ_{rec} with immersion time. Such changes are observed for polyurethanes, acrylates, and other polymers that can hydrogen-bond with water.^[80–82] Favorable enthalpy drives reorganization, with the rate depending on surface mobility. However, if the coating does not contaminate water and if surface mobility is sufficient, intrinsic θ_{adv} and θ_{rec} are restored, usually by drying in air. Until contamination effects occur, C-PDMS coatings display stable intrinsic values for θ_{adv} and θ_{rec} . Contact angle hysteresis ($35^\circ \pm 4^\circ$) is therefore also stable, because PDMS has a very low T_g , making the timescale of surface reorganization many orders of magnitude faster than the switch from advancing to receding force-distance determinations.

Although these were not especially purified macromonomers as discussed in the following section on purity requirements, the water/saline contamination effect observed for PDMS coatings has implications for biomaterials evaluation. The importance of the

protocol for detecting contamination rests in the likelihood that if a polymer coating contaminates water or saline in a DCA experiment, it is likely to contaminate a host in an implant application.

The dibutyltin diacetate-catalyzed reaction of (tridecafluoro-1,1,2,2-tetrahydrooctyl) triethoxysilane (FTEOS) with silanol-terminated poly(dimethylsiloxane), $\text{HO}(\text{Me}_2\text{SiO})_n\text{H}$, has been used to prepare surface-modified siloxane networks (ambient temperature cure). Surface phase separation occurs as a function of FTEOS concentration. FTEOS-6x compositions (where 6x is the initial SiOEt/SiOH ratio) exhibited micron-scale islands of fluorinated siliceous phase (FSP) surrounded by a siloxane-rich sea (Fig. 5), whereas the surface of FTEOS-12x was featureless due to the formation of a continuous surface FSP. Dynamic contact angle (DCA) analysis on FTEOS-12x confirmed the presence of an FSP monodomain characterized by high θ_{adv} ($135\text{--}136^\circ$) and low θ_{rec} ($55\text{--}56^\circ$), similar to previously reported values for fluoroalkyl side chain polymers.^[83] Long-term testing showed that the coatings undergo slow chemical degradation by water, with the rate depending on composition. FTEOS-12x is chemically stable in water due to the continuous FSP overlayer.

As noted earlier, poly(diethoxysiloxane) is a useful, nonvolatile condensation-cure SD precursor.^[32] With Si-OEt from poly(diethoxysiloxane) and Si-OH from $\text{HO}(\text{Me}_2\text{SiO})_n\text{H}$, compositions with SiOEt/SiOH ratios from 5 to 35 (ES40-5x-ES40-35x) were prepared. Both light microscopy and TM-AFM show that PDMS-SD compositions 5x and higher slowly develop islandlike surface features while stored at ambient conditions (Fig. 6). After a one month cure, PDMS-SD surface features are $\leq 1\ \mu\text{m}$, whereas after 6 months feature size is broadly distributed up to approximately $10\ \mu\text{m}$. In contrast, surface features developed quickly (within 24 hr) with the PDMS-FSD hybrids noted earlier. TM-AFM demonstrated that PDMS-SD surface features are often poorly adherent and easily moved compared to the robust phase-separated surface structure of PDMS-FSD materials. The stability in water of

PDMS-SD materials is strongly compositionally dependent. Over a period of 70 days, the ES40-14x composition showed the greatest resistance to mass loss, with a mass loss rate of 0.08 wt% per month.

In summary, fundamental surface science studies show that addition^[17] and condensation cured^[32] PDMS surfaces can be “alive” in the sense of diffusion of water-contaminating species. Condensation-cured PDMS shows the development of surface features due to the reactive phase-separation processes and a compositionally dependent mass loss in water.^[32] Further research is clearly warranted on specially purified resins and filled compositions that closely parallel those used in biomedical applications, so as to better understand the efficacy of purification protocols and effects on biocompatibility.

PURITY REQUIREMENTS

Medical devices intended for use in the human body are regulated by government agencies around the world. The Food and Drug Administration (FDA) is the regulatory body for devices marketed in the United States. The FDA provides guidance information for manufacturers of these medical devices.^[84] The FDA also lists selected medical device agencies outside the United States and their Websites that contain information on the requirements for marketing medical devices in those countries.^[85] Specific requirements may vary somewhat from country to country, but in general they are based upon performance of the device in the application for which it is designed. One important factor associated with the performance of an implantable device and, more specifically, its biocompatibility and toxicology, is the purity of the materials from which the device is manufactured. Silicone is no exception.

Because of its long history in the marketplace, silicone has been one of the most intensively studied biomaterials ever developed. Various characteristics of the specific silicone materials employed in devices for

human use must be assessed by a device manufacturer as part of the process of applying for approval to market a new product. Some of the characteristics that are assessed for certain devices may be specified in guidance documents, such as the FDA guidance on breast implants.^[86] Materials composing finished sterilized devices are thoroughly characterized by the device manufacturer, and the data from these characterization activities are provided to the regulatory agencies as part of the approval process for each new device. In general, attributes that are often assessed fall into the following categories: trace/low-level nonsilicone components present by design (e.g., catalysts); trace/low-level contaminants, impurities, or by-products (e.g., heavy metals); low-molecular-weight and/or volatile species; and extractable materials. Because these attributes are controlled by the silicone manufacturer, the device manufacturer develops specifications for the material. This ensures that the material attributes are suitable for the ultimate use intended for the device.

Silicone material manufacturers are not subject to regulation by the agencies that govern device manufacturing. However, silicone manufacturers often voluntarily develop quality systems that are audited by quality standards organizations such as the International Organization for Standardization (ISO).^[87] An ISO9000 certificate of conformity provides a high level of assurance that a silicone manufacturer will deliver consistently high-quality materials to its customers. Strategies employed by silicone manufacturers for controlling material purity are guided by the principles of their quality systems. These strategies are implemented in at least four different areas of the overall manufacturing process: 1) raw material purity control; 2) control of the silicone material processing environment; 3) in-process purification steps; and 4) selection of packaging materials. Each of these is discussed in greater detail in the following sections.

Raw Material Purity Control

The list of raw materials used by silicone manufacturers includes silane or silicone monomers, fillers, filler treating agents, solvents, catalysts, and cross-linkers. A control scheme for raw materials may consist of several key elements, as shown in Fig. 7.

Carefully documented specifications including the purity requirements for each of these materials are the first control point in the overall purity control scheme. For example, solvents used to disperse silicone intended for dip-coating operations must be of high purity, because the coating process typically involves removal of the solvent after film formation. Any nonvolatile contaminants, such as heavy metals in the solvent would therefore likely concentrate in and remain with the silicone in the device. Thorough analysis of several lots of a raw material from each prospective vendor, along with audits of their facilities and quality systems, is typically carried out prior to approving those vendors as raw material suppliers. Testing at this stage would likely include analyses not routinely performed on all incoming raw material lots, but important to overall characterization and assurance of final product purity nonetheless. After vendor approval, inspection of each lot of purchased raw material may include routine purity and identity checks prior to acceptance for use. In addition to incoming inspection data generated by the silicone manufacturer, a vendor's certified material data may also be accepted as evidence of acceptability after initial vendor approval is complete. Periodic checks of vendor-certified data may be conducted to provide ongoing assurance of vendor compliance.

Control of the Silicone Processing Environment

Several elements compose an effective control strategy for preventing contamination of silicone materials

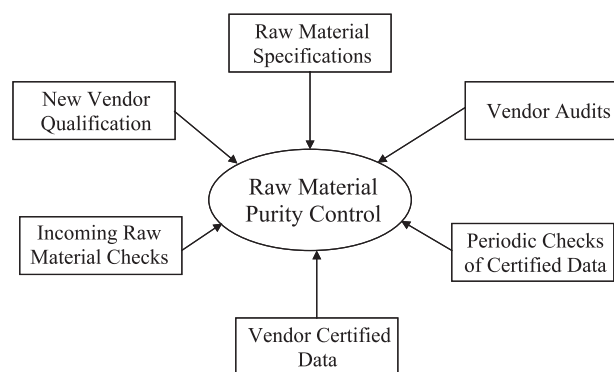

Fig. 7 Important elements in a raw material control scheme.

while they are being processed. These include atmospheric controls, equipment controls, and process controls. With respect to atmospheric controls, the nature of certain silicone materials and the manufacturing processes in which they are employed may require that they be processed within an environment that has particulate controls in place. For example, HEPA filtration, so-called white rooms, or clean rooms may be utilized to prevent particulate contamination of the silicones from ambient air. Equipment design, maintenance, and cleanliness are important factors associated with avoiding contamination by foreign materials or incompatible silicone materials that were processed in the same equipment. Mixers are used in many different places in silicone processing, and a poorly designed or maintained agitator seal, for example, might allow foreign materials to contaminate the silicone. Equipment cleaning procedures are carefully designed and conducted to prevent cross-contamination with other materials that may be processed in the same equipment. Process controls are important in preventing conditions that might generate unwanted byproducts or degradation products. For example, high-temperature processing requires the use of an inert atmosphere to prevent undesired oxidation of the silicone. Oxidative degradation is a well-known phenomenon^[88] that can be prevented by controlling process conditions carefully.

In-Process Purification Steps

After raw material and environment controls, in-process purification steps are important for ensuring silicone material acceptability. Two of the most commonly employed in-process purification methods are filtration and distillation/stripping.

Filtration

Two similar types of filtration are useful: simple physical filtration and adsorptive filtration. In either case, the choice of filtration material is important to ensure compatibility with silicone materials and the absence of leachables that might compromise purity. Physical filters remove particulates above a specified size that may be present in the various silicone materials. Examples include cartridge filters for lower-viscosity materials, such as solvent dispersions or silicone gel precursors, and screen packs placed at the outlets of extruders in which high-viscosity materials, such as high-consistency elastomer stocks, are processed. These filters are commonly used to remove incidental particulate contamination or agglomerates of fumed silica that might remain after mixing the silica into silicone polymer. Adsorptive

filtration may be used to remove color- or odor-causing species from the silicone materials. Activated carbon is widely used in the chemical manufacturing industry^[89] and is commonly used as an adsorbent in silicone manufacturing. Species removed include, for example, polymerization catalyst residues. Tetramethylammonium hydroxide (TMAH)^[90] is a commonly used polymerization catalyst in silicone manufacturing because of its high activity and its transient nature. After polymerizations using TMAH are complete, the process temperature is increased to promote internal rearrangement of the TMAH to trimethylamine and methanol, which are subsequently stripped from the polymer under vacuum (vide infra). Trimethylamine has a typical, strong amine odor that can be detected at extremely low levels. A carbon-impregnated cartridge filter may be used to remove the last traces of amine odor from the silicone polymers.

Distillation/stripping

As described earlier, one of the consequences of industrially practiced equilibrium-controlled silicone polymerization is the presence of a substantial fraction (> 10% by weight) of silicone cyclics at equilibrium and—to a degree that depends on the average molecular weight of the polymer produced—low-molecular-weight linear siloxane oligomers. The most abundant cyclics are often dimethylsiloxane cyclics (D_x ; $x=4, 5, 6\dots$). Lacking functionality, they are potential extractables if not removed from biomedical elastomers. A commonly employed method for removal of these cyclics and low-molecular-weight oligomers is distillation or stripping. These steps are often carried out at elevated temperature and/or low pressure. For the most demanding applications, the levels of D_x can be reduced to < 100 ppm by weight relative to the polymer by thin-film or wiped-film evaporation at high temperatures (> 150°C) and low pressures (< 50 millitorr).^[12]

Packaging Materials

Proper selection and control of packaging materials for silicones is important to ensure purity. Packaging at the silicone materials stages can include small vials and jars holding a few grams, plastic sheeting for high-consistency elastomers, and bulk containers holding as much as 1000 liters or more. The possible presence of particulate matter in the packaging must be addressed to prevent contamination. Careful consideration of packaging materials is also necessary to ensure that foreign substances do not leach into the silicone. Steel drums (55-gallon capacity) are often used to package dispersions of silicones in solvents, and the drum liners must be checked for degradation by aggressive

solvents. In addition, certain silicones, particularly acetoxy-endblocked silicones, contain fairly aggressive components that react with or corrode unprotected steel. A suitable drum lining material, such as a phenolic epoxy, is required for acetoxy-cured silicone in xylene to ensure corrosion and leaching resistance.

APPLICATIONS, BIOCOMPATIBILITY, AND BIODURABILITY

Table 2 outlines some of the hundreds of biomedical applications for silicones. Most of these applications have been adequately described in readily available sources.^[5,91,92]

Determining the parameters that are important in biocompatibility and biodurability remains an ongoing

challenge. With regard to long-term biocompatibility, no evidence has been found suggesting an association between silicone breast implants and connective tissue diseases.^[6]

Brandon et al. have conducted systematic studies of shells from explanted silicone gel breast implants.^[93] Their study addressed the failure mechanisms associated with silicone gel breast implants. The results indicated that silicone gel implants have remained intact for as long as 32 years in vivo and that “degradation of the shell mechanical and chemical properties is not a primary mechanism for silicone gel breast implant failure.”

The foregoing studies attest to the intrinsically safe and robust nature of silicone biomaterials.^[6,68,93] This information must be tempered with the realization that there are still important gaps in our knowledge

Table 2 Selected examples of applications of biomedical silicones according to material type and molecular architecture

Material type	Molecular architecture	Applications examples
Fluids	Uncross-linked, unfilled linear polysiloxanes	<ul style="list-style-type: none"> • Implants: retinal tamponade, gel swelling agents • Lubricants: silicone valves, syringes, needles, condoms • Antifoams: gastric “antigas” agents
Responsive gels	Lightly cross-linked, unfilled macromonomers	<ul style="list-style-type: none"> • Soft tissue implant filler: breast implants, testicular implants
Cohesive gels & films	Moderately cross-linked, unfilled macromonomers	<ul style="list-style-type: none"> • Wound care: gel sheeting
Low-durometer (soft) elastomers	Cross-linked macromonomers with low filler loading	<ul style="list-style-type: none"> • Membranes: blood oxygenation, dialysis • Encapsulants: cochlear implants, pacemakers/defibrillators • Skin contact adhesives: transdermal drug delivery, electromedical devices, ostomy appliances, surgical drapes, tapes
High-strength elastomers	Cross-linked macromonomers with moderate to high-level filler loading	<ul style="list-style-type: none"> • Plastic surgery: soft tissue implant envelopes, tissue expanders, maxillofacial implants • Ophthalmology: punctum plugs, intraocular lenses • Otolaryngology: tympanostomy tubes, tracheostomy tubes • Urology: penile implants, catheters, incontinence devices • Neurology: hydrocephalic shunts • Orthopedics: joint/cartilage/bone replacements • Cardiology: artificial heart valves/coating, pacemaker lead coatings • Others: integral septa for implanted devices (drug delivery devices, tissue expanders, vascular infusion ports, etc.), catheters, balloons, shunts, infusion sleeves, wound drains, laparoscopic devices, splints

concerning the hemocompatibility and histocompatibility of silicone biomaterials, as well as interfacial phenomena such as the release and diffusion of siloxane-containing species. Basic knowledge concerning these phenomena, the promise of molecular-level characterization of the polymer-biological interface, and ways to improve the mechanical properties of silicone biomaterials without compromising biocompatibility will no doubt lead to more widespread applications, with attendant improvements in the quality of life.

Silks

Juming Yao
Tetsuo Asakura

Department of Biotechnology, Tokyo University of Agriculture and Technology, Koganei,
Tokyo, Japan

INTRODUCTION

Silks represent a unique and important class of structural proteins in nature, providing a wide range of native functions as protective membranes to withstand environmental insults during development, high strength netting to entrap insects, and lifelines to support spiders. Silk proteins are usually produced within specialized glands after biosynthesis in epithelial cells, followed by secretion into the lumen of these glands where the proteins are stored prior to spinning into fibers. As fibrous proteins, silks differ widely in amino acid composition, structure, and properties depending on the specific source. Generally, silks are characterized by a combination of highly repetitive primary sequences that lead to significance in secondary structure, which provides unique mechanical properties. Because of these impressive properties, combined with their biocompatibility and relative environmental stability, silks have been used as an important set of material options in the fields of controlled release, biomaterials, and scaffolds for tissue engineering for decades, in addition to their uses as textile materials. There are thousands of silk-spinning insects and spiders, yet only a few have been investigated in detail.

Bombyx mori SILK

The most extensively characterized silk is from the domesticated silkworm *Bombyx mori*, which has a number of desirable properties, i.e., luster, comfort, high strength, and elasticity for textile.^[1] *B. mori* silk has been found to have potential applications in the development and construction of various biotechnological and biomedical devices.^[2–4] World silk production has declined since the 1930s because of competition from less expensive synthetic fibers. Silkworms produce silk during one stage in their lifecycle. The lifecycle of *B. mori* lasts 55–60 days and passes through a series of developmental stages or molts. Cocoon formation occurs at around 26 days in the cycle, during the later stages of the fifth instar. This stage is characterized by the extrusion of silk from a spinneret located in the head and drawing of the fiber by a characteristic figure-of-eight head movement. *B. mori* silk consists of

two fibroin protein threads adhered together with a sericin protein gum resulting in a single thread about 10 to 25 μm in diameter.^[5] The morphology of silk fibroin threads is triangular in cross-section. Here, we would like to give an overview of the key component in *B. mori* silk, fibroin, which has been studied intensively.

Bombyx mori Silk Structure

Primary structure

The unique properties of *B. mori* silk fibroin fiber should be attributed to the distribution of crystalline and amorphous domains formed in the process of spinning by protein–protein interactions. The silk fibroin from *B. mori* comprises high-molecular-weight polypeptides containing a predominance of the amino acids glycine, alanine, and serine. The overall composition of silk fibroin in mol% consists of glycine (42.9%), alanine (30.0%), serine (12.2%), tyrosine (4.8%), and valine (2.5%).^[1,5] Acidic side-chain groups predominate by 2.3-fold over basic side-chain groups. The silk fibroin consists of two primary peptides, one approximately 325,000 Da (heavy chain) and the other 25,000 Da (light chain). Using the cDNA sequencing method, Zhou et al., employing shotgun sequencing strategy combined with traditional physical map-directed sequencing of the fibroin gene of the heavy chain, predicted the presence of unusual repeat sequences in the silk fibroin,^[6] shown in Fig. 1. The silk fibroin protein can be described as a block copolymer containing crystalline domains (regions of the polypeptide containing the short side-chain amino acids), interrupted with amorphous domains consisting of the bulkier side-chain amino acids. The crystalline domain of silk fibroin is predominantly constituted with the highly repetitive hexameric AGSGAG motif. A more extended sequence has been reported for the crystalline domain precipitated after chymotrypsin hydrolysis, as GAGAGSGAA (SGAGAG)_nY, where *n* is usually 6–10. This sequence accounts for 55% of fibroin. Other characteristics of the primary structure in *B. mori* silk fibroin are repeating motifs such as AGYGAG and AGVGYGAG, as well as the irregular unit GAAS.^[6,7]

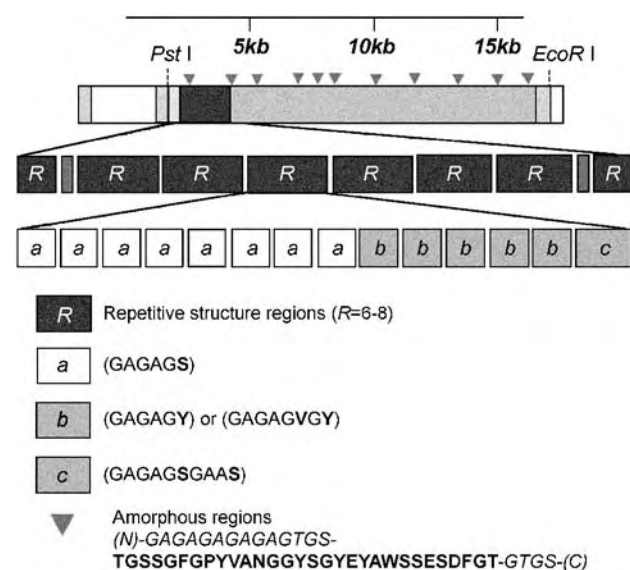

Fig. 1 Schematic representation of the organization of the *B. mori* silk fibroin heavy chain gene. (From Refs. [6,7].)

Secondary structure

Two key crystalline structures have been identified for *B. mori* silk fibroin, silk I before spinning and silk II after spinning the silk fiber. The corresponding structures have been investigated by X-ray fiber diffraction, electron diffraction, conformational energy calculations, infrared spectroscopy, and nuclear magnetic resonance (NMR). Despite a long history of studying silk I, its structure determination was difficult because any attempt to induce a macroscopic orientation of the sample for X-ray diffraction, electron diffraction, or solid state NMR readily causes a conversion of the silk I form to the silk II form. Recently, Asakura et al. have resolved the molecular conformation of silk I as a “repeated β -turn type II” (Fig. 2), using solid-state NMR methods such as 2-D spin diffusion NMR under off magic angle spinning, Rotational Echo Double Resonance (REDOR), and ^{13}C chemical shift data.^[8] Instead of *B. mori* silk fibroin, the sequential model peptide (Ala-Gly)₁₅ was used. The torsional angles of (Ala-Gly)₁₅ with silk I structure were determined as $(-60^\circ \pm 5^\circ, 130^\circ \pm 5^\circ)$ and $(70^\circ \pm 5^\circ, 30^\circ \pm 5^\circ)$ for Ala and Gly residues, respectively. The formation of the intramolecular hydrogen bonding along the chain was confirmed from REDOR NMR by determination of the interatomic distance between the nitrogen and carbon atoms composing the intramolecular hydrogen bonding.

Concerning the structure of silk II, Marsh et al. were the first to propose an antiparallel β -sheet model based on a fiber diffraction study of native *B. mori* silk fibroin fiber.^[9] Although there were some reports suggesting the possession of some intrinsic structural disorder,

Fig. 2 The conformation of a repeated β -turn type II-like molecule as a model for silk I proposed by Asakura et al. (From Ref. [8].)

they are basically in accordance with Marsh’s model. This is because X-ray diffraction cannot yield any results on the amorphous domains of silk fibroin in silk II form, in which the repeated Ala-Gly sequences are known to contain interspersed Tyr and Val residues as shown in Fig. 1. However, by using ^{13}C solid-state NMR, Asakura et al. have clarified not only the heterogeneous structure of crystalline domains, as well as a heterogeneous structure of the natural fiber from *B. mori* silk fibroin with silk II form, but also the detailed molecular conformation and packing of the protein chains in the crystalline domains.^[10] The relative proportions of the various heterogeneous components in the native *B. mori* silk fiber were determined from their relative peak intensities, as shown in Fig. 3. Although there are some contents of distorted structure, nearly 70% of the repeated sequences in the crystalline domains are present as two types of antipolar antiparallel β -sheet structures with different packing model.

Bombyx mori Silk Fiber Formation

The unique properties of silk fibers result from the primary and higher-order structures of the protein as well as the processing conditions used by the organism

Fig. 3 Expanded Ala C β peaks of native *B. mori* silk fibroin fiber, the Cp fraction, and their difference spectrum. Shown as dotted lines underneath are the spectral deconvolutions with Gaussian peaks. The detailed peak assignments are described in Ref. [10].

to spin fibers. The processing conditions function to produce molecular orientation in the protein chains. This occurs at ambient temperatures in aqueous solution, unlike the conditions employed in synthetic fiber processing.

B. mori silk fibroin is produced in a single-cell type lining a pair of long tubelike glands located on each side of the silkworm. The gland consists of three relatively distinct regions, the posterior section where the fibroin is synthesized by epithelial cells, the middle gland where the fibroin product is stored and the sericin is synthesized but separated from the fibroin, and the anterior section where mixing of fibroin and sericin occurs and the two glands join to produce a single duct leading to the spinneret. The concentration of fibroin is approximately 30% when it is stored in middle gland. The anterior division of the silkworm gland is very narrow, 0.05 to 0.3 mm in diameter, which results in a high shear rate of 2 to 400/s at 1.0 cm/s spinning rate.^[11] The soluble silk in the silk gland undergoes a conformational change owing to mechanical shear, drawing at the spinneret, and loss of water.

The fiber formation mechanism has been studied in vivo and in vitro through the use of a variety of techniques including X-ray crystallography, infrared spectroscopy, and NMR spectroscopy. Magoshi et al. first studied liquid crystalline behavior of silkworm silk and reported that fibroin from the anterior portion of *B. mori* silk gland exhibited liquid crystalline properties.^[12] A nematic liquid crystalline phase was presumed

by the authors, which can be drawn by hand at 7 mm/s, similar to the approximate rate of silkworm fiber spinning to form an orientated β -sheet conformation. They also studied the viscosity of liquid silk at different locations within the silk gland and found a decrease in viscosity as the silk progressed towards the anterior division of the gland, suggesting an ordering of structure. The pH of fibroin solution decreased to 4.0 as it approached the anterior division of the gland, which correlates with the formation of β -form crystals at pH 4.5.^[12]

Iizuka reported on shear rates required to convert the soluble silk to the β -form in the anterior portion of silk gland leading to the spinneret, and the acceleration of this effect by calcium ions.^[11] On the basis of the solution properties and evidence of ordered structure within the silk gland, it was speculated that the silkworm simulates a liquid-crystal spinning process during spinning silk fiber. At an assumed spinning rate of 1.0 cm/s, the author chose a critical shear rate of aqueous silk to be 10^2 to 10^3 /s for polymer concentrations between 15 and 30% (wt). Microfibrils formed owing to structural transition, with increasing shear rate as the solution processed toward the spinneret.

Asakura et al. have determined the molecular conformations of *B. mori* silk fibroin before (silk I structure) and after spinning (silk II structure) using solid-state NMR technique as mentioned above. To reproduce and validate the structural transition of *B. mori* silk fibroin from silk I to silk II, a molecular dynamics simulation was performed, starting from 16 fully hydrated (Ala-Gly)₆ molecules in the silk I conformation.^[13] The parameters were chosen to mimic the effects of dehydration, shear force, and stretching during spinning in the silkworm, which were proposed to induce the structural transition from silk I to silk II. After releasing the shear and stretch forces applied during the MD simulation, water was removed and the system allowed to equilibrate. The resulting ϕ and ψ angles of the Ala residues are plotted, before and after the equilibration period, respectively. A considerable amount of antiparallel β -sheet structure emerges around $\phi = -150^\circ$ and $\psi = 150^\circ$. Additionally, a significant proportion of the Ala residues assumes a β -turn conformation, as in silk I. The relative areas of these two predominant conformations are found to be 65% and 35%, when counting the number of data points within the characteristic ranges of $\phi = -150^\circ \pm 20^\circ$ and $\psi = 150^\circ \pm 20^\circ$ for β -sheets, and $\phi = -60^\circ \pm 30^\circ$ and $\psi = 130^\circ \pm 30^\circ$ for β -turns. This result agrees well with the respective ratios of 68% and 32% determined for the quasicrystalline Cp fraction in the silk II form.^[10] Thus, the structural transition from silk I in aqueous solution into solid-state silk II, i.e., the fiber formation of *B. mori* silk fibroin, could be reproduced by MD simulation.

***Bombyx mori* Silk Properties**

General characteristics

B. mori silk fibers are insoluble in water, dilute acids and alkali, and most organic solvents. In addition, silks are resistant to most proteolytic enzymes, and are hydrolyzed by concentrated sulfuric acid. Lithium bromide (9.0 M) solubilizes silk fibroin fibers, while specific mixtures of acids solubilize silk fibers without decreasing the molecular mass of the polymer. Silk assembles into a compact conformation as shown by intrinsic viscosity measurements. For example, a solution containing fibroin of molecular size 300 kDa exhibits a viscosity significantly below values obtained for comparably sized and smaller sized synthetic polymers. Silk fibers are hygroscopic, with a moisture region of 10 to 15%. The specific gravity for *B. mori* silk is 1.25.

Mechanical properties

B. mori silks exhibit an unusual combination of strength and toughness which sets them apart from other natural and synthetic fibers. The tensile strength of *B. mori* silk fibroin fiber is approximately 650 MPa, the modulus is approximately 15 Gpa, and the elongation to break is 15–20%.^[5] Silk fibers represent an exception to most materials where strength and modulus increase with increased loading rates, while elongation decreases. With silks, increasing rates of loading result in increased elongation, so that work to rupture increases at higher rates of loading. At low loading rates, *B. mori* silk has a higher modulus than nylon but lower strength, while at high loading rates silk out-performs nylon.

Utility of *Bombyx mori* Silk in Biomedical Applications

Sutures

Silk has been used most extensively as sutures for wound ligation and has become the most common natural suture used in the biomedical industry, surpassing even collagen.^[14] During decades of use, silk fibers have proven to be effective in many clinical applications. In general, sutures should be strong, handle easily, and form secure knots. Virgin silk (silk fibroin containing sericin gum), like most proteins, is a potential allergen causing a Type I allergic response in some cases and inducing asthma and specific upregulation in IgE levels. Wen et al. showed the extracted sericin was responsible for sensitization by skin testing of 64 children with asthma.^[15] Further biochemical analysis by Zaoming et al. concluded that upregulated IgEs were

produced in response to the sericin, clarifying the role of these contaminants as the main allergenic agent in silk and not the core fibroin fibers.^[16] As sutures, the silk fibroin fibers are usually coated with waxes or silicone to enhance material properties and reduce fraying; these sutures are commonly referred to as black braided silk (e.g., Perma-Hand™). The transition from virgin silk to black braided sutures occurred in the late 1970s and early 1980s; however, virgin silk is still commercially available today. Although the use of virgin silk negatively impacted the general acceptance of this biomaterial from the surgical practitioner perspective in the earlier stage, to date, there is no report found that implicates black braided silk in inducing hypersensitivity and allergic reactions. All biomaterials derived from a nonautologous source will elicit some level of foreign body response following implantation in vivo. In a comprehensive blind study, Setzen et al. statistically analyzed tissue responses to 11 types of sutures subcutaneously implanted in the rabbit.^[17] They concluded that the inflammatory response induced by silk was not greater than that in response to common absorbable sutures 30 days post implantation. Santin et al. also found that silk was no more thrombogenic than common biomedical materials such as polystyrene and poly(2-hydroxyethyl methacrylate).^[18]

Silk is degradable but over longer time periods due to proteolytic degradation usually mediated by a foreign body response. Silk fibers lose the majority of their tensile strength within one year in vivo, and fail to be recognized at the site within two years. In general, silk is slowly absorbed in vivo. The rate of absorption is dependent upon the implantation site, mechanical environment, and variables related to the health and physiological status of the patient, and the type (e.g., virgin silk and black braided fibroin) and the silk fiber size. Furthermore, alterations in silk processing may cause conformational changes in the protein structure potentially increasing or decreasing susceptibility to degradation. However, none of these variables has been studied in detail, so that it is difficult to gain a clear understanding of the relationships between structure, processing, and degradability.

Biosensors

In addition, it has been demonstrated that silk can be used as a substrate for enzyme immobilization in biosensors. In the preparation of an enzyme-immobilized film with fibroin, simultaneous insolubilization of the water-soluble film and immobilization of the enzyme in the film is possible without any chemical reagents for cross-linking.^[3] The sensor was prepared with a glucose oxidase (GOD)-immobilized silk fibroin film attached on an oxygen electrode surface and assembled in the

apparatus. Moreover, a fourfold increase in sensitivity was observed when the glucose sensor was made with the GOD immobilized on nonwoven silk fabrics compared with a GOD-immobilized silk fibroin film.^[19] The membrane potential of the GOD-immobilized silk fibroin film is induced by an enzymatic reaction after the addition of the substrate glucose. An application for the process has been shown by the preparation of a new type of glucose sensor that functions without an oxygen electrode. Biophotosensors have also been made using fibroin films with immobilized peroxidase.

The application of the immobilized peroxidase (POD) *Bombyx mori* silk fibroin membrane to biophotosensors was attempted for the purpose of determining the concentration of hydrogen peroxide generated by the luminol reaction.^[20] POD was entrapped in the silk fibroin membrane without any chemical cross-linking agents. The response time and intensity of the photocurrent from the photodiode determined after the luminol reaction depends on the character of the immobilized POD-membrane. Namely, when POD is distributed asymmetrically in the membrane, the response is very fast and strong compared with POD distributed uniformly in the membrane. The photocurrent after the luminol reaction increases linearly with the concentration of hydrogen peroxide in the aqueous solution, indicating the applicability, of such a silk fibroin membrane to biophotosensors.

Qian et al. described a procedure to prepare an amperometric H₂O₂ sensor, based on the immobilized peroxidase in regenerated silk fibroin membrane, in the use of new methylene blue N as an electron transfer mediator.^[21] The characteristics of the sensor with respect to linearity, response time, effect of pH and temperature, stability, and reproducibility were investigated. The sensor was highly sensitive to H₂O₂ with a detection limit of 1.0×10^{-7} M and a response time of less than 40 s.

Scaffolds for tissue engineering

The emergence of tissue engineering has increased the demand for a diverse set of biomaterials to support the development of tissues in vitro prior to implantation in vivo. The biomaterial or matrix plays a key role in communicating or transducing environmental cues to cells seeded within or on the matrix. Silk fibroin offers versatility in matrix scaffold designs for a number of tissue engineering needs in which mechanical performance and biological interactions are major factors for success, including bone, ligaments and tendons, blood vessels, and cartilage.^[4,14,22,23] Silk fibroin can be processed into foams, films, fibers, and meshes.

Inouye et al. demonstrated the utility of a silk fibroin film in culturing animal cells in comparison to a

collagen matrix.^[22] Films of both fibroin and collagen supported equivalent cell growth after 5 days in cell culture conditions. Comparative studies on the ability of fibroin and sericin films in supporting attachment, spreading, and growth of the L-929 fibroblast cell line support that extracted fibroin free of sericin was a suitable matrix for cell and tissue culture. Moreover, Sofia et al. chemically decorated the silk fibroin films with integrin recognition peptide (RGD) to promote integrin interactions for adhesion; the induction of bone formation in vitro was significantly enhanced.^[4] Furuzono et al. developed apatite-silk composites by using an alternate soaking process, that is, a calcium solution and a phosphate solution were applied alternatively to a silk fabric.^[23] Thus, this method may provide a bioactive material with Ca²⁺ ions that is similar to the natural bone apatite.

Recent research with silk has focused on the development of a wire rope matrix for the development of autologous tissue-engineered anterior cruciate ligaments using a patient's own adult stem cells. Human bone marrow stromal cells cultured in collagen gels were grown in a mechanically dynamic environment relevant to that present in vivo leading to the formation of ligament fibroblasts and mature tissue development in vitro. However, the poor integrity of the collagen gels and the demanding and dynamic intraarticular mechanical and biochemical environment of the knee have prompted renewed interest in silk as a long term absorbable material with good mechanical integrity and biocompatibility.

Molecular Design and Synthesis of Silk-Like Materials

The design and synthesis of artificial proteins is an emerging area of research with important implications for structural biology, materials science, and biomedical engineering. Significant progress has been reported in the design of fibrous proteins that adopt predictable secondary structures and have higher order protein folding. With virtually absolute control of sequence, chain length, and stereochemical purity, the artificial proteins can be designed to represent a new class of macromolecular materials, with properties potentially quite different from those of the synthetic polymers currently available and in widespread use.

Tirrell's group was interested in artificial fibrous proteins that are able to form crystals of defined thickness and bearing functional groups at their surface.^[24] For instance, the Glu residues were inserted in (Ala-Gly)_n at intervals varying between 8 and 14. The big size of Glu compared to Ala and Gly should prevent its insertion in the lamellar crystal. Therefore, when crystals form, the Glu residues must be found on the

surface. This is facilitated by the fact that, among the 20 amino acids, Glu is the residue that has the lowest tendency to form β -sheet. Cappello et al. focused on the production of synthetic protein analogs of *B. mori* silk, and other well known structural protein materials and tried to reproduce defined properties of their natural counterparts.^[25] Also, by combining structural blocks from different natural proteins, they hoped to obtain new properties found in neither the synthetic homoblock polymers nor the natural proteins.

Asakura's group has designed and expressed in *Escherichia coli* a number of artificial fibrous proteins derived from *B. mori* silk, as well as other proteins, such as *Samia cynthia ricini* and spider silks, and elastin.^[26,27] The examples of amino acid sequence of designed proteins are as follows, where single amino acid codes are used:

[GGAGSGYGGGYGHGYGSDGG(GAGAGS)₃AS]_n

 GAAS]_n

The target genes were cloned in pET30a plasmids (Novagen, Inc.) under control of strong bacteriophage T7 and translation signals, which contain kanamycine-resistant gene (*kan^r*), *lacI* coding gene, an origin of replication (*ori*), and an f1 origin of replication that allows the production of single stranded plasmid DNA for mutagenesis and sequencing applications (Fig. 4). For protein production, the authors transferred recombinant plasmids to *E. coli* strain BL21(DE3)pLysS. In this strain, a gene encoding T7 RNA polymerase is incorporated into the bacterial chromosome under *lacUV5* control, and protein production is induced by the addition of IPTG. The pLysS plasmid provides low levels of T7 lysozyme, which inhibits T7 RNA polymerase and suppresses the basal level of protein expression. The objective of this research is to determine the interactions between different amino acid sequences, as well as the effect of single amino acid residues. These could tell us which amino acid sequence can be introduced into the fibrous proteins to control macromolecular structure and provide novel chemical or biological activities while

Fig. 4 Structure of an expression vector used for the production of recombinant protein in *E. coli*.

maintaining the physical properties of the structural blocks.

WILD SILKWORM SILKS

Many kinds of wild silkworm produce silks, including *Antheraea yamamai*, *Antheraea pernyi*, *Antheraea mylitta*, *Samia cynthia ricini*, etc. Wild silkworm silks also consist mainly of silk fibroin and sericin, but the content of sericin is relatively low, as is expected from the fact that the size of the middle region of the silk gland is more slender than that of the posterior region of the gland. The major amino acid residues of these wild silkworm silk fibroins are alanine and glycine; as with *B. mori*, the sum of these two amino acid residues composes 74–82% of the silk fibroin. However, the relative content of alanine is larger than that of glycine, in contrast to the case of *B. mori* silk fibroin, where the reverse is the case.

The primary structures of *A. pernyi* and *S.c. ricini* silkworm silk fibroins have recently been shown to be very similar to each other. Namely, the silk fibroins mainly consist of the repeated similar sequences by about 80–100 times where there are alternative appearances of polyalanine region of (Ala)_n, where $n = 10\text{--}14$, and glycine-rich region. Structural analyses of the aforementioned two kinds of silk fibroin prepared from liquid silk in silkgland and silk fibroin fibers suggest that there is a structural transition from α -helix to β -sheet occurring in the polyalanine region.^[28] Recent results suggest that the structural transition also occurs in the glycine-rich region of *A. pernyi* and *S.c. ricini* silk fibroins.

The characteristics of wild silkworm fibroin fibers are considerably different from those of *B. mori* silk fibroin fibers. For example, the stress–strain curves are quite different. The curve is a monotonic rapid increase in the case of *B. mori* silk fiber, while the curve shows a slow increase with a flat region in the case of wild silkworm silk fibers.^[1,6] Compared with *B. mori* silk fibers, the wild silkworm silk fibers have much lower solubility, so that the aqueous solution of silk fibroin is usually prepared from the liquid silk stored in the posterior region of the silk gland directly. The cast film from this aqueous solution mainly takes α -helix structure with high thermal stability, which can be changed to β -sheet with stretching or immersing in methanol. Such kinds of films can also be used for the immobilization of GOD and applied to a glucose sensor.

SPIDER SILKS

In the past decade, spider silks have been the most attractive fibrous proteins because of their remarkable mechanical properties. All spiders can make seven kinds of silk, one type to wrap its prey, one to wrap its eggs, and five to construct the web. Each type is biologically engineered to perform its task to perfection. The different silk proteins contain repetitive amino acid sequences that vary slightly, depending on their use. These small changes in sequence can confer different mechanical properties.

Most molecular and structural investigations of spider silks have focused on dragline silk, which often refers to a major ampullate silk because it is produced in the major ampullate glands, and flagelliform silk, which is the core fiber of the capture spiral. Dragline silk, used to anchor the web and form its spokes, has a higher tensile strength than high-tensile steel of the same weight. Capture silk, which is used to snare insects, is very sticky and can stretch to three times its length before breaking. Generally, dragline silk contains multiple repeats of motifs that include an 8–10 residue–long polyalanine block and a 24–35 residue–long glycine-rich block. When fibroins are spun into fibers, the polyalanine blocks form β -sheet crystals that cross-link the fibroins into a polymer network with great stiffness, strength, and toughness.^[29] On the other hand, like all silks, the flagelliform silk is composed largely of repeated motifs. The dominant repeat of this protein is Gly-Pro-Gly-Gly-X (X is mainly Ala, Ser, Tyr, or Val), which can appear up to 63 times in tandem arrays. This motif likely forms Pro²-Gly³ type II β -turns and the resulting series of the concatenated β -turns are thought to form a β -spiral. This spring-like helix is proposed to be responsible for the elasticity of this protein.^[30]

Spiders cannot be farmed like silkworms because of their aggressive and territorial nature; therefore, materials scientists have tried to biomimic the process of spider silk production in the laboratory. Lazaris et al. describe the production of a number of dragline silk proteins in mammalian cells and show, for the first time, that harvested recombinant proteins can be spun into strong, lightweight fibers.^[26] Although the fibers are not as good as natural dragline silk, some improvements might be gained from making larger proteins by spinning the constituent proteins of natural dragline silk.

CONCLUSION

Although the substitution of natural materials has been underway for several decades, natural silks remain commercially important because of their unique properties, as well as their relative environmental stability and biocompatibility, and (in some cases) consumer preferences. During the past decade a great deal of progress has been made in understanding silk genetic and protein structures. On the other hand, materials scientists have long been fascinated by structure–function relationships in silk proteins. The illustration of the sequences of cDNAs and genomic clones encoding silks can therefore be readily exploited to construct genetically engineered silklike proteins using synthetic oligonucleotides. Cloning and expression of native and synthetic silks have been achieved in a variety of host systems. The studies on natural silks summarized here may be able to provide important insights into the nature of macromolecular materials, both natural and synthetic.

Small-Angle Light Scattering Methods for Soft Connective Tissue Structural Analysis

Michael S. Sacks

Engineered Tissue Mechanics Laboratory, McGowan Institute for Regenerative Medicine, University of Pittsburgh, and Department of Bioengineering, University of Pittsburgh, Pittsburgh, Pennsylvania, U.S.A.

INTRODUCTION

Quantification of the architecture of the soft tissue fibrous extracellular matrix is a critical step in furthering our understanding of changes in tissue function in health and disease. Moreover, many soft tissues, either in their native or processed forms, are increasingly utilized in medical therapies and devices. In the technique of small-angle light scattering (SALS), monochromatic light is passed through a thin specimen. The spatial intensity distribution of the resulting scattered light represents the sum of all structural information within the light beam envelope. For soft tissue membranes or where thin tissue sections can be prepared, SALS provides a straightforward and rapid means to map the fiber architecture. SALS has been shown to measure fiber orientation accurately for up to a tissue thickness of at least 500 μm to an angular resolution of 1° and a spatial resolution of 250 μm . The resulting information can be used to understand native tissue function, as well as to aid the development of engineered tissues. In this article, the SALS technique is reviewed as a general method to quantify connective tissue fibrous structure. In addition to providing important specific application information, it is also hoped that this chapter will serve as a general guideline for the application of SALS in connective tissue analysis.

BACKGROUND

It is well known that the collagen and elastin fibers that compose soft connective tissues can efficiently withstand tensile forces, but have low torsional and flexural stiffness.^[1] Thus, directions in which fibers are oriented can be identified with the directions in which the tissue is able to withstand the greatest tensile stresses. Gross fiber orientation thus leads to an understanding and predictability of the mechanical properties of soft tissues. Although available microscopic techniques can provide quantitative information on fiber structure,^[2] this information is by definition highly localized, making it difficult to quantify larger scale fiber

structural features. Thus we need a rapid method to map the complete gross fiber structure of planar tissues.

Several methods have been previously used for the analysis of the fiber architecture in soft tissues.^[2] Image processing techniques, which use either optical^[3,4] or scanning electron microscopic images,^[5-7] have been used to provide highly localized information on the size and orientation of fibers. However, these are destructive approaches requiring time-consuming tissue preparations, and are thus not suitable to large-scale mapping studies. Small angle X-ray scattering techniques have been used to analyze the collagen molecular architecture.^[2,8-10] In this technique, scattering patterns are recorded on film that requires long exposure time, and the technique suffers from similar mapping limitations of the electron microscopy methods. Polarized light microscopy has often been used to assess the gross collagen fiber architecture of soft tissues by taking advantage of their inherent birefringence.^[2,11] For example, Hilbert et al. applied polarized light microscopy to virgin and accelerated tested bioprosthetic heart valve tissues to visualize fiber directions and crimp.^[12] They were able to make accurate crimp measurements and could obtain general information on fiber orientation. However, this technique is difficult to apply as a detailed mapping method since it requires extensive manual operation, and the inability to distinguish multiple layers of fibers deep within the tissue accurately limits measurement to the more superficial layers.

Recently, Tower and Tranquillo developed a novel technique for extending polarized light fiber alignment methodologies by generating polarized light retardation and alignment direction directly from single images.^[13,14] The primary advantage of this approach is the ability to quantify preferred fiber directions of a complete specimen image without scanning. However, this approach is limited in that while it provides preferred fiber direction and an *index* of the strength of orientation, it does not provide the actual fiber angular distribution. Further, as in all polarized light techniques, it is only applicable to tissues composed exclusively of collagen fibers because of the need for fiber optical birefringence inherent in the technique.

In the SALS technique, monochromatic light is passed through a thin specimen. The spatial intensity distribution of the resulting scattered light represents the sum of all structural information within the light beam envelope. For soft tissues, Helium–Neon laser light is generally preferred since its wavelength ($\lambda = 632.8$ nm) is within an order of magnitude of the diameter of the collagen and elastin fibers and is unpolarized so that there is no directional dependence to any particular angular orientation. SALS has been used to quantify the fibrous structure of synthetic polymers^[15–19] and biopolymers such as collagen films.^[20,21] Moreover, Kronick and Buechler^[22] found close agreement between the fiber orientation measurements made by SALS and X-ray diffraction, indicating that SALS was an inexpensive alternative to X-ray diffraction for quantitative measurements of fibrous materials.

SALS has also been used extensively to quantify the structure of native connective tissues. Kronick and Sacks^[23] used SALS to quantify structural variations in calf skin suffering from a genetic collagen fiber pathology. Ferdman and Yannas^[24] have used SALS for skin scar analysis and were able to detect structural variations successfully in regions of scar from normal skin. Several investigators have also made extensive use of SALS to investigate the interrelationship between the layered structure of the collagen fibers and resultant light scattering behavior in the cornea.^[25–30] Over the past decade, Sacks and colleagues have applied SALS to several tissues, including the diaphragmatic central tendon,^[31] bovine pericardium,^[32–34] cranial dura mater,^[35] tissue-engineered skin,^[36] native and processed small intestinal submucosa,^[37,38] the native aortic^[39] and bioprosthetic valve,^[40,41] the native mitral valve,^[42] and the effects of TGF β on skin wound healing.^[43]

In addition to quantifying tissue structure, the fiber architectural information obtained from SALS can be related to the direction and degree of tissue mechanical anisotropy. For example, the maps of the collagen fiber structure of the diaphragmatic central tendon,^[31] and in particular the volume fraction of the collagen fiber populations, were consistent with the direction and degree of mechanical anisotropy.^[44] More mechanistic approaches were taken by Billiar and Sacks,^[45] who developed a method for measuring fiber kinematics in two-dimensional soft collagenous tissues. The technique combined SALS and biaxial stretch controlled by simultaneous optical strain measurement. Findings for the aortic valve and bovine pericardium indicate that local fiber kinematics are highly tissue specific, and that local fiber deformations may not always follow global tissue strains (i.e., are generally nonaffine). The mobility of the fibers in each tissue seems to be specialized to perform a distinct physiological function

and underscores the importance of measuring fiber kinematics for each specific tissue type that is to be modeled.

The availability of quantitative fiber architectural information obtainable by SALS motivated a recent study by Sacks^[46] wherein a structural constitutive model formulation incorporating the discrete quantitative fiber architectural data derived from SALS was developed. Demonstration of the model was performed using existing biaxial mechanical and fiber orientation data for native bovine pericardium.^[34,47] The structural constitutive model accurately predicted the complete measured biaxial mechanical response. An important aspect of this approach is that only a single equibiaxial test to determine the effective fiber stress–strain response and the SALS-derived fiber orientation distribution were required to determine the complete planar biaxial mechanical response. This study demonstrated that the fiber architectural data obtained from SALS can be directly utilized in mechanical modeling of soft tissue multiaxial behavior.

These cited studies underscore the utility of SALS as a robust technique for obtaining fiber architectural information in soft connective tissues. Moreover, direct utilization of the architectural information into structural constitutive models of soft tissue behavior can avoid ambiguities in material characterization. This is an important step since full realization of structural approaches is limited without direct quantitative structural information for direct implementation or to validate model predictions. However, as with any experimental approach, the results can depend on the exact methodologies utilized. In the following discussion, a detailed description of the instrumentation and analysis techniques utilized in our laboratory is presented. In particular, detailed validation and resolution determination of the SALS technique are demonstrated in an effort to provide investigators important information on how to apply SALS effectively, as well as to unify its application overall.

EXPERIMENTAL SYSTEM AND ANALYSIS METHODS

Introduction

Early SALS devices utilized simple photographic imaging systems or rotating photodiode arrays to digitize the scattered light intensity, as well as requiring manual positioning of the specimen.^[24] Further, analysis of the scattered light intensity data was performed manually.^[24] These methods of data acquisition and analyses are clearly unsuitable for practical applications of mapping large areas of tissue. In our laboratory, we developed a high-speed system that is

able to rapidly raster-scan tissues and automated data analyses. The following is largely drawn from our previous work^[48] and updated where appropriate.

Hardware Description

The SALS device consists of an unpolarized 4-mW HeNe laser ($\lambda = 632.8$ nm, Uniphase, Manteca, CA), spatial filter-beam expander, specimen positioner, projection screen, and a CCD NTSC-compatible auto-iris video camera (Sony Inc., Japan) equipped with a telecentric lens to minimize image distortion (Edmund Scientific, Barrington, NJ), all mounted on a rigid optical platform (Fig. 1). Since the Helium-Neon laser beam has a Gaussian intensity profile, the beam diameter is defined as the diameter of the laser beam that contains all but $1/e^2$ (i.e., 13.5%) of the total radiant laser beam power.^[49] Thus, all reported beam diameters contain 86.5% of the total beam intensity. As the laser light passes through the tissue, it is scattered by the fibrous structures, and the resultant scattering pattern is cast onto the projection screen (Fig. 1). The video image of the scattered light is digitized to a resolution of 640×480 8-bit pixels using

a PCI-bus image grabber board mounted in the personal computer (PC) (Fig. 1). Note that higher resolutions can be used (e.g., $1024 \times 1024 \times 12$ bits), but were found to be unnecessary. Use of the PCI-bus image grabber allowed analysis of the most recent acquired image while the device moved to the next test position and acquired the next image.

The sample positioner allows for two axes of movement in a plane perpendicular to the optic axis (Fig. 1). Both axes utilize a precision linear travel system using 16 threads/inch lead screws with anti-backlash nuts. Positioning of each axis is accomplished by rotating the lead screws using two PC-controlled stepper motors (Arrick Robotics, Hurst, TX) with 400 steps/rev resolution, resulting in a net movement resolution of $4 \mu\text{m}/\text{step}$ and a total travel range of 25 cm along each axis. All motion control, video processing, and data analysis is performed by custom written C++ programs using the GLUT graphics interface software (www.opengl.org). This system allows for video acquisition, initial data analysis (see forthcoming discussion), storage of the analyzed data to the hard disk, and movement to the next test location, all in 0.25 to 0.5 seconds, depending on the distance between test locations.

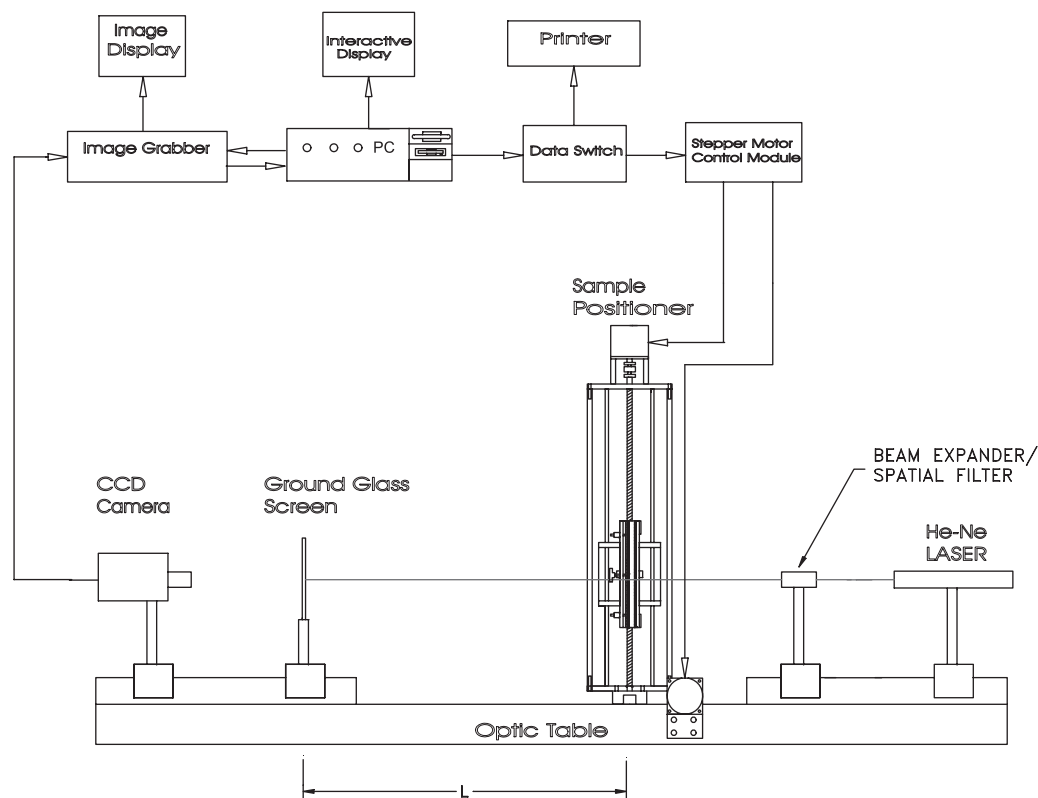

Fig. 1 A schematic of the SALS device, which consists of an unpolarized 4-mW HeNe laser, spatial filter-beam expander, sample positioner, projection screen, and a CCD video camera. The sample positioner allows for two axes of movement in a plane perpendicular to the optic axis.

Analysis of the Light Scattering Pattern

Assuming no optical interactions, a fibrous network optically behaves like a two-dimensional assembly of single slits. This is in contrast to polarized light techniques that require inherent birefringence of the constituent fibers. The Fraunhofer diffraction for a single slit of width w is given by

$$I(\theta) = I_0 \left(\frac{\sin \alpha}{\alpha} \right)^2 \quad (1)$$

$$\alpha = \frac{\pi w}{\lambda} \sin(\theta)$$

where I is the scattered light intensity measured along the scattered angle θ , and I_0 is the incident light intensity.^[50] For two slits separated by a distance d , $I(\theta)$ is now given by

$$I(\theta) = I_0 \left(\frac{\sin \alpha}{\alpha} \right)^2 \cos^2(\beta) \quad (2)$$

$$\beta = \frac{\pi d}{\lambda} \sin(\theta)$$

If the width of the separation of the slits is comparable to the slit width ($w/d \cong 1$), the intensity variations due to slit and slit separation are approximately equal, where w now represents the average of the slit size and interslit spacing. In our experience, this is a very good approximation for dense connective tissues. Although possibly limiting accurate determination fiber diameters from the rate of decrease of the scattered light from the optic axis (see Guinier for related work on X-rays^[51]), all orientation information is preserved since the fibers and the spaces between the fibers have the identical orientations.

Thus, in the case of dense fibrous tissues, the effective slit width is an average of the fiber diameters and the spaces between the fibers. According to single-slit diffraction theory, light is scattered in a direction perpendicular to the fiber axis,^[50] although there will be no observable minima due to the distribution of slit widths (i.e., fiber diameter and interfiber spaces) in the tissue. Each fiber, having an angular orientation Φ , will thus contribute its scattered light intensity at an angular orientation of $\Phi + 90^\circ$. As long as the fiber diameter and interfiber spacing distribution are independent of Φ (as has been our experience in dense connective tissues), the angular distribution of scattered light at a constant R , $I(\Phi)$ represents the angular distribution of fibers about the optic axis within the light beam envelope (Fig. 2a).

To extract the angular fiber orientation information, scattered light intensity values are taken from the digitized SALS image at 1° increments through the

angle Φ about a circle corresponding to a constant radius R centered on the optical axis (Fig. 2a). The extracted intensity distribution, $I(\Phi)$, is taken as the average detected intensity using a 3×3 -pixel grid centered on the current pixel location. Because light is scattered perpendicular to the fiber axes, all $I(\Phi)$ values are actually acquired at $\Phi + 90^\circ$, so that $I(\Phi)$ represents the true fiber orientation (Fig. 2a).

Since the light scattering pattern is symmetric about the preferred fiber direction, the $I(\Phi)$ distribution is repeated twice over the full 360° range (Fig. 2b). The two intensity minima demarcate where the axis of symmetry occurs in the scattering pattern, with the data from either symmetric segment usable for analysis (Fig. 2b). From each symmetric 180° segment, the preferred fiber directions, degree of symmetry of the fiber distribution about the preferred direction, and the degree of fiber orientation can be determined^[22,31] (Fig. 2c). First, we define the preferred fiber direction as the distribution centroid (Φ_c):

$$\Phi_c = \frac{\sum_{\Phi=\Phi_{\min}+1}^{\Phi_{\min}+180} \left[(\Phi - \Phi_{\min}) \frac{I(\Phi) + I(\Phi - 1)}{2} \right]}{\sum_{\Phi=\Phi_{\min}+1}^{\Phi_{\min}+180} \left[\frac{I(\Phi) + I(\Phi - 1)}{2} \right]} \quad (3)$$

where the summations are computed directly from a 180° segment (i.e., Φ_{\min} to $\Phi_{\min} + 180^\circ$) of the SALS data using increments of 1° (the contiguous segment closest to 0° is chosen arbitrarily). Φ_c thus represents the overall preferred direction of the fiber network and does not require the need of any distribution model such as a Gaussian as used in Ref. [31].

If the distribution is symmetrical about the Φ_c , the intensity peak Φ_p will coincide with Φ_c (Fig. 2c). Deviation from the condition of symmetry is defined as the distribution skew, $\Phi_s = \Phi_p - \Phi_c$ (Fig. 2c). More traditional methods of defining a distribution skew using distribution moments^[52] were considered, but the above definition provides a simple and physically interpretable approach. Note that large values of Φ_s will generally indicate that the fiber angular distribution cannot be considered a single population, suggesting the existence of multiple layers of fibers with substantially different orientations.

The width of the $I(\Phi)$ distribution is proportional to the degree of fiber orientation: Highly oriented fiber networks result in a very narrow peak, while less well oriented fibers yield a broader peak. We have previously used the $(\cos^2 \Phi)$ to compute the degree of orientation normalized to a percentile scale.^[31] However, the $(\cos^2 \Phi)$ has no direct physical interpretation and is a nonlinear function of the distribution width. We have defined a physically intuitive

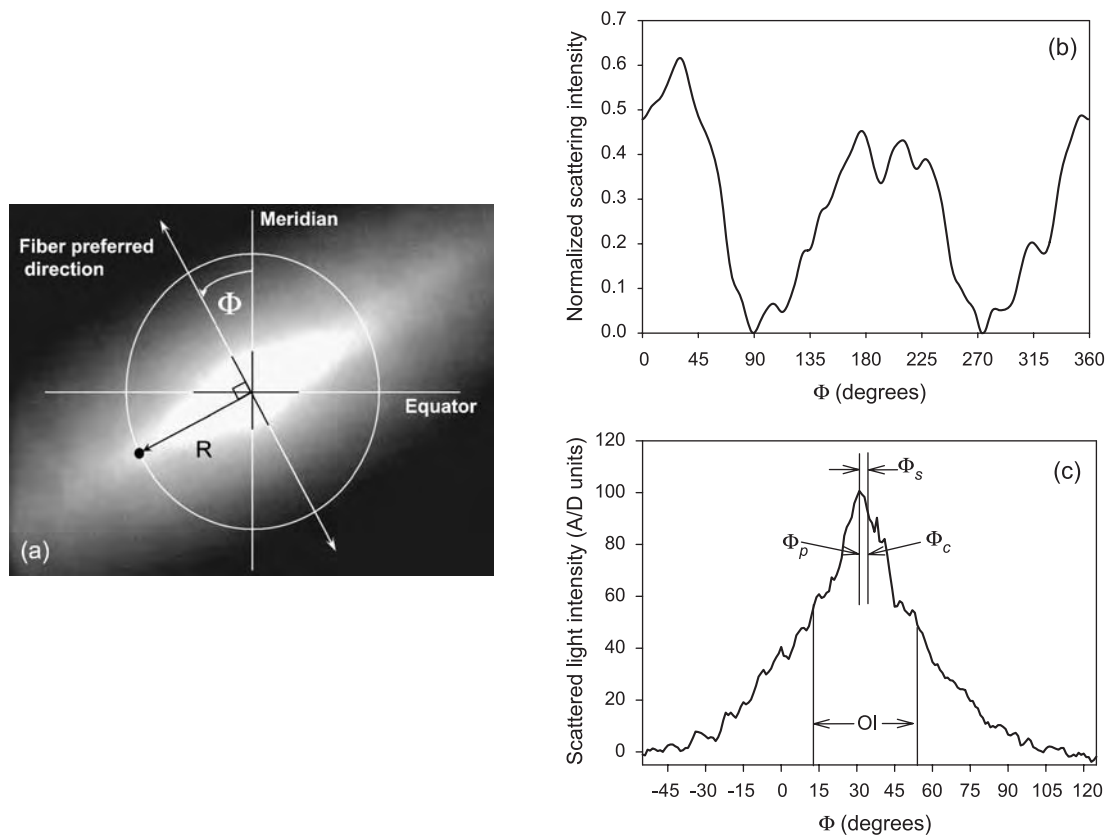

Fig. 2 (a) A digitized image of the scattered light intensity from a porcine aortic valve. The $I(\Phi)$ data is extracted from the SALS image along a circle of radius R centered on the optic axis (dot on circle), corresponding to a scattering angle $\theta = \tan^{-1}(R/L)$, where L is the distance from the specimen to the projection screen (Fig. 1). (b) The complete 360° extracted $I(\Phi)$ data showing the two intensity minima demarcating a 180° contiguous data segment. (c) locations of Φ_p , Φ_c , and the definition of the distribution skew, $\Phi_s = \Phi_p - \Phi_c$. Because light is scattered perpendicular to the fiber axes, all angular measurements are automatically shifted by 90° so that $I(\Phi)$ represents the true fiber orientation.

orientation index, OI, as the angle that contains one half of the total area under the $I(\Phi)$ distribution, representing 50% of the total number of fibers (Fig. 2c). Thus, highly oriented fiber networks will have low OI values, while more randomly oriented networks will have larger values. Note that the OI is computed directly from $I(\Phi)$ without the need of any distribution model.

CALIBRATION AND SENSITIVITY

Introduction

Evaluation of the SALS technique capabilities should include: 1) assessment of the angular and spatial resolutions, 2) sensitivity to the presence of multiple fiber populations, 3) effects of beam diameter, and 4) effect of tissue thickness. In the following section, methods and results to determine these parameters are presented.

Angular Position Accuracy and Sensitivity to Multiple Populations

To assess angular positional accuracy, two 10-mm square sections of bovine tendon (chosen for its uniformity in fiber structure, see the appendix in Ref. [31]), one at 100- μm and the other at 500- μm thickness, were mounted on a rotatable positioning device (0.1° accuracy) and tested at angular positions ranging from 0°–90°. SALS data was acquired over the entire specimen using a 1-mm spaced rectilinear grid and analyzed as discussed previously. Results indicated that the relationship between true angular position and mean Φ_c was consistently linear and demonstrated an accuracy of 1° (Fig. 3). This accuracy was observed for both the 100- μm and 500- μm thicknesses, indicating that SALS can maintain a 1° accuracy for a tissue thickness of 500 μm .

When two fiber populations exist, the resultant SALS data will contain two overlapping populations.^[28] To determine the sensitivity to multiple

Fig. 3 Mean Φ_c and angular position error vs. specimen orientation Φ for a 500- μm bovine tendon section for $0^\circ \leq \Phi \leq 90^\circ$. For all orientations, there was close agreement between measured and actual (line of identity) Φ values, along with angular position errors all below 1° . These results indicate a 1° angular resolution in Φ_c .

populations, two 200- μm bovine tendon sections prepared as above were placed partially overlapping each other in the SALS device. One specimen was rotated with respect to the other for values of the difference in preferred directions, $\Delta\Phi_c$, ranging from 0° – 90° . $I(\Phi)$ was acquired for each $\Delta\Phi_c$ value from the overlapping area of the sections using a 254- μm spaced testing rectilinear grid. Since we assumed no optical interaction between fibers, the resultant scattering pattern of the overlapping sections should be the sum of the two individual layers. To evaluate this assumption, we summed the SALS data from the individual bovine tendon sections at the same $\Delta\Phi_c$ values used in the overlapped sections to generate synthetic multiple population SALS data. Both the Φ_s and OI were computed from the synthetic data sets and compared to the actual overlapping tissue SALS measurements.

When multiple populations occurred, the gradual separation of the fiber populations becomes clearly visible in the intensity distribution curves as $\Delta\Phi_c$ increases (Fig. 4). There was also close agreement between the experimental and synthetic curves, indicating that the $I(\Phi)$ response is the algebraic sum of

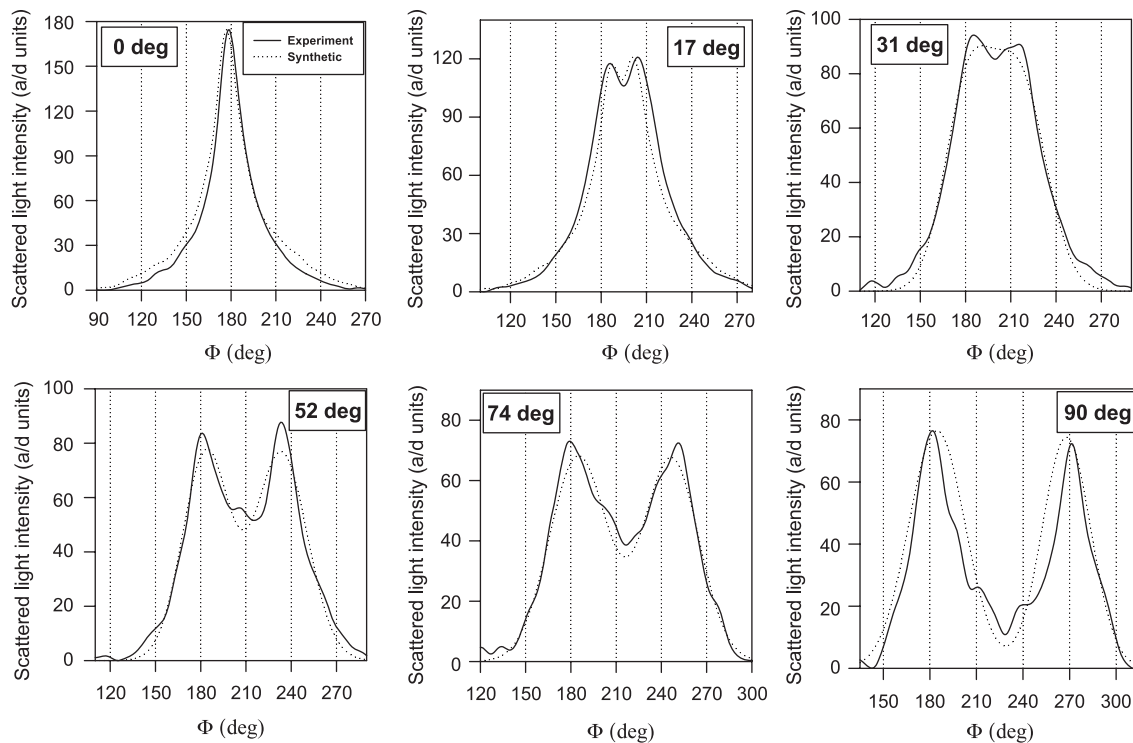

Fig. 4 $I(\Phi)$ vs. Φ data for two overlapping 200- μm bovine tendon sections rotated 0° , 17° , 31° , 52° , 74° , and 90° with respect to their preferred directions, showing both the experimentally measured and synthetically generated data. The second specimen's fiber orientation distribution can be seen to become increasingly distinct as the angle between the two specimens increases. Good agreement can be seen between the experimentally measured and synthetically generated data for all values of Φ .

Fig. 5 Comparison of the measured and synthetic SALS analysis for OI and Φ_s using the SALS data of Fig. 4 showing good agreement between experimental and synthetic data. These results indicate that the SALS device can detect multiple populations to $\sim 5^\circ$ separation in their preferred directions.

the scattered light contributions from the individual bovine tendon sections (Fig. 4). In order to determine the sensitivity of the SALS parameters (Φ_c , Φ_s , and OI) to multiple populations, the parameters were plotted against the angle between the populations $\Delta\Phi_c$ (Fig. 5). Both Φ_s and OI predictably increased at larger $\Delta\Phi_c$ values and showed close agreement between the synthetic and experimental data over the complete range of $\Delta\Phi_c$ (Fig. 5). The values for Φ_c computed from the synthetic data were within $\pm 3^\circ$ of the actual value also over the complete range of $\Delta\Phi_c$. These results indicate that the SALS device can accurately detect the presence of multiple populations when there is at least a $\sim 5^\circ$ separation in their preferred directions.

Effects of Tissue Thickness

As tissue thickness increases, multiple scattering effects caused by light rescattered by succeeding collagen fiber layers also increase, causing potential loss of structural information.^[51,53] It was previously determined using bovine tendon, a dense collagenous tissue, that thicknesses up to 400 μm do not detectably effect SALS measurements.^[31] In order to assess the effects of tissue thickness more fully, SALS data was acquired from a 19-mm \times 19-mm \times 0.7-mm thick specimen of bovine pericardium using a 2.5-mm increment grid. Next, the specimen was frozen and sectioned at 25- μm increments using a freezing microtome, with sections mounted on a glass slide. SALS data was acquired for each individual section using the same scanning grid, with care taken to ensure consistent registration of the SALS test locations for all sections. The SALS data from intact

tissue and the individual sections were then compared to determine differences in the SALS data between the individual sections and the intact, full-thickness tissue.

Results indicated that the overall fiber orientation of the bovine pericardial section changed gradually from the outer (epipericardial) to the inner (visceral) surfaces (Figs. 6a,b,c). This can be seen to occur at single test locations where the $I(\Phi)$ intensity distribution can be seen to change with thickness (Figs. 6a,b,c). Since no optical interactions between the light scattered from each fiber are assumed, the total light scattering pattern should be the algebraic sum of the contributions from each individual fiber layer. To verify this assumption, the SALS data from two locations near the center of each 25- μm section was averaged and compared with the SALS data for sections obtained before sectioning at the same location (Fig. 6d). The close agreement between the averaged and intact SALS data indicates that the SALS pattern is the algebraic sum of the contribution of each layer in the tissue and that multiple scattering effects due to tissue thickness were negligible.

A final comment on tissue thickness effects is in order. As previously mentioned, as tissue thickness increases, multiple scattering effects will tend to predominate. One of the effects of multiple scattering is the generation of a diffuse light intensity component, which produces the equivalent of a DC component in the $I(\theta)$ distribution.^[31] For highly aligned tissues (e.g., tendon), this problem can be easily circumvented by subtracting the minimum scattered light intensity from the $I(\theta)$ distribution.^[31] However, for tissues with more broad or complex fiber orientation distributions, this method could potentially remove both the diffuse light contribution and some fiber orientation information. In our extensive experience utilizing SALS for soft connective tissues, we have observed that these effects can be checked for by performing multiple-section studies as described above. Moreover, specific adjustments to the optical hardware (especially the camera light sensitivity and shutter speed) can be made using tissues with highly aligned fibers (as done using tendon in Refs. [31] and [48]) to be sure that diffuse light component is removed for the scattered light contribution without affecting fiber orientation measurements. As with any experimental measurement, it is suggested that verification studies as described above be performed for each tissue type to ensure accuracy and correct interpretation of the SALS data.

Effect of Beam Diameter on SALS Spatial Resolution

The effect of beam diameter on SALS spatial resolution was also determined using the same two bovine

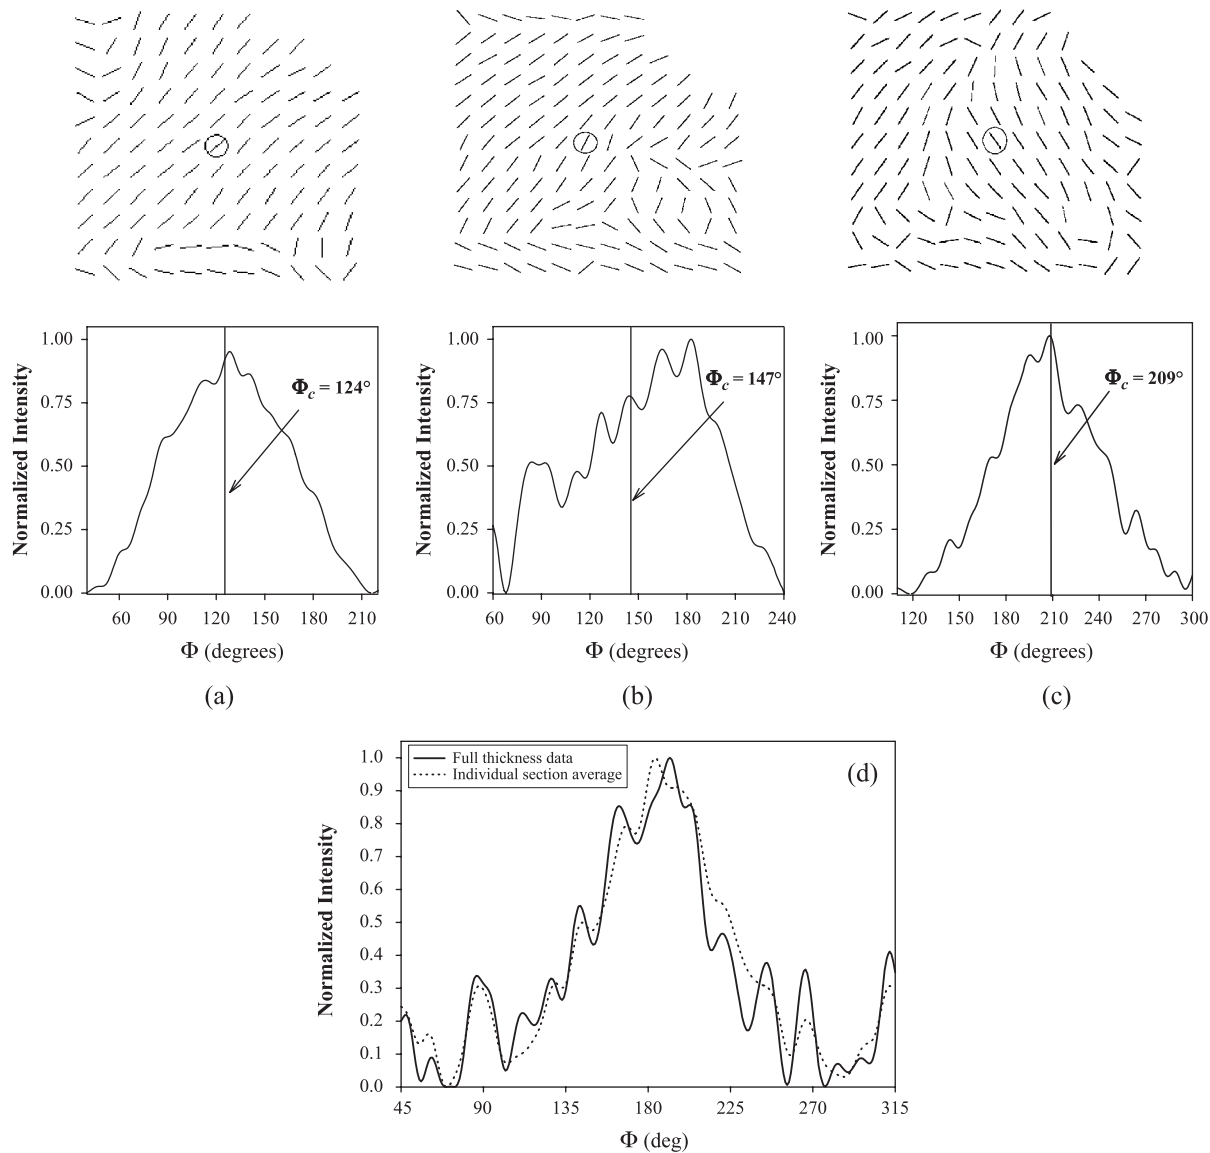

Fig. 6 Fiber preferred direction vector plots of sequential 25- μm sections taken from a single bovine pericardium specimen at depths of (a) epipericardial side, (b) 225 μm , and (c) 375 μm (visceral side). $I(\Phi)$ data from each location indicated by the circle is shown in the plots below each vector plot. (d) Averaged normalized $I(\Phi)$ data from each 25- μm bovine pericardium section shown along with the data from the intact specimen for the location indicated by the circle. The close agreement between the averaged and intact SALS data indicates that the SALS pattern is the algebraic sum of the contribution of each layer in the tissue.

pericardial sections, which were scanned using a 254- μm rectilinear grid and 100- μm , 350- μm , and 500- μm beam diameters. As beam diameter is decreased, speckle (i.e., self-interference) becomes more prominent, which appears in the SALS data as random noise that will reduce accuracy (Fig. 7). As the beam diameter increases, speckle diminishes and the scattering pattern becomes more regular. At a $1/e^2$ beam diameter of 600 μm , the least speckle was observed. In our experience with dense collagenous tissues, the best data is obtained with a beam diameter of at least 250 μm .

However, increasing beam diameter will reduce spatial resolution by averaging SALS results over larger tissue areas. In our 1997 paper, it was determined that the SALS device can distinguish tissue structures to an effective spatial resolution of $\pm 254 \mu\text{m}$ with a 600- μm $1/e^2$ beam diameter.^[48] Subsequent improvements to the spatial filter/beam expander have indicated that when using a beam diameter of at least 250 μm , an equivalent spatial resolution of 250 μm is obtained. Overall, a general rule of thumb is that distance between scans should not be less than the $1/e^2$ beam diameter.

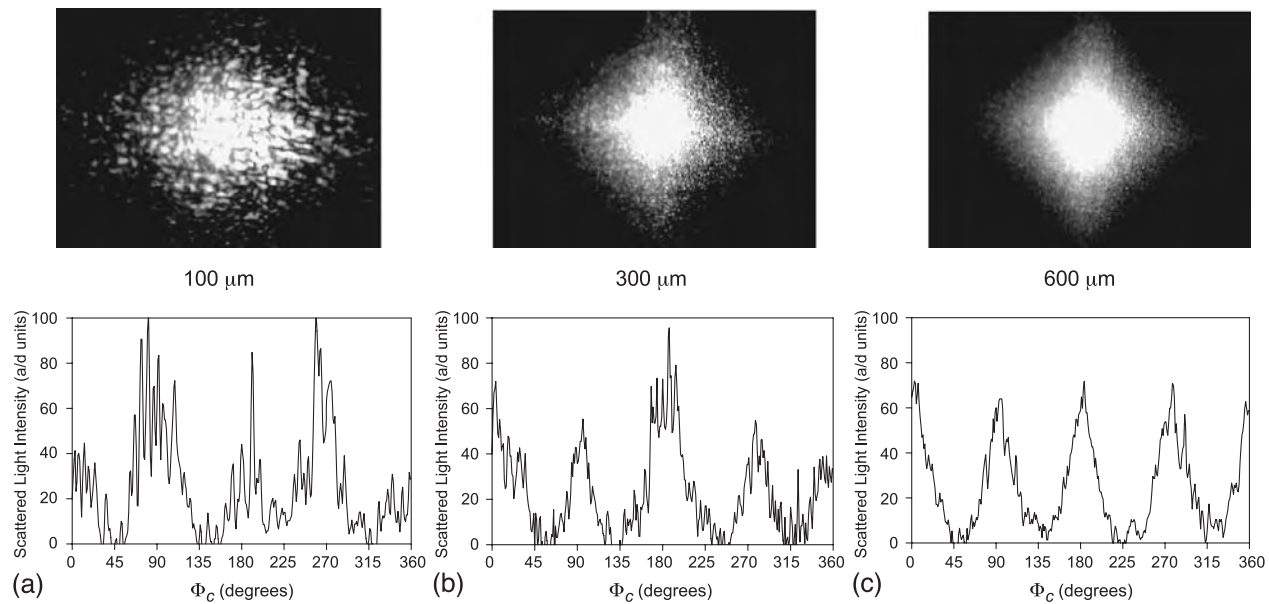

Fig. 7 Effects of laser beam diameter on the $I(\Phi)$ vs. Φ data for (a) 100 μm , (b) 350 μm , and (c) 600 μm $1/e^2$ beam diameters using two overlapping 200- μm bovine tendon sections rotated 90° with respect their preferred directions. For the 100- μm beam diameter, speckle interference noticeably degraded the $I(\Phi)$ data.

Effects of Fiber Diameter and Interfiber Spacings

As stated above, it is assumed that the fiber diameter distribution is *independent* of fiber orientation Φ . As long as this assumption is true, the angular distribution of scattered light intensity accurately represents the angular distribution of fiber orientations. Based on Fraunhofer diffraction theory (Eq. 1), larger fibers tend to scatter light closer to the beam axis and smaller fibers farther out. Thus if the fiber diameter distribution was a function of Φ , then the $I(\Phi)$ data would tend to change with θ . We examined the $I(\Phi)$ data, normalized to account for the decrease in absolute scattered light intensity for $2^\circ \leq \theta \leq 7^\circ$, to validate this assumption for bovine pericardium and porcine aortic valve leaflets. Both tissue types demonstrated no detectable change in the $I(\Phi)$ intensity distribution for all values of θ , indicating that $I(\Phi)$ is independent of fiber diameter and interfiber spacing for these tissues, *so that the fiber diameter distribution does not affect their fiber orientation measurements*. This result is consistent with the fiber morphology of these tissues, which does not indicate that the collagen bundle diameters are a function of their orientation.^[31] We have observed this same behavior in all tissues we have encountered.

Effects of Collagen Crimp

Application of SALS in determining the fiber architecture in collagenous tissues is complicated by the

presence of fiber crimp. To help clarify exactly how crimp can affect the SALS data, the following graphical explanation is presented. Consider a perfectly straight fiber with no crimping. The resulting $R(\theta)$ will be a nearly perfect intensity spike (Fig. 8a). For a crimped fiber, each segment of the fiber will scatter light according to its local orientation with respect to the overall fiber axis (Fig. 8b). Similar to a

Fig. 8 (a) Representation of a crimped collagen fiber along with its fiber axis and corresponding $R(\theta)$. (b) Same fiber shown in its stretched state with its corresponding $R(\theta)$. The small boxes outline the conceptual linear segments that make up the fiber and add to the total $R(\theta)$.

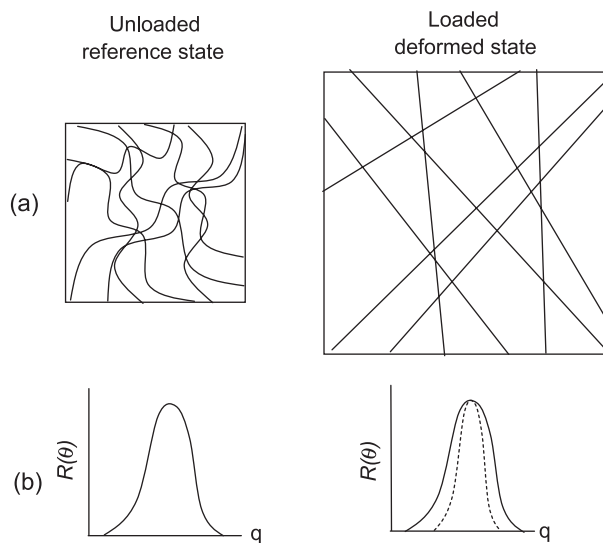

Fig. 9 (a) A schematic showing the fiber network in the reference (left) and equibiaxially deformed (right) states, where there is no fiber rotation. The corresponding $R(\theta)$ for both states is shown in (b). In the situation shown here, the uncrimping of the fibers causes $R(\theta)$ to narrow [dotted distribution shown in rightmost $R(\theta)$ plot in (b)]. When uncrimping does not affect the SALS data, then no changes in $R(\theta)$ will occur.

single fiber, the effect of crimp on a fiber network is to broaden $R(\theta)$ (Figs. 9 and 10). However, when a tissue is subjected to equibiaxial strain (i.e., same strain in both directions), the constituent fibers will stretch but not rotate. Thus, equibiaxial strain offers a straightforward method to assess the effects of fiber crimp on the accuracy of $R(\theta)$. This is shown graphically in Fig. 10a, where fibers in the unloaded reference state are crimped, and then subjected to equibiaxial strain to the point where the crimp has been removed in the deformed state. Here, if crimp affected the SALS data, its effect would be to broaden $R(\theta)$.

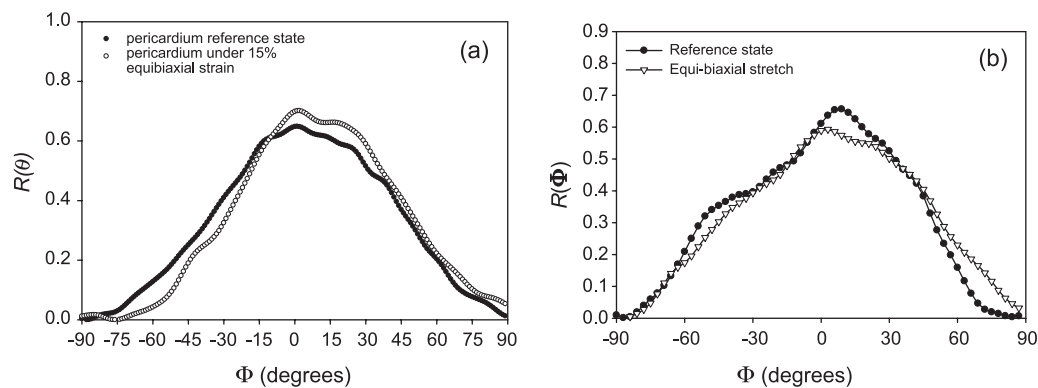

Fig. 10 Changes in $R(\theta)$ under equibiaxial strain for (a) bovine pericardium and (b) small intestinal submucosa. For both tissues, no detectable changes in $R(\theta)$ were observed, indicating that collagen fiber crimp did not affect the accuracy of the SALS measurements.

Interestingly, we have observed no change in $R(\theta)$ in either porcine intestinal submucosa^[38] or bovine pericardium^[46] (Fig. 10). This result is most likely due to the fact that the collagen crimp amplitude is small compared to the overall fiber architecture and tissue dimensions. That is, given the very large number of fibers through a typical thickness of $\sim 400\ \mu\text{m}$ (resulting in ~ 800 – 1000 fibers through thickness) and that the variations in fiber orientations are large with respect to dispersion due to crimp, crimp effects tend to be averaged out.

Maps of Collagen Fiber Architecture

One of the main advantages of SALS is the ability to produce fiber architectural maps rapidly to exact anatomical scale. An example of this is presented for the aortic valve in Fig. 11. Here, fiber-preferred directions can be seen to course smoothly along the circumferential direction in both valves, although the preferred directions are more ordered in the valve leaflet fixed at 4-mmHg transvalvular pressure (Fig. 11c,d). However, there was a dramatic change in OI with only a 4-mmHg pressure change, demonstrating substantial mobility of the fiber network in the PAV at low transvalvular pressures. The nodulii of Aranti can be seen as a more randomly oriented region, and the free edge is clearly delineated in both leaflets as a band of highly oriented fibers along the upper leaflet boundary.

APPLICATION TO ENGINEERED TISSUES

In addition to the analysis of native tissue, SALS can also be useful in the development of engineered tissues. An example of this is a study performed in our lab on DermagraftTM (Advanced Tissue Sciences, La Jolla, CA),

Fig. 11 Two PAV leaflets fixed at (a) 0 mmHg and (b) 4 mmHg. Each leaflet was SALS tested using a 254- μm spaced rectilinear grid. The corresponding Φ_c data are shown for each valve as vector plots superposed over color fringe of the OI for (c) 0 mmHg and (d) 4 mmHg, with vector data shown for every third test location for clarity. Note the dramatic change in OI with only a 4-mmHg pressure change, demonstrating substantial mobility of the fiber network at low transvalvular pressures.

which consists of human neonatal dermal fibroblasts grown on a woven mesh of biodegradable polyglycolic acid/polylactic acid copolymer. As the fibroblasts proliferate throughout the mesh scaffolding, they secrete collagen and other human dermal matrix proteins to produce a living dermal tissue.^[36]

Experimental details have been previously presented.^[36] Briefly, SALS studies were performed on five 102-mm \times 152-mm Dermagraft specimens taken from the same cell line and production run, stored at -80°C , and then thawed. Light scattering by the collagen fiber specimens was enhanced using Picro-sirius red collagen stain. Unlike native tissues, Dermagraft SALS signal contains contributions from both the collagen and scaffold fibers. The scaffold used to fabricate Dermagraft is a structurally regular woven fabric (Fig. 12, left), which produces a unique SALS pattern with four peaks corresponding to each of the four sides (Fig. 12, right).

Assuming the fiber orientation contributions from each of the four mesh sides and collagen fibers to be Gaussian distributed, and that the principle of optical superposition applies, the total scattered light intensity distribution $I(\Phi)$ can be represented as

$$I(\Phi) = c \sum_{i=1}^4 \left\{ I_p(i) \exp \left(- \left(\frac{\Phi - \Phi_p(i)}{\sigma(i)} \right)^2 \right) \right\} + I_p(5) \exp \left(- \left(\frac{\Phi - \Phi_p(5)}{\sigma(5)} \right)^2 \right) \quad (4)$$

where for the i th Gaussian population $I_p(i)$ is the peak intensity, $\Phi_p(i)$ is the direction of preferred orientation, $\sigma(i)$ the Gaussian population variance, and c a constant required to compensate for the lower light scattering power (i.e., the ratio of incident light over the scattered light) of the mesh fibers. The second term on the right-hand side of Eq. 4 is the fifth Gaussian population representing the collagen component of the SALS signal, from which the local collagen fiber orientations can be obtained.

To obtain the Gaussian fit parameters for the untreated mesh, SALS data from 50 randomly chosen locations from 10 untreated mesh specimens were averaged together. At each angular position Φ , the resulting mean $I(\Phi)$ data was fit to Eq. 4, using the Levenberg–Marquardt algorithm,^[54] with the collagen parameters temporarily removed from the fit equation and c forced to unity. This allowed us to model accurately ($r^2=0.98$) the untreated mesh SALS signal (Fig. 11b), and the fitted parameters were then used in the complete form of Eq. 4.

Equation 4 fitted the Dermagraft SALS signal well ($r^2>0.95$), revealing the collagen population to be the main contributor to the SALS signal (Fig. 11b). The fitted mesh opening side angles (Φ_p) had similar mean values with small standard errors between specimens, as well as comparable mesh vertex angles $\Delta\Phi$ computed by subtracting the two side angles at each vertex. Thus, mesh distortions during specimen processing were small. Results from Eq. 4 showed that the collagen $\Phi_p \approx 90^\circ$ (Fig. 12, left), indicating that the Dermagraft collagen fibers have a preferred direction

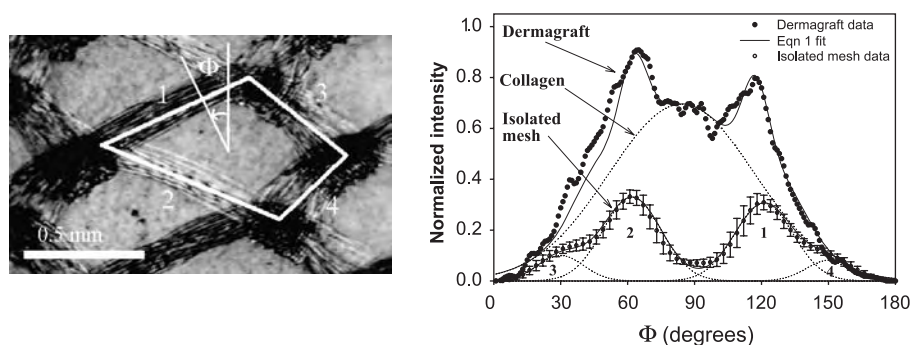

Fig. 12 (left) Photomicrograph of Dermagraft showing a kite-shaped idealization of the mesh openings, (right) an example of Eq. 4 to fit the SALS data for Dermagraft. Intensity values have been normalized to range from 0 to 1 to demonstrate more clearly that collagen was the largest contributor to the Dermagraft SALS signal. The numbers within each untreated mesh Gaussian population indicate the corresponding mesh opening side of the left image.

nearly parallel to the long dimension of the kite-shaped scaffold opening. This study demonstrated the utility of SALS as a rapid and inexpensive technique for the evaluation of gross collagen fiber architecture in engineered tissues.

SUMMARY

This chapter demonstrated that the SALS technique lends itself to rapid analysis of large areas of tissue without the need for expensive equipment and time-consuming tissue preparations. The present device provides high resolution information on local fiber orientation to an angular resolution of $\sim 1^\circ$ and a minimum recommend spatial resolution equal to the minimum $1/e^2$ beam diameter of $250\ \mu\text{m}$. Another important aspect of SALS demonstrated in this study is that the distribution of scattered intensity represents the algebraic sum of the contributions from each tissue layer. Thus, SALS measurements represent the total structure of the tissue throughout its thickness, with each layer contributing in proportion of its thickness to the total thickness. Overall, the SALS technique lends itself to the study of a wide range of soft tissue structures in health and disease.

ACKNOWLEDGMENTS

The generous support of the A.W. Ford Foundation for funding the construction of the SALS instrumentation, the American Heart Association (National, Florida, and Pennsylvania-Delaware affiliates), and the National Institutes of Health/NHLBI is gratefully acknowledged. The author would like to thank Dr. Paul L. Kronick of the USDA-ERRC (Philadelphia, PA) for introducing him to the use of SALS as a method for connective tissue structural analysis. The

author is also indebted to Drs. David B. Smith and Kristen L. Billiar, as well as Mr. Jonathan Grashow for their invaluable assistance in the SALS device design and fabrication and the development of sophisticated control and analysis software. MSS is an Established Investigator of the American Heart Association.

Spine Biomechanics

Clayton Adam

Pediatric Spine Research Group, School of Engineering Systems, Queensland University of Technology, Brisbane, Queensland, Australia

INTRODUCTION

Spine biomechanics is the study of stability, motion, and deformation in the human spine, generated by both internal and external forces acting on and through spinal connective tissues. The primary aim in studying spine biomechanics is to understand the underlying mechanical aspects of various spinal disorders and their clinical treatments, so that adverse outcomes can be avoided and optimal prevention or treatment strategies can be developed.

Theoretical tools used in the study of spine biomechanics include the equations of Newtonian mechanics and mathematical principles from continuum mechanics, porous media mechanics, fracture mechanics, and numerical analysis. Computational mechanics techniques, in particular the finite element method, have been widely applied to the analysis of spinal problems owing to their ability to solve previously intractable governing differential equations for complex three-dimensional shapes, time-varying forces, and nonlinear materials. The validation and application of theories have been accompanied by *in vitro* tests of both animal and human spines to determine stiffness, strength, strain, and failure loads of spinal segments and surgical implants. To a lesser extent, *in vivo* instrumentation has been used to measure strains and pressures in the spine during daily activities. Finally, medical imaging technologies such as biplanar radiography, computed tomography, and magnetic resonance imaging have allowed three-dimensional imaging of the spine for accurate assessment of both anatomy and kinematics.

For the purposes of this article, three categories of spinal disorder have been chosen: 1) intervertebral disc (IVD) degeneration; 2) spinal fractures; and 3) spinal deformity. To better understand the mechanics of the pathological spine, it is also important to study the behavior of the healthy spine; therefore the kinematics and kinetics of the healthy spine are discussed first, followed by a summary of tissue mechanical properties (stiffness and strength). The subsequent sections describe biomechanical aspects of pathology and treatment for each category mentioned above. Finally, a brief overview of likely future developments in the field is given. Owing to the breadth of the field, it is not

possible to mention every avenue of biomechanical investigation being undertaken in the spine, or even all the major ones. Notable areas not discussed in this article include biomechanics of the ribcage and sternum (which have a significant stiffening effect on the thoracic spine), biofluid mechanics of cerebrospinal fluid, spinal cord rheology, and tissue mechanics at the cellular level. The article assumes a basic knowledge of spinal anatomy and some understanding of the mechanical concepts of force, moment, stiffness, strength, pressure, stress, and strain.

THE HEALTHY SPINE

Kinematics

Spinal kinematics is the study of spinal movement, without reference to the forces producing the motion. The healthy human spine provides a central, flexible support structure to the rest of the body, and the complex spinal motions occurring during everyday activity can be considered in terms of primary motions in each of three orthogonal planes: midsagittal, coronal, and axial. In the midsagittal plane, spinal flexibility is asymmetric about the neutral standing position, with substantial forward flexion possible, but limited backward extension owing to the semirigid constraint of the zygapophyseal (facet) joints. Ranges of motion for both lateral bending and axial rotation are approximately the same on left and right sides.

When considering spinal motions, the vertebrae are rigid to a first approximation so that overall movement can be described in terms of the response of individual “motion segments” (also referred to as a functional spinal unit), each comprising two vertebrae connected by an IVD and the posterior complex of zygapophyseal joints, ligaments, and thoracolumbar fascia. For a single motion segment, movements in a particular plane can be described in terms of rigid-body translations and rotations of one vertebra relative to the other. The rotation component occurs about an instantaneous axis of rotation (IAR). The IAR locations have been extensively studied because shifts in the IAR can indicate abnormal kinematics.^[1] For example, variations in IAR position during spinal movement

have been used as indicators of spondylolysis and have been shown to correlate with spinal pain.^[2]

Fig. 1 shows IAR locations for the cervical, thoracic, and lumbar spines.^[1] As suggested by its name, the IAR is not stationary, but translates during motion with the locus of IAR points traced by a particular overall movement referred to as a centrode. The polycentric behavior of spinal motion segments has important implications for the design of total disc

replacement (TDR) devices. Approximate ranges of motion per segment in combined flexion/extension are 10–20° in the cervical spine, 4–6° in the upper thoracic spine, 9–12° in the lower thoracic spine, and 12–17° in the lumbar spine. For lateral bending to one side only, ranges of motion are 4–11° in the cervical spine, 5–9° in the thoracic spine, and 3–8° in the lumbar spine. For axial rotation to one side only, ranges of motion are 2–7° in the cervical spine, 2–9° in the thoracic spine, and 1–2° in the lumbar spine.

Spinal movements during everyday activities are complex combinations of primary motions in the sagittal, coronal, and axial planes. However, spinal kinematics cannot simply be considered in terms of superposition of independent primary motions, as the anatomy of the spinal joint leads to coupling between different degrees of freedom of a motion segment. For example, lateral bend and axial rotation, flexion and lateral bend, and flexion and axial rotation are all strongly coupled in the lumbar spine.^[3]

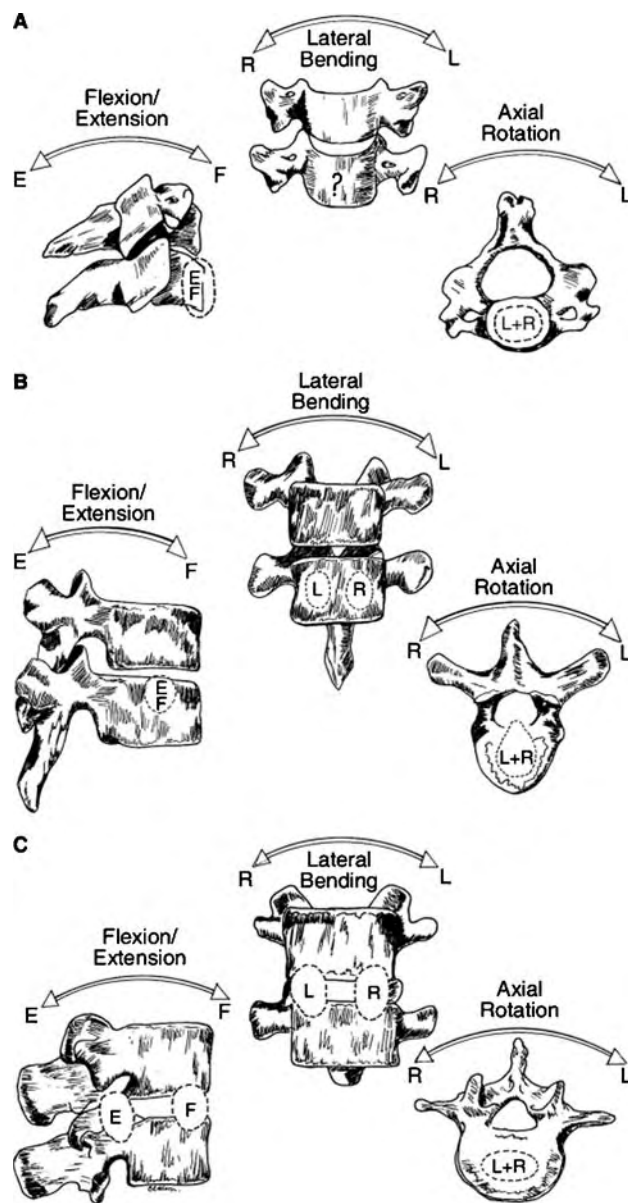

Fig. 1 IAR locations for the (A) cervical, (B) thoracic, and (C) lumbar spines for combined flexion (F)/extension (E), left (L) and right (R) lateral bending, and left and right axial rotation. (Adapted from White, A.A., III; Panjabi, M.M. Spinal kinematics. The research status of spinal manipulative therapy. NINCDS Monograph [No.15], US Department of Health, Education and Welfare: Washington, DC, 1975; 93.)

Kinetics

Spinal kinetics is the study of the forces and moments acting on the spine to either stabilize or generate motion. The earliest quantitative studies of compressive forces acting in the spine were disc pressure measurements performed by Nachemson,^[4] in which a pressure-sensing needle was inserted into the IVDs of volunteers, and the pressures generated in the nucleus pulposus during everyday tasks were measured. During relaxed standing, the compressive force at the base of the spine is equal to approximately 70% of bodyweight. Reclining reduces this pressure by 50–80%, unsupported sitting increases it by 40%, and combined forward flexion/rotation while holding a 10 kg weight increases disc pressures by 400%.

Muscle force measurements are important in static and dynamic analysis of the spine, allowing estimation of the internal forces and moments acting on passive osseoligamentous structures and the resulting tissue level stresses and strains. Muscle forces acting on the spine have been estimated via electromyography (EMG) and using mathematical models. The EMG measurements provide information on muscle activation levels during various tasks and, when combined with knowledge of muscle cross-sectional areas, can be used to infer muscle forces. The EMG measurements of the back muscles are complicated by the complexity of muscular anatomy near the spine, uncertainties in muscle cross-sectional area, and nonstraight lines of action for muscles that contact other structures between their attachment points. In recent years, magnetic resonance imaging has allowed more accurate determination of muscle cross-sectional areas, and

mathematical trunk models have incorporated more realistic muscular lines of action.

The first three-dimensional mathematical model for the whole trunk was developed by Schultz et al.,^[5] and included the rectus abdominus, oblique internus and externus, erector spinae, and latissimus dorsi muscles. Subsequent models have included dynamic (inertial) effects, lumped parameter representations of discs, ligaments, and facets, and more detailed muscle fascicle representations.^[6] Trunk models including muscles are usually statically indeterminate for a given posture, and therefore require the assumption of some muscle activation strategy (e.g., minimizing the sum of cubed muscle stresses) for solution.^[7] Dynamic activities result in higher spinal loads than static lifting,^[8] and intra-abdominal pressures do not appear to contribute substantially during dynamic lifting tasks.

Tissue Stiffness and Strength

Spinal soft tissues undergo large deformations. Pearcy and Tibrewal^[9] measured disc deformations of 35% for anterior compression and 60% for posterior extension under flexion/extension movements. They also reported a 370% increase in interspinous distance for the same motion.

The ability of spinal structures to withstand internally and externally applied forces is expressed in terms of *stiffness* (force per unit displacement) and *strength* (force required to produce failure). The stiffness and strength of ligaments, discs, and vertebrae depend, in turn, on the mechanical (stress vs. strain) properties and architecture of their constituent soft and bony tissues. In analytical and numerical studies of spine biomechanics, tissue stress-strain response is

often assumed to be linear. Although this may be a reasonable assumption for small incremental deformations, tissue material properties are generally nonlinear, exhibiting viscoelasticity, creep, hysteresis, and plasticity (permanent deformation on overloading). The nonlinear behavior of ligaments and IVDs is especially important owing to the large strains encountered in these tissues, and hyperelastic constitutive models have been developed for the annulus fibrosus.^[10] Tissue material properties are also generally anisotropic and inhomogeneous, although the common assumptions of isotropy and homogeneity in finite element studies of the spine can be somewhat justified by the need to obtain solutions for stress and strain in tissues within computing power constraints, and the fact that spinal loading for a particular structure is often predominantly unidirectional.

The stiffness and strength of spinal tissues has been assessed in numerous studies, both by direct (force vs. displacement) and by indirect experimental techniques such as indentation and ultrasound. Combined microcomputed tomography and voxel-based finite element techniques have also been used to accurately determine the stiffness and strength of vertebral trabecular bone for particular specimen architectures.^[11] Table 1 presents some of the material properties that have been used in mathematical models of spinal tissue behavior. Interspecimen variability as well as differences in testing methodology can lead to substantial ranges in reported mechanical properties between studies. For example, Adams and Dolan^[16] report a compressive strength range for the human lumbar vertebral body between 2 and 14 kN.

In addition to individual tissue properties, measurements of the stiffness of whole motion segments have been made.^[17] Some in vitro experiments on

Table 1 Summary of material properties used in mathematical models of spinal tissue behavior

Structure	Material Properties	References
Anterior longitudinal ligament	$E = 20 \text{ MPa}$, $\nu = 0.3$	[12]
Posterior longitudinal ligament	$E = 70 \text{ MPa}$, $\nu = 0.3$	[12]

whole motion segments have suggested the existence of a “neutral zone,” defined as a region of little or no resistance to motion in the middle of an intervertebral joints’ range of movement. However, the neutral zone does not appear to exist in all planes.^[18] Spinal joint stiffness increases rapidly near the anatomically imposed limits of movement, and the high forces required to flex motion segments beyond these limits lead to damage of the connective tissues (facet joints, discs, and ligaments).

BIOMECHANICS OF DISC DEGENERATION

The IVDs are the largest avascular structures in the body, withstanding high static and dynamic compressive and shear forces, particularly in the lumbar spine. The biomechanics of IVD degeneration in the lumbar spine has received much attention because of the great economic and social importance of lower back pain.

A number of studies have shown strong correlations between disc degeneration and back pain, and several mechanisms have been postulated for this connection; loss of hydrostatic pressure owing to a reduction in proteoglycan content of the disc may encourage nerve ingrowth,^[16] altered stress distributions owing to loss of disc height may exert additional force on facet joints and sensitive surrounding tissues causing pain,^[16,19] and disc prolapse may exert direct pressure on the spinal cord and nerve roots. Fig. 2 shows the clear structural differences between healthy and degenerate discs.

The structural characteristics of disc degeneration include loss of disc height, the presence of radial, concentric, or rim lesions in the annulus fibrosus, and prolapse of the nucleus pulposus. Disc prolapse is associated with disc height reduction, and loss of disc height following prolapse has been shown to continue even after surgical intervention.^[20] Loss of mechanical integrity in lumbar IVDs subjected to anterior shear forces (primarily L4-L5 and L5-S1) can lead to instability and spondylolisthesis (anterior slip of one vertebra relative to the inferior adjacent vertebra).

The causes of disc degeneration are not well understood, although biochemical, genetic, and mechanical factors are all likely to contribute. Owing to the lack of blood supply, adequate nutrient flow through the vertebral endplates into the disc is important for maintenance of healthy IVDs. Although some authors have suggested that convective nutrient transport owing to cyclic mechanical loading is important, nutrient flow into the disc appears to be predominantly diffusion driven.^[21] If current levels of nutrient demand within the disc cannot be met because of occlusion of pores in the osseous vertebral endplate or inadequate diffusion rates, cellular matrix degradation

Fig. 2 Axial sections showing (A) healthy and (B) degenerate lumbar IVDs. (Photo courtesy of Professor N. Fazzalari.)

leading to localized tissue damage and annular lesions will result. Studies using progressive dissection of annular fiber layers or artificially induced lesions have reported the loss in overall disc stiffness and strength associated with a particular level of mechanical damage.^[22] Owing to the impracticability of direct measurement, finite element studies have been used to infer stress and strain levels in the disc. Under direct compression, the inner annulus appears most highly stressed;^[23,24] however maximum stresses occurring at the outer annulus have been reported for torsional loading.^[25] Existing studies show no clear consensus on the link between predicted annular stresses and the location of clinically observed disc lesions (which often occur in the posterolateral annulus).

Spinal Fusion

Spinal fusion is currently the primary surgical intervention for pain and instability associated with

end-stage disc degeneration. Fusion constructs are required to impart stability and limit relative motion between the vertebrae to be fused. A range of surgical techniques, as well as numerous different implant designs are used; however some general biomechanical principles apply in the successful creation of a surgical construct that can withstand spinal loads in the three to six months required for bony fusion to occur.

Interbody fusion constructs are susceptible to subsidence failure, in which the graft or implant penetrates into the vertebral body, causing a loss of disc space height and kyphosis at the fused level. Pearcy, Evans, and O'Brien^[26] have shown that to avoid endplate subsidence with rectangular autograft spacers, the area of the graft spacers needs to cover at least 40% of the total endplate area. More recent finite element studies of interbody fusion mechanics^[27] have predicted stress levels owing to contact between interbody implants and the vertebral body (Fig. 3). Although the stiffness and strength of the implant material is clearly an important consideration in interbody implant design, the notion that matching implant elastic modulus to that of cortical bone will result in an optimal load transfer is incorrect. Rather, the contact stress distribution between an implant and its adjacent vertebral endplate is dependent on the initial shapes and the respective bending stiffnesses (EI , where E is the modulus of elasticity and I is the second moment of area of the member cross section) of the two structures.

For posterior rod fusion constructs, stiffness and strength can be analyzed using structural mechanics techniques.^[28] Rod diameter is usually the primary factor affecting construct stiffness and strength, because maximum bending and torsional stress in a rod of circular cross section vary with the inverse cube of rod diameter.

Fig. 3 Predicted von Mises stress (in Pascals) for finite element simulation of an interbody fusion implant contacting a vertebral body with applied compressive force of 610 N to simulate relaxed standing. (From Ref. [27].)

Performing a spinal fusion in either the cervical or lumbar spine not only effectively eliminates motion at the segment in question, but also affects the biomechanics of the surrounding spinal structures. In particular, spinal fusion may place increased mechanical demands on the adjacent IVDs, leading to accelerated degeneration at these levels, which eventually requires further intervention. Although reported incidence levels vary, so-called adjacent segment disease^[29] is widely regarded to be a largely unavoidable consequence of eliminating relative motion at one segment of a multijointed system.

Disc Arthroplasty

A current field of intense interest in spine biomechanics is the area of disc arthroplasty, or replacement of an entire IVD with an artificial joint that maintains mobility at the operated level. As previously discussed, the spinal motion segment is a complex joint, and current implant designs can only reproduce some aspects of the original joint's kinematics. Very little systematic investigation of the biomechanics of disc arthroplasty has been undertaken to date; however one recent study suggests that less-constrained implant designs allow a greater range of motion, are less sensitive to positioning inaccuracies during surgery, and apply less abnormal loading to facet joints than designs that constrain rotation about a single fixed point.^[30] Several longer term studies have shown that the motion permitted by TDR implants decreases over time, eventually becoming "kinematically equivalent to a fusion" in a significant proportion of TDRs.^[31] Whether or not disc arthroplasty avoids the adjacent segment degeneration associated with disc arthrodesis is unknown at this stage.^[32]

BIOMECHANICS OF SPINAL FRACTURES

Spinal fractures can occur either when the spine is subjected to a single traumatic loading event, or when repeated loading causes an accumulation of damage at a faster rate than at which the bone tissue can heal itself. The latter case refers to "stress fractures," which are often associated with certain repetitive occupational or sporting activities.

Damage of vertebral trabecular bone in the form of trabecular microfractures is most likely a normal physiological occurrence, and healing microcracks appear to be part of the bone modeling and remodeling process. However, when the spine is subjected to loads significantly higher than those encountered during normal activity, gross fractures can occur. Under large compressive loads, the vertebral endplates are

particularly susceptible to fractures, leading to cracking, fragmentation, and disc protrusion into the vertebral body. Endplate fractures are often undetectable on radiographs, and are a common feature of moderate energy impacts (e.g., ejection seat injuries).

Vertebral burst fractures are associated with high energy impacts such as falls and motor vehicle accidents, in which high internal fluid pressures “burst” the vertebral body, comminuting vertebral bone and causing retropulsion of bony fragments into the neural canal. Experimental attempts to simulate burst fracture in the laboratory are characterized by significant variability, although for younger spines with healthy IVDs the sequence of events seems to begin with fracture of the vertebral endplate under high intradiscal pressures, followed by herniation of the nucleus pulposus into the vertebral body, vertebral fracture, and fragment expulsion. Biomechanical investigations using strain-gauged cadaveric motion segments have indicated that facet joint loading also plays an important role in burst fracture mechanics,^[33] and that sagittal orientation (flexed, neutral or extended) affects resulting fracture patterns. Specimens tested in extension exhibit more severe fracture characteristics. In vitro experiments have also shown that burst fractures tend not to occur in the presence of preexisting disc degeneration and osteoporosis, suggesting that the elderly are prone to compression rather than burst fractures. The isolated vertebral body collapse in osteoporotic compression fractures carries less risk of bone fragment retropulsion and spinal cord damage.^[34] Metastatically involved vertebrae are at particular risk of burst fracture, and a recent experimental and finite element investigation concluded that tumor size was the principal risk factor for burst fracture initiation, followed by loading magnitude and bone density.^[35]

Other spinal fractures can occur owing to repetitive overuse, particularly in the case of nonconditioned individuals where bone microarchitecture has not had the opportunity to adapt to newly imposed repetitive loads.^[36] Stress fractures in butterfly swimmers and cricket fast bowlers are two examples of fatigue damage occurring because of microcrack coalescence over a period of extended cyclic overloading. Principles of linear elastic fracture mechanics have been applied to study fatigue crack growth in both trabecular and cortical bone, with Nalla et al.^[37] finding that the Paris law applied well to bone

$$\frac{da}{dN} = C(\Delta K)^m$$

where da/dN is the crack growth rate per cycle, C is a constant, ΔK is the alternating stress intensity factor, and m is the Paris law exponent, ranging between 4.4 and 9.5 for human cortical bone.

One of the most common age-related degenerative skeletal pathologies is osteoporosis, in which vertebral trabecular bone loss can eventually lead to vertebral compression fractures in both the thoracic and lumbar spine. Studies of vertebral load distribution have shown that in a healthy vertebral body, between 35% and 55% of vertical compressive load is carried by the trabecular bone. The loss of trabecular bone will therefore have major effects on vertebral load-bearing ability. Osteoporosis is characterized by both reduction in trabecular strut diameter and loss of struts. Structurally, loss of struts has a much more significant effect on the reduction of overall bone stiffness and strength, with Silva and Gibson^[38] reporting a 70% reduction in strength owing to a 10% decrease in bone volume by strut removal, vs. only a 20% decrease in strength for the same decrease in bone volume owing to strut thinning.

Vertebral compression fractures are commonly treated by injection of polymethylmethacrylate cements (vertebroplasty). Cement injection may be preceded by inflation of a compliant balloon in the collapsed vertebra to restore height (kyphoplasty). In vitro and computational studies of the biomechanics of vertebroplasty have concluded that while vertebroplasty can restore vertebral height and reduce the likelihood of subsequent fracture at the treated level, the high stiffness of the augmented vertebra exerts increased stresses on neighboring structures, with greater risk of damage to adjacent vertebral bodies.^[39]

BIOMECHANICS OF SPINAL DEFORMITY

Spinal deformities such as scoliosis and hyperkyphosis can be caused by a range of factors including congenital malformation, disease, neoplasm, and neuromuscular disorders, or as a secondary biomechanical manifestation of some other cause such as osteoporotic compression fractures or leg length inequality. However, the majority (70%) of spinal deformities are classified as idiopathic scoliosis.

There is still much debate regarding the etiology of “idiopathic” scoliosis, and although a number of promising hypotheses are currently being investigated as to the causes of the initial abnormal growth, there is general consensus that progression (worsening of the abnormal curve) in scoliosis is primarily a biomechanical phenomenon. The laterally curved spine leads to abnormal loading under body weight and muscle forces, and this abnormal loading causes further asymmetrical bone growth, which then worsens the deformity—an unstable “vicious cycle.”^[40]

One biomechanical theory for the initiation of scoliosis is the anterior overgrowth hypothesis,^[41] in which the anterior (vertebral) column of the spine

grows faster than the posterior column, generating internal compression in the vertebral column owing to the restraint of the posterior joint complex, and eventually leading to buckling of the entire spinal column in its least stable plane—the coronal plane. Numerous authors have made reference to the Euler equation of column buckling to describe the onset of scoliotic deformity, and Ogilvie^[42] has pointed out that girls with idiopathic scoliosis tend to have longer, more slender spinal columns, which would be conducive to buckling according to Euler's equation

$$P_{cr} = K \frac{EI}{L^2}$$

Where P_{cr} is the critical buckling load for the column, K is a constant dependent on the constraint conditions at the ends of the column, E is the modulus of elasticity of the column material, I is the second moment of area of the column cross section (with the term EI representing the bending stiffness of the column), and L is the effective length of the column. Although it may be conceptually useful, the Euler buckling equation is only valid for idealized geometry, loading conditions, and isotropic linear elastic material properties, and thus cannot be used in a quantitative sense in the study of spinal deformity.

Recent animal experiments by Stokes using in vivo rat and calf tail models have shown that the rate of vertebral growth is strongly dependent on applied load, with growth being accelerated by up to 30% above controls with a 0.1 MPa tensile stress, and growth reduced by 40–50% relative to controls with 0.2 MPa compressive stress. These results provide significant insight into the mechanical modulation of vertebral growth by endochondral ossification, because the wedge-shaped growth of vertebrae in progressive scoliosis can be predicted by models that account for the compressive pressure dependence of bone growth.^[40] Modulation of growth by mechanical forces is often referred to as the Heuter-Volkman law. Several studies have used finite element techniques to implement mechanically modulated growth in three-dimensional spine models.^[43,44] Although the models are capable of predicting scoliosis progression during bone growth and remodeling, uncertainties in model parameters can overshadow model sensitivity to small initial perturbations in spinal geometry.

Treatment of spinal deformities, whether conservative or surgical, currently involves application of corrective forces to the spine in an attempt to restore normal geometry and prevent further asymmetric growth. Biomechanically, the problem of straightening a bent column can be approached by distraction (stretching), bending in the opposite direction to the deformity, or compression on the convex side of the deformity. The use of orthoses for nonsurgical treatment of scoliosis is

an example of the second method, where the brace applies a lateral corrective force at the apex of the deformity, resisted contralaterally above and below the apical level, effectively forming a three-point bending construct. The biomechanics of bracing has been investigated both by direct measurement of pressures between the brace and skin, and using numerical simulations with personalized geometry obtained from three-dimensional imaging techniques.^[45]

Surgical treatment of spinal deformities involves the use of rods, hooks, screws, and wires to straighten and stabilize the spine. Harrington distraction rods are effective at correcting large scoliotic deformities, but as the curve severity decreases, larger distraction forces are required to generate the same corrective bending moment, with associated risk of neurological deficit owing to stretching of the spinal cord and loss of sagittal plane spinal profile. The forces acting on spinal implants in vivo have been measured directly using strain gauges, and the stiffness of various implant constructs has been assessed with in vitro experiments.^[46] The stiffness of implant constructs is particularly important for correction with fusion, because relative motion between vertebrae to be fused must be limited to allow bone growth to occur.

Anterior implant systems for scoliosis correction rely primarily on tension in the implant applying compressive forces to the convex side of the vertebral column. Both cables and rods have been used in this manner, although rods are loaded in both tension and bending, therefore allowing potentially greater curve correction, albeit with greater risk of rod fracture. Fracture of anterior rods appears to be caused by pseudarthrosis (fibrous rather than bony fusion) at an attempted fusion level, such that the rod experiences high cyclic stresses and eventually fails owing to bending fatigue several years after surgery. Anterior constructs are held in place by cancellous bone screws inserted laterally through the vertebral body. The stability of these screws is related to both cancellous bone shear strength and area of screw thread in contact with the bone; thus bone density and screw diameter are the two primary determinants of bone screw pullout strength for anterior scoliosis constructs.

Posterior correction of spinal deformity involves the positioning of implants adjacent to the posterior spinal elements, attached to the laminae or pedicles with screws, hooks, and wires. Earlier posterior constructs using two longitudinal rods were improved by the addition of transverse cross-members, allowing better correction of vertebral rotation and stability in torsion. Finite element models have also been used to simulate scoliosis correction using posterior implant constructs, and the development of patient-specific computer simulations of spinal deformity correction is an area of current research activity (Fig. 4).

Fig. 4 Coronal computed tomography image of idiopathic scoliosis patient and patient-specific solid model of vertebral column geometry from T5-T11 (with anterior correction rod) for finite element simulation to predict biomechanical outcomes of corrective surgery.

CONCLUSIONS

This article has briefly summarized three of the major areas of interest in spine biomechanics; disc degeneration, spinal fractures, and spinal deformity. The kinematics, internal forces, and tissue material properties of the healthy spine were also discussed. Important biomechanical principles for spinal implant design include the need to consider joint kinematics and the alterations in load distribution and tissue level stresses that fusion constructs or enforced changes in joint kinematics will produce. The mechanics of vertebral burst and compression fractures were discussed, in particular the importance of trabecular bone in supporting spinal compressive loads, and the potential damage to adjacent vertebrae caused by compression fracture augmentation with vertebroplasty or kyphoplasty. Biomechanical hypotheses for the initiation and progression of spinal deformity were summarized, and principles of deformity correction with orthoses or corrective implants were identified. Future advances in spine biomechanics are likely to lie at the interfaces of engineering mechanics and biology, particularly in the areas of tissue engineering and mechanobiology. Further understanding of the role of mechanical forces in modulating tissue growth and remodeling will lead to improved interventions: minimally invasive and preserving normal kinematics as closely as possible. The wide use of numerical simulation in spine biomechanics will continue, with more robust algorithms and greater computing power leading to patient-specific applications of spinal finite element analysis. Finally, further advances in medical imaging technology will enhance our ability to accurately measure spinal anatomy and movement for both healthy and pathological states.

ACKNOWLEDGMENTS

The author would like to thank Professor Mark Percy, Professor John Evans, Dr Geoffrey Askin, and Mrs Maree Izatt for their contributions to this article.

S

INTRODUCTION

The words “stem cell” were once reserved for special cells that are capable of giving rise to all cells of an organism, such as embryonic stem cells, or all cells of a tissue, such as the hematopoietic stem cells. However, the classical definition of stem cell has evolved as we have learned more about cellular plasticity and discovered the presence of multipotential stem-like cells in many adult tissues. In today’s world, words such as transdifferentiation and dedifferentiation seem less like science fiction and more like real phenomena. In the past decade, we have read reports of remarkable cells from adult bone marrow and muscle able to repair damage and regenerate function in critical organs such as liver, brain, and heart.^[1–3] One study offered evidence that a single bone marrow–derived cell when transplanted into a recipient could home to a variety of tissues and differentiate into several functional cell types including liver, lung, GI tract, and skin.^[4] Likewise, researchers have demonstrated that embryonic stem cells can be expanded in vitro and differentiated into a wide variety of cell types in vitro and in vivo.^[5] Stem cells have the potential to profoundly impact the development of new therapeutics for a wide variety of human diseases. In this article, we will discuss the key properties of stem cells, as well as some potential pitfalls regarding their use in human therapeutics. Furthermore, we will provide examples and discussion of the importance of interactions between stem cells and biomaterials.

THE STEM CELL PHENOTYPE

In the broadest sense, a stem cell is a cell that is capable of self-renewal and differentiation into at least one functional cell type. If we think of stem cells existing along a continuum of plasticity, embryonic stem (ES) cells would be on one end of the spectrum, while other cells with limited differentiation potential (e.g., committed progenitors of the hematopoietic system) would be on the other end. There are some markers that have been suggested for stem cells, and these markers are routinely used as tools to selectively isolate ES cells, mesenchymal stem cells (MSCs), and hematopoietic

stem cells (HSCs). The NIH has provided an informative web publication that outlines the markers, research progress, and potential issues surrounding these specific stem cell types, as well as others (please refer to www.nih.gov/news/stemcell/scireport.htm). For a partial list of markers associated with some specific stem cells, see Table 1. Although the presence of specific markers on a particular cell may give an indication of the stem-like phenotype of a cell, it would be perhaps naïve to assume that these markers are all-encompassing or are absolutely definitive. A cell’s ability to self-renew and differentiate in vivo is a better indication of its stem-like nature than expression of specific markers in vitro.

ANALYSIS OF STEM CELLS

Classical analysis of well-characterized stem cells such as ES cells, MSCs, and HSCs usually involves detection of specific markers on the cells’ surface using a panel of antibodies and flow cytometric analysis (see Table 1 for listing of classical markers). There are many other ways in which cells that are believed to be stem-like in nature can be characterized in vitro. When normal tissues such as liver, kidney, prostate, and intestine are dissociated mechanically or enzymatically, it is possible to obtain short-term cultures of the differentiated cells of that tissue. However, establishment of cell strains or lines that can be propagated in vitro through multiple passages and for longer periods of time is difficult without genetic manipulation. In primary cultures of some tissues, such as adult rat liver, colonies of small epithelial cells will emerge as the majority of the fully differentiated cells die; these small cells can be propagated long-term in vitro but they express few markers and do not secrete albumin or have characteristics consistent with mature liver cells (hepatocytes).^[7] However, upon in vitro treatment with a potent differentiating agent (sodium butyrate) or after transplantation into the liver of syngeneic rats, the cells differentiate into functional hepatocytes.^[8] Thus, the mere fact that these cells could emerge and be propagated from a primary culture of cells from a normal adult tissue is a sign that they are self-renewing, a characteristic of

Table 1 Marker profile of embryonic stem cells (ES), hematopoietic stem cells (HSC), and mesenchymal stem cells (MSC)

Stem cell type	Putative marker profile	
	Negative	Positive
ES	SSEA-1	SSEA-3, SEA-4, TRA-1-60, TRA-1-81, Alkaline phosphatase, Oct 4, Telomerase
HSC	CD38, Thy-1 (-/low), Lin	CD34, c-kit (CD117), CD133
MSC	Lin	CD34, Sca-1, Thy-1, c-kit (CD117)

The information in this table was compiled from Ref. [6].

stem cells. The additional fact that the cells can be stimulated to differentiate into specialized cell types by changing their microenvironment in vitro and in vivo provides additional evidence of their stem-like nature. Functional analyses such as these are as critical as marker expression in evaluating the stem-like potential of a particular cell. Experiments aimed at in-vivo analysis of stem cells deserve a few words of caution. It has come to light recently that transplanted cells (usually tagged with a genetic marker such as beta galactosidase or a fluorescent protein) may fuse with host cells, creating cells that contain genetic material from both cells.^[9,10] The phenomenon of cell fusion may lead to the misinterpretation of results, as host stem cells that may have picked up the genetic tag during the fusion process can be mistaken for the transplanted cells. Ideally, the transplanted cells should be recovered from the in-vivo environment and compared genetically to a sample of the cells taken prior to transplantation; evidence of fusion, such as an increase in ploidy, could be detected. Further protection against misinterpretation of results related to transplantation of stem cells can be achieved by transplanting the cells into a disease model and looking for functional correction of the disease state rather than simple appearance of cells.

SOURCES OF STEM CELLS

Stem cells have been isolated from embryonic tissues and from a variety of adult tissues, including blood, bone marrow, muscle, liver, pancreas, and intestine.^[11] An interesting debate has arisen over the possibility that stem cells that reside in adult tissues are recruited to those tissues as needed from the bone marrow. In 1999, researchers at the University of Pittsburgh demonstrated, in a rodent model of liver damage, that

progenitor cells in the bone marrow were able to home to the site of damage in the liver and participate in the repair process, ultimately giving rise to cells with a phenotype consistent with normal functional hepatocytes in the liver.^[1] Subsequent studies from a group at Albert Einstein University suggested rescue of lethally irradiated mice after transplantation of a single progenitor cell from the bone marrow; cells derived from the transplanted cell were subsequently identified in many tissues throughout the animal, including liver, lung, intestine, and skin.^[4] Since these seminal studies, there have been a large number of similar studies whereby transplantation of stem cells has resulted in the incorporation of those cells into host tissues and subsequent rescue of disease phenotypes. These studies have included rescue of animals from liver failure, cardiac failure, diabetes, and neurological deficits.^[12] Recent research from the University of North Carolina has now demonstrated that stem-like cells isolated from unmanipulated adult rat liver can differentiate into functional hematopoietic cells when transplanted into the bone marrow.^[13] Taken together, these studies provide strong evidence that stem cells within adult tissues are somewhat interchangeable (Fig. 1). Regardless of their origin, adult tissue stem cells represent a viable source of cells for research and for therapeutic applications.

Fig. 1 The interchangeable stem cell hypothesis. Primitive stem cells may exist within the bone marrow that are capable of homing to tissues that need repair or regeneration (solid lines). Likewise, progenitor cells from an adult organ, such as liver, may act as a source of re-generation-competent cells for another tissue, including the bone marrow (dotted lines).

HOW DO STEM CELLS DIFFERENTIATE?

If stem cells are indeed interchangeable, how do they know what cell types to become? If cells from the bone marrow can differentiate into hepatocytes, why don't we find hepatocytes in the bone marrow? The answer to this question lies within each individual cell and its ability to interpret the signals from its surroundings. Each cell in the body exists within a microenvironment consisting of the unique set of neighboring cells, structural molecules, and soluble factors, all of which are able to initiate signaling cascades that ultimately affect the gene expression profile and phenotype of that cell. No two microenvironments in the body are exactly the same, so it is reasonable to assume that the same stem cell transplanted to two distinct microenvironments (such as the liver and the bone marrow) will receive tissue-specific signals that govern the growth and differentiation of that cell. There are many examples of cells exhibiting distinct growth and/or differentiation characteristics upon transplantation into different tissues. Therefore, it is reasonable to assume that the general properties of stem cells that reside within tissues are distinct from stem cells that reside in the bone marrow, even if they are interchangeable or have a precursor/progeny relationship. Returning to the continuum of plasticity described previously, bone marrow-derived stem cells may have a wide differentiation potential, but they must go through many steps in order to be differentiated into highly specialized cells of a tissue. In contrast, stem cells that reside in an adult tissue may have a more narrow range of plasticity, but they are only a step or two away from differentiating into the specialized cells of that tissue, thus making them an interesting option when tissue-specific therapies are developed. For example, in a normal mammal, the fully mature hepatocytes of the liver are able to act as the stem cells of the liver; in the event that 2/3 of the liver is removed surgically, the remaining hepatocytes proliferate to restore the functional mass of the liver within days.^[14] Grompe et al. have demonstrated that, in a damage model where the host hepatocytes are unable to proliferate, transplantation of fully differentiated hepatocytes results in a full restoration of liver mass and alleviation of the disease state.^[15] Serial transplantation experiments demonstrated that fully differentiated hepatocytes could undergo 7.3×10^{20} -fold expansion to restore liver mass and provide correction of liver disease.^[15] In contrast, transplantation of less differentiated stem-like cells from liver or from extrahepatic sources leads to incomplete restoration of liver mass and a slower recovery.^[16] This is likely due to the necessity for the transplanted stem-like cells to receive the appropriate signals from the hepatic microenvironment that allow the cells to differentiate into

hepatocyte-like cells; until these signals are received, interpreted, and implemented, the stem-like cells are incapable of initiating repair. These microenvironmental signals that govern the differentiation state of transplanted cells are important considerations in tissue engineering as new tools are developed for the expansion, differentiation, and in-vivo delivery of cells for therapy (see the following section).

S

BIOMATERIALS AND STEM CELLS

Cell–Biomaterial Interactions

Biological tissues and organs consist of cells surrounded by a complex molecular framework that is known as the extracellular matrix (ECM). ECM is a complex mixture of different macromolecules, such as collagens, proteoglycans, glycoproteins, and elastin and one of its important roles is to provide tissues with the appropriate structural integrity.^[17] In addition, cell–ECM interactions, mediated by cell surface receptors, such as integrins and syndecans, have been shown to promote signaling pathways that influence key cell function, such as proliferation, migration, and differentiation.^[17,18]

Due to the important role of ECM in the development and maintenance of living tissues and organs, the development of an artificial substitute for ECM has been a focus of biomaterial research with the goal to model and understand cell function and eventually to enable reconstruction or regeneration of damaged tissues and organs. The approaches range from polymer surfaces coated with different ECM molecules to surfaces modified with peptide sequences from ECM molecules that have been identified as cell-adhesion motifs. These approaches have led to the development of a number of three-dimensional matrices, so called scaffolds, which are commonly used today in biomaterial research and tissue engineering. In the following, we review a few examples of stem cell research that utilize such biomaterials.

Applications of Biomaterials in Stem Cell Research

Hematopoietic stem cells

Hematopoietic stem cells (HSCs) reside in the human bone marrow and they give rise to all blood cells, including lymphocytes, red blood cells, platelets, and leukocytes. Cell transplants containing HSCs, e.g., bone marrow transplants, are currently used to restore the hematopoietic system of cancer patients whose bone marrow is compromised as a result of radiation- or

chemotherapy. HSCs are rare cells and transplants are hindered by the availability of a sufficient amount of these cells. Current research efforts are focused on in-vitro expansion of HSCs while maintaining the stem cell character, as measured by the ability to restore hematopoietic function.

So far, in-vitro HSC expansion has only been achieved with mouse bone marrow in long-term cultures on stromal feeder layers.^[19] For clinical applications, however, HSC expansion cultures need to be well defined; thus, an undefined stromal layer of potentially animal origin is unacceptable. Attempts to substitute the stromal layer with growth factor cocktails have shown only partial success. In another approach, Rosenzweig et al. investigated the influence of topographical cues provided by an inert, three-dimensional, tantalum-coated biomaterial scaffold in the absence of exogenous growth factors (but presence of serum) on hematopoietic progenitor cells.^[20] More hematopoietic progenitor cells were maintained in culture on the three-dimensional scaffold compared to a two-dimensional culture on stroma or two-dimensional culture on the scaffold material, indicating that HSC phenotype may be maintained in short-term cultures on three-dimensional scaffolds. In a later study, hematopoietic progenitor cells were cultured on the same (fibronectin) scaffold but in the presence (or absence) of various growth factors.^[21] The results from that study suggested that a synergy exists between use of a three-dimensional scaffold and low-dose cytokine cocktails, resulting in the preservation and expansion of both more mature and immature hematopoietic progenitor cells.

Mesenchymal stem cells

Mesenchymal stem cells (MSCs) also originate from the bone marrow and can give rise to chondrocytes, osteoblasts, adipocytes, myoblasts, and even neural cells.^[22] MSCs present a potential cell source for cartilage and bone repair and have thus been the subject of a number of tissue engineering studies. Martin et al. described the in-vitro formation of cartilaginous and bone-like tissue when culturing chick-embryo bone-marrow stromal cells on three-dimensional polyglycolic acid scaffolds in the presence of fibroblast growth factor-2.^[23] Similarly, bovine MSCs were found to form either cartilaginous or bone-like tissue when cultured on poly(lactic-co-glycolic acid) and poly(ethylene glycol) scaffolds in the presence of the right stimulants.^[24] MSCs in a collagen matrix, seeded onto a pretensioned polygluconate suture, were found to aid tendon repair in vivo when the MSCs-collagen-suture construct was implanted into a tendon gap model.^[25,26]

Neural stem cells

Neural stem cells (NSCs) are of interest as a potential cell source for the repair of spinal cord or brain injury, following stroke, for example, or as cells used for therapies to alleviate neurodegenerative diseases such as Parkinson's disease or Alzheimer's. Some promising tissue engineering approaches have been reported. For example, a polymer scaffold seeded with NSCs and implanted into a spinal-cord defect of a rat was found to promote long-term function as exhibited in weight-bearing hindleg stepping.^[27] When seeded onto a polyglycolic acid mesh, NSCs were found to profoundly adhere, grow, and migrate in vitro.^[28] When this cell-scaffold construct was implanted into an extensively injured mouse brain, NSCs were found to differentiate, and interactions with the surrounding host tissue occurred, leading to the formation of a neuronal fiber web composed of both host and implanted cells. In this example, the scaffold helped to bridge a large lesion in the mouse brain and thus supported the formation of new tissue that structurally integrated with the host tissue.

Preadipocytes

Adipose tissues (soft or fat tissue) are composed of fragile nonproliferating mature adipocytes and proliferating preadipocytes that differentiate into adipocytes. Adipose tissue augmentation for congenital deformities, posttraumatic repair, cancer rehabilitation, and soft tissue defects in general is challenging because of the fragility of the soft tissue and often muscle or other materials, including silicon and collagen have been used as substitutes.^[29] Tissue engineering approaches to adipose tissues have focused on using preadipocytes in combination with different scaffolds. Attachment, proliferation, and differentiation of preadipocytes on fibronectin-coated polytetrafluoroethylene mesh was reported by Kral et al.^[30] Similarly, a poly(lactic-co-glycolic) acid scaffold was found to be a suitable substrate for preadipocyte differentiation.^[31]

CONSIDERATIONS OF STEM CELLS FOR IN-VIVO THERAPY

Stem cells are a promising tool in the field of regenerative medicine. The therapeutic value of stem cells is clear, given their critical use in reconstitution of bone marrow after chemotherapy for hematopoietic cancers.^[32] There is much excitement about the use of stem cells in the therapy of other diseases such as diabetes, neurodegenerative disorders, and cardiac

dysfunction. However, the clinical reality of cell therapy requires further consideration. Most studies today are conducted using syngeneic animal models, whereby cells from the donors are a near-perfect match to cells of the diseased host, thus enabling transplantation of cells without immune suppression. Immune-deficient models, such as athymic mice, SCID mice, and Rag1 mice, enable xenotransplantation without immune suppression, so that assessment of human cells in an in-vivo environment is possible.

Clinical therapies for human diseases will require that the cells that are delivered to the diseased individual are: 1) autologous, i.e., isolated from that same individual; 2) delivered along with immune suppressants to prevent rejection; 3) enclosed within a barrier that prevents immune-mediated destruction while retaining full function; or 4) delivered along with a regimen aimed at providing immune tolerance to those cells. The down side of immune suppressive regimens as they are given today is the ultimate complications related to those drugs, which include unpleasant daily side effects and the greatly increased risk of developing cancers such as lymphomas. The development of situation-specific immune suppressants, as opposed to the broad-spectrum steroidal approach to immune suppression, has led to fewer side effects and risks.^[33] The ideal solution is to deliver cells that were isolated from the diseased individual or a living related donor, so that little or no immune suppression is required. However, this strategy may not be effective in diseases with an autoimmune component, such as diabetes, where autoantibodies involved in the disease mechanism may continue to destroy any insulin-producing cells that are transplanted. Coating or encapsulation of transplanted cells in semipermeable membranes is an option that is being explored for applications in diabetes; however, many encapsulation strategies have been abandoned due to poor performance and reproducibility.^[34]

Another question arises as we consider the implications of transplanting stem cells for disease therapy—how will these cells function in vivo after transplantation? There are many reports of stem cells that are able to participate in regeneration after tissue damage, as well as reports of stem cells that can be pushed to differentiate into a specific phenotype through modulation of culture conditions in vitro. However, the phenotypic characteristics of stem cells in vivo are modulated by their microenvironment, as discussed above. The site of delivery as well as accessibility of the cells to the vascular system will influence their ability to perform the desired function in vivo. In many cases, it is not feasible for the therapeutic cells to be delivered directly to the site of injury. For example, islet cells transplanted for the purpose of type I diabetes therapy are delivered to the liver, not the

pancreas.^[35] Although many animal models involve delivery of stem cells to the bone marrow, homing of the transplanted cells from the bone marrow or peripheral blood to the site of tissue injury may not be sufficient to provide a therapeutic benefit.^[10] The ability of therapeutic cells to achieve and maintain a functional state of differentiation will depend on the consistent presence of the environmental signals that modulate cellular phenotype. In the growing fields of stem cells and biomaterials, the challenge may be to develop engineered biomaterials that support tissue-specific differentiation of stem cells and provide the structure and signals necessary to maintain the desired phenotype in vitro and in vivo.

S

CONCLUSION

The science of stem cells has captured the interest of many in the past decade. New stem cells and markers are being discovered throughout the world across a variety of scientific disciplines. The potential value of stem cells in therapeutics has brought them to the forefront of research in regenerative medicine, with active research in a vast array of disease applications, including diabetes, neurodegenerative disorders, cardiovascular disorders, and genetic diseases. As demonstrated by the discussion presented in this article, many of the dogmatic assumptions regarding stem cells have fallen away in recent years, giving rise to an emerging theory that stem cells can exist in many adult tissues and are characterized by varying degrees of phenotypic plasticity. The field of regenerative medicine stands to benefit considerably as we gain knowledge related to the identification, isolation, propagation, differentiation, and in-vivo delivery of stem cells.

Stent Grafts, Endovascular

Timothy A.M. Chuter

Division of Vascular Surgery, University of California San Francisco, San Francisco, California, U.S.A.

INTRODUCTION

As the name suggests, this type of endovascular prosthesis combines two elements, a stent and a graft. The graft conveys blood from one end of the prosthesis to the other, isolating the surrounding artery from the circulation. The stent framework supports the position, shape, and dimensions of the graft, at the same time generating a seal between the ends of the graft and the surrounding artery.

STENT-GRAFT APPLICATIONS

Endovascular repair abdominal aortic aneurysm (AAA) was the first,^[1] and remains the commonest, application of stent-graft technology. Once deployed, the stent-graft performs much like a surgical graft, bridging the dilated segment of distal aorta, or aneurysm, and excluding it from direct arterial flow. In theory, the excluded aneurysm is protected from arterial pressure, dilatation, and rupture. The surgical and endovascular methods of repair differ in the means of graft insertion and attachment. Whereas the surgical graft is sutured into the open aneurysm, the stent-graft is introduced and secured without opening the abdomen or interrupting aortic flow. As a result, endovascular aneurysm repair causes less physiological stress, leading to lower morbidity and quicker recovery.

Because the primary goal is to exclude the aneurysm from the circulation, continuing perfusion of the space outside the stent-graft (endoleak) is regarded as a failure (Fig. 1A–D). However, not all forms of endoleak have the same effect on aneurysm pressure,^[2] dilatation,^[3] and risk of rupture.^[4] High pressure, aneurysm pulsatility, aneurysm dilatation, and continuing risk of rupture are associated with direct endoleak, either at the implantation site (type I) or through a gap in the stent-graft (type III). Intermediate values are associated with indirect endoleak (type II) through collateral routes to lumbar or inferior mesenteric branches of the aneurysm.^[4] In addition, porous stent-grafts are prone to type IV endoleak, with diffuse leakage through the stent-graft, and endotension, with pressurization in the absence of endoleak.

Short-term success depends on atraumatic transfemoral insertion, accurate deployment, and secure

hemostatic attachment proximal and distal to the aneurysm. Unfortunately, many patients with aneurysms have narrow tortuous iliac arteries and short angulated implantation sites. Some stent-grafts, and their delivery systems, cope well with these forms of anatomic distortion; others do not. During the decade since the first clinical application of stent-grafts for aneurysm repair, successful features have been copied and unsuccessful features have been eliminated. With a few notable exceptions, such as the Trivascular device, stent-grafts have undergone a process of convergent evolution so that current systems have many features in common. Nevertheless, every element of stent-graft design offers a wide variety of options, each with important consequences for stent-graft performance. Examples include: stent-graft configuration, tubular or branched; stent-graft construction, one piece (unibody) or multi-component (modular); stent type, balloon-expanded or self-expanding; stent materials, stainless steel, Elgiloy, or Nitinol; stent-graft attachment, barbs or suprarenal stents; stent distribution, fully-stented or partially stented; and graft materials, PTFE or polyester.

STENT-GRAFT BRANCHING

The shape of the stent-graft is dictated by the location of the aneurysm or, more precisely, by the location of the nondilated implantation sites proximal and distal to the aneurysm. The goal in endovascular aneurysm repair is to exclude the aneurysm, at the same time maintaining downstream flow. When the aneurysm has important branches, the stent-graft must also have branches. The simplest example of this principle is bifurcated stent-graft repair of an AAA involving the aortic bifurcation. A more extensive aneurysm, which encroaches on the origins of the renal or internal iliac arteries, requires a more complicated multibranched form.

Unbranched Stent-Grafts

Abdominal aorta

The original AAA stent-grafts were unbranched,^[1] with a single lumen connecting the one proximal orifice to one distal orifice. The proximal orifice was implanted between the renal arteries and the aneurysm

Fig. 1 A. Type I endoleak between the graft and an implantation site. B. Type II endoleak between two branches of the aneurysm. C. Type III endoleak between two components of the stent-graft. D. Type IV endoleak through many small holes in the stent-graft.

in a nondilated segment referred to as the neck, and the distal orifice was implanted between the aneurysm and the aortic bifurcation. The aorto-aortic approach proved to be of limited use on infrarenal aorta because the aneurysm typically involves the entire distal aorta.^[5] Most cases have absolutely no nondilated distal aortic implantation site. Attempts to use short, wide, conical, thrombus-lined implantation sites resulted in a high rate of detachment and leakage. Stent-grafts that were implanted in a cuff of thrombus often showed no signs of leakage into the aneurysm, and yet the aneurysms continued to enlarge. The probable explanation for this phenomenon of “endotension” was transmission of pressure through the rim of thrombus.

Thoracic aorta

The descending thoracic aorta is bounded proximally by the subclavian artery and distally by the celiac

artery. The lack of major branches makes this segment of the aorta a better location for unbranched stent-grafts.^[6] The endovascular repair of thoracic aortic aneurysms is a particularly appealing alternative to open surgery because the patients are often old, sick, and female. They tolerate thoracotomy and supraceliac interruption of aortic flow poorly. Consequently, surgical repair has high mortality and morbidity rates.

In cases of intramural hematoma, penetrating ulcer, and isolated saccular aneurysm, stent-graft implantation is quick, easy, and effective. However, typical thoracic aortic aneurysms are far more difficult to treat. The implantation sites are often short, wide, angulated, and widely separated. Large-diameter implantation sites require large-diameter stent-grafts, which in turn require large stiff delivery systems that may be difficult to insert. Small iliac arteries often preclude transfemoral insertion of such large sheaths, especially in women. The alternative is insertion into the common iliac artery or aorta, either directly or through a surgically-created conduit. Larger delivery systems also tend to be stiffer, leading to difficulty in cases of arterial tortuosity. Three problem areas are the iliac arteries, the aorta at the diaphragm, and the aortic arch. Stiff guidewires and trackable delivery systems are helpful in the iliac arteries, which can straighten, but of less use in the less mobile segments of the aorta. Angulated implantation sites make specific demands of stent-graft performance that are discussed in more detail later in the context of stent-graft attachment and flexibility.

One way to lengthen the proximal implantation site is to cover the subclavian artery. In most cases, the lack of direct prograde flow into the subclavian artery has no serious effects. In the presence of a left internal mammary graft to the coronary circulation, or a dominant left vertebral artery, bypass from the left carotid artery to the subclavian artery should precede endovascular stent-graft implantation. Otherwise, subclavian artery bypass will need to be performed later, if the endovascular repair causes left upper extremity ischemia.

It is not yet clear whether stent-grafts will have any role in the treatment of aortic dissection. Currently, the acute management of aortic dissection depends on the location of the dissection and the presence of ischemic complications. Type A dissections, proximal to the subclavian artery, require urgent surgical repair. Type B dissections, distal to the subclavian artery, can be managed medically with antihypertensive agents unless there are signs of end-organ ischemia, in which case stent-grafts have been used to cover an intimal tear in the proximal descending thoracic aorta and to direct blood into the true lumen.^[7] Reports of false lumen thrombosis and healed dissection suggest that this approach may have a role, but there are problems. For

one, there are often multiple intimal tears producing multiple communications between the true and false lumens. A stent-graft that covers them all is more likely to exclude flow through intercostal arteries to the anterior spinal cord, causing paraplegia.

Bifurcated Stent-Grafts

Although as many as 80% of open surgical AAA repairs can be performed using aorto-aortic tube grafts, the aorto-aortic stent-graft is rarely successful in the long term. The anatomic requirements for surgical anastomosis and endovascular stent-graft implantation are very different. Endovascular stent-grafts need more than a sewing ring for secure hemostatic implantation. These days, few manufacturers even produce unbifurcated stent-grafts for AAA repair.

The first bifurcated stent-grafts were inserted whole (unibody) and pulled into position using cross-femoral catheters.^[8] However, most current systems employ a different (modular) approach whereby the bifurcated stent-graft is assembled in situ from two or more components. The relative advantages and disadvantages of the modular and unibody approaches are discussed in detail below in the section on stent-graft construction.

Multibranch Stent-Grafts

Indispensable aortic branches in the arch, proximal abdomen, and pelvis have in the past defined the limits of endovascular aneurysm repair. Conventional endovascular repair of aneurysms that involve these areas requires prior surgical bypass into the affected branches.^[9] Alternatively, the stent-graft must be provided with branches to feed these arteries.^[10-13]

Like bifurcated stent-grafts, the more complicated multibranch versions divide into two broad groups, unibody and modular. Inoue et al.^[13] have used multibranch unibody stent-grafts to treat aneurysms of the aortic arch, thoracoabdominal aorta, and common iliac arteries. Their success is a reflection of enormous ingenuity and technical skill. In a unibody stent-graft, multiple branches require multiple control wires or catheters. There is an exponential increase in the degree of complexity with every additional branch. Cases with three or more branches have been few and the complication rates high. Others have limited the unibody approach to the provision of an internal iliac branch, but failure to implant the internal iliac branch was common in the presence of usual iliac tortuosity or internal iliac stenosis.

We have experimented with modular multibranch stent-grafts in the aortic arch, thoracoabdominal aorta, and iliac bifurcation. Our approach is to implant

an aortic component with short branches, which we then extend into the branch arteries using simple tubular bridging stent-grafts.

Thoracoabdominal aorta

In the thoracoabdominal aorta, the aortic component has one orifice proximally, four small side branches (one for each visceral artery), and one orifice distally for a standard infrarenal type reconstruction. All five branches point distally. The four side branches are catheterized in turn from above through the brachial artery. Once the catheter has been passed out through the branch of the stent-graft, it is directed into the corresponding branch of the aorta. We then exchange the catheter over a stiff guidewire for a guiding sheath and the delivery system for the side-branch extension. We have experimented with a variety of stent-grafts for use as the extension. The basic requirements are a low profile, a trackable delivery system, and a flexible stent-graft of predictable length. In our experience, the two best are the self-expanding PTFE-covered Smartstent (Cordis), no longer available, and the balloon-expanded PTFE-covered JoStent (JoMed). Both work well in the short-to-medium term, but the balloon-expanded JoStent is vulnerable to permanent kinking or compression where the celiac artery passes through the diaphragm.

Aortic arch

Our aortic arch system is not really multibranch, but bifurcated. We insert the stent-graft through the right carotid artery, leaving its trunk in the ascending aorta, its long narrow limb in the innominate (brachiocephalic) artery, and its short wide limb in the aorta. Flow through the innominate artery is distributed to the rest of the brachiocephalic circulation through a previously created carotid-carotid bypass and left subclavian-carotid transposition. A large-diameter tubular stent-graft is inserted transfemorally and used to extend the short wide limb into the descending thoracic aorta.

Iliac bifurcated stent-grafts

In cases of bilateral common iliac aneurysm, we preserve flow to an internal iliac artery by performing an endovascular reconstruction of the common iliac artery using a bifurcated stent-graft. We place the long limb of a bifurcated component into the ipsilateral external iliac artery, the short limb just above the internal iliac orifice, and the trunk in the proximal common iliac artery. A cross-femoral sheath is inserted

Fig. 2 A. Catheters, sheaths, and guidewires within the iliac bifurcation component. B. The iliac bifurcation component with its internal iliac extension in place.

from the contralateral side over a cross-femoral guidewire. A second puncture of the sheath valve provides access for insertion of a catheter and guidewire, which are directed through the short limb of the bifurcated component into the internal iliac artery. This bridging catheter is replaced over-the-wire for a bridging sheath, followed by a bridging stent-graft of the same type used in thoracoabdominal reconstruction, only a little wider (Fig. 2). The trunk of the bifurcated component then serves as the distal implantation for a conventional bifurcated reconstruction of the infrarenal aorta. The eventual result is a stent-graft that bifurcates once in the aorta and again in the common iliac artery. It has one proximal implantation site in the infrarenal neck and as many as four distal implantation sites in the internal and external iliac arteries.

Fenestrated Stent-Grafts

One solution to the problem of implantation site encroachment is to provide each vital branch of the

aneurysm with a branch of the stent-graft. Another is to perfuse each arterial branch through a hole, or fenestration, in the stent-graft. The danger is that blood will also flow through the fenestration into the aneurysm. One solution is to pin the orifice of the stent-graft fenestration to the orifice of the branch artery using a flared bridging stent.^[14] This has the added benefit of fixing the fenestration in position so that neither malposition nor migration ever interrupts branch artery perfusion. Although fenestrated stent-grafts require precise sizing, manufacture, and deployment, the approach is now practiced at 35 centers in Australia and Europe. The modified Zenith device is manufactured by Cook, Inc., Australia, according to the measurements entered on a standard order form.

S

MODULARITY

Each branch point in a stent-graft represents the intersection of two separate lines of insertion. In a unibody stent-graft, the device is deposited along one line of insertion and its branches pulled into the other line of insertion by a system of catheters or wires.^[8] This translocation cannot occur with the limb in its expanded state, so there also has to be a mechanism to maintain the limb in a compressed state until it reaches the target artery. In a modular stent-graft, separate components take different lines of insertion. The point of intersection is the point at which these components join one another to form the final composite stent-graft.

Because the unibody stent-graft has no connections, there is no possibility of component separation or intercomponent leakage, as there is with the modular stent-graft. In all other regards, the modular stent-graft is superior to its unibody equivalent. Not needing to position catheters makes the delivery system narrower and simpler with less to pack and less to fail. Modular systems are more versatile and more flexible. Each component has a range of lengths and widths, so that every additional component adds two dimensions to the matrix of possible combinations. For example, a stent-graft with three components, each having five possible lengths and five possible diameters has 1565 possible combinations. A unibody stent-graft could achieve such a wide range of configurations only if it were custom-made. Besides, variability in the length of overlap between components provides another opportunity to adjust the dimensions of a modular stent-graft, which is particularly advantageous because it allows in situ adjustment.

The modular approach facilitates the development of new stent-graft configurations and applications. The new stent-graft can be constructed by modifying or adding a single component. This keeps to a minimum

the amount of new untested technology and reduces the degree of uncertainty regarding its performance. In this way, the design of device can advance through a series of small relatively predictable steps. The corresponding advances in implantation technique proceed in a similar way.

These advantages account for the overall ascendancy of the modular technique. The first unibody bifurcated stent-grafts were developed in 1991 and used clinically in 1993.^[8] Although this device was abandoned in 1996, a similar unibody stent-graft, the Ancure (Guidant), was manufactured until 2003.^[15] The Ancure stent-graft was stable and effective. However, a narrow range of sizes and a potential for device malfunction during implantation limited its application, especially outside the United States where more versatile alternatives were readily available. In early 1994, Lawrence-Brown and Hartley began a series of in vitro experiments with various bifurcated stent-grafts of their own design. Problems with the unibody bifurcated approach prompted them to adopt a modular system. The first clinical implantation of this bifurcated modular stent-graft followed in August 1994. Their device, the Zenith (Cook, Inc.), has continued to evolve ever since to become the most widely used stent-graft in the world, with multiple versions for increased flexibility, additional branches, and fenestrations.

New Designs

Despite its many disadvantages, the unibody approach still has many adherents who point to high rates of component separation, secondary type III endoleak, and aneurysm rupture with the use of modular devices, the Vanguard (Boston Scientific) in particular.^[16] This group, most of whom are surgeons, regard the potential for component separation as a fundamental flaw of the modular approach, but that is not the case. Inter-component connections are not necessarily unstable. Even a simple friction joint can be made more stable simply by increasing the length of the overlap zone. This design feature has the added benefit of increasing the range of in situ length adjustment through a variable degree of tromboning one component inside the other. Furthermore, there are many ways of making the junction even more secure using barbs, abrupt changes in stent-graft profile, or combinations of interlocking stents, plastic rings, and cuffs.

GRAFT FABRIC

The evolutionary history of the stent-graft is apparent in the choice of materials for the conduit or graft. The

two current alternatives, PTFE and polyester, are the same materials used in conventional surgical grafts, and their characteristics reflect the desired goals of surgical graft implantation. Both are porous enough to allow connective tissue ingrowth and impervious enough to prevent bleeding. Endovascular applications probably have different requirements for optimal performance. For example, the lining of an aneurysm has no tissue that would ever propagate into the interstices of the graft, nor does it require immediate hemostatic sealing. The long-term goal is to exclude the aneurysm from pressure, but there is no risk of trans-graft bleeding because the space around the graft is already bounded by the intact walls of an artery, however dilated and weakened by the lytic processes of aneurysm formation.

Polyester

The most widely used stent-graft (Zenith) is constructed from conventional woven polyester surgical grafts, the primary design objective being durability. Most other stent-grafts use thinner fabrics in an attempt to minimize delivery system size. The reduction in wall thickness reflects a smaller fiber diameter (Dernier size) and a tight weave to limit porosity.

PTFE

The PTFE fabrics used in stent-graft construction all have the familiar node/fibril structure of conventional grafts. However, the relative dimensions of these features vary widely, as does the overall thickness of the membrane. Thin-walled PTFE differs from woven fabric in several important regards.

PTFE tends to have less suture retention. Sutured attachment points between the stent framework and graft need to be at the margins of the fabric, or other places where a hole will not impair the barrier function of the graft. Alternatively, the stent-graft attachment needs to be suture-free. One approach is to sandwich the stent between adherent layers of PTFE. The Excluder (WL Gore), for example, traps a sinusoid Nitinol stent between the primary graft and an outer wrap of PTFE ribbon, whereas the Fluency (Bard, Inc.) has inner and outer tubes of PTFE. The opposite approach is employed in the JoMed stent-graft with inner and outer stents separated by a single tube of PTFE.

PTFE has a low friction surface. A PTFE-covered stent-graft cannot rely on frictional forces to resist migration. This point was illustrated well by the original Endologix (Bard) stent-graft, which migrated immediately, and only stopped moving when its bifurcation straddled the aortic bifurcation; hence, the

need for an extension cuff in a large proportion of cases.

Porosity

The optimal porosity of an endovascular fabric is unknown. In vitro and animal models differ from clinical circumstances in important ways, rendering experimental findings of uncertain predictive value. Experimental work has shown, however, that short wide thrombus channels between the aortic lumen and the aneurysm transmit pressure, whereas long thin ones do not.

The most porous stent-graft ever put to clinical use was a Strecker stent that was co-knit with polyester. This proved to be an effective barrier to flow in experimental and clinical studies, yet it had no effect on aneurysm pressure or dilatation. The thrombus seal eliminated endoleak, but permitted endotension (see Stent-Graft Technology). Among current stent-grafts, the highest rates of endotension are seen with AneuRx and Excluder.^[17] Both grafts are porous, although in different ways.

The AneuRx stent-graft has many thousands of suture holes where the stents are attached to the outer surface of the graft, disrupting the weave pattern. A new category of endoleak (type IV) was created to describe the diffuse leakage of contrast through the walls of this graft at the time of implantation. Although type IV endoleaks tend to resolve as these holes fill with thrombus, the holes do not disappear. Indeed, they tend to get larger due to suture-induced fiber separation, especially with the loose weave pattern of the predicate design.^[18] The occasional result was a recurrence of diffuse endoleak that looked like a water sprinkler at the time of conversion. More often there was no leakage, yet aneurysms treated with the AneuRx device shrink at a lower rate than with other stent-grafts, and some even dilate.^[19]

The Excluder stent-graft has no suture holes and the pores in its fabric are very small. Nevertheless, aneurysm shrinkage rates are low and dilatation rates high. In my opinion, this graft sometimes behaves as a kind of semipermeable membrane, allowing the aneurysm to distend with transudate. A similar phenomenon is known to occur following surgical implantation of PTFE grafts, whereby clear fluid collects around the graft.

Erosion

The barrier and attachment functions of the stent-graft require different mechanical properties, hence, the combination of a metal stent with a fabric graft. However, the combination of two such different

components is a potential source of instability in the long term. Every point of contact between the two has to be secured to prevent damage to the graft. Most current designs do so using multiple sutures, yet the sutures themselves can disrupt the structure of the graft. The Vanguard experience provided the most extreme example of stent-induced fabric erosion.^[16] The polypropylene sutures holding the stent framework in proper alignment broke, allowing stent apices into contact with the flimsy polyester fabric. This is a failure mode not seen with any of the current systems, but fabric erosion is far from rare. For example, explanted AneuRx stent-grafts have more than two fabric holes per device.^[18] These holes are rarely large enough to cause endoleak, but they may be large enough (1 mm) to pressurize the aneurysm sac.

New Designs

The graft component of a typical stent-graft serves two distinct functions: it isolates the aneurysm from the circulation and it connects the stents. These functions demand different properties. The barrier function requires that the graft be impervious to blood flow and pressure, whereas the structural function requires the strength and durability to withstand large hemodynamic forces, continual movement, and a compliance mismatch. Current stent-grafts combine these functions in one fabric tube, which must be both strong and impervious. An alternative is to divide the functions of the graft between two layers of graft material, each with properties tailored to optimize its role. The outer (structural) layer would serve as a foundation garment for the stents, just as a soldier's jacket holds the plates of body armor in place. This layer need not be impervious to blood and it need not be constructed from the polyester or PTFE of traditional graft material. The inner layer, freed from the need to support the stents, could be very thin-walled. The two layers would come together at the implantation sites to provide optimal attachment and sealing with or without additional stents.

A quite different approach involves integrating the stent and graft into a more homogeneous structure. The Wallgraft and Corvita stent-grafts (both from Boston Scientific) exemplify this approach. They suffer from the undesirable characteristics of the braided stent, such as insecure graft/artery attachment, weak expansion, and unpredictable shortening, but they do show the advantageous effects of integrated structure on stent-graft durability.

STENTS

The two basic types of stent are self-expanding, which opens through elastic deformation toward an

expanded “resting” diameter, and balloon-expanded, which undergoes plastic deformation to an expanded state under the action of an intraluminal balloon. Both types have been incorporated into stent-grafts, although the self-expanding type predominates. Differences between balloon-expanded and self-expanding stents have significant effects on the way they function in endovascular aneurysm repair.

Balloon-Expanded Stents

Balloon-driven stent expansion stretches both the stent and the surrounding artery. When the balloon deflates, the artery contracts onto the relatively unyielding stent, generating high frictional forces and encouraging stent incorporation into the arterial wall. Once expanded, the balloon-expanded stent has stable dimensions, so it reinforces the structure of the artery and limits dilatation. Since the mechanisms of attachment (friction and incorporation) both depend on arterial stretching, precise sizing of the aorta and balloon are important. Too little oversizing causes insecure attachment and leakage; too much causes the aorta to tear.

Self-Expanding Stents

At the time of implantation, self-expanding stents open to fill all the available space, and may continue to expand with the surrounding artery after implantation. Assuming the graft is oversized, the stent pushes continually outwards against the artery. The forces involved are low compared to the forces generated by arterial pressure. It is unlikely that stent expansion would cause implantation site dilatation, but it is equally unlikely that the self-expanding stent will resist the natural tendency toward arterial dilatation the way a balloon-expanded stent does. Since high degrees of oversizing rarely cause leakage, the exact dimensions of the stent-graft are less critical. An association between oversizing and neck dilatation migration would suggest otherwise. However, it is far from clear that oversizing causes migration or neck dilatation. Experienced users apply high degrees of oversizing to accommodate irregular or thrombus-lined necks, both of which are likely causes of implantation site instability. Less than 20% oversizing is associated with an increased risk of implantation site (type I) endoleak. For this reason, most patients are treated with stent-grafts 28 mm or more in diameter.

Stent Breakage

Stent materials include Nitinol, 300 series stainless steel, and Elgiloy. Late-occurring stent fracture has

been reported with all current stent-grafts. However, some are more prone to breakage than others.

The early Nitinol stents were a particular problem.^[20] Nitinol is an attractive option in the manufacture of self-expanding stents. Its shape memory properties allow the creation of complex forms from Nitinol wire or laser-etched tubes of Nitinol. Much has been made of the temperature-dependent transition of Nitinol from plastic to superelastic, but this phenomenon probably plays a more important role in intellectual property lawsuits than in stent-graft performance. While the low-temperature plasticity certainly helps in loading, subsequent stent expansion has little to do with temperature change. The stent-graft warms to blood temperature well before it is released from the delivery system unless iced saline is infused constantly through a side port, which it never is.

The surface of Nitinol passivates by forming a layer of titanium oxide, which gives raw Nitinol its characteristic black, or dark gray, appearance. On a microscopic level, raw unpolished Nitinol has many surface irregularities, each of which becomes the nidus for a stress fracture or erosive pit when the stent is exposed to the pulsatile movements and corrosive fluids of the arterial circulation. All of the early Nitinol-based stent-grafts suffered from this problem. Examples include Vanguard,^[16] AneuRx,^[18] and Talent.^[21] The Vanguard device had many other problems and was abandoned. The other two are still available, but their stents have undergone a number of changes, including better electropolishing. Time will tell whether these changes produce the desired improvement in durability.

Steel and Elgiloy stents are on the whole more durable than those of Nitinol, with a few notable exceptions. The original United States multicenter study of the Lifepath (Baxter) was stopped because each balloon-expanded wireform (Baxter’s term for a stent) was susceptible to multiple fractures, causing complete loss of proximal attachment. This study has now resumed following changes in stent manufacture. Rumor has it that scratches in the stent surface were causing stress fractures. In the early Zenith (Cook, Inc., Australia) experience, a high rate of fractures was seen at the distal end of the main body, just above the bifurcation.^[22] This finding agrees well with the observed movement of this stent on cine-fluoroscopy, and with an analysis of the hemodynamic forces acting at the bifurcation. The substitution of two short stents for the single long stent of the original design seems to have solved the problem.

Corrosion of welded and soldered joints represents another potential cause of late failure. Examination of explanted Zenith stent-grafts, for example, showed corrosion of all solder points. Accelerated durability

testing produced similar findings. However, the process is considered too slow to pose a threat to the structural integrity of the device.^[22] Engineers involved in stent-graft design have long avoided placing different alloys in close proximity for fear of Galvanic corrosion. On the other hand, most physicians have not been so scrupulous. Nitinol-based stent-grafts have been reinforced with stents of Elgiloy and steel, and stainless steel-based stent-grafts have been reinforced with stents of Elgiloy and Nitinol, all without a single reported case of stent fracture in a region of stent material admixture.

Future Designs

The ideal stent for use in a stent-graft has the following features: 1) high enough hoop strength to press the graft firmly against the walls of the implantation site, creating a hemostatic seal in inducing arterial ingrowth, but not so high that it accelerates implantation site dilatation; 2) high ratio of diameter to length, so that the stent-graft conforms well to noncylindrical implantation sites; 3) high expansion ratio for larger arteries and small delivery systems; 4) multiple anchor points for easy attachment of the fabric component and reduced potential for fabric erosion; 5) no sharp points that might impinge on the fabric, causing erosion; and 6) durability in the face of wide-ranging pulsatile movement.

None of the current designs meets all these criteria. A full discussion of potential solutions to all of the above is clearly beyond the scope of this article, but one fundamental (universal) problem deserves a special mention. Stents expand and contract by deformation of the angle between adjacent struts. The smaller this area is, the less durable the stent; the larger this area is, the more space the stent occupies when compressed. No such compromise limits deformation of the struts. Stents that expand by strut deformation are both durable and highly expansile. A strut of this type functions like a long bow or a carriage spring, with a wide range of movement at the ends, but minimal focal deformation at any point throughout its length.

FIXATION

Blood flow and pressure subject stent-grafts to caudally directed forces of up to 10N.^[23] The forces increase with increasing flow rate, proximal diameter, angulation, diameter change, and branching of the stent-graft. All of these features are common in aortic applications. Thoracic stent-grafts have the highest diameters, flow rate, and angulation, whereas aortic stent-grafts have a branch point with an abrupt

diameter reduction. The tendency toward caudal migration is resisted by a combination of barb-mediated anchoring, friction, arterial ingrowth, and column strength. Of these, only barb-mediated anchoring appears to provide secure long-term fixation.

Barbs

The importance of barb-mediated fixation is illustrated by comparing the two stent-grafts first approved for use in the United States, the Ancure^[15] and the AneuRx.^[18,24] The Ancure had no column strength to transmit support from the iliac implantation sites, no external stents to become incorporated, little radial expansion to promote friction, and little oversizing to accommodate implantation site diameter. Its only apparent means of attachment was a series of balloon-driven barbs projecting almost at right angles from its orifices, and yet large prospective multicenter studies showed the migration rate to be very low. The AneuRx, on the other hand, was (and still is) sheathed entirely in strong self-expanding external stents, which provided column strength by resisting both bending and longitudinal compression. It lacked only barbs, and yet many studies have shown migration rates that rise steadily from the time of implantation. At three years the migration rate is 20–30%, depending on study design.^[18,19,24]

Column Strength

Longitudinal connections between stents resist compression and bending, and allow the distal end of the stent-graft to support the position of the proximal end, a feature known as column strength. In practice, column strength contributes little to the stability of proximal stent position because high column strength deprives the stent-graft of the flexibility it needs to accommodate the tortuosity of the typical aneurysmal infrarenal aorta. In cases of neck angulation, the rigid stent-graft often fails to adopt the axis of the neck, causing leakage, or fails to remain within the neck, causing migration. The resulting type I endoleak causes aneurysm pressurization and rupture, as exemplified by high rates of rupture following repair with early versions of the AneuRx.

Length is another factor in the relationship between stent-graft flexibility and stability. This is particularly important in the graft limbs, which can vary in length according to stent-graft design. Short stiff limbs are more stable than long flexible limbs (Fig. 3). Most stent-grafts have long limbs and a short body,^[16] whereas others, such as the Zenith,^[22] have short limbs and a long body, a combination that has proven to be far more stable.

Fig. 3 A. A bifurcated stent-graft with a short trunk and long (unstable) limbs. B. A bifurcated stent-graft with a long trunk and short (stable) limbs.

Incorporation

Myointimal hyperplasia usually produces some incorporation of the uncovered, or external, proximal stent, especially when the stent is pressed forcibly into the surrounding artery. However, the effect on migration rate is uncertain. The best-incorporated of the self-expanding stents, in the AneuRx device, has high migration rates, whereas the least-incorporated, the Ancure, has low migration rates.

Suprarenal Stent

The adventitial layer of the aorta between the renal and the celiac arteries is richly endowed with elastin, which resists the dilating tendency that elsewhere leads to aneurysm formation. Consequently, this segment of the aorta is the most stable. Several stent-grafts take advantage of this by seating an uncovered stent in this area. The main concern of suprarenal stent attachment is the possible effect on renal function. However, mathematical modeling, animal experimentation, and clinical observation have all shown no significant effect.

Migration Rates

Although the Ancure is no longer manufactured, barb-mediated fixation is a prominent feature of several other devices, most notably the Zenith. While the Ancure barbs were driven into the aortic wall by a high-pressure balloon, the Zenith barbs deploy through caudal migration of the proximal stent at the time of, or shortly after, implantation. The inflation of a low-pressure compliant balloon may assist this process by transmitting hemodynamic forces through

the occlusive balloon to the stent-graft, but the caudally-directed barbs are not forced into the wall by the outward expansion of the balloon alone. In addition to the presence of 10–12 barbs, the Zenith is secured by a large uncovered suprarenal stent, robust stent expansion, and routine oversizing. Three-year data from the ASRNP (Australian Government) registry, four-year data from the Eurostar registry, and five-year data from UCSF all show very low rates of significant migration.

Most other stent-graft designs have migration rates somewhere between Zenith and AneuRx. Examples include: Talent, which has a suprarenal stent and significant column strength, but no barbs;^[21] and the Excluder,^[25] which has barbs, but no suprarenal stent. Other devices, such as the Cordis and Trivascular models, are too new for long-term data, although their features give some indication of expected behavior.

Endovascular Rescue of Stent-Graft Migration

The large numbers of AneuRx stent-grafts already implanted in the United States, the high rates of migration at long follow-up,^[18,25] and the serious consequences of migration are all causes for concern. The only remedy is early detection and re-intervention. On plain abdominal radiographs, migration is more apparent as a change in the shape and orientation of the stent-graft than a change in its position. Apparent movement of the stent-graft is often nothing more than an artifact caused by small changes in angle or magnification.^[26] On the other hand, bowing of the stent-graft usually means that one, or the other, end of the stent-graft is migrating into the aneurysm. Changes in aneurysm shape and length are far less likely causes.

Early detection of migration allows the opportunity for endovascular correction using an additional stent-graft to bridge the gap between the original stent-graft and its implantation site. The new stent-graft needs a better means of attachment than the original, or migration is likely to recur. Ideally, the new stent-graft should be implanted above the bifurcation of the original to maintain prograde flow to both lower extremities. This may not be possible when the original stent-graft was of a short-body/long-leg configuration, as is the case with AneuRx. Under these circumstances the safest approach may be aorto-uniiliac reconstruction with femorofemoral bypass and contralateral common iliac occlusion.

SEALING

Orificial stents are the sutures of the nonvascular device. They push the graft against the inner wall of the

implantation site, creating a seal. In this role, a stent on the inside performs better than a stent on the outside, and a short stent conforms better to a non-cylindrical implantation site better than a long one. Perhaps an even better seal is obtained through the hydrostatic action of an intramural balloon rather than a stent (Trivascular).

Many stent-grafts, such as Zenith and Talent, separate the sealing and attachment functions between two stents, one above the renal arteries uncovered by graft fabric, and the other within the graft fabric below the renal arteries. The Trivascular device takes this approach to an extreme, dispensing with the sealing stent altogether. The main advantage is staged delivery, whereby the graft itself contains no stents and occupies little space; hence, the low profile of the Trivascular delivery system.

COMPLETE STENT SUPPORT

The original concept of stent-grafts was a direct descendant of the traditional surgical approach with the stents taking the place of sutures. Indeed, the first Lazarus patent had no real stents, just a ring of staples. In the evolution of the EVT (later Ancure) device, these were connected together to form a rudimentary stent at each orifice of the graft, but there were no stents in between,^[27] nor were there any stents in the body of the original Parodi aorto-aortic device.^[1] More extensive stent support first appeared with the advent of modular bifurcated stent-grafts, which had to remain stable during re-instrumentation. This remains the primary role of the stent skeleton in fully-stented devices. Once the modular device is assembled, the stents provide radial support, helping to prevent kinks. They also provide longitudinal dimensional stability, especially in devices that rely on column strength, but the necessary rigidity can be a disadvantage in the presence of aortic tortuosity.

In general, flexibility and stable length are mutually exclusive. When a stent-graft bends, the outer surface lengthens relative to the inner surface in direct proportion to the stent-graft's diameter. The wider the stent-graft, the greater the length differential. If the stent-graft lacks the capacity for changing length, one of two things will happen. Either the stent-graft will resist bending, or its walls will come together in a kink. A kink resolves the disparity by eliminating, or greatly reducing stent-graft diameter in the plane of the bend.

Most stent-grafts are inserted in an extended state, and shorten as they are deployed inside tortuous arteries. It is important to remember this when selecting the stent-graft, especially in thoracic aortic applications. The required length corresponds to the dimensions of the outer curvature, not the center line.

The wider the artery, the greater the effect. In most cases, the necessary shortening is accomplished by crumpling the fabric between stents. The greatest flexibility is seen in stent-grafts, such as the Zenith Flex, with wide gaps and short stents. Alternatively, the stents themselves can overlap, as in the case of the Excluder stent-graft.

Although this capacity for shortening enhances flexibility, it makes the stent-graft unable to resist compressive loading. Such stent-grafts cannot simply be pushed from a sheath without collapsing the stent-graft, which increases the forces of deployment and imparts excessive redundancy. The original Stentor (later Vanguard) stent-grafts suffered from these problems.^[28] The deployed length was as much as 3 cm shorter than the nominal length. Subsequent lengthening in situ caused bowing and kinking of the graft limbs.

The Talent device incorporates a single longitudinal strut, which stabilizes the overall length of the device, while retaining flexibility. When the strut is on the outer aspect of the bend, the fabric on the inner curve crumples, the stents come together, and the stent-graft flexes. However, when the strut ends up on the inner aspect curve, there is no capacity for shortening. Furthermore, there is no capacity for lengthening on the outer aspect of the curve because the graft fabric is inelastic and there is no redundancy at the time of deployment. The frequent result is buckling of the longitudinal strut, which eventually breaks.^[21] In theory, the solution is always to implant the stent-graft with the strut on the outer aspect. In practice, this requirement just adds another potential source of failure.

Stents limit the flexibility of the stent-graft by fixing the longitudinal dimensions of opposing walls, but they also add radial support, which helps to prevent kinking. The unsupported stent-graft limbs of the Ancure had the highest rates of occlusion.^[29,30] The rates for fully-stented devices are generally less than 5%.

DELIVERY SYSTEM DIAMETER

Endovascular aneurysm repair is commonly referred to as percutaneous, which is not strictly true. Current stent-graft delivery systems make a large hole in the femoral artery, which has to be repaired when the delivery system is removed. The simplest, most widely-practiced method of repair involves surgical exposure and suture of the arterial access site. Alternatively, sutures can be inserted percutaneously at the access site before delivery system insertion using a special system of catheters and needles. At the end of the procedure, the sutures are tied with a sliding knot, closing the

defect in the femoral artery or the overlying femoral sheath.^[31] The expense and potential for failure have limited use of the percutaneous suturing system. Consequently, most stent-grafts are inserted through surgically exposed femoral arteries. That may change if smaller-diameter systems, such as the Trivascular device, prove to be effective.

CONCLUSION

Much of what we know about stent-graft performance is the result of a vast human experiment. Stent-graft design has benefited greatly from the painful lessons of the early experience. We hope that future advances will rely more on improved preclinical testing, based on a better understanding of materials science and the long-term demands of the endovascular environment. Yet fundamental assumptions in the modeling and testing of device durability remain poorly founded. For example, we still know very little about the pressure changes within the aneurysm sac after endovascular repair, or their effects on the trans-graft pressure, hemodynamic force, and pulsatile movement of a stent-graft.

INTRODUCTION

Stents are metallic implantable tubular devices (Fig. 1) used as mechanical scaffolds to the vascular wall during revascularization procedures of coronary or peripheral arteries or lumen enlargement of hollow structure such as the tracheobronchial tree biliary duct and urinary tract. 316L stainless steel, nitinol or NiTi alloy, tantalum, and cobalt-chromium-based alloys are the materials most commonly used in the design of endovascular devices. The beneficial effect of coronary stenting over conventional balloon angioplasty has been demonstrated in the BELgian–Netherlands STENT (BENESTENT-I) and STent REStenosis Study (STRESS) studies in the early 1990s. In these landmark studies, restenosis, defined as the renarrowing of a vessel (definition angiographic: >50% diameter stenosis at 6 months follow-up), was significantly reduced. Since then, intensive research in the field of adjunctive pharmacological therapies, implantation techniques, and stent design have further reduced the clinical outcomes associated with stent implantation, namely subacute thrombosis and the need for target vessel revascularization (restenosis). Stenting is now a well established technique in endovascular interventions, representing as much as 70–85% of all percutaneous coronary interventions and about 50% of peripheral interventions, with about 1,000,000 stents being placed each year worldwide. Currently, more than 50 types of stents, and, more recently, stent-grafts with various designs (mesh structure, coil, slotted tube, ring, etc.) and compositions, have received FDA approval or CE marking. The worldwide market is estimated to be U.S. \$5 billion in 2002 for both coronary and peripheral interventions, with an annual growth rate of 5%. The recent availability of drug-eluting stents with perspectives of even greater restenosis reduction potential is likely to change the features of interventional cardiology.

HISTORICAL PERSPECTIVES

Charles Dotter introduced the idea of endovascular stents (Fig. 1) in 1964 and demonstrated in 1983 its

feasibility in the revascularization of diseased arteries. Stents were initially investigated to prevent recoil and cover intimal tears in order to prevent acute closure of balloon-revascularized arteries. In 1986, Jacques Puel performed the first human coronary stent implantation in Toulouse (France) using an ancestor of the self-expandable Wallstent. Since then, the BENESTENT and STRESS studies have shown the beneficial effects of elective coronary stenting following balloon angioplasty, versus angioplasty alone, in coronary revascularization (Table 1).^[1,2] The beneficial effect of stent over balloon angioplasty has been attributed to larger acute lumen dimensions and to the prevention of constrictive remodeling. The Palmaz–Schatz stent was the first FDA-approved device in 1994. Two major breakthroughs have clearly expanded the use of stents in percutaneous revascularization procedures and significantly improved the initial outcomes of the procedures: intravascular ultrasound (IVUS) and antiplatelet therapy. IVUS studies have demonstrated the importance of *optimal* stent deployment (symmetry, struts apposition, minimal area) and the need for high-pressure balloon postinflation to achieve proper stent expansion within the vessel.^[3] The optimal stent deployment concept suppressed the need for anti-vitamin K therapy (Warfarin) and in turn reduced the risk of bleeding. The benefit of antiplatelet therapy over traditional therapy, based on heparin and coumadin, along with aspirin and dipyridamole, namely a significant reduction in subacute thrombosis and bleeding, was demonstrated in the randomized ISAR and STARS trials (Table 1). Current revascularization procedures with stents are characterized by thrombotic occlusion rates lower than 2% and very high procedural success rates (>95%).

CLINICAL INDICATIONS

Stents reduce the risk of acute vessel closure and its consequence, the need for emergency coronary artery bypass graft surgery, and have been demonstrated to improve clinical outcomes in specific conditions. From

Fig. 1 Current stent designs and materials allow increased flexibility. Nitinol SMART stent from Nitinol Devices & Components.

randomized trials, those conditions are the treatment of abrupt or threatened vessel closure during angioplasty, primary reduction in restenosis in de novo focal lesions in vessels > 3 mm in diameter, focal lesions in saphenous vein grafts, and chronic total occlusions.^[4] Stents are also successfully used in many other conditions such as restenotic lesions, acute coronary syndromes (unstable angina and acute myocardial infarction), multivessel diseases, and the treatment of iliac and renal artery stenosis. However, their benefit in bifurcating lesions, in small vessel diameters (<3 mm), in diabetic patients, and in diseases of the femoral, popliteal, and carotid arteries is still being debated.

The use of stents is likely to increase due to the recent availability of devices designed to treat these specific conditions, such as small artery or vein graft disease, as well as the broadening of the available stent properties.

COMPLICATIONS

In spite of major technical advances in the past two decades, endovascular revascularization procedures remain limited by the cascade of events subsequent to device implantation.

S

Subacute Thrombosis

Early stent implantations were plagued by a high rate of thrombotic occlusions (8–10%) of the revascularized vessel, mainly due to suboptimal deployment of the devices and its inherent thrombogenicity. As previously mentioned, high-pressure deployment techniques combined with enhanced antiplatelet therapy have drastically reduced the risk of vessel thrombotic occlusion (1.7%). The thrombogenicity of the metallic alloys may still contribute to platelet activation, and in turn initiate neointimal hyperplasia.

Table 1 Selected randomized clinical trials

Trial		Composite events	Restenosis
BENESTENT	Balloon	AC = 2.7%	32%
	Stent	AC = 3.5%	22%

In-Stent Restenosis

Despite reduced restenosis rates in short lesions such as demonstrated in randomized trials, stenting is still associated with late in-stent restenosis. Based on clinical studies, restenosis rate can range from 8 to 50% depending on lesion complexity, reference vessel diameter plaque burden, and systemic conditions such as diabetes.^[5,6] In-stent restenosis is a multifactorial phenomenon that involves thrombus formation, inflammation, cellular proliferation, and extracellular matrix synthesis within the treated vessel.^[7] The cascade of events is initiated by arterial injury following angioplasty and is usually limited to the first 6 months following the procedure. Thrombus growth resulting from exposure of the extracellular matrix in the endothelium-denudated vessel wall and from the presence of the metallic device leads to the release of biological factors, including PDGF- β , TGF- β , bFGF, thrombin, etc., which in turn can initiate medial smooth muscle cell migration (SMC) and proliferation. Medial injury with disruption of the internal elastic lamina also directly stimulates SMC migration and proliferation. This cell growth is associated with extracellular matrix secretion that further participates in the neointimal thickening. The presence of inflammatory cells has been reported in addition to SMCs in the surrounding tissues.^[8] A strong correlation between the extent of medial damage, inflammation, and restenosis has been reported from human pathological studies.^[7] There is growing evidence that neointimal hyperplasia following stent implantation is strongly related to a prolonged inflammatory state of the stented artery.

Issues such as stent embolization, side branch occlusion, coronary perforation, or infection of the stented vessels are infrequent complications but could have potentially catastrophic effects.

METALLIC ALLOYS USED IN ENDOVASCULAR PROCEDURES

While many efforts have focused on the development of devices with improved design, biofunctionality, and surface properties, only a few alloys are routinely employed for stent manufacturing. They are generally made from one of three alloy classes: 316L stainless steel, nitinol (or NiTi alloy), and, to a lesser extent, cobalt–chromium alloys such as Elgiloy[®].

The differences in the mechanical properties of these materials strongly influence the properties of the devices and thus possibilities in terms of design. Stainless steel–based stents are balloon-expandable devices that require a plastic deformation to be deployed in the treated artery. Nitinol is gaining popularity in the

design of multiple permanent vascular implants, such as coronary and peripheral stents, atrial septal defect occlusion systems, and vena cava filters, due to its unique mechanical properties. These devices can be designed as self-expandable due to the superelasticity of nitinol. Tantalum was also used in the manufacture of coronary stents such as the Wiktor-GX but was nearly abandoned due to its exaggerated radiopacity. Cobalt–chromium alloy stents are currently under investigation (Multi-link Vision, Guidant and S8, Medtronic AVE). These alloys enable thinner strut thickness compared with stainless steel–based devices without reducing radial strength and radiopacity. They may also be less prone to biocorrosion than stainless steel devices.

New materials are being investigated to improve mechanical properties, radiopacity, MRI compatibility, and hemocompatibility.^[9,10] Differences in RX radiopacity and magnetic resonance compatibility inherent in the materials themselves translate clinically into differences in the visibility of the devices. Radiopaque markers, mainly gold and platinum, may be used to improve the visibility of these devices (e.g., beStent with proximal and distal gold markers).

BIOMECHANICAL CONSIDERATIONS

“The greater the lumen the better” concept that has prevailed based on minimal lumen diameter as the strongest predictive factor for restenosis, has led to the idea that all stents were equals in terms of clinical outcomes. As a consequence, stents were evaluated on their potential to achieve maximal lumen gain. There is now evidence that stent design also strongly influences the outcome of the revascularization procedure. Recent studies have indeed pointed out the dependency of thrombus formation and neointimal proliferation on the type and design of the stent.^[11–13] Follow-up angiography in a cohort of 3370 patients has shown that stent design was the second strongest risk factor, after artery size, with restenosis ranging from 20.0% to 50.3%, depending on the stent type.^[13] It seems that reduced strut thickness represents the crucial factor for restenosis prevention. Much work remains, however, to determine precisely which features of the stent are detrimental to implantation.

The ideal stent should have a low profile, good trackability, and flexibility with a high and well distributed radial strength for optimal scaffolding (Table 2). The delivery system should be highly reliable and allow precise placement of the device. The improvements in both delivery system and device properties have drastically increased the conditions wherein stents can be used, e.g., the availability of a stent designed specifically for small arteries. The beStent (4-crown

from Medtronic AVE) was compared in randomized studies to balloon angioplasty and proved to be superior in the treatment of <3 mm vessels. In addressing a wide variety of vessels and indications, the concept of an ideal stent has been evolving toward the idea that a different stent would best suit each indication. Nonetheless, it is likely that the choice of the best device will continue to rely on the clinician's expertise on a case-to-case basis.

The properties of balloon-expandable stents are mainly related to their design. Three designs are widely used, i.e., slotted tubes, corrugated rings and, to a lesser extent, coils. Slotted tube stents are the most widely used devices (beStent 2, Multilink Tetra and Zeta, BiodivYsio, etc.) and are characterized by good radial strength but less conformability compared with ring stents (AVE S670-S7, NIR, etc.), which are made of repeating cells and usually display good flexibility and are more suitable for the treatment of lesions requiring good conformability. New slotted tube design devices with thinner stent struts, such as the PURA AS, the Sorin Carbostent, or the 0.08-mm Tenax, could also perform well in such applications.

Nitinol-based devices rely on the mechanical properties of the alloy to be self-expanded within the vessel (Fig. 2). Comprehension of the material's characteristics is necessary in order to understand the device's properties. Self-expansion has been reported to reduce endothelium damage^[14] by minimizing the need for balloon postdilatation and allowing more uniform radial expansion along with less longitudinal shortening, in comparison with balloon-expandable devices.^[15] The effects of the continual expansion of oversized nitinol stents (10–15%) have been demonstrated to accommodate neointimal formation, but this remains controversial.^[16] Conversely, the over-expansion required to compensate for the acute recoil of balloon stents can be expected to increase injury to the vessel. Therefore, selection of a properly sized stent will influence its performance. As defined by D. Stoeckel, the

**Fig. 2** Deployment of a self-expandable stent.

crush-recoverability and the biased stiffness (or stress hysteresis) of NiTi alloys are particularly well adapted to the design of peripheral endovascular devices.^[17] Despite higher radial strength, stainless steel devices can be permanently deformed if outside forces exceed their buckling resistance. Nitinol devices, however, will return to their deployed shape even if completely crushed, which may be extremely important in superficial vessels such as the carotid artery.

SURFACE TREATMENTS

The surface properties of an endovascular device may strongly influence the outcome of a procedure. As stated in the FDA's cardiology guidance documents, particular attention should be paid to the surface treatment of endovascular devices.^[18] Surface properties such as roughness, surface energy, and chemistry are known to mediate the compatibility of blood-contacting surfaces. We have previously shown that, independent of other surface characteristics, the material itself affects the hemocompatibility of the device.^[19]

In addition, metallic materials used in endovascular applications are passive alloys or metals that impart their corrosion resistance and surface properties from surface oxide layers. In the presence of oxygen, oxides spontaneously grow on the alloy surface, e.g., Cr₂O₃ for stainless steel and Elgiloy[®], TiO₂ for nitinol or Ta₂O₅, and TaOH for tantalum. Therefore, the biostability of metal implants often relies on appropriate processing and a surface finish that reinforces the native oxide layer. Treatments such as acid passivation or electropolishing, used extensively in the final manufacturing process for endoluminal stents, as prescribed in the ASTM F86 standard,^[20] have been reported to improve the stability of materials such as nitinol and stainless steel significantly. Electropolishing removes the native oxide to form a more homogeneous oxide layer, resulting in a smoother surface, with roughness

in the range of nanometers, suitable for blood contacting devices.

INORGANIC COATINGS

Inorganic coatings have been investigated on endovascular stents, such as diamondlike carbon, hydrogen-rich amorphous silicon carbide (a-SiC:H) and amorphous titanium oxide.^[21–23] Such inorganic coatings improve the overall biocompatibility of the stent with the advantage of low thrombogenicity in comparison with uncoated devices. In addition, titanium–nitric-oxide–coated stainless steel stents significantly reduced neointimal hyperplasia in an experimental model.^[24] Along with increased biocompatibility, these inorganic coatings may also improve significantly the corrosion properties and in turn reduce the release of ions in the surrounding vessel wall. Five inorganic-coated stents are available: Tenax (Biotronik, Germany), Sirius Carbostent (Sorin Biomedica Cardio, Italy), Diamond Flex (Phystis, Germany), BioDiamond (Plasma Chem, Germany), and the MAC carbon stent (AMG, Germany). To date, the long-term beneficial effects of inorganic coatings have not been demonstrated by randomized trials. Gold coatings have also been used with the expectation that the inertness of gold would increase the overall biocompatibility while increasing the radiopacity of the device. Clinical studies have, however, reported an increased likelihood for restenosis that may be related to a coating defect rather than the gold itself.^[25] This strongly suggests that, along with biomechanical considerations, the processing itself could influence the outcome of the procedure.

THROMBORESISTANT COATINGS

Many approaches have been investigated to reduce thrombogenicity of metallic endovascular stents, using heparin, phosphorylcholine, or r-hirudin coatings, for instance. While these coatings have been proven to reduce thrombus formation on the device and as a consequence lower the subacute thrombosis rate in an animal model, the beneficial long-term clinical impact of these devices remains uncertain. Heparin-coated stents are commercially available and have been investigated in many experimental and clinical studies. For example, the heparin-coated BX Velocity stent, wherein heparin is immobilized on the surface and remains free to inhibit thrombi formation, has recently been accepted by the FDA. These devices are well tolerated but failed to prevent neointimal hyperplasia.^[5,6] Along with its anticoagulant properties, heparin has been shown, *in vitro*, to have an anti-proliferative action on SMCs. However, local delivery

of heparin from either delivery catheters or stents did not prove to be beneficial. The lack of activity of heparin-coated devices is likely to be related to sub-optimal tissue concentration of the drug. Phosphorylcholine-coated *Biodiv Ysio* stents also hold promise in the revascularization of small arteries, which remains a very challenging issue. Phosphorylcholine coating has been demonstrated *in vitro* to prevent platelet adhesion to the metallic surface. The phosphorylcholine-based coating is also being investigated as a drug delivery platform through hydrophobic interactions.^[26,27]

MEMBRANE-COVERED STENTS

As initially described by Parodi, stent grafts or membrane-covered stents are subclasses of stents developed for the endovascular treatment of abdominal aortic aneurysms (AAA).^[28] Stent-grafts are made of a conventional segment of bypass graft supported at the ends by expandable metallic stents. Membrane-covered stents are endovascular stents covered with or covering a synthetic membrane (Fig. 3). The membrane is usually made of a conventional surgical material such as Dacron, ePTFE, or polyurethane. These devices are currently being used or are in clinical trials for aneurysmal or AV-fistula repair, arterial rupture sealing,

Fig. 3 Membrane-covered stent during its deployment.

coronary and peripheral occlusive diseases, and for the treatment of aortocoronary vein graft disease.^[29–32] The underlying concept resides in vessel wall exclusion by complete semi-porous materials. In the particular setting of saphenous vein graft disease, membrane-covered stents, either PTFE sandwiched between two stainless steel layers (JOGRAFT, JOMED) or stainless steel sandwiched between two PTFE layers (SYM-BIOT, Boston Scientific), are being investigated with the goal of reducing the risk of distal embolization of the friable plaque and reducing restenosis.

Chronic inflammatory reactions and delayed endothelialization of the membrane have been reported following implantation. The impaired endothelialization of the synthetic membranes could translate into higher risk of subacute thrombosis rates. One-year implantation studies, however, by Virmani et al. have demonstrated good results with ePTFE-nitinol grafts, with complete endothelialization observed within 6 months.^[33] Issues such as graft migration, graft fretting against the vascular wall, extravasation of blood into the aneurysm sac after stent-graft deployment, so-called endoleak, and structural failure of the graft, such as those reported by Guidoin et al., however, give rise to some concerns about the long-term efficacy of these devices.^[34]

RADIOACTIVE STENTS

Brachytherapy, i.e., the use of radiotherapy to inhibit neointimal proliferation, represents the treatment of choice if in-stent restenosis occurs. Radiation treatments inhibit the ability of cells to clonogenically divide, thus preventing acute cellular proliferation and migration, usually triggered by vascular wall injury. It is delivered in situ via a catheter-based, removable radioactive source (Ribbon or Beads Beta source or Gamma source—deeper penetration with radiosafety concerns). Stents have also been investigated as a radiation delivery platform with the idea that prolonged exposure of the arterial wall to low radiation doses may be beneficial.^[35] Most of the experiences have been performed using 32-phosphorus ion implanted stents. Dose-dependant inhibition has been reported with the β -emitting ³²P stents.^[36] Edge restenosis caused by intense radiation decay at stent outer limits and high rate of subacute thrombosis have limited their development.^[37] The hot-ends approach has been proposed to circumvent the edge-effect by reducing the dose's fall-off at the stent margins. Conversely, the investigation of radionuclides with more appropriate physical properties (γ radiation, shorter half-life, etc.) could renew interest in the field. The emergence of efficient antirestenosis drug-eluting stents will likely

restrict the use of radiation therapy as a mode of treatment of restenosis.

BIODEGRADABLE STENTS

While the scaffolding effect of the stent is beneficial in the short term, the presence of metallic devices may mediate chronic inflammatory reactions and in turn stimulate restenosis. To circumvent the latter, the concept of a biodegradable stent has been proposed. This stent should display the same mechanical properties, e.g., radial strength, of a metallic implant but then slowly disappear (biodegrade) once the artery is stabilized. Tamai and coworkers have recently reported the first clinical application of biodegradable stents made of poly-L-lactic acid (PLLA) monofilament. Follow-up at 6 months indicated an acceptable rate of restenosis (10.6%).^[38] The potential of local delivery of biologically active components from such biodegradable stents may favor their development.

It is noteworthy that the intriguing concept of a metallic biodegradable stent based on corrosion biodegradation of magnesium or iron (Fe > 99.8%) has been recently introduced, respectively, by Heublein et al. and Peuster et al.^[39,40]

DRUG-ELUTING STENTS

The development of drug-eluting stents that could efficiently deliver biologically active drugs to the vascular wall has been the object of much investigation in recent years. Early works using various drugs and coatings were often disappointing due to poor drug efficacy, uncertain drug dosage or required duration of delivery, and most commonly unstable and proinflammatory polymeric coating. The excellent results recently reported using antiproliferative drugs, such as sirolimus and paclitaxel, have, however, generated hope that restenosis will no longer compromise endovascular revascularization.^[41–44] These cytotoxic hydrophobic drugs derived from cancer chemotherapy or kidney allograft rejection treatment can be retained in the vascular wall when eluted from the stent and can selectively target proliferating cells within the artery. The mechanical scaffold offered by the metallic stent conjugated with the antiproliferative properties of these drugs translate, at least in initial clinical studies, into very low restenosis rates. The CE Mark and FDA approval of the sirolimus-coated Cypher™ stent (Cordis) and the enthusiastic results of the US SIRIUS trial with this device have further motivated ever increasing activity in the field of drug-eluting stents. Sirolimus is a natural macrocyclic lactone with potent antiproliferative and antiinflammatory properties. Sirolimus eluted from the

stent platform binds to SMCs' cytosolic receptor proteins and inhibits cyclin-dependent kinase complexes, thus mediating cell arrest in the late G1 phase. Paclitaxel prevents microtubule organization and as a consequence inhibits several steps in SMC migration and proliferation. Along with sirolimus and paclitaxel, many drugs are currently under investigation for stent-based delivery. These include everolimus, tacrolimus, estradiol, dexamethasone, angiopeptin, batimastat, and c-myc antisense oligonucleotide.

Regardless of the type of drug, proper coating and drug delivery platform remain the key issues in optimizing the antirestenotic effect of these devices. Two different approaches are currently being used to achieve delivery of the drugs: polymer-coated devices (Cordis/sirolimus Cypher stent and Boston Scientific/paclitaxel stent) and direct elution from dip-coated stents (Cook/paclitaxel stent). The potential long-term degradation and inflammatory effect of the polymer coatings versus control of the release rate are the key elements in the debate between these two approaches. The disappointing results obtained in the Guidant's DELIVER trial, using Cook Inc.'s ACHIEVE™ stent, which did not employ a polymer coating to elute the drug, suggest that sustained release is highly desirable to optimize the beneficial action of the drug. However, much work remains to be done to assess the long-term safety of these new devices and determine their clinical potential. Along with possible damaging effects to the artery of the antiproliferative components, the biocompatibility of the coated surfaces requires further investigation and potentially optimization. In particular, delayed reendothelialization and late thrombosis seem to be a potential outcome of these antiproliferative strategies.^[45] The very low restenosis rates observed so far (<5%) in clinical trials using drug-eluting stents may just represent a delayed healing, and long-term studies in humans are required to show whether the benefit is maintained.

CONCLUSIONS

Over the past decade, stenting has become the procedure of choice in many intraarterial revascularization procedures. Advances in stent technology are likely to increase their use further in an always growing number of conditions. In particular, new devices with excellent mechanical properties based on improved design or new materials offer exciting possibilities to treat challenging pathologies. The availability of devices designed to specific situations such as small vessel diseases or bifurcation lesions is also noteworthy. Drug-eluting stents that locally deliver therapeutic amounts of antiproliferative drugs may solve the issue of restenosis that has continuously plagued stent

implantation. Despite the increase in cost associated with the use of these devices, the elimination of restenosis will translate in more percutaneous transluminal treatment of occlusive vascular and nonvascular disorders, whereas surgical treatment modalities will be reserved for a minority of extremely complex diseases. The success of the pharmaceutical strategies combined with stents has, however, increased the hope that pharmaceutical strategies alone will be able to cure endovascular diseases. Systemic therapies with new drugs, nanoparticles-based local drug delivery, and gene therapy, for example, are promising research areas that could in the future reduce the need for the mechanical scaffold to the vascular wall offered by the stents.

S

INTRODUCTION

The development of more complex medical devices and specific targeting nanodrugs requires materials able to guarantee special mechanical performance, physical–chemical characteristics, and properties of interaction with the biological environment and tissue interfaces.

Beside the specific design, shape, dimension, and functionality of the medical device, as well as surface and bulk properties of biomaterials, are fundamental parameters to obtain the desired diagnostic or therapeutic effect. In addition, many applications require devices and preparation to guarantee an absence of contaminant species in the finished product. Therefore, there is a need to process materials and release medical devices that satisfy the condition of sterility.

Sterilization is indeed the best practice to limit or prevent risk of infection related to the use of medical devices. For instance, the contamination of perimplant tissue is the foremost reason for complications post-intervention and often triggers the failure of implanted devices in the short and medium term. Sterility is, therefore, mandatory for every critical medical device that enters into contact with anatomic sterile districts (internal organs, blood tissue, etc.), but is also frequently desirable for semicritical devices used on integral mucosas of the digestive tract and respiratory apparatus.

Processes and technologies developed to guarantee the destruction or inactivation of microorganisms are based on physical or chemical agents and, often, on the synergic combination of two or more treatments. Sterilization aims to deactivate cell processes involved in metabolism or genetic transcription, inducing cell death or stopping the replication ability of contaminant species. Because many microorganisms, especially bacterial spores, have excellent resistance to environmental stresses, the achievement of sterility requires exposure to aggressive treatments and conditioning in artificial environmental conditions that are entirely different from what the material is designed for. Currently all available techniques induce, to different extents, some modifications in the sterilized material.

The development of sterile medical devices requires conciliating complex characteristics of biocompatibility, bioreabsorption, biomimesis, etc., to sterilization treatment. This paper aims to address the selection of the most appropriate sterilization technique by fixing some important procedural steps. An overview of the currently available sterilization methods, with discussion of some of the effects of traditional and experimental sterilization processes on medical devices, is presented.

BIOMATERIALS AND MEDICAL DEVICES

A material is of biomedical interest in accordance with its specific clinical use and the purpose for which it has been conceived, projected, and realized. Material design and destination of use are identified in the finished medical device. The medical device is then usually sterilized before use. The sole alternative to sterilization is to process sterile raw material in an aseptic environment from the inception to the packaging of the final product. The medical device includes all chemical, physical, and functional properties, in addition to hygienic requirements. The current legislation does not regulate the materials per se, but regulates their final shape with potentials and risks as medical devices.

The European Union and the United States have similar classifications for medical device risk that account for the global risk associated with the device including the infection risk, malfunctioning risk, electrical risk, and personnel risk. For sterilization purposes, the Spaulding classification, based on infective risk, is pertinent.^[1] According to this classification, medical devices are grouped into critical, semicritical, and non-critical and sterilization treatment is required, advisable, or not necessary, as detailed in Table 1.

STERILIZATION PROCESS

The final result of the sterilization process requires the absolute absence of living forms from the surface and

Table 1 Infective risk classification of medical devices according to Spaulding^[1]

Application	Level of risk	Spaulding classification	Recommendation
In close contact with a break in the skin or mucous membrane	High	Critical	Sterilization
For introduction into sterile body areas			
In contact with intact mucous membranes	Intermediate	Semicritical	High-level disinfection or sterilization
Prior to use in immunocompromised patients			
In contact with healthy skin	Low	Non-critical	Low-level disinfection

bulk of the item. The World Health Organization (WHO) states that sterilization is any chemical or physical process that implies the destruction of all living forms, including bacteria, fungi, virus, and spores. The achievement of the sterility status comes from a probabilistic process, which takes into account presterilization procedures of cleaning, disinfection, and packaging, the effectiveness and correct use of sterilizing media and apparatus, and the suitability of storage conditions and times.

WHO's definition simplifies the concept of sterility that can be operatively defined only on a statistical basis. To this end, the sterility assurance level (SAL) has been defined as the probability of finding a living microorganism in the sterilizer load after treatment. The SAL for a validated sterilization process is 10^{-6} . This requirement demands a minimal reduction in bioburden equal to $6+x$ decades, where x is the expected microorganism load before sterilization, expressed in decades. This complies with the need to reduce the microbial load and assures a SAL of 10^{-6} (Fig. 1).

As a result, any microbiologic test developed to assess sterilization effectiveness should utilize a minimal bioburden greater than 10^6 microorganisms. Procedures for testing effectiveness of sterilization treatments usually aim to reveal a reduction greater than 6 log in microorganisms selected among the most resistant species to the specific sterilization process.

PRESTERILIZATION PROCEDURES

From the operative definition of sterilization follows the importance of reducing the initial bioburden as much as possible before sterilization. Presterilization procedures account for any cleaning and disinfection process able to minimize inorganic and organic soil and microbiologic burden before sterilization.^[2] In the case of device reuse, the possibility of iatrogenic transmission must also be considered and the first treatment immediately after clinical use (usually

referred as decontamination) is mandatory to minimize the risk of disease transmission to health care professionals.

Cleaning and disinfection should be pursued using detergents (solvents, surfactants, enzymatic solutions, etc.) and biocides (chlorine, compounds, polyphenolic,

Fig. 1 Schematic representation of three possible sterilization kinetics and their efficiency with respect to SAL. Differences in the D_{10} value (time required to reduce the bioburden by 10 times) between kinetic A and B guarantee a SAL of 10^{-6} in 4 and 8 min, respectively, when considering an initial bioburden of 10^2 microorganisms. For higher initial bioburden (kinetic C), the same D_{10} value of kinetic B allows a SAL of 10^{-2} in the same time frame (8 min), which is considered insufficient for sterilization purposes. For a standardized process, inactivation kinetics usually follow simple exponential decay, which results in linearity in a semilog scale, but significant deviation from this ideal time course must be considered for non-conventional sterilization techniques.

aldehydes, etc.), respectively. Structured protocols and proper sequences of treatments should be considered to optimize presterilization protocols (Fig. 2).^[3]

Chemical properties of solutions could be highly enhanced by mechanical cleaning (spray washing, brushing, turbulation, ultrasonic cleaning, etc.). Special attention must be given in flushing and rinsing narrow and long lumens, cavities, and holes. Suitable rinsing and drying should guarantee the removal of biologic and chemical residuals, any eventual particulate, and water from exposed and inner surfaces. Effective drying is strictly required for low-temperature sterilization using ethylene oxide or hydrogen peroxide gas plasma to avoid the production of toxic byproducts (ethylene chlorohydrin, ethylene glycol) or inactivation of the sterilization efficiency, respectively. The residual biologic burden before sterilization should be lower than 10^2 microorganisms per device. Any other non-viable soil, especially organic material, albumin, nuclei acids, sugar, and starch, should be reduced to a minimum to avoid local inhibition of

chemicals, shielding of microorganisms, and a general inefficiency of the process.

MAIN STERILIZATION TECHNIQUES

A number of sterilization techniques are currently available, including traditional methods by saturated steam, ethylene oxide, ionizing radiation, and more recent processes based on low-temperature plasmas in the vapor or gas phase.

Despite this large panel of techniques, an elective process able to guarantee the sterilization of all materials while preserving them from modification does not exist. Each process presents pros and cons, and many undesirable effects are related to the incompatibility between the material properties and the process parameters of the sterilization technique.

In researching and selecting the most suitable sterilization technique for a specific device, it is mandatory

S

Fig. 2 Low-vacuum scanning electron microscopy after different decontamination-cleaning protocols on cardiac catheters soiled by bacterial spiked blood. Significant differences in cleaning efficiency are visible at the interface between the two device components: the polyurethanic shaft (dark gray) and platinum electrode (light gray). (a) Chlorine solution followed by enzymatic solution: massive blood residuals (white arrows) on the electrode surface. Black arrows indicate thick deposits. (b) Enzymatic solution followed by chlorine solution: meniscus-like residual at the electrode–polymer interface. Black arrows indicate a clean segment between the remaining soiled interfaces. (c) Polyphenolic emulsion: optimal cleaning with no residuals (black arrow). Electrode imprint and dislodging on the catheter shaft (white arrows) promote interstitial soiling. (d) Polyphenolic emulsion followed by enzymatic solution: optimal cleaning of the critical interface area (white arrow). Images are presented at different magnifications to highlight different levels of residual soil. From Tessarolo et al.^[3]

to perform in-depth compatibility analyses of the material with the operative parameter of the process.

Saturated Steam

Water-saturated steam at high temperature (121–134°C) and pressure (1.1–2.1 bar) is the most common sterilization technique used in hospitals and health care facilities. Different from the less effective treatment using unsaturated steam, a prevacuum is required in autoclave before the injection of water vapor. Steam is non-toxic, inexpensive, and has a high sporicidal effect with short application times (4–15 min). Steam is highly recommended for sterilizing heat-resistant material and metals. Conversely, steam is inapplicable to heat-sensitive materials. The elevated humidity and pressure can induce softening, degradation, and hydrolysis in many biomedical polymers.

Changes in the mechanical properties, surface degradation, and byproduct formation has been reported on metallic, polymeric, and biologic biomaterials.^[4,5] Because of its numerous advantages, steam has also been applied to biomedical polymers. Vascular polytetrafluoroethylene prosthesis, polyvinyl chloride hematic circuit, and polyurethanes used for pacemaker cables, ventricular-assisted devices and catheters have been sterilized by steam autoclaving. Although the thermal stress could be sustained without compromising polymer characteristics, low-temperature sterilization techniques are generally preferable for polymeric materials, especially in the case of multiple sterilizations.

Dry Heat

Dry heat sterilization is obtained in an oven (Pasteur stove) by hot air that destroys pathogens by oxidation, volatilization of light components, and deep dehydration of microorganisms. The slow penetration rate requires the achievement of a high-temperature (150–170°C) for a prolonged time (60–150 min). Dry heat has several constraints and limitations because of the high temperature and time required for microorganism inactivation. Only thermoresistant materials can be processed, and usually steel and glass are sterilized using this technique. Different from saturated steam, dry heat does not induce superficial corrosion and deposits and allows the effective sterilization of complex designs with closed cavities.

Ethylene Oxide

Ethylene oxide (EtO) sterilization is a commonly used sterilization technique for processing thermosensitive

products in the medical device industry. The sterilization process includes a vacuum phase in autoclave and a subsequent injection of EtO gas in concentrations ranging from 600 to 1200 mg/L. The chamber is kept between 30 and 50°C with a relative humidity of 40%–50%. The cycle lasts for 2–8 h according to the specific sterilization protocol and sterilizer load.

EtO is a non-colored, flammable, explosive gas, as well as an extreme irritant to skin and mucosa. The addition of carbon dioxide or chlorofluorocarbons lowers the flammability and explosive risk, but complicates environmental compatibility and treatment of exhausted gas.

Bactericidal, sporicidal, and virucidal effect result from the alchilation of sulphhydrylic, carboxylic, and hydroxylic groups in nucleic acids, which induces cell death.^[6]

The main advantage of EtO sterilization is related to the low-temperature process and the wide range of material compatibility. Conversely, the sterilization cycle should include a postprocess aeration for detoxification of gas residual that can last 12 h in forced systems or even 14 days if spontaneous. The Food and Drug Administration fixes the maximal level of EtO in a ready-to-use device at 25 mg/L, and the high permeability of polymeric materials to EtO requires monitoring of the residual levels. Handlos and coworkers^[7] demonstrated that the degassing process is mainly a diffusion-controlled phenomenon. Time courses of degassing are known for a wide range of materials, and the forced degassing procedure assures a time-effective process. However, EtO systems require costly installation, and concerns remain about potential exposure of personnel to the gas, which is highly toxic, mutagenic, and a suspected carcinogenic.^[7]

Although the exposure of polymers to EtO sterilization usually induces slight effects on molecular weight, degradation rate, mechanical properties, and surface chemistry,^[8] byproduct formation and alchilation reactions were observed with urethanic and urea groups.^[9] In specific biomedical applications, morphological and compositional degradation of surfaces were also reported.^[5,9–11]

Plasmas

Cold plasma techniques are currently the most effective alternative to EtO for low-temperature sterilization of thermosensitive materials. Cold plasma is a partly ionized gas including ions, electrons, ultraviolet photons, and neutral reactive species such as radicals and excited molecules generated by the application of an electric or magnetic field in specific gas or vapor phases. In the early 1990s two commercial plasma sterilization systems were marketed under the

trademark Sterrad™ and Plazlyte™. These technologies are based on hydrogen peroxide and a hydrogen peroxide-peracetic acid mixture, respectively.^[10] Their biocidal effectiveness is mostly related to the chemical sterilization phase obtained by the vaporization of the chemical solutions in an evacuated autoclave. The plasma phase is then used in both treatments to neutralize the residual active species and to provide a sterile device in a short processing time with no need for aeration or detoxification. Sterrad™ and Plazlyte™ should therefore be considered a low-temperature (> 55°C) chemical sterilization, different from the pure plasma-based techniques that are in development. Although various authors reported surface oxidation and roughening of biopolymers by these commercial plasmas (Fig. 3),^[10,12,13] no marked modifications in thermal or mechanical properties existed on the polymers. The release of 4,4-methylene dianiline was not revealed in repeatedly sterilized polyurethanes.^[10]

The high compatibility with a large number of polymers and the short sterilization cycle makes these techniques available for difficult tasks such as reprocessing single-use medical devices.^[13]

Ionizing Radiations

Sterilization by exposure to ionizing radiation is widely used in the medical device industries as a room temperature treatment and end-point process of chain production. Both γ -photons from ^{60}Co or ^{137}Cs sources and high-energy electrons from accelerators are ascribed to this technique. γ -Rays are able to deeply penetrate low-density materials, such as polymers, whereas high-energy electrons usually interact with the superficial layer of materials. To assure the homogeneous exposure of products to the required dose (a dose of 25 kGy is generally considered effective),

S

Fig. 3 Atomic force microscopy $80 \times 80 \mu\text{m}$ scans on the external surface of a polyurethane shaft for endovascular devices. (a) New and sterilized (b) one, (c) four, and (d) eight times by hydrogen peroxide gas plasma (Sterrad™ technology). Changes in nanoroughness of the shaft surface are evident after four cycles of reprocessing, documenting the etching effect of the plasma sterilization technique. From Tessarolo et al.^[13]

a relative displacement of materials with respect to the source is usually provided.

Although this technique allows treatment of large amounts of products in a time-effective manner, the application is limited by the huge investment required to realize the treatment facility and manage the radiation hazards.

Several papers have reported posttreatment modifications of sterilized polymers, such as increased brittleness, discoloration,^[14] hardening,^[8] softening, and variations in melting temperature and molecular weight.^[8,15] These modifications are the consequence of two opposing phenomena involved in the polymer radiation process: chain scission and cross-linking. Chain scission produces low-molecular-weight fragments with unsaturated chemical bonds and possible gas formation. Significant decreases in strain resistance and changes in crystallinity were reported in γ -radiated biopolymers after chain scission.^[8] Cross-linking usually results in an initial increase of tensile stress and decreased impact resistance. Polymers containing aromatic groups are typically less alterable than aliphatic chains, while terminal methyl groups are often cross-linked.

Superficial defects are usually enlarged after irradiation,^[9] and oxidation of superficial layers in biomedical polymer sterilized in aerobic environments was reported.^[8]

γ -Radiation can induce the production of toxic byproducts such as 4,4-methylene dianiline after decomposition of high-molecular-weight polyurethanes^[11] or other low-molecular-weight degradation compounds, which can induce cellular lysis. Resterilization by EtO of polyvinyl chloride devices previously treated by γ -radiation should be avoided because of the production of toxic epichloridrine.

Steam Formaldehyde

An effective method of sterilization by steam-formaldehyde was originally reported by Vink.^[16] The treatment is performed in an autoclave at about 0.1 bar with alternated injections of saturated steam and vaporized formalin. Several injections and evacuations of the chamber are required because of the low penetration ability of formalin with respect to EtO. Microorganism inactivation by formaldehydes, similar to other aldehydes, proceeds by the high chemical reactivity of carbonylic terminals able to alchilate aminic, hydroxylic, and sulphhydrylic groups of cell constituents.

Steam-formaldehyde sterilization is non-explosive and non-flammable and presents a markedly lower detection level by smelling than EtO, which allows earlier detection in the case of leakage and autoclave malfunctioning.

Formaldehyde residues have been detected on medical devices after steam-formaldehyde sterilization and the amount of residual is strongly related to the polymeric material and process parameters with a crucial role of the detoxifying and cleaning phases obtained by steam injections.^[16] Aldehyde residuals can be observed both as monomeric formaldehyde adsorbed into the materials and paraformaldehyde on the surface. Paraformaldehyde can be created by dissolution of formaldehyde on a moistened surface with the formation of polymeric hydrates. After polymer dehydration, paraformaldehyde can precipitate. As a result, hydrophilic and permeable polymers (polyamides, polyurethanes) with the possibility of absorbing larger percentages of water retain a greater amount of aldehydes than hydrophobic and non-permeable polymers.^[17]

Glutaraldehyde and Other Liquid Chemical Sterilizations

A class of chemicals such as glutaraldehyde, orthophthalaldehyde, performic acid, and peracetic acid, although defined as disinfectants because they are unable to realize a rapid inactivation of bacterial spores, can obtain sterilization through prolonged exposure time.^[18]

Glutaraldehyde is characterized by a marked reactivity similar to that described for formaldehyde, but with higher polymerization properties as a result of the double-ended molecule. Glutaraldehyde is usually available as an aqueous solution to be activated by regulating the pH. The strongest biocidal activity is reached at alkaline pH and increases with temperature to a maximum at 70°C.

Devices should be immersed completely in the sterilizing solution and then a careful rinsing with sterile water must be applied to remove chemical residual from the processed device. When compared to widespread disinfectants such as chlorine, glutaraldehyde does not affect metal components. Mixtures of glutaraldehyde and other disinfectants agents such as phenolic compounds are often used to obtain synergic biocidal effects.

Liquid-chemical sterilization techniques are widely used in hospitals for rapid low-temperature sterilization of thermosensitive materials, but do not offer the same hygienic assurance as heat-based or radiation-based techniques.^[2]

Other Available Sterilization Techniques

Several other ad hoc methodologies for sterilization are available. Microwaves are frequently used for rapid sanitization of infected waste, but significant

application for sterilization of catheters, air ventilators, and polymeric tubing are possible. X-rays obtained from Röntgen tubes or converted from e-beam accelerators are also available for low-temperature sterilization of thermosensitive materials such as polymers.

Mechanical filtration is a possible alternative for sterilization of soluble substances that are thermally and chemically sensitive and would be damaged by heat, radiation, or chemical sterilization. This method is widely used for protein solutions and pharmaceutical compounds. A filter with pore size 0.2 μm will effectively remove bacteria. If viruses must also be removed, a much smaller pore size, around 20 nm, is required.

NEW AND FORTHCOMING STERILIZATION TECHNIQUES

The increasing development of new biomedical materials with structural and superficial characteristics for highly specialized applications necessitates the parallel research and development of new sterilization techniques based on different chemical and physical principles that can assure strong biocidal effects as well as limited modification on sterilized materials.

Experimental Plasmas

Numerous studies are being conducted on plasmas for surface modification that demonstrate good biocidal properties with respect to bacteria and viruses. These techniques, properly called plasma treatments, are based on the exposure of materials to ions and activated molecules obtained by exciting selected mixtures of gases with radiofrequency or microwave electromagnetic fields. Low-temperature sterilization under direct exposure to the plasma could be realized by direct current, radiofrequency (1–100 MHz), or microwave (MW; > 300 MHz) discharges. The plasma condition can be obtained by MW excitation in the pulsed mode or by a very-low-frequency oscillating field (1–10 Hz) as needed to operate the corona discharge mode or dielectric barrier mode.^[19]

The choice of gas in the efficiency of spore inactivation, which is the most resistant contaminating agent to plasma, has special relevance. A high efficiency in spore inactivation was demonstrated independent of the type of discharge for O₂, N₂, SO₂, SF₆, NO₂, H₂O, H₂O₂, CO₂, halogens, air, and aldehydes.

Beside the chemical and physical etching, a non-negligible biocide role is attributed to ultraviolet radiation. Highly energetic UV photons (3.3–6.2 eV) provide a marked biocide effect because they correspond

with the frequency of maximum absorbance in DNA and nucleic acids.

An in-depth revision of the operative parameters involved in plasma sterilization was reported by Lerouge and collaborators,^[19] who demonstrated how gas composition, field power, excitation frequency, inlet gas flux, chamber pressure, and geometric factors could be modified to optimize the biocidal effect and minimize material alteration.

S

Electron Cyclotron Resonance Plasma

Chao and coworkers proposed a sterilization plasma reactor based on the electron cyclotron resonance (ECR) effect.^[20] When plasma is generated and maintained by MW, the application of an external magnetic field induces rotational trajectories in the free electrons. Variation of the magnetic field creates a variation in the angular frequency of electrons and a resonance with MW excitation can be obtained. In ECR mode the energy for sustaining plasma is minimal and a strong etching effect could be obtained. ECR plasmas offer a high ionization rate, low average temperature, and a large operative range in pressure and temperature.

The main disadvantage of plasma sterilizations is the low penetration of the active species, which are deactivated in the first layer of material. Similarly, shadowing effects must be considered and the presence of packaging markedly generally reduces the sterilization efficiency. Some studies proposed the use of an additional irradiation by UV in the range of 254 nm, which is the most efficient against microorganisms,^[19] but the large application of pure plasmas for batch sterilization requires a deeper understanding of the process.

Supercritical CO₂

Treatment by supercritical CO₂ was successfully applied to the inactivation of many bacterial species and yeasts in food,^[21] but was considered also for the sterilization of biomaterials.^[22] The treatment of materials in operative conditions near the critical region requires temperatures and pressures able to induce supercritical fluidity. The inactivation of *Escherichia coli* was reported under moderate pressure conditions (73.8 bar) and temperatures (31.1°C). Higher temperature and pressure were required for spore inactivation.^[21] Spilimbergo and coworkers demonstrated that the sterilization effect is mainly based on the diffusion of CO₂ into the cell and the extraction of cytoplasmic material through the membrane.^[22] The amphiphilic properties of supercritical CO₂ allow the rapid diffusion through and the fluidification of the cell

membrane. Cytoplasmic pH is therefore altered and the structure is compromised, inducing cell death.

Treatment of sensitive biopolymers (polylactic and polyglycolic acid polymers) did not demonstrate any macroscopic effect of degradation or variation in mass or molecular weight.

Additional studies are required to validate the operative protocol against many pathogenic species, but supercritical CO₂ sterilization could be of interest for treating sensitive material and drugs because of its intrinsic low reactivity to non-severe chemical-physical conditions and its high penetrating capability into cavities of the medium.

Pulsed Electric Field

Sterilization treatments based on high-intensity pulsed electric field (PEF) are realized by the application of high-voltage pulses (20–80 kV/cm) to substrates interposed between electrodes for less than 1 sec at room temperature.

These techniques are promising methods for sterilizing foods and the ability to inactivate large number of microbial species^[23] suggests the possibility of sterilization of biomedical materials as well.

The mechanism of microbial inactivation is mainly the result of membrane disruption following the application of the electric field. Breakage of the bacterial membrane is reached for a transmembrane potential of about 1 V, which, for *E. coli*, corresponds to about 10 KV/cm.^[23] This process has been called electroporation and induces cell swelling and membrane disruption.

The increase in pulse number usually increases the biocidal effect, but the first pulse mainly affects bacterial viability. Microorganism inactivation can also be improved by combining PEF with other physical or chemical stresses such as variation of pH, ionic strength, and pressure.

Spilimbergo et al. proposed the combination of PEF and supercritical CO₂ to inactivate bacterial spores at temperature lower than 40°C^[22] by favoring the penetration of the supercritical fluid with the electroporation process.

Little information is available regarding PEF treatment of biomedical materials, but its good compatibility and low alteration of food properties indicate a possible compatibility with thermosensitive materials and biomedical polymers.

STERILIZATION OF NON-CONVENTIONAL AGENTS

Non-conventional pathogenic agents, such as abnormal prions and bacterial endotoxins, are not

considered in the former definition of sterilization because they are non-viable contaminants. However, the increasing incidence of prion-related disease and the possibility of pyrogenic adverse events require treatments and techniques able to significantly reduce these contaminants. In this context the term sterilization is usually extended and refers to a process able to guarantee a reduction in the contaminating agent for more than 6 decades. Prions and endotoxins are notoriously highly resistant to inactivation by standard sterilization processes. The most common and safe approach to sterilization of these agents uses thermal techniques (dry heat or saturated steam) for a treatment time ranging from 3 to 6 times the normal sterilization cycle for microorganisms.^[24] Specific chemical treatments are also available but require harsh working conditions. Plasma sterilization, because of its peculiar etching properties able to inactivate and remove contaminants, could have some potential in this field.^[25]

A POSSIBLE APPROACH TO THE DEVELOPMENT OF A STERILE DEVICE

The usual approach to the individuation of an elective sterilization technique is based on a wide range of multidisciplinary experimentation. Material differences pre- and posttreatment and modifications induced by different sterilization techniques should be elicited to determine the technique that minimizes material alterations with respect to the final device use.

In-depth studies are required for some classes of devices to establish the maximum number of sterilization or reprocessing sustainable under safe and effective conditions. In this process of analytical characterization, experimental parameters such as biocompatibility, bioactivity, cell and bacteria adhesion, mechanical and rheological properties, and byproducts release are usually considered.

Close to the traditional process *ex post*, in which the objective is to identify the correct form of sterilization for minimizing modifications on the finished material, is the *ex ante* approach. The in-depth knowledge of sterilization techniques and their actions on materials could be used to define *ex ante* the sterilization treatment by considering it an integral part of device production. In a similar process, sterilization is not an additional and external step, but a functional phase to the implementation of desired parameters. Unavoidable modifications induced by sterilization could be turned into expected ameliorations of the finished device.

The possibility of obtaining material improvement and the availability of a ready-to-use sterile device are the immediate advantages of implementing a sterilization protocol as an integral part of the production

process. An example is represented by sterilization of the ultrahigh-molecular-weight polyethylene for joint prostheses. γ -Radiation in a non-oxidizing environment allowed proper modulation of cross-linking without increased polymer oxidation, therefore improving the mechanical properties of the sterile finished device.

In this field, the potential properties and parameters of plasma-based sterilization techniques might represent a source of new and interesting solutions for both sterilization and material processing. Plasmas are already widely used for surface functionalization and modification of biomaterials, important phases in the production process. The effort currently in progress to verify the efficacy of these techniques on microorganism inactivation indicates great potential in production-sterilization combined systems.

CONCLUSIONS

No available sterilization technique is applicable to all medical devices, and each sterilization method induces modifications to some extent in the chemical, physical, and thermomechanical properties of biomedical materials. Sterilization treatments can affect device properties and in vivo functionality, making the choice of the correct sterilization treatment a crucial step in medical device development and application.

Stress Fractures

S

INTRODUCTION

Stress fracture represents overuse injury of bone. It can be defined as a partial or a complete bone fracture that results from repeated application of a stress lower than the stress required to fracture the bone in a single loading. The first clinical description of stress fracture is credited to Breithaupt, a Prussian military physician. In 1855, he described the clinical picture and symptoms of metatarsal bone stress fractures in soldiers and termed the condition march fracture. The present understanding of stress fractures and the bone's response to loading has been advanced by numerous studies investigating the incidence of stress fractures in military personnel and athletes, and stress fractures have been described in nearly every bone of the human body. Stress fractures usually occur when excessive, repetitive loads on the bone cause imbalance between bone resorption and bone formation. Most common stress fractures occur in the lower-extremity weight-bearing bones, followed by pars interarticularis stress fractures of the lumbar spine, and then on some bones of the upper extremity. The origins of stress fractures are most likely site specific and depend on the bone density and geometry, the direction of the load, the vascular supply to the bone, the surrounding muscular attachments, the skeletal alignment, and the type of athletic activity. In addition to mechanical influences, systemic factors, including nutritional deficiencies, hormonal imbalances, collagen abnormalities, and metabolic bone disorders, can contribute to the development of stress fractures. Epidemiology, predisposing factors, pathophysiology, diagnostics, and treatment options of the stress fractures will be discussed in this entry.

EPIDEMIOLOGY

Stress fractures are common problems in sports medicine, comprising between 1.1% and 10% of all athletic injuries, while in the population of runners, they account for 15% of all injuries (although the data may vary from one medical institution to another).^[1–5] The

global incidence of bone stress injuries in sports has been estimated to be 2–4% in men and 7% in women.^[6]

Age

The average age of patients ranges from 19 to 30 yr. Considering the present-day tendency of including children and adolescents in top athletic activities, the number of overuse injuries in pediatric athletes is increasing. Nevertheless, stress fractures in pediatric athletes are less common than in adults.^[7] Hulkko and Orava surveyed 368 patients with stress fractures and found 9% among children younger than 15 yr of age, and 32% among those aged 16–19 yr.^[8] In addition, the distribution of stress fractures is somewhat different in pediatric athletes. The tibia is the predominant site of stress fractures in pediatric athletes with an incidence of 51%.^[8] Other sites, in descending order, are the fibula 20%, pars interarticularis 15%, femur 3%, metatarsal 2%, and the tarsal navicular 2%.^[8] The so-called epiphyseal stress fractures have been reported on the humerus, olecranon, distal radius, distal femur, and proximal tibia, although when compared to apophyseal overuse injuries (Osgood-Schlatter's disease, Sever's disease, etc.) they occur much more rarely.^[9]

Sex

Various studies have found that women have a higher incidence of stress fractures compared to men.^[10,11] Identical military conditions and physical training have shown that women are 3–12 times more often affected by stress fractures than men.^[12,13] This increased risk ranging from 1.5 to 3.5 times has also been observed in athletic populations.^[14] This difference may be due to biomechanical differences between the sexes and the female athletic triad (disordered eating, amenorrhea, and osteoporosis).^[15,16] Multiple studies have demonstrated that stress fractures occur more commonly in women with amenorrhea or oligomenorrhea than in eumenorrheic women.^[17] Significant sex differences have been noted in the site distribution of stress fractures. The tibia is the most common site

for stress fractures in men and women who participate in jumping and running sports. However, studies suggest that women develop more metatarsal and pelvic stress fractures and fewer fibular fractures than men.

Race

In a questionnaire-based study, the prevalence of stress fractures was much lower among black athletes than among white athletes.^[12] Military studies also have suggested this.^[13] These studies surmised that lower stress fracture risk in blacks may be related to their higher bone density or to their different biomechanical features that may protect against stress fracture development.

Type of Activity

The site and frequency of stress fractures in athletes depend to a large extent on the type of activity. Evidence shows that certain stress fracture sites are reported more often in some athletes, than in others, e.g., ribs stress fracture in golfers and rowers, tarsal navicular stress fracture in sprinters and high jumpers, etc. (see Table 1).

PREDISPOSING FACTORS

A cause must be sought for every overuse injury and predisposing factors should be carefully analyzed for every individual athlete. The cause may be quite obvious, such as a sudden increase of training quantity, poor footwear, or an obvious biomechanical abnormality. On the other hand, it can be subtler, such as running on a cambered surface, muscle imbalance, or leg-length discrepancy. The causes of overuse injuries are traditionally divided into intrinsic factors, which pertain to the individual itself and cannot be easily changed, and into extrinsic factors, which can be more easily influenced and modified.

Intrinsic Factors

Biomechanical factors

Research evidence shows that certain anatomical deviations on lower extremities, e.g., genu varum, tibia vara, forefoot varus, flatfeet, and cavus feet, by altering the distribution of load, contribute to the development of stress fracture.^[19] Varus alignments are common in athletes with stress fractures, especially with

Table 1 Sports and activities commonly associated with various stress fractures sites

Site of stress fracture	Sport or activity
Coracoid process of scapula	Trap shooting
Humerus	Throwing and racquet sports
Ulna—olecranon	Javelin throwing and pitching
Ulna—shaft	Racquet sports
Radius	Gymnastics
Ribs (I)	Basketball and ballet
Ribs (IV–IX)	Rowing and golf
Pars interarticularis	Gymnastics, dancing, weightlifting, and pole vaulting
Sacrum	Long-distance and marathon running
Pubic ramus	Long-distance and marathon running
Femur—neck	Long-distance running and gymnastics
Femur—shaft	Long- and middle-distance running and hurdling
Tibia—shaft	Running and ballet
Tibia—midshaft	Basketball, volleyball, pole vaulting, and high jumping
Tibia—medial malleolus	Basketball, high and long jumping, and sprinting
Fibula	Running, gymnastics, and figure skating
Tarsal navicular	Sprinting, hurdling, basketball, and high and long jumping
Metatarsal—general	Running, dancing, and gymnastics
Metatarsal—second	Ballet
Metatarsal—fifth	Basketball, soccer, football, and throwing (javelin and hammer)
Sesamoid bones of great toe	Running, dancing, gymnastics, and basketball

(From Ref. [18].)

femoral and tarsal stress fractures. Cavus feet is found more often in athletes with stress fracture of the metatarsal bones and the femur, while flatfeet with excessive pronation significantly contributes to the development of stress fractures of the tibia, fibula, and tarsal bones. Leg-length discrepancy may also predispose to the development of stress fracture. For instance, stress fractures of the femur, tibia, and metatarsal bone occur more often in longer legs, while stress fractures of the fibula are more common in shorter legs.

Muscles

The condition and tone of the skeletal muscles, i.e., their strength, are directly related to stress fracture. During a rapid increase of physical activity, the muscular tone also increases resulting in stresses stronger than those that the bone can withstand and a stress fracture may occur. In contrast to this, muscular weakness may predispose to the development of stress fracture by causing an increase or redistribution of stress to bone. Fatigued muscles have decreased contractility and their ability to absorb shock is diminished causing altered stress distribution and high-compression loads and shear stresses. Increased tightness and poor flexibility of muscles and tendons have also been regarded as major causes of chronic stress conditions. This is precisely why stretching and strengthening exercises of muscles are essential.

Extrinsic Factors

Training errors

Training errors are the most frequently encountered causes of stress fractures. There is vast research evidence showing that training errors cause stress fractures in as many as 22–75% of cases.^[5,10,14] They are characterized by “mileage mania” (excessive mileage), extremely intensive training, or too rapid changes in both the qualitative and the quantitative aspects of training. Studies in military recruits and athletes have revealed that modification of the training regimen to include rest periods intermittently with periods of strenuous activity significantly decreased stress fracture risk by providing time for bone microdamage to be repaired and by decreasing the load applied to the bone.

Surface

The type of ground for running (tartan, asphalt, grass, etc.), i.e., the surface quality of a playground (parquet, concrete, asphalt, etc.), is extremely important in the event of stress fracture.^[14] Running on hard surfaces

may be associated with an increased risk of stress fractures because of the mechanical shock introduced to the bone. During the assessment of two groups of runners having stress fractures, it has been found that 50% of them were running on hard surface.^[20] Running on an uneven surface may increase the risk of stress fracture by causing increased muscle fatigue and redistributing load to the bone. Running along the margin of the road, i.e., on a sloped surface, leads to the so-called short-long leg syndrome, which may cause tibial stress fracture.

Footwear

Athletic footwear is designed to reduce impact on ground contact and provide stability by controlling foot and ankle motion. Shoe age has been shown to be a better indicator of shock absorbing quality than shoe cost. It has been shown that training in shoes older than 6 mo increases the risk of stress fracture. There has been no association, however, between shoe cost and stress fracture risk. But new shoes can also lead to the development of stress fractures. Increased cushioning, which reduces the body's sensory-feedback mechanism (originating in the plantar surface of the foot), can lead to injury during running. This sensory disturbance has been described as a pseudoneuropathic condition; it also applies to other changes (running on a different surface, using a different tennis racquet, trying a different pitch, etc.).

PATHOPHYSIOLOGY

Bone is an adaptable tissue capable of repair, regeneration, and remodeling of itself in response to environmental, particularly mechanical, signals. Bone is exposed to both stress (i.e., load) and strain (i.e., deformation) with weight-bearing exercise, and it remodels in direct response to the forces applied. If the bone is subjected to repetitive cyclical loading, at a certain point (physiological threshold) reparative mechanisms are overwhelmed, microdamage begins to accumulate, and the process culminates in a stress fracture. Two competing, but not mutually exclusive, theories may explain the development of stress fractures.^[21] One theory holds that during the initial increase in exercise activity, the osteoblastic activity lags behind osteoclastic activity by a few weeks resulting in a period during which the bone is more susceptible to injury. Torsional and bending stress forces from repetitive use result in microfractures that consolidate into stress fractures. The other theory emphasizes strong and repetitive stress on the bone at the insertion point of muscles resulting

in focal bending stresses beyond the ability of the bone to tolerate.

DIAGNOSTICS

Similar to other overuse injuries, when attempting to diagnose a stress fracture, it is essential to have the possibility of such a condition constantly in mind. Thus, clinical diagnosis represents the basic procedure followed later on by other diagnostic methods.

Clinical Diagnosis

The main symptom of stress fracture is pain.^[1,3,5,7,21–23] Classically, the patient describes a history of insidious onset of pain in the area of the fracture that has its onset during activity, but disappears with rest. If the activity is continued, the pain may begin earlier, at an increasing intensity, in the course of that activity and persists after the activity. Later on, the pain increases so much that activity has to be stopped. Finally, the pain may be present despite cessation of the activity and at rest. It should be noted that night pain is a frequent complaint. A comprehensive history should include a review of the exercise or the training program, in particular any recent changes in the type or level of activity, as well as changes in surface, equipment (especially shoes), and technique. A history of previous similar injury or any other musculoskeletal injury should be obtained. In addition, the patient's general health, medications, diet, occupation, and personal habits should be assessed. A careful menstrual history should be obtained from all female patients. The hallmark of stress fracture is localized tenderness to palpation at the fracture site. Point tenderness may be best provoked over bones that can be easily palpated, such as the metatarsal bones or the fibula. For bones that are deep, such as the pelvis or femoral neck and shaft, pain may be elicited through gentle range of motion or specific diagnostic tests. Deformity is usually absent at the fracture site. Physical examination may also show swelling and erythema. Percussion of the affected bone distal to the fracture site causes pain. Muscle atrophy, weakness, and limited range of motion are usually not present. If the diagnosis is still in doubt after palpation, applying stress to the area involved will help to reproduce a patient's symptoms. Activities, such as walking, walking on toes, or running in place, can reproduce a patient's symptoms in the physician's office. Passive stretching can also elicit pain in the affected area. In this case, muscle pull rather than weight bearing induces stress on the bone. As part of a thorough physical examination, the practitioner

should assess the athlete's flexibility, lower-limb alignment (including leg lengths), foot structure, and motor function.

Radiography

Standard x-ray imaging may well show the bone lesions in only 30–70% of stress fracture cases.^[3,5,24] It has also been found that from the onset of pain to the moment when alterations become visible on a standard x-ray film, it takes from 2 weeks to even 3 mo, depending on the fracture site. For certain locations, e.g., tarsal bones, femur, or spine, it is often not possible to identify any changes whatsoever, even if followed up for a longer period of time. The first noticeable radiographic signs of stress fracture in cortical bone are periosteal reaction (in diaphyseal fractures) and medullar sclerosis and endosteal thickenings (in metaphyseal fractures). These changes are not so easily recognized, i.e., they can be identified with greater certainty only on tangential radiographs or tomograms. The initial changes of cancellous bone stress fractures, known as trabecular fractures, are characterized by hardly noticeable flake-like patches of new bone that may be seen 10–21 days following the onset of symptoms (see Fig. 1).^[5] Later, the patches transform into wider cloud-like areas of mineralized bone, and then an area of focal linear sclerosis oriented perpendicular to trabeculae appears within the bone, being among the most characteristic signs of cancellous bone stress fracture. Plain radiographs are necessary in the initial assessment to rule out other causes of localized bone pain, such as complete fracture, infection, or malignancy. Special views must be used in some cases, e.g., orthograde projection for tarsal navicular bone, oblique views for lumbar spine, etc. It is important to remember that stress fractures are dynamic in nature, and the radiographic appearance is also a continuum. However, despite a negative radiograph, the diagnosis of a stress fracture should be considered if the prodromal signs and symptoms and clinical index of suspicion are still high.^[3,5,24]

Scintigraphy

A triple-phase bone scintigraphy is highly sensitive, but it lacks specificity and anatomic resolution. On account of higher specificity of x-ray findings, bone scan is recommended only when the radiograph seems negative in spite of reasonable doubt that stress fracture might be the issue. According to this, the triple-phase technetium 99m diphosphate bone scan is the current gold standard for the diagnosis of stress fracture.^[25] Bone scan may demonstrate bony changes within 6–72 hr following the appearance of initial stress

Fig. 1 Radiogram (AP view) demonstrating stress fracture of the fibula (arrow).

fractures symptoms. A typical scintigraphic finding of a stress fracture is characterized by an oval or a spindle, sharply bordered focus of increased uptake that involves one cortex or occasionally extension of the width of the bone (see Fig. 2). In stress fractures, all three phases (the angiogram phase, the blood-pool phase, and the delayed image phase) of the triple-phase bone scan are positive.^[25] Some other overuse soft-tissue injuries would be positive only in the angiogram and blood-pool phase, thereby enabling bony pathology and pathology involving soft tissue to be differentiated. The bone scan is diagnostic of the stress fracture if focal isotope uptake is seen in the area of interest on the third phase of the scan. The asymptomatic accumulation of radionuclide, the so-called stress reaction, only indicates remodeling of the bone caused by a physical stress. Because scintigraphic finding may remain positive for several months, clinical and radiographic findings are used as discriminative ones for the follow-up of stress fracture treatment.

Computed tomography

Computed tomography (CT) may be used in conjunction with scintigraphy to fully delineate the

Fig. 2 Bone scan (AP view) demonstrates focal uptake in the right medial malleolus.

pathologic process. Computed tomography is very useful for differentiating conditions that may mimic stress fracture: various malignancies, osteomyelitis with Brodie's abscess, etc. Computed tomography scans can show stress fractures that are not apparent on plain radiographs and may also be used to evaluate healing when plain radiographs do not adequately demonstrate the fracture. They are particularly helpful in identifying stress fractures of the sacrum, pelvis, and spine, and in proposing treatment of tarsal navicular stress fracture (see Fig. 3).^[26] A disadvantage of CT is that, in many circumstances, scanning is limited to the axial plane, which does not allow views of transversely oriented fractures. An alternative, helical, or spiral CT can be used to minimize this limitation.

Magnetic resonance imaging

Magnetic resonance imaging (MRI) is proving useful in identifying stress fractures.^[24,27] It is highly sensitive for the diagnosis of stress injury to bone, and usually allows depiction of abnormalities several weeks before the development of radiographic alterations. It has comparative sensitivity to bone scintigraphy for detection of bone abnormalities. Besides having higher specificity than bone scintigraphy in distinguishing bone involvement from soft-tissue injuries, MRI is helpful in grading the stage of certain stress fractures and, therefore, predicting the time to recovery. In

Fig. 3 Computed tomography scan shows navicular tarsal stress fracture (arrow).

addition, MRI avoids exposure to ionizing radiation and requires less time to complete the test than triple-phase bone scan. Recent advances in MR availability, including the increasing availability of relatively low-cost dedicated extremity scanners, likely will expand further the application of MR for the detection of bone abnormalities, and could challenge conventional radiography as the primary diagnostic tool used to detect stress injuries to the bone.

DIFFERENTIAL DIAGNOSIS

The two major reasons for failure to diagnose a stress fracture are neglect of it as a diagnostic possibility and acceptance of negative radiography, which has been taken prematurely or examines the region inadequately. The differential diagnosis for stress fractures is extensive and includes stress reaction, periostitis, muscle strain, infection, neoplasm, bursitis, exertional compartment syndrome, and nerve entrapment. In children and adolescents, it is of utmost importance to differentiate stress fracture from osteogenic sarcoma and Ewing's tumor. A follow-up roentgenogram, repeated after 2–3 weeks, usually solves the problem of diagnosis. Looser's zones of transformation should be differentiated from stress fractures. They are incomplete stress fractures, which heal with callus, lacking in calcium. This is a pseudo-fracture seen in osteomalacia. On x-ray, it appears as a thin, translucent band, about 2 mm in width, which runs perpendicular to the surface of the bone extending from the cortex inward. Another condition that should be differentiated from stress fractures is Milkman's

syndrome—a generalized bone disease marked by multiple transparent stripes of absorption in the long and flat bones. Differential diagnosis of stress fracture and overuse injuries of soft tissue cannot be based solely on the clinical findings and radiological diagnosis; it also requires scintigraphy, and sometimes even MRI. A negative scintigraphy rules out bone stress injuries with great certainty. For example, in medial-tibial stress syndrome, an increase in the uptake is seen in a large area on the surface of the shinbone. The signal is seen only in the collecting phase, but not with angiography or bone-pole phases in connection with bone stress injuries. Magnetic resonance imaging shows swelling only in the periosteal area.^[5] Osteoid osteoma is commonly mistaken for a stress fracture, because it presents with pain and discrete focal area of increased uptake on bone scintigraphy. Two distinguishing features of osteoid osteoma are presence of night pain and relief of pain with the use of aspirin.

TREATMENT

The foundation of treatment for stress fractures is activity modification. Interruption of the cycle of overload is essential to permit the bone to heal. The main treatment of stress fractures is rest from the offending athletic activity; a concept known as “relative rest.”^[5,7,22,23] There is a group of stress fractures, called high-risk stress fractures, that requires additional treatment to relative rest.^[28] High-risk stress fractures include those in the femoral neck (tension side), patella, anterior cortex of the tibia, medial malleolus, talus, tarsal navicular, fifth metatarsal, and great toe sesamoids.^[26] The duration of treatment may vary according to the individual patient, the bone involved, and the particular sport. For most patients with stress fractures, the period of relative rest may last 4–12 weeks. Compliance is critical to the success of treatment. In some cases where the activities of daily living are painful, it may be necessary for the patient to be non-weight bearing or partially weight bearing on crutches for a period of time. Exercise is very important to prevent detraining in affected athletes. General conditioning can be maintained by exercising other areas of the body, and by partaking in alternate training, such as water running, swimming, cycling, etc. The alternate activity must not produce pain or tenderness. When the athlete has been free from pain for 2–3 weeks and full-weight bearing is normal, they may gradually return to their sport. The athlete must have no bony tenderness at the time of resumption of the sport. Furthermore, the athlete must be cautioned to resume the sport at a frequency, intensity, and duration well below the level that previously produced symptoms. In general, increasing the volume or

intensity of training, no more than 10% per week, will avoid recurrence of the stress fracture. The patient must be sequentially monitored during recovery. If they develop any pain during athletic participation or tenderness afterward, they should decrease or modify the activity for an additional 2-week period.^[26] In rare instances, surgical treatment may be indicated if there is a high-risk fracture, the stress fracture has progressed to a complete fracture, or the fracture has become an established nonunion.

OVERVIEW OF THE MOST COMMON STRESS FRACTURES

Various bones have very different mechanical and biological individual properties that affect their healing and treatment. Only the most common stress fractures will be discussed in this section, but the physician should be aware that the general treatment principles mentioned below apply to all stress fractures.

Tibia

The tibial shaft is the most common stress fracture site.^[3,5,10,22] Unfortunately, shin pain is common among athletes and can result from a variety of causes, including tibial periostitis (i.e., shin splints) and exertional compartment syndromes (a potentially serious condition). A careful history is necessary in distinguishing between these entities. Pain that occurs early in the exercise program and then improves with ongoing activity suggests periostitis. Pain precipitated by the exercise that worsens progressively with continued activity may herald a stress fracture. Stress fractures of the tibial shaft on the posteromedial aspect (compression side of the bone) are most common in sports that include running, such as distance running, soccer, basketball, and ballet dancing.^[3,5,10,22] The main symptom is pain appearing during activity and disappearing during rest. With time, it may be present with activities of daily living, or even at night. Physical examination reveals painful tenderness to palpation and percussion at the fracture site, while at a later stage callus may be palpated. Occasionally, swelling is present. Radiological diagnosis is possible only 2–5 weeks following the appearance of pain, when callus as well as the fracture line may be seen (usually oblique radiographs are also required) (see Fig. 4).

Besides, for early diagnosis, the bone scan helps to differentiate stress fracture from the posterior tibialis muscle syndrome, tibial periostitis, and exertional chronic compartment syndrome. Treatment is rest, in which a period of non-weight bearing on crutches for pain relief is sometimes required, until the patient is

Fig. 4 Radiogram (AP view) of the tibia demonstrating stress fracture at the proximal metaphyseal-diaphyseal junction (arrow).

pain free and has no bony tenderness. Most tibial stress fractures heal within 6–8 weeks, with an average time to return to full sports, of 8–12 weeks. The atypical stress fracture of the anterior cortex of the midshaft of the tibia (tension side of the bone) occurs almost exclusively in athletes performing repetitive jumping and leaping activities. This type of stress fractures has been reported in basketball players, runners, pole vaulters, high-jumpers, volleyball players, handball players, figure skaters, and ballet dancers.^[17,29] These stress fractures require prolonged healing time. Initial treatment consists of rest with or without immobilization for a minimum of 3–6 mo. If after 3–6 mo there is no evidence of healing either clinically or radiologically, surgical management is indicated. Another variety of atypical tibial stress fracture occurs in the medial malleolus. Stress fractures of the medial malleolus have been reported in athletes participating in running and jumping activities, i.e., in basketball players, hurdlers, high- and long-jumpers, sprinters, and gymnasts. Nondisplaced stress fractures of the medial malleolus should be treated with immobilization for a period of 6 weeks, while displaced fractures require open reduction and internal fixation.

Metatarsal Bones

The metatarsals are the second most frequent stress fracture site, common especially among military

recruits, distance runners, and ballet dancers. The second metatarsal is injured most frequently of all the metatarsals, followed in order by the third, first, fourth, and fifth metatarsals. In more than 80% of metatarsal bone stress fractures, the shaft of the second and the third metatarsal bone is affected.^[30] Less common locations include the base of the second metatarsal and the base of the fifth metatarsal bone. Metatarsal shaft stress fractures are typical in runners, dancers, basketball players, soccer players, figure skaters, and gymnasts. Diagnosis is very simple once the stress fracture is suspected. Patients complain of forefoot pain that is aggravated by running, jumping, or dancing activity. Although the pain is not severe at first, it gradually worsens when activity is undertaken. Physical examination reveals tenderness over the involved bone and sometimes a mass can be palpated along the shaft of the involved bone, which represents fracture callus. Radiographic changes may not be evident for at least 2–3 weeks following the onset of patients' symptoms, but thereafter a subtle fracture line with periosteal reaction may be present. If radiographs do not confirm that a stress fracture is present, a bone scan can be conducted. Rest from athletic activities for 4–6 weeks and immobilization in a boot cast with a heel for walking (2–4 weeks) yield good results, i.e., complete bone healing. Patients are observed clinically and allowed to commence a graduated activity program once the symptoms have resolved and there is no local tenderness at the fracture site. Stress fractures of the proximal fifth metatarsal distal to the tuberosity, also known as Jones' fracture, should be pointed out as a separate entity, especially as it tends toward delayed union, nonunion, and refracture. The Jones' fracture is most common in basketball players, football players, soccer players, runners, and throwers (javelin and hammer). The main symptom is pain in the lateral foot region. Physical examination reveals pain on palpation in the proximal end of the fifth metatarsal (about 1.5 cm

distally from the tuberosity). Pain is exacerbated by inversion of the foot. Based on radiography staging, immobilization in a short-leg cast with non-weight bearing for 6 to 8 weeks is suggested for early lesions, and surgery is suggested for advanced lesions as well as for nonunions.^[31] Choices for surgical intervention include intramedullary screw fixation or corticocancellous bone grafting (see Fig. 5). Currently, the most popular choice in athletes is intramedullary screw fixation.

Femur

A stress fracture of the femur may be located in the neck, the shaft, and supracondylar and condylar regions. The most common stress fracture of the femur is that of its neck, but not for its frequency as much as for the resulting complications: delayed union, nonunion, dislocation of fragments, and avascular femoral head necrosis.^[32] Owing to this, the primary goal of management should be to prevent complications through early diagnosis and careful treatment. Stress fracture of the femoral neck most often occurs in military recruits during basic training and in long-distance runners. However, it has also been reported in basketball players and gymnasts. The initial and the most frequent symptom is anterior groin (inguinal) pain. The pain is often exacerbated by weight bearing or activity, resulting in an antalgic gait. Night pain is occasionally present. Physical examination reveals pain at the extremes of gentle passive hip motion and slight limitation of flexion and internal rotation. Bone tenderness is often minimal owing to the depth of soft tissue overlying the femoral neck. Axial compression or percussion over the greater trochanter may also elicit pain. An additional test that has been found to be helpful is the "hop test" in which the patient attempts to hop on the injured leg, inevitably reproducing the pain that these patients experience if an undisplaced

Fig. 5 Postoperative roentgenogram of the stress fracture of the fifth metatarsal bone (Jones fracture) (white arrow) managed with intramedullary screw fixation.

stress fracture is present. If physical findings suggest a femoral neck stress fracture, it should be considered present until proved otherwise. If the diagnosis is suspected, radiographs may be obtained, keeping in mind that changes (when present) normally lag behind the onset of symptoms by 2–4 weeks (see Fig. 6).

Bone scan or MRI should be performed to make an early, definitive diagnosis (see Fig. 7). Compared with bone scan, MRI has a similar sensitivity, but an improved specificity, and is becoming the diagnosis procedure of choice. In the case of a normal radiograph and a positive bone scan, or of sclerosis without overt fracture line, nonoperative treatment will suffice. This comprises absolute bed rest until the pain resolves, followed by advancement from partial- to full-weight bearing on crutches as symptoms permit. Once the patient is free of pain, he is allowed to progress to a cane and then to unprotected weight bearing. A progressive walking and then running program is prescribed and the patient is returned over several months to full activity. If the patient presents with or develops an undisplaced or displaced cortical crack more aggressive treatment is required, i.e., internal fixation. Displaced femoral neck stress fracture is an orthopedic emergency. Early, accurate reduction and internal fixation are essential.

Lumbar Spine

Stress fractures of the lumbar spine occur most often in the pars interarticularis, although they may also be

Fig. 6 AP radiograph of the left hip demonstrates stress fracture of the femoral neck (arrow).

Fig. 7 Bone scan demonstrating intense radiotracer uptake on the proximal third of the femoral shaft.

located in the pedicle or lamina (see Fig. 8). The most common vertebral level affected is the L5 segment followed by the L4 and L3 levels. Stress fracture of the pars interarticularis is especially common in sports that involve repeated hyperextension of the lower back, such as gymnastics, dancing, weightlifting, hockey, pole vaulting, football, basketball, and running.^[33]

The basic signs of pars interarticularis stress fracture comprise absence of periosteal reaction and the great possibility of refracturing, i.e., development of spondylosis and, sometimes even, spondylolisthesis. The patients typically present with localized, unilateral low-back pain. The pain worsens with sports activities, especially extension and hyperextension, and is relieved by rest. The one-leg lumbar hyperextension test (commonly called the stork test), in which the patient is asked to hyperextend the back while standing on the ipsilateral leg of the affected side, usually reproduces the pain. They also often have diminished straight-leg raising secondary to hamstrings spasm. Radiographic assessment should include anteroposterior, lateral, and oblique views of the lumbar spine. Many stress fractures may be too subtle to detect radiographically, and require nuclear imaging. Bone scanning with single-photon emission tomography has been particularly helpful in delineating stress injury to the pars interarticularis.^[34] Advanced imaging with CT or MRI may be needed to ascertain the acuity of the lesion, assist in identifying a particular pars lesion as potentially symptomatic, and exclude other spinal pathology that may be present. Early recognition of the fracture and rest from athletic activities together with thoracolumbar orthosis are essential for good treatment

Fig. 8 Spondylolytic defect in the vertebral arch (black arrow) causes spondylolisthesis (gray arrow) of the fifth lumbar vertebra.

outcome.^[35] When the athlete is pain free, he or she may begin a graduated rehabilitation program emphasizing a spinal stabilization program consisting of abdominal and paraspinal muscle strengthening.

CONCLUSIONS

Stress fractures can cause long-lasting damage, especially in athletes and military recruits, if not diagnosed and treated properly. Diagnosis has been traditionally based on clinical, radiographic, and scintigraphic examinations, but MRI has become increasingly important. High-resolution MRI is particularly valuable for the grading of bone stress injuries. The clinician should be aware of the wide range of bone stress injuries and available diagnostic methods. Early diagnosis is essential for avoiding long-lasting complications. Most bone stress injuries heal with closed treatment, but surgery is necessary in some cases. They heal well if the diagnosis is not delayed and the treatment is adequate. As in most of the injuries belonging to the overuse group, prevention is the keyword. To prevent stress fractures and other overuse injuries, it is of utmost importance that the athlete, coach, and

physician cooperate. It is essential to identify the group at higher risk of stress fracture, most commonly, athletes with biomechanical irregularities in the lower extremities. These athletes should be kept under constant surveillance and provided with various orthotic devices. In extreme cases, surgery may be required to correct biomechanical disorders. Female athletes and their coaches and parents need to be alerted to the adverse effects of eating disorders and hormonal abnormalities. Identification of female athletes with “female athlete triad” is especially important so that early interventions may be initiated. Furthermore, athletic and training activities should be adapted to the age and abilities of individual athletes, i.e., maximum load should be achieved gradually. Also, rest periods should be incorporated with periods of strenuous activity. Athletic requisites are also very important for the prevention of stress fractures, especially the condition of the running shoes and quality of playground surface. An important preventive measure also entails stretching and strengthening exercises, which also diminish stressful forces on the bone.

INTRODUCTION

Biomaterials are synthetic and natural materials that are in contact with biological systems or used in medical devices. The field of biomaterials has continually evolved over almost more than half a century and has found many uses in medicine and biology.^[1] The cohesion of these applications is the interaction between synthetic or modified natural materials and biological systems. Biomaterials are not often used on their own but are more commonly combined into medical devices such as dental fillings, bone grafts, wires plates and pins for bone repair, artificial skin, artificial blood vessels, total artificial hearts, pacemakers, total artificial joint replacements, and implants.^[1]

The high toxicity of some organic solvents in food processing, drug formulation, and biomedical materials processing created interest in developing new and clean technologies for processing.^[2] Supercritical fluids such as carbon dioxide and water have been particularly of interest^[7] for many years. The commercial applications of supercritical fluid (SCF) technologies remained restricted, however, because of high costs of equipment and unfamiliarity with equipment operation. More recently, SCF processing contributed to both the production of biocommodities, such as extraction of fermentation products, and the production of high-value-added biomolecules such as proteins via purification and processing.^[3] In the following chapter the fundamentals of supercritical CO₂ and water-based technologies will be explained, and different applications will be illustrated.

SUPERCritical FLUIDS

An SCF is any substance for which the temperature and pressure are higher than critical values. Below the critical point, the fluid can coexist in both gas and liquid phases, but above the critical point there can be

only one phase.^[3] SCFs are also of interest because their properties are intermediate between gases and liquids and are readily adjustable. The pressure–temperature phase diagram for a pure substance (CO₂) is presented in Fig. 1, where the four phases of a substance (solid, liquid, gas, and SCF) are illustrated. In the SCF state the physical properties of the fluid, such as density and viscosity, become transient between that of the gas and liquid phases of the substance.^[3]

Unlike that of liquid solvents, the density of SCFs can be changed by altering the pressure and temperature of the fluid and therefore the dissolution power of a SCF can be enhanced. SCFs can have gas-like diffusivities, which have important implications for reaction kinetics, as well as liquid-like densities, which allow the deliverance for many compounds.^[4]

The most widely used SCF is carbon dioxide because of its relatively low critical pressure and temperature (T_c of 31.1°C and P_c of 7.38×10^4 MPa, respectively) and because it is relatively non-toxic and inflammable.^[7] Table 1 presents commonly used SCFs and their related critical values. Consideration of the properties of supercritical CO₂ suggests that it is suitable for extraction of different materials and it can be used as a reaction medium for polymerization. Supercritical carbon dioxide is an excellent non-polar solvent for many organic compounds; it has solvent power similar to a light hydrocarbon for most solutes. However, fluorinated compounds are often more soluble in supercritical CO₂ than in hydrocarbons. This increased solubility is important for polymerization reactions (such as biopolymers or scaffolds for tissue engineering). Organic compounds such as alkenes, alkanes, aromatics, ketones, and alcohols up to a relative molecular mass of around 400 dissolve in SCF CO₂. Very polar molecules, such as amino acids, sugars, and most inorganic salts, are insoluble in this fluid.^[4] However, there are some disadvantages in the usage of SCF technology as a reaction medium, such as expensive equipment and a complicated system thermodynamics.^[5]

Fig. 1 Phase diagram for CO₂. T_c , critical temperature; P_c , critical pressure.

Another commonly used fluid in supercritical technology is water. Its critical temperature is 374°C and critical pressure is 220 bar. Water has been growing in importance as a medium for chemical reactions recently because of the potential for synthesis of different materials. The most important advantage of supercritical water technology is the possibility of varying the properties of the reaction medium over a wide range, basically by altering the pressure and temperature and optimizing the reaction in this way without changing solvent. Moreover, the reaction kinetics can be influenced in the supercritical region by varying the pressure. Additionally, many non-polar organic substances such as cyclohexane and different kinds of gases are highly soluble in supercritical water (critical pressure and temperature = 374 and $P_c = 2.2 \times 10^4$ MPa, respectively) so that mass transfer restrictions according to phase boundaries do not apply. However, there are disadvantages to working at high pressures, such as high investment and possibly energy costs. The other problem is related to corrosion, and expensive alloys frequently are used.

One of the main applications of SCFs regarding biomaterials is the precipitation of solid products from SCF solutions. Different techniques provide a high

degree of control over the precipitation process, such as rapid expansion, antisolvent precipitation, and atomization of fluid or liquid-like phase.^[6] Considerable efforts have been directed toward the processing of biomaterials and pharmaceuticals using SCF by using different methods. The fundamentals of these methods are mentioned below.

Rapid Expansion of Supercritical Solutions (RESS)

RESS has a considerable role in precipitation of different materials. By application of RESS, a large number of fine-powdered materials can be precipitated. The apparatus used for this procedure consists of a reservoir of supercritical solution and an expansion nozzle. Supercritical containing solute is subjected to rapid expansion over the nozzle by reducing the pressure. This process results in supersaturation and particle formation. The advantage of the RESS technique is that it has the ability to produce narrow particle size distribution, which is important in drug delivery systems. However, the main disadvantage of RESS is that it can only apply to certain kinds of materials that are soluble in supercritical CO₂. Therefore, a large amount of fluid is needed in order to produce a small amount of particles. As a result, the technique is relatively expensive and can be used for laboratory-based processes involving high-value-added products such as pharmaceuticals.^[6] The RESS process can produce pure and high-quality drug particles. However, as mentioned previously, because of the extremely low solubility of polar drugs in supercritical CO₂ (SC-CO₂), RESS has limited commercial applicability. To overcome this major limitation, a modified process for rapid expansion of supercritical solution with solid cosolvent (RESS-SC) is recommended, which uses a solid cosolvent. The recommended RESS-SC process solid cosolvent delays the particle growth and, as a result, hinders the formation of small nanoparticles.^[6,7] During the rapid expansion of solutions in SCF CO₂ (RESS), the sudden loss of solvent powder results in the precipitation of fine particles.

Gas Antisolvent (GAS)

The applications of SCF CO₂ as an antisolvent have become a main area of industrial interest. The use of supercritical antisolvents is similar to layering poor solvents above a solution to induce precipitation and crystallization in normal synthetic chemistry. There are different types of this method, all of which involve injecting the organic solution into a vessel containing either dense CO₂ or co-injection of CO₂ and organic

Table 1 Supercritical parameters for commonly used supercritical fluids

Substance	Critical temperature, T_c (°C)	Critical pressure, P_c (bar)
CO ₂	31.1	73.8
Fluoroform	25.9	48.2
Water	374.0	220.6
Ammonia	132.4	113.2
Ethane	32.2	48.7

solution in a typical vessel. The advantage of this method is that the flow rate of the fluid and the temperature and density of the supercritical CO₂ can be optimized in order to control the morphology and particle size of the precipitated materials.^[10] The principle of this method is similar to that of conventional liquid antisolvent crystallization. Regarding high miscibility of organic solvent in SCF, volume expansion of the solvent leads to a simultaneous reduction in the density and solvent capacity. As a result, the levels of particle formation, supersaturation, and solution recrystallization increase. This method is suitable for crystallization of materials that are slightly soluble in SCF.^[7]

Supercritical Antisolvent (SAS)

In the SAS process, a solution of a drug that is dissolved in organic solvent is sprayed through a capillary tube into a continual SCF stream. Controlled-release drug delivery and protein particles preparation are examples of applications of the SAS method.^[7]

APPLICATIONS OF SCFS IN BIOMATERIALS

Processing of Biological Materials

Over the past 3 decades, supercritical CO₂ has been used for the production, extraction, and isolation of valuable natural or synthetic biomaterial compounds. Supercritical CO₂ was selective in the separation, extraction, and preparation of desired biomedical materials for different applications. In this section some of the applications of supercritical technology in biomedical materials are illustrated briefly.

Processing of biological molecules

Recently, different studies mentioned the application of supercritical CO₂ technology in processing biomolecules such as proteins, phospholipids, and DNA. Some examples of these procedures are mentioned here. Webb et al.^[8] reported new methodologies for dissolving ionic and polar species in supercritical CO₂, which, as a result, led to a broadening of the range of applications for SCF technology. Webb et al. used fluorinated surfactants in order to prepare water in carbon dioxide microemulsions to permit solubilization of ionic and biological species such as phospholipids. They also reported the preparation of supercritical CO₂ soluble metal precursors such as metal complexes that can be impregnated efficiently into polymeric substrates. The clean synthesis of such

composites can be applied to the development of improved medical implants.^[8]

The major components of cellular membranes are phospholipids, biological surfactants that are able to form unilamellar and multilamellar vesicles. Liposomes, which have applications in controlled drug delivery, have been formed using purified phospholipids. Badens et al.^[9] applied the RESS method in order to produce microparticles of lecithin. In their experiments ethanol was used as a cosolvent to dissolved lecithins in pressurized CO₂ in the RESS process. Spherical, fairly agglomerated particles in the 1- to 50-nm range were obtained from this procedure under proper conditions. Whereas increasing the liquid flow rate decreased the particle size and tightened the particle size division, there was no effect of pressure on particle size. This was recognized to better atomization and, therefore, enhanced mass transfer and supersaturation at higher liquid flow rates. Ethanol was not detected in the processed lecithins when analyzed for remaining solvent content via infrared spectroscopy.^[9]

Plasmid DNA, in the form of vaccines for mucosal administration and intranasal inhalation, has been considered a promising therapy for treatment of diseases such as diabetes and Parkinson's. There is increased interest in producing plasmid DNA powders. As an example of these recent works, Tsevistas et al.^[10] studied the effect of SCF CO₂ on extraction of DNA. They concluded that exposure to SCF CO₂ in the absence of free water did not degrade plasmid DNA. Isopropanol-modified SCF CO₂ was used to produce plasmid DNA micropowders. Tsevistas et al.^[10] precipitated pSV β , a 6.9-kb plasmid, by supercritical CO₂ technology. They reported that SCF technology is a promising approach in the processing of biomaterials such as DNA.^[10]

Proteins are currently one of the most important families of biomolecules in the pharmaceutical industry. Many studies demonstrated the ability of supercritical technologies to prepare and precipitate different types of proteins that can be used in several therapeutic methods. Sievers et al.^[11] demonstrated that supercritical CO₂ technology can be applied as an aerosolization agent in order to prepare protein microparticles such as bovin serum albumin. They used a bubble drying technique in their experiments, which has the advantage of using pure aqueous systems without the addition of organic solvents.^[11]

SCF technology has the ability to swell and plasticize a broad range of amorphous polymers. A plasticized polymer has a reduced viscosity and allows for incorporation of soluble material into the swollen polymer. Subsequent depressurization entraps the insoluble material and creates a porous structure. This process has been exploited to incorporate a variety of inorganics, pharmaceuticals, and biomolecules in

biodegradable polymeric matrices that can be used in both tissue engineering and drug delivery. Howdle et al.^[12] used this technique in encapsulation of ribonuclease A, catalase, and β -D-galactosidase in poly(lactic acid) (PLA). Release studies of preserved protein demonstrated an initial burst of less than 10% in the first 2 days, followed by zero order of release for 70 days.^[12]

Bacterial inactivation (sterilization) and enzyme denaturation

The effect of SCF on enzyme activity and enzymatic reaction for food and pharmaceutical processing is typically explored. In presence of a CO₂ supercritical situation, 10 MPa pressure is required to denature monomeric proteins; on the other hand, hydrostatic pressures of more than 600 MPa are required to have the same effect on the proteins. Enzymatic denaturation by SCF-CO₂ in the food industry caused increased digestibility, foaming, and emulsifying in the treated food.

Current methods of sterilization, which include ethylene oxide, γ -radiation, electron-beam, steam, and hydrogen peroxide plasma, have limitations regarding their biomedical applications. These methods altered the structure and characteristics of materials, especially when applied to thermally and hydrolytically sensitive polymers. Pressures slightly above 10⁻² MPa inhibited a range of fungi, bacteria, and yeasts. Supercritical CO₂ treatment provides an effective method of sterilization for thermally and hydrolytically labile biomedical materials by inactivation of a variety of bacterial microbes. Carbon dioxide has unique properties that make it an appealing medium for sterilization. At relatively low pressures and temperatures carbon dioxide transitions to a supercritical state, often referred to as a dense-phase gas. The use of supercritical CO₂ as a sterilizing medium is all the more appealing because it is non-toxic and easily removed by simple depressurization and outgassing. It has the ability to eliminate pathologic and spoilage microorganisms from food products, polymers, and other biomaterials.^[12]

Extracting of biologically active substances

Extraction is one of the oldest commercial applications involving supercritical carbon dioxide.^[13] The increasing demand for natural food antioxidants encouraged worldwide researchers to extract biologically active substances from a variety of raw plant materials. Supercritical CO₂ allows the extraction of active ingredients from herbs and plants with a better imitation of flavor or fragrance in comparison with conventional

operations. As a result of the operation at decreased temperature, thermal degradation and decomposition of labile compounds are avoided, while the lack of oxidative factors such as light and oxygen prevents oxidation reactions. This latter point is of particular interest for the extraction of antioxidants, warranting the preservation of their biological properties.^[13]

Pharmaceutical Formulations

Conventional methods for particle formation, micronization, coprecipitation, impregnation, and encapsulation of pharmaceuticals can be challenging because the heat and mechanical stresses involved can cause thermal and chemical degradation of the drug and change the properties of the drug. In addition, application of large amounts of solvent and surfactants-emulsifiers can lead to undesirable levels of residual impurities, which require further purification procedures. With regard to its advantages, such as being environmentally benign and having adjustable solvent properties and produced particles that are free from solvent residues, supercritical CO₂ technology appeared to be a promising substitute for the solvents that are currently used in the pharmaceutical industry. SCF technology provides a clean way to produce active particles for controlled delivery in the body process of thermally labile biological materials. Freeze drying, spray drying, precipitation, and other conventional methods for powder production have significant disadvantages for this application. SCF technology facilitates controlled particle size formation and solvent removal from the products.^[14]

Drug delivery and controlled release of drugs

In advanced drug delivery technologies, new approaches for the delivery of pharmaceuticals will be required. For example, beside traditional methods, inhalation techniques will be applied more for drug delivery into the bloodstream. This new methodology requires injection devices in order to shoot the small particles of the drug through the skin of the patient instead of being applied with a needle. Particles that can be used in this method should have a specific size range and well-defined particle size distribution. Different processes use supercritical CO₂ and have been used for particle formation, such as RESS and GAS recrystallization.^[14]

The application of SCF such as supercritical CO₂ provided an effective and clean solvent substitute for drug and polymer processing. Gong et al.^[15] impregnated indomethacin (IM, a non-steroidal antiinflammatory drug) into chitosan thermosets for the preparation of controlled release formulations. The

results indicated that the SCF impregnation process resulted in IM being amorphyously dispersed within the chitosan matrix. Fourier transform infrared spectroscopy data implied that the aliphatic carbonyl group of IM interacted with the amine group of the chitosan backbone. In vitro dissolution studies (via UV-vis spectroscopy) demonstrated that the dissolution rate of IM significantly increased after processing in supercritical CO₂.^[15] In another study by Gong et al.^[16] supercritical carbon dioxide (SC-CO₂) was used to prepare coprecipitates of IM and poly(vinylpyrrolidone) (PVP) in order to enhance the dissolution rate of the drug. The coprecipitates of IM and PVP at various proportions were prepared using a stirred batch reactor containing SC-CO₂ as a gas-saturated solution. The results indicated that as the PVP weight fraction decreased, IM displayed an increasing amount of crystalline material. The dissolution rate of IM was increased with the incorporation of PVP. IM and PVP at various weight fractions exhibited comparatively higher dissolution rates than crystalline IM alone. The supercritical CO₂ technology produced a solvent-free, completely amorphous porous IM solid dispersion with a fast dissolution pace.^[15,16]

Particle size reduction of drugs; Preparation of drug nanoparticles

Particle size is an important factor that influences the rate of dissolution of a drug in biological fluids and therefore has a major effect on bioactivity and bioavailability. Numerous researchers utilized SCF technologies as substitute approaches to reduce the particle size of drugs. Compared with conventional methods, the SCF process is advantageous because it has better control over particle size distribution and morphology. In different reviews, the temperature and pressure mainly determine the particle morphology. Pressure and temperature have a large effect on SCF CO₂ density; these parameters are expected to have a strong effect on the resulting properties of the particles. The temperature is also expected to affect the solubility of the protein, the antisolvent in the solvent, and the solubility of the solvent in the antisolvent, thus modifying the precipitation kinetics and crystal growth.

One of the main applications of SCF CO₂ processing is the production of nanosize particles. SCF has been used in order to synthesize nanoparticles such as titanium dioxide. This technology is especially interesting for the development of dry powder inhalation systems and dry powder injection systems in the pharmaceutical field, as well as in useful biomaterials such as nanohydroxyapatite. Thakur and Gupta^[17] reported a new process for phenytoin drug synthesis using menthol solid cosolvent in a modified RESS

method. The results of this study demonstrated that this technique has the capability of nanosize particle formation. The average particle size of synthesized phenytoin in the conventional RESS process was 200 nm, whereas upon the addition of cosolvent in the RESS modified process, the average particle size decreased to 120 nm at 96 bar and 45°C. By increasing the pressure and temperature, the particle size decreased.^[17]

Recently, supercritical CO₂ was used to prepare silver nanoparticles within commercially available silicone and polyurethane polymers in a controlled and reproducible manner. Silver is a non-toxic, naturally occurring metal that can kill many harmful microorganisms and is a very good antibacterial agent. This alternative approach seems to be a promising way to manufacture materials with controlled loadings and a high surface area of silver. Moreover, it provides an alternative to the use of conventional antibiotics and the inherent problems of antibiotic resistance as a route to prevent infection in medical devices.^[14]

Stabilization of proteins in dry powder formulations

Therapeutic proteins have become vital in the treatment of many diseases. Their formulation in dry form is often required to improve their stability. Traditional procedures for protein drying, such as freeze-drying or spray-drying processes, are often harmful to labile proteins. Alternative drying techniques have been explored for drying pharmaceutical protein formulations, each of which has its specific advantages and disadvantages. Among the available drying methods, the SCF drying procedure is popular because it is cost effective, has mild conditions for the procedure, and has the capability of producing microparticulate protein powders. Supercritical CO₂ mixing technology has also been applied in the production of release systems for controlled delivery of proteins or other bioactive components.^[15]

Tissue Engineering, Medical Implants, and Bone Grafts

Tissue engineering

Certain tissues and organs cannot heal effectively by themselves after injuries and, in order to restore their function, they require special treatments. A standard therapy in this case is transplantation but because of a shortage of donor tissue, not enough patients can receive the organ or tissue transplantations they need to survive. Therefore, researchers recently concentrated on developing methods for tissue regeneration. Three-dimensional polymer scaffolds with porous structures

can be used as cell supports to offer mechanical stability and structural guidance and to permit seeding of a high density of cells before or after transplantation into the body. Drugs, nutrients, hormones, and growth factors can be inserted into these porous appliances to promote cell differentiation and then vascularization of the growing tissue.

Conventional techniques for preparation of polymer scaffolds or particles typically use organic solvents and high temperatures that may be harmful to adherent cells, nearby tissues, or biologically active factors. Therefore, the use of SCF, in particular supercritical CO₂ technology, is an appealing alternative approach for a wide range of biomedical applications in tissue engineering.^[18]

The advantages of supercritical technology in comparison with other conventional methods in preparation of scaffolds in tissue engineering include the absence of organic solvents, the ability to incorporate delicate biological matter without loss of activity, and control over the morphology of an internal porous architecture. Tissue engineering scaffolds must possess an interconnected pore structure and high degree of porosity, which ensures adequate cell attachment throughout the 3-D matrix. Porosity is created during the SCF process by the thermodynamic instability that results following depressurization around the liquidated polymer. The porosity and pore structure of the resultant scaffold can be controlled by altering the amount of gas added and the release rate from the polymer.^[18]

Synthesis of biopolymers. A number of manufacturing techniques have been applied to produce scaffolds from synthetic and naturally derived biodegradable polymers such as PLA, poly(glycolic acid), collagen, and chitosan, in addition to inorganic materials such as hydroxyapatite.

Gas foaming using supercritical technology is a substitute method applied to create porous structures for scaffolds in tissue engineering. Pores are created from a gas-polymer solution by sudden depressurization, which induces bubble nucleation. Foaming with CO₂ has the ability to eliminate the need for organic solvents and high temperatures for plasticization, and is a process that is best suited for biomolecules.

Application of this technique can result in a wide range of morphologies and porosities. Bioactive elements such as proteins or growth factors can also be added in this method. Gas foaming is a solvent-free technique used to produce porous structures with a wide range of characteristics. These characteristics seem adequate for bone tissue engineering applications. Polyurethanes have been successfully used as a biomaterial with uses ranging from heart catheters to bone scaffolds. Porous polyurethane has been synthesised at 40°C using gas foaming method, which

Fig. 2 Microcomputerized tomography image of a PEMA/THFMA scaffold processed in SC-CO₂.^[18]

compared relatively well to conventional solvent polymerization at 130°C. Barry et al. utilized supercritical CO₂ to fabricate porous poly(ethylmethacrylate/tetrahydrofurfuryl methacrylate) (PEMA/THFMA, a non-degradable polymer proposed as a support material for cartilage repair) foams (Fig. 2) with controlled porosity, pore geometry, and interconnectivity.^[21] The cross-linked polymer system was plasticized with supercritical CO₂ at 100 bar for a period of 8 h, followed by controlled depressurization. Total porosity was greater than 80%, with at least 60% being open porosity. The results were significantly greater than the 10%–30% porosity obtained in other conventional polymer processing systems. Pore sizes ranged between 35 and 400 mm depending on the pressure, exposure time, and depressurization time.^[18]

Different techniques have been used to produce porous polymers and hydrogels such as freeze drying, particulate leaching, gas-foaming methods, and the use of gas-forming agents. Hydrogels with broad macropore size distributions and a mixture of open and closed pores are often produced as a result of these techniques, whereas emulsion templating techniques can sometimes produce polymers with a more defined and controlled pore structure. Butler et al. used carbon dioxide in water emulsion templating to successfully produce porous polyacrylamide polymers. However, because of the slow polymerization rate of hydroxyethyl acrylate (HEA) and the destabilization of the CO₂-in-water emulsion, they were not successful in synthesising hydrogels based on HEA and hydroxyethyl methacrylate using the same method.^[22]

Partap et al.^[19] reported an emulsion templating “oil-in-water” technique to prepare highly porous alginate hydrogels (Fig. 3) using application of supercritical water technology by coupling a templating oil-in-water emulsion reaction with an internal gelation reaction to lock in the structure from the internal oil. They mentioned that both an organic solvent (isooctane) and a dense-phase CO₂ (above the critical point of CO₂) have been used as the internal oil phase for the templating step. The results demonstrated that they developed a new generic method of producing

Fig. 3 Scanning electron microscopy image of a sample of synthesized porous calcium alginate hydrogels.^[19]

porous alginate hydrogels by combining emulsion templating with an internal gelation reaction. Highly porous alginate hydrogels with a narrow range of macropore sizes (without the use of an organic solvent) were produced in their experiments, as presented in Fig. 3.^[19] A narrow range of macropore sizes (without the use of an organic solvent) was produced using the new RET (reactive emulsion templating) reaction, which utilizes carbon dioxide in water emulsion to template the pores. The RET hydrogels exhibit an open, well-interconnected pore network with a narrow pore-size distribution that is potentially suitable for tissue-engineering applications [85%–90% total porosity and less than 250 μm (23–43 μm) mean pore diameter].

Medical implants

Different researchers demonstrated that supercritical technology can be used for surface modification of biomedical devices. One recent work involved the application of SCF for surface modification of coronary stents with a drug-eluting polymer matrix. Drug-eluting stents reduced early-state restenosis in clinical trials. Intrinsic process control limitations of current solvent-based methods, as well as challenges associated with maintaining structural and morphological integrity of the therapeutic agents deposited during the coating process, have been significant challenges to date. Improvements in surface modification technologies such as uniformity, conformity, and control of drug morphology, along with the use of other potential classes of active therapeutic agents, may help to address these issues. SCF-based technology has the ability to deliver the next generation of drug-eluting stents that can afford control over drug morphology and may allow manufacturing processes to apply

separate and independent therapies within a single, multitherapy coating. The morphology of the drug is maintained by avoiding the need to dissolve the drug in a liquid solvent, which is compulsory in traditional processes. One advantage of the application of this method is that it provides the possibility of increasing the constancy of the material.

The other application of SCF technology is the coating of orthopedic implant replacements such as hip implants. Failure of these implants is common and is caused by gradual wearing of the polymer surface. As the ball segment of the implant moves around in the socket of the implant, the polymer degrades at the load-bearing surface through the process of adhesive wear. This leads to production of submicrometer-size particles from the coated layer of the implant, which the body simply cannot remove. Macrophage cells in the body unsuccessfully try to digest and remove the particles, which leads to a severe toxic response and finally to rejection of the implant. Webb et al.^[8] attempted to develop SCF methods to improve the adhesive wear properties of the implant surface by application of certain metals, metal oxides, and metal sulfides as fillers in polymeric substrates that can considerably enhance the wear lifetime. They applied silver-based precursors to the preparation of silver composites by impregnation from supercritical CO_2 solution. Results of preliminary mechanical testing on the composites indicated that there was an improvement in adhesive wear properties. In addition, the presence of silver particles led to visibility of the desired part of the implant in X-ray imaging.^[8]

Bone graft materials

Hydroxyapatite (HAp) is a promising material used in orthopaedics as a bone graft material. There are many

Fig. 4 Transmission electron micrograph of hydroxyapatite nanorod made using supercritical water at 400°C and 24 MPa in the hydrothermal flow system.^[20]

Fig. 5 Scheme of the three-pump (P1, P2, and P3) hydrothermal flow system used for the synthesis of nanohydroxyapatite. P, pump; C, cooling; F, filter; B, backpressure regulator; R, reactor; T, Tee piece mixer.^[20]

techniques for synthesis of this bioceramic, such as wet chemical synthesis and the sol-gel technique. Chaudhry et al.^[20] synthesised nanoparticles of HAp, which can be used as a synthetic bone replacement material or for coating of implants, using a three-pump hydrothermal flow process (up to 400°C and at 24 MPa) with the application of supercritical water technology. The process used by Chaudhry et al. decreased the time required for maturation of the reagents from over 18 h to less than a few seconds and avoided the need for further crystallization heat treatment steps such as sintering. The results demonstrated that the product was obtained as a highly crystalline and phase pure material, without the need for an aging step or subsequent heat treatment.

Fig. 4 illustrates the transmission electron microscopy micrograph of the nanohydroxyapatite synthesized using this method, whereas Fig. 5 presents a schematic figure of the hydrothermal flow system used for synthesis of hydroxyapatite nanoparticles by application of the supercritical water technology.^[20]

Haque et al. synthesized high-pressure carbonated apatite in supercritical carbon dioxide with high carbonate content and good mechanical and biological properties. They also used reduced calcination temperature and tried to change the reagent ratios to ensure phase purity. In another study, Haque et al. synthesized calcium phosphates in SC-CO₂ at low pH without the use of ammonia solution to allow the pH to drop below 9.

CONCLUSIONS

SCFs (particularly CO₂ and water) have covered a wide range of chemical reactions and processing in the pursuit of advanced biomaterials and natural product

extraction. In particular, supercritical carbon dioxide is a good non-toxic alternative to organic solvents in the manufacture of biomaterials with well-defined properties. By controlling the characteristics of biomaterials (size, size distribution, porosity, surface area), SCF processes can allow a better match to clinical requirements.

The next decade may see an expansion in the number of applications of SCFs in biomaterials, and much promise has already been evidenced. For example, many opportunities exist for the manufacture of more robust and well-defined tissue engineering scaffolds in which degradation and other properties must be acutely controlled. The authors of this review do not doubt that the application of suitable SCF technologies could hold the answer to this and other challenges in the biomaterials field.

S

INTRODUCTION

Surface coatings have a long history in medical products. Earlier, colorful coatings served chiefly in decorative or identification roles on pills. Later, surface coatings became a way to modify the properties of medical devices and implants. By using different bioactive components, coatings can enhance the surface wettability, electrical conductivity, X-ray radiopacity, and echogram visibility. Coatings can impact physical properties such as coefficient of friction and thus enhance maneuverability without loss in device functionality. Anticrustation coatings reduce the surface mineralization on ureteral stents to keep the lumens open for urine flow. Thromboresistant coatings prevent blood clotting on the device surfaces to maintain oxygen-exchange efficiency. Antimicrobial coatings reduce infectious complications to prolong the useful life of devices and implants. Finally, coatings that promoted cellular adhesion enable bone implants to have stronger fixation. These applications and others illustrated that surface coatings were essential to the continual improvement of medical products.

A recent development in coating technology is the use of drug delivery mechanisms to promote selected biological functions. Drug functionality elevates the importance of surface coatings to the point that the coating is an equal contributor to the therapeutic goal, as is the naked device. This statement is dramatically demonstrated by the success of drug-eluting stents. Sirolimus-eluting coatings boost the clinical outcomes of stenting to levels that never have been achieved with bare stents. In the near future, surface coatings will be the essential players in fulfillment of physicians' therapeutic goals.

SURFACE COATINGS AND MEDICAL DEVICES

Medical device and implant manufacturing frequently includes surface coatings steps. Surface coatings provide add-on benefits to enhance the surface properties without significantly altering the bulk properties of

medical products. From a methodology viewpoint, a coating passively or actively modifies the surface properties of medical devices and implants. The so-called passive method alters selected properties of the substrate surfaces without delivery of drugs or other agents. In contrast, the active approach delivers bioactive compounds that influence biological responses in order to achieve desirable outcomes. From a strategic aspect, surface coatings generally offer benefits such as improved maneuverability, functionality, and additional therapeutic effects for medical devices. Regarding maneuverability, tailor-made surface coatings alter surface wettability, electric insulation, and coefficient of friction of medical devices. Moreover, certain surface coatings can improve the image quality of medical devices under X-ray fluoroscope and ultrasound set-ups and thus greatly further the surgical outcomes. Regarding functionality, surface coatings can prevent mineralization, thrombosis, and microbial colonization on devices. Coatings can promote cell adhesion to ensure that the devices' performance is not compromised due to foreign body reactions.

Drug-eluting coatings are the latest development in the medical device coating industry. Surface coatings act as reservoirs for local drug release. Properly formulated surface coatings enable delivery of medications to site-specific lesions and thus achieve desirable therapeutic long-term results. In this section, applications of surface coatings and methods of making such coatings are broadly reviewed.

Surface Coating Improves the Maneuverability of Medical Devices

For smooth procedures, unique surface properties including wettability, electric isolation, radiopacity, echo visibility, and lubricity are desirable for many medical devices.

Wettability is an important physical factor for designing membrane-type biosensors or filtration devices. Enhanced surface wettability shortens the analysis time,

improves biosensor accuracy, and promotes cell viability for filtration devices.^[1] Several methods including corona discharge, gas plasma exposure, flame treatment, and acid etching are available to improve the wettability of polymeric porous materials. However, the wettability introduced by these processes dissipates after treatment, particularly when exposed to aqueous washing, elevated temperatures, or even simple storage in air. A more stable surface coating-based polyethylenimine (PEI) grafting has been developed that creates permanent wettability. The process of PEI coating includes plasma pretreatment and wet solution immersion. Substrates are first primed with O₂/CO₂ plasma under mild conditions. PEI is then grafted to the activated surface via ionic binding. The wettability of membranes is maintained for more than a year.

During conventional manufacturing of cardiac rhythm managing devices (implanted pulse generators (IPGs), for example), superior electric insulation coatings are needed to prevent local muscle stimulation and myopotential sensing in unipolar pacing. Parylene (polyparaxylylene) coating has been selected to meet the performance requirements for decades due to its inert/biocompatible properties (noncytotoxic, non-systemic toxic, and hemocompatible). However, conventional parylene coating processed via vapor deposition polymerization (VDP) has always been plagued by poor substrate adhesion. A modified coating process has been developed to overcome adhesion limitations.^[2,3] The new process integrates traditional parylene VDP process with plasma molecular activation. Substrate surfaces are first primed with hydrogen plasma. Then, without breaking containment, parylene is deposited on the primed surfaces. Consequently, molecular-level binding is created between the substrate and parylene. Coatings generated via the process uniformly and completely cover substrates and can range from 2 to 25 μm in thickness. The shelf life is more than two years.

Radiopacity is another important physical characteristic for devices including guidewires, catheters, and metal stents used in interventional cardiology. Radiopacity improves devices' image quality and allows physicians to have a reliable method to trace the exact location of a guidewire or catheter through vasculature. This assists in the successful evaluation of lesions as well as the accurate deployment of stents. Radiopacity was conventionally achieved by applying metal bands or implanting noble metals such as gold, tantalum, iridium-platinum and platinum, or heavy metal salts such as barium sulfate, onto guidewires and into catheters. Ion beam-assisted deposition (IBAD) is a traditional way to apply those metals onto devices. However, clinical practitioners were concerned about cellular debris entrapment with the metal band and had difficulties with the transparent unfilled portions of

catheters. Coatings produced by IBAD are also plagued by unreliable adhesion. A new alternative to IBAD process, microfusion, was developed to answer these questions.^[4] Briefly, in microfusion, devices are first placed in the unbalanced magnetron filed and set up as the negative bias. Ions are injected through unbalanced magnetron sputtering and bombard the device surfaces. The negative-bias voltage on the substrate controls the traveling speed of ions. The processing time determines the coating thickness. Consequently, coating adhesion is stronger and uniformity is better. Microfusion has the advantage of providing multiple ions deposition from multiple orientations simultaneously.

Another image-enhancing surface coating is known as echo coating. Echo coatings were developed to enhance the ultrasonic image quality of needles and interventional devices. The echogenicity is a result of microbubbles generated by the coating matrix. Through a dip-coating and curing processes, a polyurethane-based microporous coating is created. Microcavities in the coating are on the scale of a few microns and have minimal impact on coating lubricity. Under agitation, microbubbles exit the polymer matrix, become excellent ultrasound reflectors, and help to dramatically enhance the image in Doppler sonogram. The improved ultrasonic images increase the technical success rate of the examination by reducing examination time and patient discomfort.

Less friction and more lubricity are common characteristics required for guidewires, catheters, probes, needles, and implantable ports. Two types of lubricious coatings are common. The first type is dry-film lubricious coating. Parylene and expanded polytetrafluoroethylene (ePTFE, Teflon[®]) are frequently used for dry-film lubricious coatings. Both coatings are about equivalent in the measurement of static and dynamic coefficients. Dry-film lubricious coatings are ideal for tiny lead wires requiring electric insulation, chemical resistance, and abrasion resistance.

When in contact with sensitive, fluid-rich tissue/organ systems, surfaces with better lubricity are needed. Slippery-when-wet coatings were specifically developed to meet the challenges. The principle of slippery-when-wet coatings is to employ water molecules as lubricants. Typically, lubricious coatings are polyurethane or poly(ethylene-co-acrylic acid) based. During the preparation of coating, the resins are cross-linked either through chemical or photochemical reaction, and polyvinylpyrrolidone (PVP) is incorporated via a network interpenetration mechanism (Fig. 1). The polyurethane or poly(ethylene-co-acrylic acid) network provides good adhesion and allows the PVP to protrude in order to adsorb water molecules. Since PVP is highly hydrophilic, it produces a microlayer of water that reduces the wet coefficient of friction to nearly zero. This minimizes the damage/invasion that

Fig. 1 Slippery-when-wet coating. Polyurethane or poly(ethylene-co-acrylic acid) matrix provides strong adhesion for coating and substrate. Embedded hydrophilic polyvinylpyrrolidone protrude outward to grab water molecules at contact with body fluid. This watery microlayer increases the surface lubricity of the substrate.

imposed onto the epithelium and mucus layers during the device positioning and greatly assists physicians in the navigation of devices through tortuous vasculature.

Surface Coatings Ensure the Functionality of Medical Devices

Medical devices and implants are developed to improve life quality in many ways. Good maneuverability enables physicians to have smooth operations in positioning medical devices or implants and thus minimize patient discomfort or injury. Equally important is to ensure that devices and implants function as designed after procedures. Devices and implants inevitably have contact with body fluids and tissues. In some cases, devices fail due to natural biochemical reactions. Encrustation on urinary stents and catheters is an example. Encrustation is the mineralization resulted from pH change in urine. Moderate to severe encrustation blocks the urine flow and predisposes stents and catheters to replacement. In other situations, cell or bacterial adhesion endangers the functionality of implants. For example, platelet adhesion on cardiopulmonary bypass (CPB) leads to thrombosis and further blocks the blood flow, which jeopardizes the successful surgery outcomes. Postsurgical lens epithelial cell deposition on intraocular lens (IOL) results in failed implantation. Bacterial adhesion on catheters leads to nosocomial catheter-associated infections, which compromise the functionality of catheters. In these cases, minimal bacterial/cell adhesion on devices and implants are most desired. In other cases, implants are expected to coordinate with cell/tissue responses to achieve better performance. For instance, orthopedic metal implants need better bone ingrowth (osteogenicity) for stronger fixation.

Biomaterials that devices and implants are made from frequently do not have the surface properties to respond properly to physiological environments. For example, polyurethane has a higher tendency to cause encrustation than does silicon, and polymethylmethacrylate (PMMA) IOLs induce more epithelialization than do

polyacrylate ones. Surface coatings bridge the device functionality and cell/tissue responses and allow for a greater range of choices in base material selection. Both active and passive surface coatings are applied to prevent compromised functionality.

Antienrustation Coating

Mineral encrustation is a common complication associated with the use of urethral stents and catheters. In encrustation, components in the urine deposit, grow into crystals, and eventually encrust the surface of the device. The mechanism has many variables. It is understood, however, that in many *in vivo* systems, bacterial colonization generates biofilms that become mineralized. In sterile urine, the development of encrustation has been shown to be dependent on urinary properties such as pH and ionic strength as well as the biomaterials properties. Urine is generally free from bacteria in ureteral stents and thus in the stent environment, it is the chemistry of the urine whose variables dominate. In infected urine, urease produced by the adhered bacteria hydrolyzes the urea to produce ammonia. This elevates urine pH, a condition that thermodynamically favors the precipitation of magnesium and calcium in the form of struvite ($\text{NH}_4\text{MgPO}_4 \cdot 6\text{H}_2\text{O}$) and hydroxyapatite ($\text{Ca}_5(\text{PO}_4)_3\text{OH}$). These minerals are two of the major components of encrustation found in urinary prosthetics. Encrustation frequently leads to the blockage and fracture of the devices. Conventional strategies have focused on minimizing the effect of one variable without addressing the others. For example, use of different biomaterials had limited effect on minimizing encrustation. Hydrophilic surfaces (poly(ethylene oxide)/polyurethane composite hydrogel) discourage bacterial adherence and hence the formation of biofilm. However, they have shown no significant effect on encrustation reduction. Other approaches currently being evaluated include coating the surface with glycosaminoglycan heparin and with urease inhibitors such as acetohydroxamic acid and fluorofamide. While promising *in vitro* data has been published, *in vivo* results are pending.^[5,6]

Thromboresistant Coatings

Medical devices involving blood contact often fail due to the formation of blood clots on the surface. For example, cardiopulmonary bypass, an extracorporeal blood circulating system, maintains the circulation throughout the body and provides nutrients and oxygen necessary for life, while the cardiothoracic surgeons are fixing cardiac defects. The efficiency of CPB can be impaired by the adhesion of blood cells on biomaterial surfaces. Catastrophic surgery outcomes may result from consequential severe thrombosis and inflammation. During surgery, heparin is routinely administered to prevent blood clotting. Heparin binds to antithrombin III (ATIII) to become an acting inhibitor to thrombin, factor X, and other enzymes (IX, XI, & XII). Even so, clotting on the surface of devices still occurs while the heparin activity decayed. To better prevent the incidence, permanent and drug-release types of antithrombotic coatings were developed to render the device surfaces thromboresistant. Heparin covalent bonded surfaces are one of the most popular permanent antithrombotic coatings. The use of heparin-coated biomaterial surfaces in CPB has been shown to decrease platelet adhesion and inflammatory responses resulting from the extensive contact between blood and artificial surfaces.

The two most commonly used heparin-coated systems for CPB are the Carmeda BioActive Surface (CBAS) and the Duraflo II coating. The Carmeda thromboresistant coating process involves covalent binding of biomaterial surfaces and degraded heparin attached to spacer arms (100 Å in length) at endpoint. As a result, the active sequence of heparin is available for binding with ATIII. This prevents surface thrombosis formation. The competing Duraflo II heparin coating ionically binds alkylbenzyltrimethyl ammonium-heparin complex onto the biomaterial surfaces. Slowly released heparin lifts the thromboresistant capability. Optimized coating formula and processing retard heparin leaching from Duraflo II coating. The heparin release capability enables Duraflo II to be distinguished from BioActive surface.

Duraflo II heparin coating is one example of a drug-release-type antithrombotic coating. The application of drug-release-type antithrombotic coatings is also popular for indwelling catheters. For indwelling catheters used in the vascular system, antithrombotic and lubricous properties are equally desired. Lubricious hydrogel coatings, as described earlier, with releasable heparin salt ingredients meet the dual needs of lubricity and thromboresistance. When the coating is hydrated, the microwater layer on the catheter surface promotes the lubricity. Meanwhile, a diffusion mechanism drives the release of heparin from the polymer matrix into the surface water layer.

Released heparin then further prevents blood clotting on the device surfaces.

Anti Cell Adhesion Coating

Although heparin coatings are well known for their thromboresistant functionality, attempts to apply heparin coatings to reduce postoperational cell adhesion on intraocular lenses (IOL) have also been tried.^[7,8] IOL implantation is the most effective surgical procedure in treating cataracts. Unfortunately, postsurgery epithelial cell adhesion to the lens is a major cause of IOL implantation failure. In some clinical reports, heparin coatings on polymethylmethacrylate (PMMA) IOLs have been reported to reduce cell adhesion and to maintain the vision-rehabilitation function of IOLs. However, the overall efficacy of heparin surface-modified IOLs remains controversial. Alternatives to heparin coatings on IOLs are being researched, with albumin-affinity coatings emerging as one with a promising future.^[9] To generate such a coating, PMMA IOLs are passivated with cibacron blue dye, an affinitive compound to albumin. Lenses are first aminated via plasma surface treatment. Amine functional groups on PMMA IOLs are covalently bound with aldehyde groups on the modified cibacron blue dextran. The uniqueness of this coating is its high affinity to albumin in tissue fluid, which enables coated IOLs to be covered by albumin in seconds. When albumin covers the surface, other proteins that promote cell adhesion cannot attach. Thus, the IOL surface becomes less favorable to cell adhesion. The efficacy of the coating is theoretically long-lasting since the attachment of albumin on the coating is reversible and thus the albumin does not become denatured. Larger scale trials of this albumin-affinity cibacron blue dextran coating on live subjects are worthy of future follow-up.

Antimicrobial Coating

Infectious complication frequently predisposes medical device and implant to failure. Various antimicrobial coatings have been developed to address the problem. In general, there are two types of antimicrobial coatings: passive and active ones. Passive antimicrobial coating permanently binds antimicrobial agents onto the device/implant surface and does not allow their release. Microorganisms are killed on contact. Active antimicrobial coatings use the principles of drug-controlled release. They incorporate chemical compounds into the coating matrix for release into the vicinity of devices/implants to perform bactericidal functions.

Silver coatings were typical examples of passive antimicrobial coatings. Silver has been used as an antiseptic compound since the 14th century. Silver coatings kill microorganisms by denaturing membrane protein/polysaccharide upon contact with the silver surface. Elemental silver (Silzone coating) was permanently coated onto the sewing cuff of mechanical valves via ion beam-assisted deposition in order to reduce the risk of prosthetic valve endocarditis (PVE). Passive antimicrobial silver-coated mechanic valves failed to achieve clinical satisfaction because of complications irrelevant to infection. Other applications like permanent silver coatings on surgical tools and supplies show dramatically reduced risk of infection.

Drug release-type antimicrobial coatings are constructed by infusing a polymer matrix with antiseptic components. The polymer matrix can be hydrogel or nonhydrogel-based. During solution preparation, polymer solutions (solvent-based or water-based) are homogenized with various antimicrobial actives (antibiotics and antiseptics). After curing, the polymer matrix tightly attaches to coating substrates. Simple diffusion or ion exchange at the interface of body fluid and coating drive the release of antimicrobial agents. One good example of a nonhydrogel type, antibiotics containing coating that relies on the diffusion mechanism, is minocycline and rifampin containing PVB-coVA-coVA (polyvinyl butyryl-co-vinyl alcohol-co-vinylacetate) coating. Central venous catheters coated with minocycline and rifampin have proven efficacy in clinical environments. Minocycline is primarily bacteriostatic and exerts its antimicrobial effect by inhibiting protein synthesis. Minocycline is an active against a wide range of

gram-negative and gram-positive organisms. Rifampin inhibits bacterial DNA-dependent RNA polymerase activity and is bactericidal in nature. Rifampin possesses a broad spectrum of activity against a wide range of gram-positive and gram-negative bacteria. The combination of minocycline and rifampin has a strategic advantage since microorganisms developing simultaneous resistance to the two antibiotics have not been reported. An unfortunate characteristic of diffusion-dependent release mechanisms is that a high initial loading of active agents is required to prolong the effectiveness. As a result, an initial spike followed by exponential decay is the characteristic release profile.

Another example of antimicrobial coatings is hydrogel-based coatings that release antiseptic compounds in a controlled manner. Ion-exchange mechanisms have been frequently adopted to achieve controlled-release outcomes. In general, antiseptic agents (silver salts, for example) are first ionized in proper solvent systems and homogenized with negatively charged polymers (carboxylated polyurethane, for example). Under mild conditions, ionic bonds are formed between silver ions and the carboxyl groups on the polyurethane. Afterward, the polyurethane containing silver ions is cross-linked and polyvinylpyrrolidone (PVP) is incorporated into the matrix via the previously described interpenetrating network mechanism. At the moment of tissue contact, water molecules adsorbed by PVP hydrate the coating. Ion exchange then occurs between Ag^+ in the polyurethane matrix and Na^+/K^+ in the fluid, as illustrated in Fig. 2. Released Ag^+ in the surrounding devices performs the antimicrobial function. Na^+/K^+ concentration in

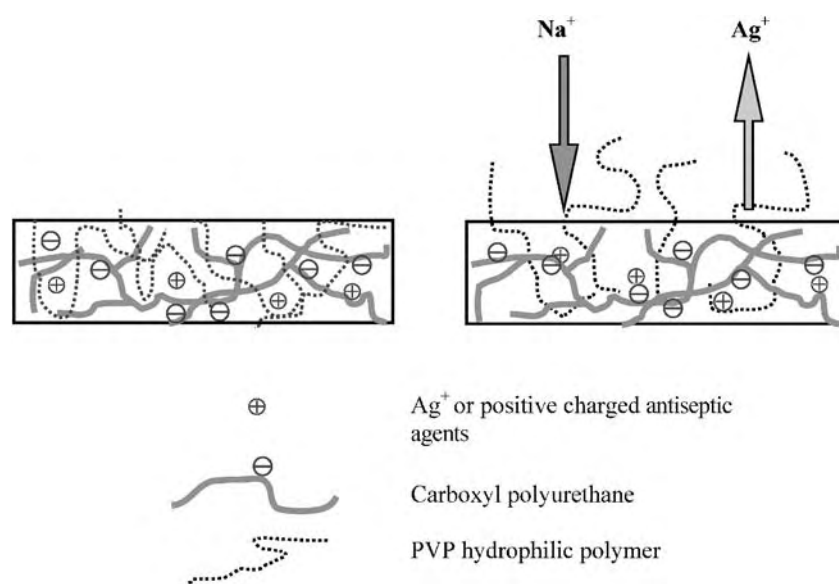

Fig. 2 Controlled-release antimicrobial coating. The mechanism of controlled, long-term release of silver ions from antimicrobial coating. Silver ions or antiseptic agents first couple with the negatively-charged polyurethane matrix. PVP results in a swollen, gellike watery layer. The ion exchange between silver and sodium ions occurs in the watery layer.

Fig. 3 Silver ion release profile from the controlled-release antimicrobial coating. The silver release profile was conducted by incubating antimicrobial coating in citric buffer at 37°C for two weeks. Buffer solution was replaced daily and the amount of released silver ions was determined by measuring the light absorbance of Bromopyrogallol red-1,10 Phenanthroline-Ag⁺ complex in extracting solutions. The solid line represents the actual measurements and the dotted line indicates the numerical regression result.

the tissue fluid determines the release rate of Ag⁺. Na⁺/K⁺ concentration is normally at a constant level in tissue fluid, which results in constant release profile of Ag⁺ Fig. 3.

Osteoconductivity-Promoting Coating

In some cases, cells' adhesion onto the surface of implants is desired to ensure the functionality of implants. Orthopaedic metal implants for fracture repair (bone nails, plates, and meshes) and joint replacement (knee, hip, and elbow replacement) have been successful because they exhibit two characteristics: superior mechanical functionality and the absence of adverse effects on surrounding soft tissues. However, reported proximal bone resorption, osteolysis, and fibrous ingrowth have frequently compromised the functionality of implants. Hydroxyapatites (HA) coating have been introduced to avoid those complications by enhancing fixation. Hydroxyapatites coatings are applied through a well-established process on both metal and polymer substrates. Among the many techniques used to fabricate HA coatings, plasma-spraying has become the most popular method due to the availability of technology and equipment, cost-effectiveness, efficacy, and reproducibility. Hydroxyapatites had been selected for coating materials due to its excellent osteoconductivity. Bone implants with higher osteoconductivity enabled the growth of bone tissue into gaps with a depth of up to 1 mm without significant formation of intermediate fibrous tissue.^[10] Better ingrowth or ongrowth of bone tissue on implants resulted in stronger fixation.

Surface Coatings Provide Therapeutic Benefits

Drug-release antimicrobial coatings prevent bio-material-related infections and ensure the functionality of medical devices/implants. The success of drug-release antimicrobial coatings reveals a possibility that surface coatings could play an active role in the attainment of dramatic therapeutic results. The development of drug-eluting stents is one vivid example.

Abundant evidence shows that restenosis following stent placement entails a series of interrelated host responses: thrombosis, inflammation, and smooth muscle cell (SMC) proliferation. Stent treatments have addressed each of these three responses. The earliest view held that metal stent strut-induced thrombogenesis ultimately resulted in restenosis. Thus, major efforts were made to reduce the thrombogenic property of metal stents. As thrombosis was controlled, it became clear that other (inflammatory) processes governed the restenosis rate. Broader strategies, employing both passive and active surface modification, were called for to reduce the host response. The so-called passivation methods altered selected properties of the stent surface without delivery of drugs or other agents. These techniques were expected to remove surface initiators of the host response, although less intense cellular responses to the surface may continue. In contrast, active surface modification provided a drug-release matrix to block or otherwise alter cellular responses. Significant reduction of platelet aggregation, inflammation, and SMC proliferation was achieved by some of these means.

Surface Passivation

The passivation approach is frequently employed to generate a thromboresistant coating. Both organic and inorganic compounds are used. Among many non-polymeric organic chemicals, phosphorylcholine (PC) has had the most attention as a stent passivation method. PC mimics phosphatidylcholine, a major component of the outer membrane layer of cells that inhibits the activation of formed and unformed elements of blood. There is good evidence to show that PC-coated stents reduce thrombotic complications. A recent clinical trial of the PC-coated Bio-divYsio stent yielded encouraging results. In six-month implantations, angiographic evidence of stenosis decreased from 89 to 5.6%.^[11,12] However, the PC coating is subject to erosion. Optimization of the PC-coating and longer-term studies are needed to prove its superiority.

Organic polymeric materials are also used for stent surface modification. Both biostable and biodegradable polymer coatings have been studied. Most polymer-coated stents are in the developmental stage and

frequently have been tested only in experimental animal models. Biostable polymer coatings include expanded polytetrafluoroethylene (ePTFE), polyester (Dacron), a blend of methylmethacrylate (MMA) and 2-hydroxyethyl methacrylate (HEMA), fluorine-acrylstyrene-urethane-silicon (FASUS) copolymer, parylene, and amphiphilic polyurethane. Variable success rates in reducing thrombus formation or neointimal growth have been reported. Biodegradable polymer poly(organo)phosphazene and poly(L lactic acid) (PLLA)-coated stents have also been reported to be less thrombogenic. Despite the short-term successes, a major concern for all these polymer coatings is the longer-term tissue/materials response. As noted earlier, mild to severe foreign-body responses associated with biodegradable and biostable polymer coatings have been observed. In some cases, an overwhelming inflammatory response has been closely linked to later restenosis, an unacceptable outcome.

Inorganic compounds—including gold, silicon carbide, hydrogenated carbon, and titanium nitride/oxide—have been tested as thromboresistant surfaces for metal stents. Gold is believed to be a biocompatible material. However, gold-coated stents revealed poor thromboresistance in an *ex vivo* human stasis model. The 12-month outcome from a randomized trial of a gold-coated stent yielded less favorable neointimal proliferation.^[13] Silicon carbide, postulated as a less thrombogenic semiconducting material, was shown to inhibit IgG, fibrinogen, and fibronectin adsorption. Fibrinogen is easily activated when it contacts a metallic surface, and activated fibrinogen, in the presence of thrombin, can be converted into fibrin to start the clotting process. Patients implanted with silicon carbide-coated stents showed less acute and subacute stent thrombosis, even when only antiplatelet medication was received postprocedure. This finding was confirmed in a larger scale randomized trial. However, the long-term benefit of silicon carbide coating was not confirmed in the same study.^[14] Hydrogenated diamondlike carbon and titanium nitride oxide are other inert materials that have been applied as stent coatings. By means of plasma or electronic beam techniques, diamondlike nanocomposites and titanium nitride/oxide coatings were deposited onto stent surfaces. Significant reductions of adherent thrombus on both coated stents were demonstrated in a short-term, porcine model study. Reduction of neointimal proliferation was observed only for the titanium nitride/oxide coating.

In general, metal stent surface modifications by these passive approaches achieve only a certain degree of thromboresistance, without significant reduction of neointimal hyperplasia. Thus, approaches that are more aggressive must be taken in order to reach a satisfactory outcome.

Active Surface Modification

The active approach aims for tissue responses beyond thrombosis resistance, since thromboresistant surfaces are achievable with some surface passivation methods. A number of active surface modification approaches are based on the successful development of stent-coating procedures. These stent coatings function as reservoirs for specific therapeutic agents. The rationale is that drugs are gradually and locally released from the coating matrix and taken up by surrounding tissues. A reduction in neointimal hyperplasia is expected, at least for the period that the beneficial drug actions remain in effect and perhaps beyond, if healing processes are sufficiently advanced. An optimal combination of drugs and coating matrix maximizes the local therapeutic benefit, thereby maintaining the patency of the stented vessel.

A variety of pharmacologic agents have been used to prevent thrombosis and restenosis. The agents are loaded in bulk by physical entrapment or by chemically bonding to the polymer chain.^[15] Four types of drugs have been studied in experimental animal models or human clinical trials: anticoagulants, antiplatelet, antiproliferative, and immunosuppressive agents.

The rationale for immobilized heparin, the most intensively investigated stent-coating agent, is to inhibit thrombin-dependent positive feedback reactions at the stent surface. Heparin-coated stents have been used in a primary antirestenosis strategy (BENESTENT II, MENTOR) and in the context of primary angioplasty for acute myocardial infarction (PAMI stent pilot trial) and total coronary occlusion (TOSCA).^[16–19] Although thrombogenicity was reduced in the BENESTENT II study, investigators doubted the importance of the heparin coating. In the longer term (six-month follow-up), the heparin coating did show improved angiographic evidence of restenosis. Stents coated with the anticoagulant hirudin have been shown to reduce neointimal formation. Despite these findings, it is now generally believed that anticoagulant coatings are unnecessary when proper stent deployment techniques are coupled with effective antiplatelet medication, e.g., aspirin and ticlopidine.

Antiplatelet agents employed in drug-eluting stents include nitric oxide donors, glycoprotein IIb/IIIa receptor antagonist/antibodies, and thrombin inhibitors. Significant reductions in platelet deposition and thrombosis have been demonstrated for several of these agents in animal studies. Unfortunately, no indication was revealed that the palliation of thrombosis by these means resulted in the inhibition of neointimal growth.

Antiproliferative drug-eluting stents combat restenosis by directly inhibiting vessel smooth muscle cell (SMC) proliferation. Drugs designed to inhibit SMC

migration, or to arrest the SMC cell cycle at the G2/M transition have been studied.^[20,21] Stents coated with such drugs proved to reduce neointimal growth in animal studies. Paclitaxel-eluting stents attracted particular attention. A paclitaxel-eluting stent was the first device reported to have six-month inhibitory efficacy on neointimal growth.^[22] This six-month efficacy was reproduced in a human clinical trial, although the antiproliferative efficacy was not maintained in the 12-month follow-up, as measured by angiographic restenosis.^[23] Postponed thrombosis and uncompleted wound healing were later reported in more thorough animal examinations.^[24] The paclitaxel-eluting stent experience nevertheless implies that the optimal combination of drug and coating matrix may yield a long-term, restenosis-free therapy.

A fourth, exciting area of progress concerns stents coated with immunosuppressive drugs. These coatings attack neointimal growth in a different way, possessing both potent antiinflammatory and immunosuppressive effects. Such drugs have been shown to decrease the migration and functional capabilities of inflammatory cells. Some of these drugs prevent cell cycle progression in the G1 stage, and consequently inhibit cell proliferation. In a pig coronary artery model, methylprednisolone-eluting stents showed promise in reducing the foreign-body reaction and restenosis at six weeks. In one month, porcine and rabbit models, a rapamycin (sirolimus)-eluting stent, inhibited restenosis. Moreover, the long-term behavior of the sirolimus-eluting stent is as encouraging as its short-term property. Multiple experiences in human clinical trials show that the antirestenotic efficacy of the sirolimus-eluting stents is sustained for 12 months.^[25–27] In contrast to their opinion of paclitaxel-eluting stents, interventional cardiologists are optimistic about the 12-month follow-up angiographic outcome with this device.

The benefit of drug-release therapeutic coatings is evident. Metal stents were invented as supportive mechanical structures to rescue artery occlusions, but never obtain satisfactory clinical outcomes. Thanks to the active, drug-eluting strategy of surface coatings, coated stents ignite a promising future in overcoming restenosis.

CONCLUSION

As recently as just 20 years ago, surface coatings were considered mere supplements to medical devices and implants. As knowledge accumulated about host responses to biomaterials, surface coatings became more indispensable to the manufacture of safe medical devices and implants. Coatings provide benefits of lubricity, electric isolation, wettability, enhanced

imaging, antiencrustation, thromboresistance, anti or promoting cell adhesions, antiinfection, and anti-restenosis. The recent clinical success of drug-eluting stents moves the application of surface technology forward. Surface coatings are beginning to be regarded as equally important to the success of the device as the physical device itself. In the near future, surface coatings are expected to be an important partner in the achievement of desired therapeutic results in many diseases.

INTRODUCTION

While materials selection for most biomedical devices is generally based upon bulk properties, it is the surface's properties that may ultimately determine the success or failure of the device. Today the need for efficient and effective methods of surface modification for biomedical applications is becoming increasingly evident. Advances in biological array, diagnostics, and tissue engineering are currently hampered by problems that can, in large part, be controlled by tailoring the surface properties. Surface modification aims to tailor the surface characteristics of a material for a specific application without detrimentally affecting the bulk properties. At present a range of biological, physical, and chemical methods are used to effect surface modifications on biomedical devices and biomaterials. This article introduces and discusses the application of a number surface modification techniques used in both industrial production and fundamental research of materials for biomedical applications.

SURFACE MODIFICATION METHODS

Surface modification generally falls into one of two categories: 1) modification of the existing surface, e.g., etching or chemical modification or 2) coating the surface with a different material, e.g., plasma deposition or polymer grafting. As illustrated in Fig. 1, these approaches can be used to affect a range of properties, including wettability, permeability, biostability and/or chemical inertness, adhesion, biocompatibility, topography, electrical characteristics, and optical and frictional properties.

While complicated and expensive surface modification techniques may be applicable in fundamental research, these may be impractical when considering a commercial application. Table 1 lists some of the common surface modification techniques used at present in biomedical engineering and the materials properties they influence. A successful commercial product therefore requires any surface modification to be one that is readily transferable to a larger scale and

preferably to a variety of substrates. In addition, any surface modification should be physically, chemically, and biologically characterized. A range of highly sensitive surface analytical methods exist and their applications in biomedical and biomaterials applications have been recently reviewed by Castner and Ratner.^[36]

RADIATION-BASED SURFACE MODIFICATION METHODS

Radiation-based surface modification techniques, including gamma, ultraviolet (UV), laser, electron, and ion beams, can be used to surface modify biomedical materials.^[18] Specific applications range from ion implantation for improved wear, corrosion and biocompatibility of metal alloys in orthopedics and dentistry to surface chemical patterning via photolithography and radiation-initiated polymer grafting.

Ion Beam Techniques

Ion beam techniques can be considered in one of two categories: 1) thin film formers, e.g., ion beam-assisted deposition (IBAD); and 2) surface chemical modifiers, e.g., ion implantation. In both applications, an ion source is used to produce the appropriate ionized species that are then separated and subsequently accelerated in an electric field. The ions reach the surface with energies between 20 and 200 keV,^[37] which enables the delivered ion beam to induce modifications of the macromolecular structure through gas evolution, formation of double bonds, chain scissions, and cross-linking over a thickness corresponding to the penetration depth of the ions.^[21] Major parameters affecting ion implantation are the ion species, the beam energy and dose, and the beam current density.^[20]

In the case of metals and ceramics, the atomic and nuclear collisions induced by ion implantation lead to the formation of highly disordered and sometimes amorphous structures. Chemical processes result in the formation of new surface phases with significantly different mechanical properties from the bulk.^[20] The formation

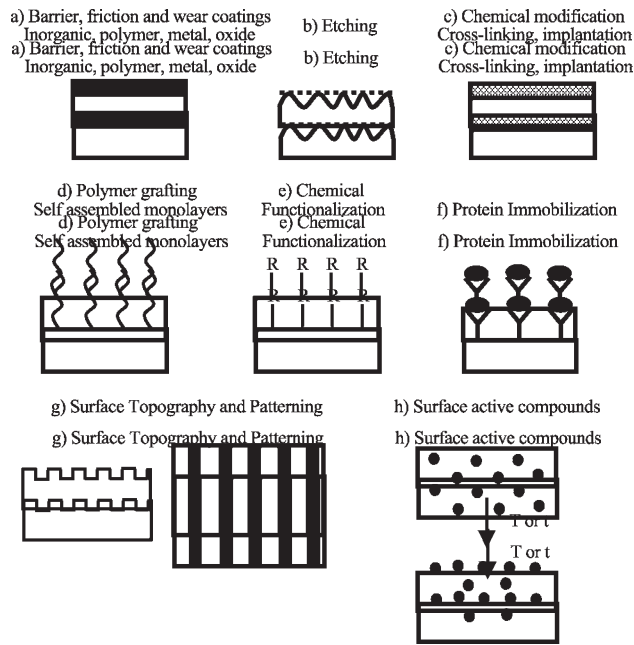

Fig. 1 Surface modification methods used in biomaterials and biomedical engineering.

of hard phase nitride, carbide, and oxide precipitates hardens the surface, which improves the wear resistance of titanium and titanium alloy orthopedic implants.^[38] Changes induced in the crystalline structures of titanium alloys 316L stainless steels and Co–Cr alloys have also been shown to improve friction properties.^[20,39]

In the case of polymers, chain cross-linking and scission compete during the ion implantation process.^[21] Cross-linking results in surfaces with higher wear resistance, but polymer degradation can occur if processing parameters are not well-controlled.^[20] Ion implantation has been used to increase surface hydrophilicity of silicone catheters to reduce the incidence of thrombus formation^[40] and improve cell adhesion, proliferation, and spreading on polyurethane and polyethersulphone.^[41] Nitrogen ion implantation of polycarbonate results in complex three-dimensional, cross-linked surface, which results in increased solvent resistance and significant improvements in the wear and friction characteristics.^[42]

Ion implantation can also be used to introduce specific chemical species at the surfaces of polymers, ceramics, and metals.^[19,20,38] The wear, corrosion resistance, and bone conductivity of titanium alloys have all been shown to be improved with nitrogen, calcium, and/or phosphorus ion implantation, respectively.^[38,43] In polymeric materials, the incorporation of silver (Ag) ions have been used to impart both the antimicrobial properties that are typically associated with silver and reduce the occurrence of thrombus formation on indwelling catheters.^[22,44]

The second category of ion beam process is the thin film former. The bone conductivity, corrosion, and

wear resistance of metal substrates can be improved with the formation of apatite, TiO₂, and TiN coatings.^[38] Traditional plasma spraying of these materials results in a film with controlled chemical composition but poor adhesion properties.^[38] Ion beam-assisted deposition (IBAD) combines physical vapor deposition with ion beam implantation. An electron beam evaporator or plasma vapor deposition (PVD) is used to generate the metallic or inorganic coating atoms as gaseous ions are simultaneously accelerated towards the surface. Ions interact with the coating atoms, which drives them into the surface, and produces a low-stress, uniform, and adherent coating.^[20]

IBAD has been used to produce hydroxyapatite coatings on titanium alloys, alumina, and UHMWPE with a greater coating/substrate adhesive strength than the traditional plasma spraying methods.^[45] Thin, clear sealant coatings of alumina have also been developed to prevent oxygen and water vapor permeation into polymers.^[20,37] The process has also been used to produce titanium alloy coatings on Co–Cr substrates for improved cellular integration in orthopedic applications^[6] and C–N coatings that are both biocompatible and wear-resistant.^[20] Commercially, IBAD is used to produce antimicrobial silver coatings that will adhere to a range of polymeric substrates^[21,22,37] and diamondlike carbon (DLC) coatings that are chemically inert, optically transparent, extremely hard, and have a low friction coefficient.^[20] These DLC coatings are used to treat the bearing surfaces of orthopedic implants to improve wear and friction properties and reduce the incidence of wear debris.^[37]

Laser, Ultraviolet, and Gamma Radiation Techniques

Controlled exposure of a surface to excimer lasers and UV lamps can produce a range of surface chemical modifications, including etching, deposition, and polymerization.

UV and laser treatments have been demonstrated to introduce oxygen containing species on the surface of expanded-polytetrafluoroethylene (e-PTFE)^[18] and poly(ethylene terephthalate) (PET).^[17] This improves surface wettability and changes surface morphology plus improves cell proliferation and growth on surfaces that would normally display poor cell growth characteristics.^[18] Gamma irradiation and vacuum ultraviolet (VUV) radiation have both been used to improve the wear resistance on the load-bearing surfaces of orthopedic implants and cross-link UHMWPE to reduce the incidence of wear-related failure.^[46]

Radiation techniques have long been recognized as a method of initiating polymer and biomolecule grafting on a variety of polymeric substrates.^[18] In the

majority of the studies, radiation grafting has been implemented as a means of improving the biocompatibility of the device surface.^[13,15,47] Gamma, laser, and UV radiation have been used to immobilize poly(ethylene oxide) (PEO) containing Pluronic[®] surfactants,^[48,49] hydroxethyl methacrylate (HEMA),^[15] n-isopropylacrylamide (NIPPAAm),^[50] and acrylic acid^[14,47] to a variety of biomaterials.

There is increasing interest in the spatial control of protein and cell adhesion for biosensors and tissue engineering. The introduction of masked irradiation and the ability to focus the energy source has enabled laser and UV radiation techniques to revolutionize the spatial manipulation of surface topography and chemistry.^[14] By incorporating photosensitive groups into the polymer backbone, Ward et al. have shown that it is possible to use a mask and a UV source to micropattern a range of biomedical polymers, including poly(ethylene glycol) and create surfaces that are capable of selective protein adsorption and cell adhesion.^[51] In other studies, laser ablation has been used to micropattern surfaces to control cell location and shape^[52] while a UV laser coupled to a scanning near-field optical microscope has been used to induce photo-oxidation and nanometer scale patterns in self-assembled monolayers.^[53] Laser excimer beam technology has also been used to introduce high-resolution topography on polymeric surfaces to investigate the effects of three-dimensional structures on cell/surface interactions and as a possible route to controlling cell proliferation and growth.^[54]

PLASMA SURFACE MODIFICATION TECHNIQUES

Plasmas consist of highly excited atomic, molecular, ionic, and radical species. The excitation can be achieved using gaseous (e.g., radio frequency, corona, or microwave), metallic, and laser-based sources. The resulting gaseous environment is highly reactive and capable of eliciting a range of plasma–surface interactions, even on inert materials such as ceramics. Plasma-based treatments enable adhesive metallic, ceramic, and polymeric coatings to be applied to a range of materials. In specific formats, they can be used to etch, cross-link and oxidize materials, and introduce specific chemical functionality at the material interface. These factors make plasma techniques particularly useful for the surface modification of biomedical materials, e.g., in the oxidation of polystyrene for tissue culture applications. In this section, two techniques, plasma source and plasma immersion ion implantation (PSII and PIII) and plasma modification/polymerisation, are discussed. For further detail of the

application of plasmas to biomaterials, the reader is referred to recent reviews by Chu,^[1] Chan,^[8] and Favia.^[3]

Plasma Ion Implantation Methods

Plasma ion implantation techniques, such as plasma source ion implantation (PSII) and plasma immersion ion implantation (PIII), are able to introduce elements into the surface without thermodynamic constraints.^[1] They have one major advantage over the standard ion implantation methods discussed in the previous section. They are not line of sight techniques, a factor that enables the modification of complex shapes commonly found in biomedical applications.^[5]

In PIII and PSII, samples are surrounded by high-density plasma and pulse-biased to a high negative potential relative to the chamber wall. Ions generated in the plasma are accelerated across the sheath formed around the samples and implanted into the surface. The gaseous plasma can be induced using a variety of sources, including radiofrequency and microwave. Typically, oxygen is used in these systems to produce Ti–O coatings on the surface of titanium alloy (Ti₆Al₄V and NiTi shape memory alloy) implants. The resulting coating improves the mechanical properties, wear resistance, corrosion, and biocompatibility of the device.^[4,5,55] Treatments using argon, xenon, oxygen, and nitrogen have also been used to improve the electrical and adhesion properties of a number of polymers.^[56,57]

Traditionally it is very difficult to make a good adherent metal layer on a polymer due to the lack of chemical bonds. Combinations of gas plasma systems with metallic plasma from vacuum or cathodic arc plasma sources enable a number of elements to be introduced to the plasma simultaneously. These plasma-assisted processes allow interface mixing, which results in a coating with low intrinsic stress, a factor that reduces the probability of delamination on both polymeric and metallic substrates.^[58] This approach has been used to surface modify skeletal prosthetic implants with titanium alloy coatings for cell recruitment while maintaining the mechanical properties of the Co–Cr substrate^[55] and deposit carbon and Ti–N coatings on both metals and polymers from improved wear and scratch resistance.^[58]

Plasma Modification and Polymerization Methods

Radio frequency glow discharge (RFGD) or plasma polymers have been applied to biomaterials and biomedical devices since the 1960s^[59] (Table 2). An electric field at radio frequency is applied across a vapor or

gas-filled chamber, ionizing a fraction of the molecules, and generating electrons, ions, free radicals, photons, and molecules in both ground and excited states within the gas plasma.

Plasmas can be used to modify surfaces by etching or coating surfaces by deposition. In the case of surface modification, the interaction between plasma and substrate leads to two competitive reactions, modification and degradation. When degradation is prominent, etching will occur on the polymer surface. The rate of materials loss depends on both the plasma energy and the nature of the polymer substrate.^[1] Plasma etching or cleaning is commonly used to remove contaminants from the surface and improve the adhesive properties of both metals and polymers. With all plasma treatments, there is a possibility that surface reactions will result in unexpected surface bound

species. The selection of the treatment gas and plasma conditions is critical in ensuring that the reaction products do not readsorb to the cleaned surface.^[85] In some instances, a specific phase of the material may be more susceptible to the plasma, which results in an etched surface with the chemistry of the plasma-resistant material.

In the modification regime, chemical species are introduced to the surface of the material. These non-depositing plasmas typically use inert gases such as argon, ammonia, oxygen, nitrogen, air, and water to influence surface chemistry and topography. A common application for these types of chemical modifications are as pre-activation step for polymer copolymerization in which the plasma creates radicals in the polymer chains that can then be used to initiate polymerization when placed in contact with monomers in the liquid or gas phase and form grafted copolymers at the surface.^[8] Specific gases such as oxygen or nitrogen can also be used to produce TiO₂ and TiN modifications on the surfaces of titanium alloy orthopedic implants.^[85] Plasma treatments are also used in a range of biomedical applications to introduce specific functional groups at the interface that enable, e.g., biomolecule and drug immobilization.^[81,86] The presence of specific chemical species on plasma-modified surfaces has also been shown to influence cell attachment and growth in cell culture.^[87]

In the case of surface-depositing plasmas, the deposition process involves the volatilization of a liquid monomer into an evacuated process chamber. Excitation of the monomer results in reactive species impinging on a surface within the plasma zone, which creates reactive sites that may be available for the covalent attachment of other species. The process results in the deposition of a polymeric film from the vapor phase.^[73] As detailed in Table 3, plasma deposition has

Table 3 Advantages of RFGD plasma deposited films in biomedical applications

Conformal Films: Due to their gaseous nature, plasma can penetrate complex structures and conform to their surface.
Substrate Adhesion: The polymer films adhere well to a range of substrates because free electrons impinge on the surface and create sites for covalent attachment.
Low Leachables: The polymer is highly cross-linked and so contains negligible amounts of low molecular weight material that may cause adverse biological responses. The presence of the film may in some cases prevent leaching of additives from the bulk material.
Barrier Function: The densely cross-linked and pinhole-free nature of these coatings make them adaptable to barrier and protective applications.
Sterility: When removed from the reactor system, the coatings are sterile.
Range of Chemical Functionalities: A wide range of monomers are available that are able to introduce a variety of chemical functionality.
Surface Specificity: The film thickness can be closely controlled, which results in a negligible effect on bulk mechanical properties.
Rapid processing: Films are easily prepared following process optimization.

(From Refs. [7,73].)

a number of specific advantages over alternate surface modification techniques with a key strength lying in its ability to form an adherent coating on a range of materials.

A wide range of monomers have been used to produce plasma polymer coatings with tailored surface characteristics. Organo-silicon monomers such as silanes and disiloxanes are used to produce coatings with thermal and chemical resistance as well as specific electrical optical properties. Fluorine- and hydrocarbon-containing monomers are used to produce hydrophobic surfaces while acid-containing monomers produce hydrophilic coatings.^[1] Amine and acid-rich plasma polymers are used to provide a stable functionalized surface for the attachment of biomolecules^[28,77-80] while a range of monomers can be used to functionalize surfaces prior to wet chemical grafting of polymers.^[94,95] In general, plasma polymers do not reproduce the chemistry of the monomer. Instead, the process tends to form complex, cross-linked polymers with random structures that incorporate various structural fragments of the monomer.^[73]

Plasma-polymer surfaces that retain the functionality and specific characteristics of their monomer are of increasing interest and include poly(ethylene oxide)like surfaces for protein resistance and nonfouling,^[72,88] thermally responsive N-isopropylacrylamide (NIP-PAAm) surfaces,^[89] and hydrogel hydroxyethyl methacrylate (pHEMA).^[90,91] Monomer characteristics can be retained by modifying the deposition condition by using lower powers or pulsed systems^[7,88-90,92] or copolymerising the functionalized monomer with a diluent hydrocarbon monomer.^[93] The resulting materials have been shown to retain higher monomer functionality and, in some cases, specific physicochemical properties normally associated with multi-step polymer grafted surfaces. The development of single-step plasma-polymer films present distinct advantages for the production of biomedical devices.

WET CHEMISTRY

Surface Modification by Polymer Grafting

Polymer grafting provides a further, versatile approach to the modification of surfaces. Grafted surfaces can be produced by direct coupling of existing polymer molecules to surfaces containing functional groups or graft polymerization of monomers. Graft polymerization methods include chemical graft polymerization and grafting using high-energy radiation—both ionizing and non-ionizing—or oxidizing agents such as ozone or acid treatments. Detailed reviews on polymer grafting and the physicochemical characteristics of graft layers have been written by Uyama,^[94] Kato,^[12]

Kang,^[95] Claesson,^[96] and Bamford.^[97] Grafting techniques for polymeric biomaterials have been used to generate surfaces that exhibit nonfouling properties, selective protein adsorption, and improved biocompatibility. In the case of nonfouling surfaces, a number of water soluble polymers have been used including polyacrylamide, poly(ethylene glycol), polysaccharides, and phosphorylcholine. Grafting has been achieved by covalent coupling, surface graft polymerization, surface segregation, and interpenetration of the surface. A number of reviews specifically focused on surface modification for nonfouling have been written recently by Kingshott,^[25] Malmsten,^[98] and Hoffman.^[24]

Factors known to affect the properties of a grafted polymer layer include polymer molecular weight, the extent of chain branching, the density of functional and charged groups on both the substrate and polymer, and the solubility of the polymer.

Self-Assembled Monolayers

Self-assembled monolayers (SAMs) also provide a flexible approach to the creation of surface chemical and biological functionality. SAMs are highly ordered, surface coatings that form spontaneously on certain substrates, e.g., alkanethiols ($\text{HS}(\text{CH}_2)_n\text{X}$) on gold or silver.^[34] SAMs can also be formed from the interactions of chlorosilanes with OH-terminated oxide surfaces^[99] and a number of acids on metal oxide surfaces.^[33] SAMs provide well-defined surface structures, can be patterned using microcontact printing and photolithography,^[100] and have chemistries amenable to a range of modifications.^[23,101,102] SAMs have been widely used as model surfaces in the study of protein adsorption and cell adhesion^[23,103] and the investigation of cell adhesion peptide sequences,^[101,104] but they have also found commercial applicability in biosensors and nucleotide arrays.^[33] There has been a considerable research effort in recent years investigating the formation and structure of SAMs that are capable of resisting protein adsorption by the incorporation of derivatives of poly(ethylene glycol) and other specific end groups. The results of which have been reviewed by Ostuni.^[23]

Biomolecule Attachment and Biomimetic Surfaces

Coatings incorporating biologically active and/or inactive molecules to generate specific, predictable, and controlled responses in the biological environment have been of considerable interest in recent biomaterials research. These so-called intelligent materials are designed to provide specific signals that result in

biologically functional surfaces.^[36,102,105,106] A wide range of biomolecules, including proteins, peptides, polysaccharides, lipids, and oligonucleotides, have been immobilized on surfaces with the aim of eliciting specific, predictable, and controlled biological responses. Of particular interest in the biomaterials field has been the incorporation of peptide sequences (e.g., RGD) from the receptor-binding domains of adhesion proteins in order to promote cell adhesion.^[105,107] The success of strategies designed to present biological ligands is maximized if the immobilized molecule is coupled to a surface capable of preventing nonspecific adsorption. The subsequent biological response is influenced by the presentation, average density, and the spatial distribution of the immobilized molecule.^[105]

Biomolecule immobilization methodologies encompass both physical and chemical techniques and range in their degree of specificity and resulting functionality. In their simplest incarnation, nonspecific adsorption results in a surface with randomly oriented molecules deposited in a noncontrolled manner. While these coatings have displayed some short-term functionality, their efficacy is diminished by denaturation and biomolecule desorption. Covalent immobilization has also been used to couple biomolecules to suitable surface functionalities using a range of chemistries.^[108] Chemical modification of the surface to introduce functional groups can be achieved by using a variety of the techniques outlined in previous sections, including plasma polymerization, and photochemical grafting. But, nonspecific covalent immobilization gives little control over orientation or activity of the biomolecule. The introduction of polymer or amino acid spacer chains with reactive functional groups enables the biomolecule to be attached in a manner that can provide greater access to specific sites on the biomolecule, which reduces the incidence of denaturation and thus maintains biomolecule activity. Specific examples of this type of approach are the site-specific modification of proteins with cysteine or biotin tags that enables immobilization of the proteins in specific orientations on gold- and streptavidin-modified surfaces.^[109]

CONCLUSION

An extensive range of surface modification techniques can be used to affect changes in surface properties of biomaterials while maintaining the bulk properties of the material. Several of these modification techniques have found application in commercial devices and are likely to continue to be used for some considerable time. However, the focus of surface modification is increasingly directed toward the design of bioengineered surfaces that are able to elicit and control biological responses.

Recent years have seen an increased focus on the study and design of surfaces incorporating specific recognition molecules that are precisely oriented and at an appropriate density for optimal biological function. In addition, there is increasing interest in surfaces that borrow from structures observed in nature, so-called biomimetic surfaces. Examples of these include protein template imprinted structures and tethered lipid bilayers. At the same time, well-defined model systems continue to give insight into the parameters that control biological responses to implanted materials. Surfaces based on the principles of self-assembly provide valuable insight into interfacial interactions and are likely to find increasing application for in-vitro and diagnostics applications. In the same vein, nonfouling surfaces continue to be critical to the development of a range of in-vitro biomedical applications, including diagnostics and microfluidic devices.

S

INTRODUCTION

It has been long recognized that mammalian cells are sensitive to topographical features of their underlying substratum, whether they be other cells, extracellular matrix proteins, or implant surfaces. With the increased use of artificial materials in medicine, understanding which stimuli promote desirable reactions from cells in surrounding tissues has become critical to improve implant performance. When considering suitable materials for implantation, two key aspects have been identified that influence cellular response, namely, the chemistry and the topography of the material. Initial research models used to investigate topography were criticized owing to the difficulty in the separation of the effects of material chemistry from topography. However, by the harnessing of techniques used in the microelectronic industry, the fabrication of substrata with precisely defined topographies and uniform chemistry has been developed. Through the use of such substrata, the effects of topography on cell behavior have been identified on well-characterized materials. The aim of this entry is to review the types of surface topographies currently investigated and the types of reactions such substrata evoke from cells and/or tissues.

SIGNIFICANCE OF TOPOGRAPHICAL REACTION

The importance of topographical reactions and gaining an understanding of the mechanisms lying behind it has been obvious in development and wound repair. Directed cell migration is essential during development, where the movement of cells from one part of the embryo to another must be under precise control.^[1] A number of cues including cell–cell interactions and topography have been identified as playing key roles in this patterned migration. In addition, topographical control of cell migration is also thought to play a part

in pathological processes such as cancer metastasis, where local invasion of tumor cells often occurs along aligned sheets of collagen.^[2] In such in vivo situations, however, it is uncertain whether topography alone is responsible for the migration of the cells. The possibility that extracellular matrix chemistry or chemotactic gradients could be influential cannot be excluded.

FIRST OBSERVATIONS OF TOPOGRAPHICAL REACTIONS

Ross Harrison first observed the direct reaction of cells to topography.^[3] He cultured cells on spider webs, and observed that the cells became oriented and their movement guided by the fine silk threads. The control of cell behavior by fibers was confirmed by Weiss, who cultured cells on networks of fibrin in plasma clots.^[4] He observed that when two explants of chick embryonic tissue were placed a small distance apart in a plasma clot culture, growth from each explant was directed along the fibers. Weiss termed this phenomenon of cell orientation by the underlying topography “contact guidance.”

TYPES OF SURFACE TOPOGRAPHY

Much of the early work carried out on topography employed natural substrata, structures that were derived from biological materials. The reasoning behind this was that such substrata could be of biological importance in understanding guidance cues during development.^[1] Unfortunately, there are disadvantages in using biological materials. First, the chemistry of the material could affect the behavior of the cells, and consequently, any results observed may not be due to topography alone.^[1,5] Second, the chemistry of such substrata could be variable. Despite the disadvantages, certain biological substrata have been shown to align

cells in vitro, proteins such as collagen (when aligned), and fibronectin fibrils. Neuronal cell processes, neural crest cells, and leukocytes have all been shown to react to these substrata, cell shape being oriented and locomotion guided. However, to fully investigate the effects of topography, substrata with well-defined features and, more importantly, uniform chemistry needed to be designed.

Microfabrication and Defined Surface Features

For many years, little work was carried out using artificial topographies in vitro to investigate cellular reaction to surface morphology, mainly because of lack of suitable materials that had well-defined and uniform surface morphology. Methods of fabrication employed lacked flexibility in dimensions and the surfaces were complicated owing to heterogeneities introduced during fabrication. With the advent of the use of techniques harnessed from the microelectronic industry, it has become possible to produce structures with precisely defined surfaces in cell biological studies, thus allowing the reaction of cells to defined topographic features to be observed.^[6]

Synthetic materials such as silicon and glass, cellulose acetate, epoxy, araldite, polystyrene and metals such as titanium and titanium alloys have all been employed to produce precisely characterized topographies.^[5] Manufactured substrata have the advantage that the material can be designed to precise dimensions and can be fully characterized in terms of

surface chemistry. Using such methods of fabrication, fibers of glass can be drawn out to precise dimensions, and structures such as ridges and grooves can be made using photolithography and etching techniques in silicon. The process of photolithography is shown diagrammatically in Fig. 1.

Topography Vs. Chemistry

One argument that needs to be addressed at the outset is whether the methods of fabrication of topography result in the production of altered chemistry across the surfaces, raising the possibility that the chemistry influences cell reaction. This area has been the subject of much research and has been addressed in great detail elsewhere. One approach to alleviate this problem is to coat the material with titanium, making it unlikely that differences in chemistry would be present.^[6] Another approach would be to blanket etch the substratum after topographic patterning by etching. For a more in-depth review of alternate approaches, see Curtis and Wilkinson.^[5]

Single Steps (Cliffs)

Single steps or cliffs are one of the simplest structures to employ and have both an acute and obtuse edge. Clark et al. found that a variety of cell types reacted to this type of structure.^[7] They noted that cell response was influenced by the direction from which the cells

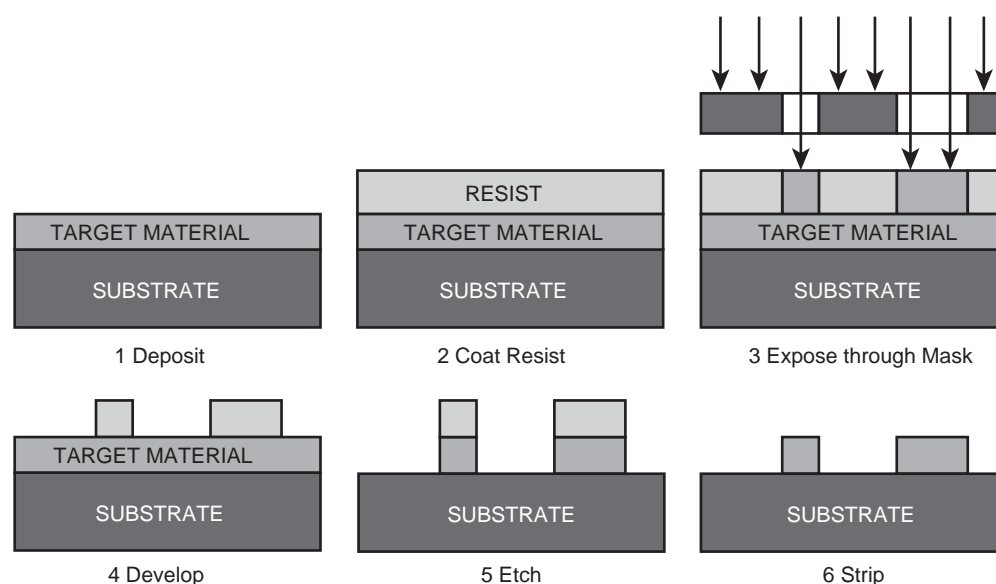

Fig. 1 Schematic representation of the photolithography process. The target surface (1) is cleaned and resist applied to the target material (2). A photomask is then created and developed onto the substrate (3), through the mask (4). The substrate is then etched (5), and the resist is removed using acetone (6), leaving the desired topography etched onto the substrate.

approached the cue. For certain heights of cliffs, the cells could climb up the step, but could not descend from the top. Ridges have also been employed that are essentially double cliffs. Depending on spacing, cells responded by accumulating on the ridges and extending along them. In some instances, the cells were guided in their migration by the ridges, a phenomenon termed ridge walking.^[1]

Fibers

The use of fibers in the field of regenerative medicine first appeared in a study by Jenkins and colleagues in 1977, with a view to applications in ligament repair and regeneration.^[8] Since this time, fibers have been produced using materials such as titanium, poly-glycolic acid, poly-lactic acid, polypropylene, glass, chitosan, ceramics, as well as natural materials such as fibronectin and collagen (Fig. 2A). The advantages of fiber-based systems include being able to extrude the fibers to any length required as well as being able to knit the fibers into meshes.^[9] Another major advantage of fiber-based systems is the ability to create a porous structure without any loss of mechanical strength of the material, thus producing an implant that is able to withstand physiological biomechanical stimuli as well as promote cellular ingrowth. The tendency of cells to align with the long axis of the fibers, regardless of the material chemistry, mimics the *in vivo* architecture of cells in tissues such as tendons, ligaments, and striated muscle.

Repeating Grooved Substrata

Initial attempts to fabricate grooves relied on techniques such as commercially available ruling engines or methods used to produce sound recording techniques.^[10,11] However, such methods often left features that were highly variable, not only from a topographical perspective, but also in surface chemistry. With the use of photolithography, followed by reactive ion etching, it became possible to fabricate highly ordered topographies with precise dimensions, such as repeating groove and ridge structures.^[6] Processes such as etching allow exact control over the depth, repeat spacing, and shape of the substratum. The techniques rely on the etching of materials such as silicon along precisely defined planes. By selecting silicon with different crystal orientations, it is possible to fabricate grooves of rectangular or V-shapes. Grooves are defined by the depth, width, and pitch (repeat spacing).

The application of V-shaped grooves produced from silicon (1,0,0) to study cell response on substrata was first reported by Brunette, Kenner, and Gould.^[6] Rectangular grooves could be produced using silicon

110. Since then, many studies of the effect of grooved substrates of varying dimensions on cell behavior have been reported. Increased adhesion, alignment, migration, and changes in gene expression have all been reported in various cell types cultured on grooves (for details see section “Cell Behavior Influenced by Substratum Topography”). In general, cells align to the groove long axis (Fig. 2B) and migrate in the same direction; depth seems to be the most important determinant in alignment. However, recent investigations have shown that certain cell types, such as chondrocytes, do not show the typical reaction to grooves as exemplified by fibroblasts or osteoblast.^[12,13] However, repeating grooved structures have proven to be an invaluable tool in understanding cell reaction to topography, and further, have translated well to the *in vivo* environment (see section “*In Vivo* Applications of Cell–Topography Interactions”).

Pits/Holes

An attractive possibility of using micromachined topographies is the ability to change the microenvironment around the implant surface, possibly providing conditions to promote implant integration. The use of pitted surface and holes has shown great potential in this regard, especially related to macrophage biology and osseointegration. Dow et al. reported on the “trapping” of macrophages in pit-type structures, opening the intriguing possibility of being able to control the positioning of macrophages around implant surfaces (Fig. 2C).^[14] As will be highlighted later in this entry, the benefits of macrophages around newly implanted constructs is of great importance, especially with regard to implant integration into bone.

Microenvironment has been shown to play a pivotal role in matrix and mineral deposition. Qu, Chehroudi, and Brunette, demonstrated that osteoblasts grown in truncated pits would form mineral within 2 weeks of culture, with the mineral deposited toward the bottom of the pit (Fig. 2D).^[15] In this study, the pits had a depth of 120 μm , and the investigators suggested that the cells effectively conditioned the immediate environment with growth factors and matrix, which promoted osteogenesis. It is likely that any surface that promotes mineralization on the implant in this way will stand to promote long-term integration and successful retention of the implant. In addition, recent work in our laboratory using pits on the order of 10 μm in depth has promoted very similar results, suggesting that it could simply be the microenvironment directly adjacent to the cells that is of importance. Although the optimal dimensions are not known, pits and hole-type topographies show great promise for promoting implant integration into bone.

Fig. 2 Representative images of surface topographies currently investigated in research laboratories. (A) Epithelial cells growing on fibers, (B) actin staining of mesenchymal stem cells growing on repeating grooves, (C), P388D1 macrophages growing in cell traps, (D), rat calvarial osteoblasts growing in “pit”-type topographies, (E) fibroblasts growing on a convex topography, (F) ovine chondrocytes cultured in 240 μm -diameter quartz tube, (G) microtubule staining of human gingival fibroblasts growing on a discontinuous edged topography, and (H) human gingival fibroblasts cultured on SLA roughened titanium. The figure also highlights different methods for visualizing the cells. A, C, D, E, G, and H are scanning electron microscope images, B and G are epifluorescence, and F is phase contrast microscopy.

Tunnels/Tubes

Several cell types within the body, such as endothelial cells in blood vessels, live within tube-like structures. There has, however, been only scant attention paid to the response of cells to concave surfaces, in contrast to numerous reports of cell response to convex surfaces (Fig. 2E). In perhaps the most comprehensive examination to date, Riehle et al. investigated chondrocytes, osteoblasts, endothelia, and fibroblasts, and noted a differential response to concave features based on cell type.^[16] Initially, all cell types attached to the inner surface of the quartz tubes, including those with a diameter as small as 25 μm , although no specific orientation or alignment was noted. However, macrophages and fibroblasts were observed to become apoptotic within a relatively short space of time. In contrast, chondrocytes and osteoblasts thrived in such environments for up to 21 days, irrespective of the tube diameter. Both cell types formed large, motile cords, (Fig. 2F) and in the case of osteoblasts, large mineralized deposits were observed.

Discontinuous Substratum

Recently, we have begun investigation into the behavior of cells on microfabricated substratum that are discontinuous at the micrometer level.^[17] The rationale for designing such topographies was to understand further the mechanisms that underlie the process of contact guidance. Traditionally, the theory of contact guidance centers on the presence of a continuous edge, guiding a cell in a specified direction. The design of the discontinuous edged topographies (DES) is such that essentially the topographies comprised repeated open square boxes, with gaps at each corner. Examples of the DES topographies are shown in Fig. 2G. Our recent investigations using fibroblasts and epithelial cells have shown that DES topographies have great potential to be used not only *in vitro* to investigate cell guidance (Fig. 3A), but also *in vivo* to organize tissue around percutaneous implants (Fig. 3B).

Roughened Surfaces

Surface roughness was defined by Curtis and Clark as a randomly produced topography.^[1] The characterization of rough surfaces is a complex affair, as it is dependent on the scale length and the resolution of the measuring system, which may be based on mechanical, optical, or electron optical principles. The most widely accepted characterization is the average vertical amplitude or R_A value, which is calculated from an average of the feature sizes. In general, the higher the R_A value, the rougher is the surface. For example, a surface with

Fig. 3 Discontinuous edged surface topographies produced by microfabrication. (A) Human gingival fibroblasts cultured for 4 days on the DES topography. Note the alignment of the cells at diagonals to the ridges. (B) Toluidine blue staining of a DES topography implanted subcutaneously in a rat for 1 week. Black arrows indicate the presence of macrophages close to the implant surface. The white arrows highlight the fibrotic tissue composed of matrix and fibroblasts.

an R_A value of 0.6 μm would be considered to be rougher than one with an R_A value of 0.3 μm .

The simplest way of producing a rough surface is to rub the material with abrasive particles. A harsher method often used on metallic surfaces such as titanium and its oxides is to blast the material with abrasive grits such as aluminum or titanium oxide, giving rise to materials that have pits and peaks distributed more or less randomly.^[5] This process causes local deformations in the surface, and the R_A value depends on the size of the particle used. Other techniques to produce rough surfaces include titanium plasma spraying, which involves the coating of melted droplets of titanium onto the material surface, which then cool to form protruding structures (R_A value of $\approx 5.85 \mu\text{m}$). Acid etching, commonly accomplished using an aqueous mixture of nitric acid and hydrofluoric acid at a ratio of 10:1, results in a surface that has an R_A value of $\approx 0.59 \mu\text{m}$. Roughening procedures can also be used in combination. For example, blasting of titanium, followed by etching with acid, produces a surface (SLA) with an R_A value of $\approx 4.39 \mu\text{m}$.

The rationale for using rough surfaces is that the contact area between the tissue and the implant surface is increased, thus facilitating interaction between the tissues and the device. As will be discussed in the section "Cell Behavior Influenced by Substratum Topography," certain cell types appear to be more attracted to rough surfaces, a phenomenon termed rugophilia, but roughness also affects cell adhesion and spreading (Fig. 2H). Although most studies indicate that osteoblasts prefer rough surfaces, one study found that an

R_A value of $0.15\ \mu\text{m}$ promotes better cell attachment than R_A values of up to $1.2\ \mu\text{m}$. It appears that the geometry of the features as well as the overall roughness affect cell behavior. It has also been observed that with increasing time, enhanced mineralization and matrix deposition occur on rougher surfaces.

Nanotopography Vs. Microtopography

As techniques used to produce microfabricated topography evolve, the range of dimensions that can be fabricated increases. One area on which many research laboratories are currently focused is the use of nanometric sized surface features, such as pillars and holes. The logic of using such small features is that they are in the same size range as molecules such as collagen and other extracellular matrix molecules that cells will encounter within the body. While providing an excellent model for understanding cell sensing of small features, their applicability in implanted devices may be limited as matrix absorption at the tissue–implant interface would most likely mask such small topographical features, which are in the region of $10\text{--}100\ \text{nm}$ in size. One desired reaction at the implant surface is good mechanical interlocking, especially in bone contacting regions, because a major cause of implant failure is micromotion and friction at the tissue–implant interface. The implants that incorporate micrometer sized

pores, grooves, or even random rough surfaces have generally been found to lead to better implant integration. However, further investigations will be required to delineate the optimal size and geometry for optimal interaction with diverse tissues.

CELL BEHAVIOR INFLUENCED BY SUBSTRATUM TOPOGRAPHY

Cell Types Sensitive to Topography

Epithelial cells, fibroblasts, osteoblasts, chondrocytes, nerve axons, and macrophages are some of the cell types that have been demonstrated to be sensitive to topography.^[5] Table 1 lists cell types that have been shown to respond to substratum topography.

Adhesion

It has been long known that rougher surfaces generally promote adhesion of some cell types such as osteoblasts, whereas cells such as fibroblasts prefer smooth surfaces. When cells attach to a biomaterial, they demonstrate structures such as close contacts or focal adhesions. Cells that form a large number of focal adhesions are generally accepted to be better attached, to the material, although focal adhesion formation

impacts on other cellular processes, as will be further highlighted in this section. The general rule to follow is that surface topography influences cell adhesion, although the nature and extent of the influences depends on the cell type involved, as well as the dimensions of the substratum topography.

The differential response of cell types to topography opens the possibility of using surfaces to select certain populations of cells based on their adhesive properties. For example, when considering surfaces to promote osseointegration, it would be anticipated that the desired populations of osteoblast would preferentially adhere to rough surfaces, in preference to cell types such as epithelium or fibroblasts. Macrophages are also known to prefer rougher surfaces, and indeed have their secretory profile altered on such surfaces.^[18] Indeed, it has recently been suggested that the presence of macrophages around bone contacting implants may be advantageous, and this possibility will be discussed later in the entry.

Alignment and Orientation

Within many tissues, the architecture or spatial arrangement is an important determinant of function. When considering cartilage, for instance, the cells and matrix are positioned in a way to allow the dispersion of compressive forces without causing damage to the tissue.^[12] However, when cartilage is damaged, the ability to perform this function is lost owing to the alteration in tissue architecture. Many tissues such as ligaments, tendons, and muscle rely on the specific position of the cells with regard to the surrounding matrix, and in many cases the cells have a determined alignment and orientation within the tissues.

Fibers, and repeating grooved substrates, in particular, have been shown to have a pronounced effect on cell and tissue alignment. For most cell types, it has been found that groove depth is a more important determinant of cell alignment than groove width. However, cells such as chondrocytes and macrophages have been shown to align to gratings only 80 nm in depth. Different cell types also vary in their reaction time to grooved substrates, with macrophages responding within 5 min, fibroblasts within 2 hr, and chondrocytes up to 6 hr. In general, cells align parallel to the groove long axis, although in the presence of chemical patterns superimposed perpendicular to the grooves, alignment of cells becomes dependent on the dimensions of the grating.

Contact Guidance

Contact, or topographic guidance refers to the tendency of cells to be guided in their direction of

locomotion by a continuous, physical edge, whether this is a groove, fiber, or other type of topographical structure. Many different cell types have been observed to show contact guidance, although cells such as chondrocytes have been observed to show guided migration without aligning parallel to the groove long axis.^[12,13] Controlled guidance of cells *in vivo* is of great importance during development, and has also been demonstrated to play a role at the tissue/implant interface. However, the exact mechanisms underlying contact guidance still remain unclear.

Differences in the adhesiveness of grooves, inflexibility of the cytoskeleton, and confinement of focal adhesions, have been put forward as drivers of contact guidance.^[19–21] Dunn and Heath suggested that substratum morphology and shape imposed restrictions on the formation of linear bundles of microfilaments located between focal adhesions of the leading lamella and the nuclear region.^[20] These bundles were thought to be relatively inflexible, so any attempt by the cell to accommodate curvature or angles, would result in the shortening of the leading lamella, which is important in cell spreading and locomotion.

Although the theory of Dunn and Heath seemed to explain cell reaction to topography on single-feature surfaces, O'Hara and Buck stated that it did not explain cell reaction to substratum with multiple features like grooved surfaces.^[21] Using multiple grooved substrata with features smaller than cell size, they showed that cells were sufficiently rigid to bridge over grooves, such that cell–substratum contact was confined to the surfaces of the ridges between the grooves. Brunette, Kenner, and Gould, however, found that focal adhesions could bend round the edges of grooves.^[22] Curtis and Clark suggested that cells simply aligned actin filaments and focal adhesions at discontinuities in the substrata.^[1] However, Oakley et al. subsequently demonstrated microtubules (MT) to be more sensitive to topography than F-actin, and that MT played key roles in elongation, alignment, and directed migration of cells in response to grooved substrata.^[23] Interestingly, a recent paper by Andersson et al. suggested that elongation and guidance of cells only occurs in the presence of a continuous edge.^[24]

Gap Guidance

Our laboratory is currently investigating the response of cells to discontinuous topographies, with an emphasis on understanding the conditions for the oriented guidance of cells.^[17] Results with gingival fibroblasts and periodontal ligament epithelial cells have shown that a continuous edge may not be a prerequisite to guiding a cell in a specific direction. We have termed this phenomenon “gap guidance” to

distinguish it from contact guidance.^[17] Analysis of cytoskeletal components suggests that a primary driver of gap guidance is focal adhesion stability. Reaction of cells to topographies such as grooves has been hypothesized to be a probabilistic affair, based on the likelihood that a cell will form a stable adhesion in any specified direction.^[25] Further results using DES have added further weight to this hypothesis. If focal adhesion stability is favored in any given orientation upon attachment and spreading, it is likely that the direction of locomotion will similarly follow that direction. Our results using DES have shown that cytoskeletal reaction is secondary to focal adhesion formation in determining alignment, but it is likely the cytoskeleton plays a larger role in migration and spreading.

Contact Guidance: Gene and Protein Expression

Although the general behavior of cells on topographical cues has been well described, the alterations in cell physiology at the molecular level remain elusive. Initial attempts to decipher altered gene expression on topographical cues required gene selection and analysis. Chou et al. showed that grooved substrata evoked an increase in fibronectin mRNA and its stability, as well as increased deposits of fibronectin in the secreted matrix.^[26] Recent developments in microarray technology have permitted more comprehensive investigations into genetic regulation by topography. Dalby and colleagues used microarray technology to compare the gene expression of human fibroblasts on grooved and flat surfaces, and demonstrated a large alteration in the pattern of expression.^[27] Interestingly, they noted that 24 hr postplating, many genes showed an upregulation, but at 5 days, many more genes were downregulated. For example, at 24 hr, genes such as the extracellular matrix protein, fibronectin, the ribosomal proteins 60S, 40S, the cytoskeletal component tubulin, and signal transduction molecules such as ras and protein kinase C were all significantly upregulated, but by 5 days were downregulated below the level of the controls. Such observations suggest that certain genes are required for cellular reaction to topography initially, but with increasing time are not required. However, it has been shown that cells will still respond to grooved substrates, even in the presence of cycloheximide, which blocks protein synthesis. Therefore, new protein synthesis is not required for cells to adhere and align on these types of substrates. At present, the role of such gene changes in cellular response to surface topography requires more investigation.

IN VIVO APPLICATIONS OF CELL—TOPOGRAPHY INTERACTIONS

Implants can be classified based on their chemical composition, topographical features, and additionally, the type of tissue with which they will interface. Implants can be fully (artificial hips, breast implants) or partially embedded (dental implants, catheters). For the purpose of this discussion we will limit our attention to partially embedded implants, specifically dental or percutaneous devices that penetrate the epithelium.

Dental implants face complex problems because they interface with three different tissue types, bone, epithelium, and connective tissue. In vitro experiments have shown that each cell type demonstrates preferential attachment to different topographical cues: bone (rough surfaces), epithelium (smooth), and fibroblasts (smooth, grooved). Therefore, the design of dental implants might benefit by incorporating multiple topographies to enhance the attachment of the different cell types at desired locations.

From a clinical standpoint, a vulnerable area of a dental implant, or any percutaneous device, is the region where the implant penetrates the epithelium. One reason for the failure of such devices is related to the downgrowth of epithelium (Fig. 4), which can lead to marsupialization, permigration, and avulsion at the implant tissue interface. Therefore, one could conceive of altering the topography on the implant surface that is intended for connective tissue to a surface that epithelial cells dislike, so as to impede this downgrowth. Chehroudi and colleagues in 1989 demonstrated a striking example of in vivo contact guidance by implanting V-shaped grooves of 10 μm depth with the grooves oriented either parallel or perpendicular to the long axis of the implant.^[28] As predicted from in vitro studies, the horizontally oriented grooves inhibited, whereas the vertically oriented grooves promoted, epithelial downgrowth. Additionally, it was demonstrated that not only are the fibroblasts aligned by the grooves, but so is the collagen and other matrix laid down by the cells.

Titanium and its alloys are commonly used in dental applications as they have good mechanical properties and biocompatibility. Such materials can be roughened through processes such as blasting, and acid etching, which is commonly done to ensure good integration in bone. The use of topographies produced by these processes has been successful clinically. The most common reason given for this excellent integration of dental implants with rough surfaces with bone was preferential adhesion of osteoblasts onto the rough material. However, osteoblasts are unlikely to be the first cell type to encounter the implant surface. One of the first cell types to be shown to attach, as well as to persist at the implant surface, is the macrophage.

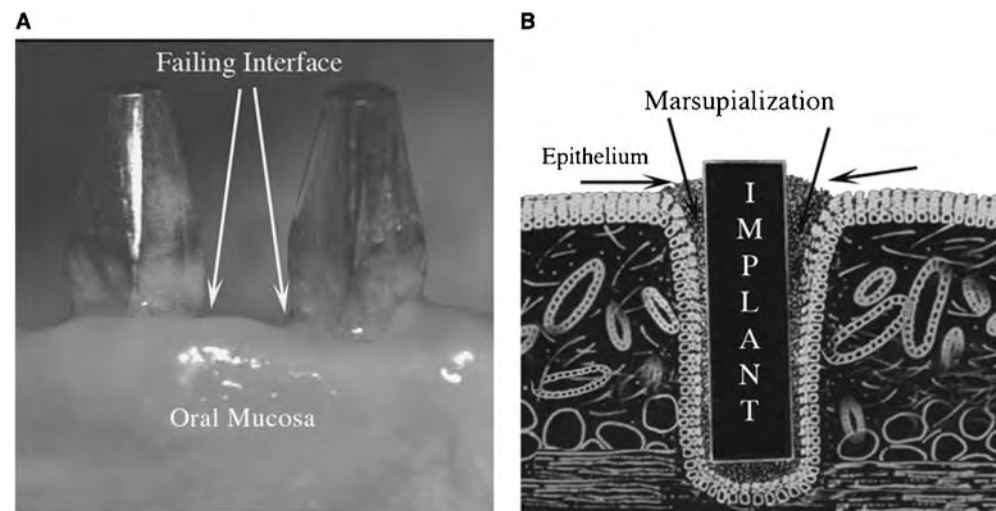

Fig. 4 Representative images of the failing interface in dental implants. (A) The rapid failure (4 mo) of an osteointegrated implant. Bacterial plaque (white material at base of the implant) can be seen, and the surrounding gingival tissue is inflamed. (Image courtesy of Dr. B. Chehroudi, Scident Family Dental Clinic). (B) Schematic representation of marsupialization of an implant. (Modified from Grosse-Siestrup et al. *J. Biomed. Mater. Res.* **1984**). Epithelium from the surface of the gingival grows down the side of the implant preventing optimal connective tissue attachment and osseointegration. Bacteria will then accumulate within the pocket, and the implant is eventually extruded from the tissue.

Although the presence of macrophages has always been associated with wound healing, they have always been treated with suspicion at the implant surface, as cells from the monocytic family are known to form osteoclasts. There has also been coassociation of macrophages with deposition of fibrous tissue and the formation of a capsule. Preliminary results from our laboratory suggest that the presence of rough surfaces at bone contacting surfaces could advantageously influence macrophage activities (unpublished data). In vitro, it was demonstrated that rough surfaces such as SLA stimulate ED1 macrophages (recruited

macrophages) to secrete interleukins 1β , and 6, as well as tumor necrosis factor α and monocyte chemoattractant protein 1.^[18] Recent in vivo work has shown that these same ED1 positive macrophages are present at the implant surface for up to 1 week postimplantation (Fig. 5A). These findings open the possibility that macrophages on some surfaces, could contribute to successful osseointegration.

Although, roughened surfaces produce osseointegration, little information exists as to how connective tissue responds in vivo to the presence of such surfaces. Recent investigations in our laboratory have studied

Fig. 5 In vivo performance of various surface roughened materials. (A) The presence of ED1 macrophages in connective tissue 1 week postimplantation of a titanium coated SLA implant in a subcutaneous model. Macrophages are visualized using epifluorescent techniques. (B) Polished and (C) SLA titanium implants placed in connective tissue at 6 weeks postimplantation. Note the separation from the implant on the polished surface. Tissue is stained with toluidine blue.

the influence of different roughened surfaces on connective tissue formation at the interface of tissue and implant. The implants were placed subcutaneously in rats for between 1 and 11 weeks, and analysis comprised attachment, capsule thickness, and degree of separation of the tissue from the implant. Overall, surface roughness promoted stable connective tissue attachment, and a significantly lower magnitude and frequency of separation at the implant/tissue interface (see Figs. 5 and 5D). In addition, rougher surfaces had a thinner capsule present. Interestingly, acid etched surfaces, which have a significantly lower R_A value than SLA, performed comparably with the rougher surfaces, suggesting that not only roughness but also feature geometry affects cell reactions.

A possible explanation for the successful rough surface connective tissue integration is that surface topography can promote fibronectin expression in gingival fibroblasts, and correlates closely with cell shape, and in particular thickness. In many cellular systems, changes in cell shape are associated with altered cell behavior. Wieland et al. demonstrated that fibroblasts had a significantly greater thickness on rough surfaces compared with smooth.^[29] It is possible that the cell attachment on rough surfaces results from the absorption of the fibronectin produced by active cells to the implant surface, followed by deposition of collagen and other connective tissue matrix components, leading to good mechanical interlocking.

CONCLUSIONS

Although cell behavior has been well documented on surface topography in vitro (cell adhesion, shape, migration, cytoskeletal function), two areas will require further investigation:

1. The long-term function of different surface topographies in vivo.
2. Further analysis of the alterations in cellular function by topography at the molecular level.

Given that different cell types show desirable reactions to different surface topographies, the potential exists to produce implants with topographies at different locations that interact appropriately with the tissue type with which they interface. Further utilization of micromachining techniques will enhance the possibility of producing tissue-specific "designer" implants to further the field of regenerative medicine. As more precise methods of fabrication have evolved, so has our understanding of the role of topography in cellular response, particularly at the implant interface. Topography not only allows development of more suitable implant designs, but further provides

information on the mechanisms cells utilize to sense their surrounding environment.

Sutures

C.C. Chu

Department of Textiles and Apparel & Biomedical Engineering Program, Cornell University, Ithaca, New York, U.S.A.

INTRODUCTION

Every wound requires the use of biomaterials to close for subsequent successful healing. The complexities involved in wound healing—such as the various degrees of wound strength during the process of healing, the involvement of different type of tissues in a wound, the presence of biomaterials, or the variety of surgical wounds each with its own healing problems—call for different types of wound closure materials. The choice of these biomaterials is based largely on the type of wound and surgeons' preferences.

OVERVIEW

Wound closure biomaterials are generally divided into three major categories: sutures, staples/ligating clips, and tissue adhesives. The sutures have the longest use history, have received the most attention, and are the most widely used in wound closure. Ligating clips and staples facilitate anastomosis with minimal trauma, necrosis, or interruption of tissue function and their use has steadily increased in specific clinical conditions, particularly with the availability of synthetic absorbable ligating clips and staples. Tissue adhesives are the least frequently used for wound closure at the present time, even though they received considerable attention in the 1960s; however, some new tissue adhesives have recently received increasing attention. There are several reviews about wound closure biomaterials.^[1–9] In this article, the focus is on suture-based wound closure biomaterials because they are the most frequently used and studied. All aspects of suture-based wound closure biomaterials, their classification, and their chemical, physical, mechanical, biological, and biodegradative properties will be concisely covered.

A suture is a strand of material, either natural or synthetic, used to ligate blood vessels and to fasten tissue together. Textile materials were the earliest and most frequently used materials for surgical wound closure. Linen was used as a suture material as early as 4000 years ago. Since then, numerous materials have been used as ligatures and sutures: iron wire, gold, silver, dried gut, horse hair, strips of hide, bark fibers, silk, linen, and tendon. Among them, catgut and silk

dominated the suture market until 1930. The introduction of steel wire and synthetic nonabsorbable fibers such as nylon, polyester, and polypropylene during and after World War II greatly expanded the chemical composition of suture materials. During the early 1970s, the introduction of two synthetic absorbable suture materials, Dexon[®] (Davis & Geck, Danby, CT) and Vicryl[®] (Ethicon, Inc., Somerville, NJ), opened a new milestone for suture materials. Owing to their precisely controlled manufacturing processes and uniform and reproducible properties, these synthetic absorbable sutures have received a great deal of attention from both surgeons and researchers. Since then, several new synthetic absorbable suture materials such as PDSII[®] (Ethicon), Maxon[®] (US Surgical/Davis & Geck), Monocryl[®] (Ethicon), and Biosyn[®] (US Surgical, Norwalk, CT) have become commercially available. The most important advantage of synthetic absorbable sutures is their reproducible and predictable degradability inside a biological environment. This property enables the sutures to minimize chronic undesirable tissue reactions after the sutures have lost most of their mechanical properties. The latest introduction of sutures is the one having multifunction, and a typical example is Triclosan-coated Vicryl, Vicryl Plus[®], which has antimicrobial capability to reduce the chance of wound infection.^[10,11] Today, surgeons can choose between a large number of suture materials with various chemical, physical, mechanical, and biological properties.

NEEDLES

The surgical needle, to which a suture is attached, has the primary function of introducing the suture through the tissues to be brought into apposition. Ideally, the needle has no role in wound healing but inappropriate needle selection can prolong the operating time and/or damage tissue integrity, leading to such complications as tissue necrosis, wound dehiscence, bleeding, leakage of anastomoses, and poor tissue apposition. Clearly, needle selection is an important factor in suturing and the progress of wound healing. For maximum effectiveness, the surgical needle must be able to carry the suture material through tissue with minimal trauma

Table 1 Needle selection criteria

Minimal tissue trauma
High sharpness (acuity)
Corrosion resistance
High strength
Stable shape
Proper balance
Abrasion resistance
Smooth profile

and, to achieve this goal, needles are required to satisfy several criteria shown in Table 1.

Needles are commonly fabricated from stainless steel, a material that has high strength, is readily available, presents few manufacturing problems, can be polished to a smooth finish, and is relatively inexpensive. Because the gripping action of needle holders and the repeated grip-release action during surgical procedures can damage the needle surface, wear and abrasion resistance is a necessary prerequisite for surgical needles.

A wide variety of surgical needles exists but all types have basically three components: the point, the body, and the eye, swage, or attachment end. Differences between needles arise from variations and modifications within these basic parameters.

The most important biomechanical performance parameters for surgical needles are acuity or sharpness, bending resistance, and ductility. Needle acuity is the most important biomechanical parameter because the needle is required to penetrate tough or fibrous tissue without undue trauma, creating a pathway through which the body of the needle and the attached suture will then pass with minimum drag. Further, the relative ease of tissue penetration with a sharp needle facilitates surgical dexterity, at the same time reducing the risk of needle bending or deformation during use because less force has to be applied to a sharp needle.

COMMERCIAL SUTURES, THEIR SIZES, AND THEIR PHYSICAL CONFIGURATIONS

Suture materials are generally classified into two broad categories: absorbable and nonabsorbable. Absorbable suture materials generally lose their entire or most of their tensile strength within two to three months; those that retain most of their initial strength longer than two to three months are considered nonabsorbable. The absorbable suture materials are catgut (collagen sutures derived from sheep intestinal submucosa), reconstituted collagen, polyglycolide (Dexon[®],

Dexon II[®], Dexon S[®]), poly(glycolide-lactide) random copolymer (Vicryl[®]), antimicrobial-coated Vicryl[®] (Vicryl Plus[®]), poly-p-dioxanone (PDS[®], PDSII[®]), poly(glycolide-trimethylene carbonate) block copolymer (Maxon[®]), poly(glycolide-ε-caprolactone) (Monocryl[®]), and Glycolide-dioxanone-trimethylene carbonate block copolymer (Biosyn[®]). The nonabsorbable sutures are divided into the natural fibers (i.e., silk, cotton, linen) and man-made fibers (i.e., polyethylene, polypropylene, polyamide, polyester, polytetrafluoroethylene (Gore-Tex[®]), and stainless steel). Table 2 summarizes all of the commercial suture materials that are available mainly in the United States, Europe and the Pacific area, their generic and trade names, their physical configurations, and their manufacturers. Fig. 1 shows the scanning electron images of some of the most popular commercial sutures.

Suture materials are also classified according to their size. Currently, two standards are used to describe the size of suture materials: USP (United States Pharmacopoeia) and EP (European Pharmacopoeia).^[9] Table 3 summarizes both EP and USP standards. The USP standard is more commonly used. In the USP standard, the size is represented by a series of combinations of two Arabic numbers: a zero and any number other than zero, such as 2-0 (or 2/0). The larger the first number, the smaller the suture material diameter. Sizes greater than 0 are denoted by 1, 2, 3, etc. This standard size also varies with the type of suture material.

In the EP standard, the code number ranges from 0.1 to 10. The corresponding minimum diameter (mm) can be easily calculated by taking the code number and dividing by 10. The EP standard does not separate natural from synthetic absorbable sutures as the USP standard does.

In terms of the physical configuration of suture threads, they can be classified into monofilament, multifilament, twisted, and braided. Suture materials made of nylon, polyester, and stainless steel are available in both multifilament and monofilament forms. Catgut, reconstituted collagen, and cotton are available in twisted multifilament form; Dexon[®], Vicryl[®], Monosyn[®], Polysorb[®], PolySyn FA[®], Safil[®], BioSorb[®], silk, and polyester-based and polyamide-based suture materials are available in the braided multifilament configuration. PDS[®], Maxon[®], Monocryl[®], Biosyn[®], Caprosyn[®], MonoPlus[®], polypropylene, and Gore-Tex[®] (polytetrafluoroethylene) suture materials exist in monofilament form only. Stainless steel metallic suture materials can be obtained in either monofilament or twisted multifilament configurations. Another unique physical configuration of suture material is available in polyamide (nylon 6) and has the trade name Supramid[®]; it has a twisted core covered by a jacket of the same material.

Table 2 List of commercial sutures, their trade names, and their manufacturers

Generic name	Trade name	Physical configuration	Surface treatment	Manufacturer
<i>Natural absorbable sutures</i>				
Catgut			Plain and chromic	Surgical Specialties Corporation
Catgut			Plain and chromic	Dyneke Sutures
Catgut		Multifilament	Monofilament finish, plain, and chromic	SURU
Collagen—bovine	Surgical gut		Plain, chromic, and mild chromic	USS/DG
Collagen—bovine, ovine	Surgical gut		Plain and chromic	Ethicon
<i>Synthetic absorbable sutures</i>				
Glycolic acid and trimethylene carbonate—copolymer	MAXON	Monofilament	Clear or dyed green	USS/DG
Glycolic acid and trimethylene carbonate—copolymer	MAXON CV	Monofilament	Clear or dyed green	USS/DG
Glycolic acid—homopolymer	DEXON II	Braided	Dyed green or bicolored or undyed; coated with polycaprolate	USS/DG
Glycolic acid—homopolymer	DEXON S	Braided	Dyed green or undyed	USS/DG
Glyconate	Monosyn	Mid-term braided	Dyed violet or undyed	B. Braun Melsungen AG
Lactomer	POLYSORB	Braided	Dyed violet or undyed	United States Surgical
Poliglecaprone 25	MONOCRYL	Monofilament	Dyed or undyed	Ethicon
Polydioxanone	PDS II	Monofilament	Dyed or undyed	Ethicon
Polyester—glycolide (60%), dioxanone (14%), trimethylene (26%)	BIOSYN	Monofilament	Dyed violet or undyed	USS/DG
Polyglactin 910	Coated VICRYL	Braided	Dyed or undyed	Ethicon
Polyglactin 910	VICRYL RAPIDE	Braided	Undyed	Ethicon
Polyglactin 910	Coated VICRYL Plus Antibacterial	Braided	Dyed violet or undyed; coated with glycolide and lactide (polyglactin 370) and calcium stearate	Ethicon
Polyglycolic acid	PolySyn FA	Braided	Undyed	Surgical Specialties Corporation
Polyglycolic acid (PGA)	SURUCRYL	Braided	Coated with polycaprolactone calcium stearate	SURU
Poly(L-lactide/glycolide) copolymer	Panacryl	Braided	95% lactide/ 5% glycolide and coated with 90% caprolactone/ 10% glycolide copolymer	Ethicon (discontinued in late 2003)
Polyglycolic acid—low molecular weight	Safil—Quick	Mid-term braided	Coated	B. Braun Melsungen AG
Polyglycolic acid—pure	Safil—green	Mid-term braided	Coated; dyed green	B. Braun Melsungen AG
Polyglycolic acid—pure	Safil—violet	Short-term braided	Coated; dyed violet or undyed	B. Braun Melsungen AG

5	6	9	0.90–0.99
6	7	10	1.00–1.09

Suture materials are frequently coated to enhance their handling properties, particularly to reduce tissue drag when passing through the needle tract and to ease the sliding of knots down during knotting (i.e., knot tie-down). Although nonabsorbable bee's wax, paraffin wax, silicone, and polytetrafluoroethylene (Teflon) are the traditional coating materials, new coating materials have been reported, particularly those that are absorbable. This is because the coating materials used for absorbable sutures must be absorbable; traditional nonabsorbable coating materials such as wax are not appropriate for absorbable sutures.^[12–14] Furthermore, absorbable coating materials have better tissue biocompatibility because of the lack of chronic tissue reaction. There are basically two types of absorbable coating materials: water-soluble and water-insoluble. Water-insoluble coating materials have chemical constituents similar to those in the suture and they are broken down by hydrolysis. They remain on the suture surface longer than water-soluble coatings. A typical example is polyglactin 370 used for Vicryl suture. Dexon II sutures have a polycaprolate coating which is water-insoluble. Water-soluble coating materials dissolve promptly to reveal the underneath uncoated suture after wound closure. A typical example is poloxamer 188 found on Dexon Plus. There is, however, one technical concern about using water-soluble coating

material in actual wound closure. Suture materials are frequently soaked in saline after their removal from packages before use. Some or the bulk of water-soluble coating materials might be removed by this routine soaking practice. Thus, it is important to minimize the time of soaking when dealing with water-soluble coated suture materials. Multifilament sutures are more commonly coated than monofilament sutures. For example, multifilament Vicryl and Dexon Plus or II have coating materials applied, whereas monofilament PDS and Maxon sutures have no coatings.

Although coating of suture materials facilitates easy passage through tissue, it frequently results in poor knot security. For example, Dexon Plus and coated Vicryl require four or five square throws to form secure square knots, whereas the uncoated Dexon and Vicryl sutures form secure knots with only two throws (1 = 1).^[15,16] Water-soluble coating materials such as poloxamer 188, found on Dexon Plus, do not suffer from the adverse effects of water-insoluble coating materials on knot security.

There are several other patented procedures and materials reported to improve knot tie-down performance (the ease of sliding a knot down the suture into place during knotting) or/and knot security (the ability of a knot to hold after knotting).^[17–20] In general, a coating designed to improve knot tie-down can reduce knot security. It is difficult to achieve both ease of knot tie-down and enhanced knot security of sutures. There are very few reported treatments that would achieve these two contradictory and mutually exclusive properties. One of them is the use of a combination of both coating and textured yarns.^[17] The coating materials used in that study included sucrose fatty acid ester, bees wax, paraffin wax, polytetrafluoroethylene, silicone, poly(oxyethylene-co-oxypropylene), polyglactin-370, and gelatin. Other recently reported absorbable but water-insoluble coating materials that can improve knot tie-down and knot security are high-molecular-weight poly- ϵ -caprolactone, a copolymer of at least 90% by weight of caprolactone and 10% at most of other biodegradable monomers such as glycolide, lactide, and their derivatives,^[18,19] or a random copolymer of 25–75% by weight of glycolide and the rest of trimethylene carbonate.^[20] The observed improved knot tie-down and knot security was attributed to deep penetration and even distribution of the coating materials into the interstices of suture filaments.

ESSENTIAL PROPERTIES OF SUTURE MATERIALS

There are four essential properties of suture materials: physical and mechanical, handling, biological, and biodegradative. Table 4 summarizes the characteristics

Table 4 Four major categories of the characteristics of suture materials

Physical/mechanical	Handling	Biocompatibility	Biodegradation
USP vs. EP size (diameter)	Pliability	Inflammatory reaction	Tensile breaking strength and mass loss profiles
Mono vs. multifilament	Memory	Propensity toward wound infection, calculi formation, thrombi formation, carcinogenicity, allergy	Biocompatibility of degradation products
Tensile breaking strength and elongation	Knot tie-down		
Modulus of elasticity	Knot slippage		
Stiffness	Tissue drag		
Stress relaxation and creep			
Capillarity			
Swelling			
Coefficient of friction			

S

of each of the four essential properties. It is important to recognize that these characteristics are interrelated. For example, capillarity of a suture material, a physical/mechanical property, is closely related to the ability of the suture to transport bacteria which is a biological property. The modulus of elasticity, a physical/mechanical property, is frequently used to relate to pliability of sutures, a handling property. A brief description of each of those essential properties will be discussed subsequently; they are listed in Tables 5–9. Readers should be aware of the fact that the data in the tables will vary, depending on specific clinical and/or physical environments that suture materials are subjected to and the constant refining of manufacturing processes by suture manufacturers.

Physical and Mechanical Properties

Physical and mechanical properties are probably the most important ones in terms of suture function, i.e., to close wounds and carry physiologic load during healing. They include those related to strength, stiffness, viscoelasticity, coefficient of friction, compliance, size, form (monofilament or multifilament), fluid absorption, transport, etc. Strength includes knotted and unknotted (straight pull) tensile strength, modulus of elasticity (relating to stiffness), elongation at break, and toughness.

The tensile strength character is the most frequently reported and studied physical/mechanical property of suture materials. Because tensile strength is expressed in terms of the cross-sectional area of the material, it is normalized based on the dimension of the material and hence can be used to compare sutures having different

chemical structure or/and sizes. Tensile breaking force, however, does not take into account suture size (i.e., diameter). Thus, a larger size suture will have a higher tensile breaking force than the same suture of a smaller size, even though the two sutures may have the same tensile strength. Therefore, a meaningful comparison of tensile breaking force of several sutures should be made using the same suture size (diameter) and form. In addition, knotted tensile strength or breaking force is frequently lower than for the unknotted suture. Strength values are obtained in either dry or wet conditions. The ASTM testing conditions that stipulate the cross-head speed, gage length, temperature ($21 \pm 1^\circ\text{C}$), and humidity ($65 \pm 2\%$) of testing room should be followed, if possible, for obtaining and reporting strength data.

Bending stiffness is a complex mechanical phenomenon and it closely relates to the handling characteristic of suture materials, particularly knot security. There are very few reported data describing bending stiffness of sutures. Most reported stiffness of sutures was derived from the modulus of elasticity obtained from a tensile strength test. Because a knot involves bending of suture strands, stiffness based on modulus of elasticity may not adequately represent the performance of knot strength, security, and tie-down. There are two reported studies of bending stiffness of sutures.^[23,24]

Chu et al.'s study^[23] of bending stiffness was based on the force required to bend a suture to a predetermined angle. The measured bending force was converted to flexural stiffness in pounds/in² according to an ASTM formula. Braided sutures were generally more flexible than monofilament sutures of equivalent size, irrespective of their chemical constituents. Coated

^bData in () are in psi units. (*Source*: Ref. [21].)

sutures had a significantly higher bending stiffness than the corresponding uncoated ones. This increase in bending stiffness is attributable to the loss of mobility of constituent fibers under bending force. An increase in suture size significantly increased their stiffness, and the magnitude of increase depended on the chemical constituent of the suture. The large porous volume inherent in the Gore-Tex monofilament suture was the reason for its lowest flexural stiffness. The second bending stiffness study of a few sutures^[24] was based on attaching a constant weight to each of the two ends of a bending suture and measuring the distance between these two ends after one minute of loading. Bending stiffness data from these two studies agree with each other that braided sutures are generally more flexible than monofilamentous sutures, and that the Gore-Tex suture has the lowest bending stiffness.

Suture compliance (also referred to as elasticity) is a mechanical property that closely relates to the ease of a suture to elongate under a tensile force. It is believed that the level of suture compliance should contribute to the compliance of tissues at the anastomotic site. Suture compliance is particularly important in surgery where there is a tubular or vascular anastomosis. Compliance mismatch between a vascular graft and host tissue has long been suggested as one of several factors contributing to graft failure.^[25] Compliance mismatch at the anastomotic site constitutes a major component of overall compliance mismatch associated with vascular grafts. Because sutures are the only foreign materials in the anastomotic site, it is expected that a wide range of suture compliance might result in

different levels of anastomotic compliance. There is only one reported study that examined the effect of suture compliance on the compliance of arterial anastomotic tissues closed with two sutures vastly different in compliance: 6/0 Novafil and Prolene.^[26] Novafil is an elastomeric suture made from polybutester and is characterized by a high elongation at low tensile force, low modulus of elasticity, and high hysteresis, whereas the Prolene suture has relatively higher modulus of elasticity, low elongation at low tensile force, and low hysteresis. In a clinical condition of minimal tubular compliance and diameter mismatch such as artery-artery anastomoses, a far more compliant anastomosis was achieved with Novafil ($5.9 \pm 2.0\%$) than with Prolene ($3.3 \pm 0.6\%$) suture. Thus, arterial anastomoses closed with a more compliant suture such as Novafil produced on average over 75% more arterial anastomotic compliance than those closed with the less compliant Prolene suture.

Handling Properties

Handling properties describe those that relate to the feel of suture materials by surgeons during wound closure. It is the only category of suture property that is the most difficult to evaluate objectively. Handling properties include pliability (or stiffness), ease of knot tie-down, knot security, packaging memory, surface friction, viscoelasticity, tissue drag, etc. They are directly and indirectly related to physical/mechanical properties of a suture. For example, the term pliability

Table 6 Mechanical properties of nonabsorbable sutures^a

of a suture is a subjective description of how easily a person can bend it and hence relates to the surgeon's feel of a suture during knot tying. It is directly related to the bending modulus of a suture and indirectly to the coefficient of friction. Packaging memory, another

handling property that indirectly relates to pliability, is the ability to retain the kink form of sutures after unpacking them. The ability to retain such kink form after unpacking would make surgeons' handling of sutures more difficult during wound closure, particularly tying a knot. This is because sutures with high memory such as nylon, polypropylene, PDS, and Maxon tend to loosen their knots as they try to return to their kink form from packaging. Thus, packaging memory should be as low as possible. In general, monofilament sutures have more packaging memory than braided ones. The three exceptions are the newly available Monocryl, Biosyn, and Gore-Tex monofilament sutures which were reported to have exceptionally low packaging memory. The easiest means to evaluate packaging memory of sutures is to hang them in air and measure the time required to straighten out the kink form from packaging.

Table 7 Relative tissue reactivity to sutures

Polydek	Braid	High	Moderate	Good	Good	Fair	–
Tevdek	Braid	High	Moderate	Poor	Poor	Fair	–
Fore-Tex	Monofilament	Fair–Poor	Low	Very good	Fair	Poor	No packing memory and knot construction has virtually no effect on breaking strength
Stainless steel	Monofilament, twist, or braid	High	Low	Poor	Good	Poor	May kink

(Data partially from Ref. [1].)

Knot tie-down and security describe how easily a surgeon can slide a knot down to the wound edge and how well the knot will stay in position without untying or slippage. This handling property relates to surface and mechanical properties of sutures. The relatively smooth surface of a monofilament or coated braided

suture will have a better knot tie-down than a suture with a rough surface such as an uncoated braided suture, if everything else is equal. The coefficient of friction of sutures also relates to knot tie-down and security. A linear relationship between knot security and coefficient of friction was reported by Herman.^[27]

A high coefficient of friction makes knot tie-down difficult but leads to a more secure knot. This is because a high friction suture provides additional frictional force to hold the knot together. This high friction suture surface also makes the passage of suture strands difficult during knot tie-down. It thus appears that knot tie-down and knot security are two contradictory requirements. There is no reported standard test for evaluating knot tie-down capacity. However, Tomita et al. recently reported a method to objectively quantify the knot tie-down capacity of 2/0 silk, polyester sutures, Gore-Tex, and an experimental ultrahigh-molecular-weight polyethylene suture (Nesplon®).^[24]

Biological Properties

Biocompatibility of suture materials describes how sutures, which are foreign materials to the body, can affect surrounding tissues and how the surrounding tissues can affect the properties of sutures. Thus, biocompatibility is a two-way relationship. The extent of tissue reactions to sutures depends largely on the chemical nature of the sutures and their degradation products if they are absorbable. Sutures from natural sources such as catgut and silk usually provoke more tissue reactions than synthetic ones because of the availability of enzymes to react with natural biopolymers. Besides the more important chemical factors and physical form, the amount and stiffness of suture materials have been reported to elicit different levels of tissue reactions. For example, a stiff suture will result in stiff projecting ends in a knot where cut. These stiff ends can irritate surrounding tissues through mechanical means, a problem associated with some monofilament sutures but generally not found in braided multifilament sutures.

Because the quantity of a buried suture relates to the extent of tissue reaction, it is a well-known practice in surgery to use as little suture material as possible, such as a smaller knot or a smaller size, to close wounds. The use of a smaller size of suture for wound closure, without detriment to the provision of adequate support to wounds and without cutting through wound tissue, is due to the square relationship between diameter and volume which suggests that a slight increase in suture size or diameter would increase its volume considerably.

There are two basic means to study biocompatibility of suture materials: cellular response and enzyme histochemistry. The former is the most frequently used and provides information about the type and density of inflammatory cells at a suture site. In the cellular response approach, sutures without tension are implanted in the gluteal muscle in small animals such as the rat. This implantation site has given a very consistent reproducible cellular response for valid comparisons, even though it is not a common site for suture in surgery.

However, Walton recently questioned the use of this common test procedure, particularly in orthopedic surgery,^[28] due to the observed inflamed nature of the postoperative synovial tissue and the mechanically stressed nature of the suture. Histological stains with a variety of dyes such as the most frequently used H & E are the standard methods of evaluation of cellular activity at the suture sites. Figure 2 is a typical example of histological photomicrographs of PDS and Maxon sutures at 35 days postimplantation in a variety of tissues.^[29] In addition to a qualitative description of cellular activities, tissue response can also be graded by the most frequently used and accepted Sewell et. al. method or its modification.^[30]

The enzyme histochemical approach is a more objective, quantitative, consistent, and reproducible method than cellular response. Enzyme histochemistry is based on the fact that any cellular response to a foreign material is always associated with the presence of a variety

Fig. 2 Light histologic photomicrographs of tissue adjacent to PDS and Maxon sutures at 3 and 5 days postimplantation in a variety of tissues of New Zealand White rabbit ($\times 130$). (A) PDS in peritoneum; (B) PDS in fascia; (C) Maxon in peritoneum; (D) Maxon in fascia. (From Ref. [29].)

of enzymes; however, this approach is more tedious and requires more sophisticated facilities and better experience. The data obtained provide additional insight into the functions of those cells appearing during various stages of wound healing. The enzymatic activity of a suture implant site is quantified by microscopic photometry of a cryostat section of the tissue. For example, van Winkle et al. reported that the high level of cellular response to silk suture observed from histological study is confirmed in their enzyme histochemical study.^[31–33] Enzyme histochemistry is also useful for studying the biodegradation mechanism of absorbable sutures.

The normal tissue reaction to sutures can be grouped into three stages, according to the time for the appearance of a variety of inflammatory cells.^[1,31,33,34] They are: initial infiltration of polymorphonuclear leukocytes, lymphocytes and monocytes during the first three to four days (i.e., acute response); appearance of macrophages and fibroblasts from day 4 to day 7; and beginning maturation of fibrous connective tissue formation with chronic inflammation after the seventh to the tenth day. During the first seven days post-implantation, there is virtually no difference in normal tissue reaction between synthetic absorbable and non-absorbable sutures. However, a slightly higher inflammatory reaction to synthetic absorbable sutures can persist for an extended period until they are completely absorbed and metabolized, whereas synthetic non-absorbable sutures, in general, are characterized by a minimal chronic inflammatory reaction with a thin fibrous connective tissue capsule surrounding the sutures usually by 28 days postimplantation.

In addition to the normal tissue reactions to sutures, there are several adverse tissue reactions that are suture- and site-specific. Some examples include urinary stone or calculi formation, granuloma formation, thrombogenicity, propensity toward wound infection, and recurrence of tumor after radical surgery and allergy.

Monofilament sutures are considered to be a better choice than multifilament ones in closing contaminated wounds. This is because not only do multifilament sutures elicit more tissue reactions which may lessen

tissue ability to deal with wound infections but also multifilament sutures have a capillary effect that could transport microorganisms from one region of the wound to another. The reason that multifilament sutures generally elicit more tissue reactions than their monofilament counterparts is because inflammatory cells are able to penetrate into the interstitial space within a multifilament suture and invade each filament. Such an invasion by inflammatory cells, well evident in histological pictures, cannot occur in monofilament sutures. Thus, the available surface area of a suture to tissue should bear a close relationship to the level of tissue reaction that a suture could elicit.

S

Biodegradation and Absorption Properties

Biodegradation and absorption properties are the most important issue of absorbable sutures, but are far less relevant for most nonabsorbable sutures, particularly those of synthetic nature. This biodegradation property is also responsible for the fact that absorbable sutures do not elicit permanent chronic inflammatory reactions found with nonabsorbable sutures. The most important characteristics in biodegradation and absorption of sutures are the strength and mass loss profiles and biocompatibility of degradation products. Although there is a wide range of strength and mass loss profiles among the available absorbable sutures, they have one common characteristic: Strength loss always occurs much earlier than mass loss, as shown in Table 10. This suggests that absorbable sutures retain a large portion of their mass in tissue while they have already lost all their mechanical properties required to provide support for tissues during wound healing. Thus, an ideal absorbable suture should have matched mass loss and strength loss profiles, and none of the current commercial absorbable sutures can achieve this ideal biodegradation property.

The observed wide range of strength and mass loss profiles among the available absorbable sutures is attributable not only to the chemical differences among

Table 10 Absorption delay of commercial synthetic absorbable sutures

Suture materials	Time to complete loss of tensile strength (days)	Time to complete mass absorption (days)	Absorption delay (days)	Useful lifetime (%) ^a
Dexon [®]	28	50–140	22–112	20–56
Vicryl [®]	28	90	62	31
PDS [®]	63	180–240	117–170	26–35
Maxon [®]	56	210	155	27
Monocryl [®]	21	90–119	69–98	18–23

The higher percentage denotes the better absorbable suture.

^aThe ratio of [the time to complete loss of tensile strength] to [the time to complete mass absorption].

the absorbable sutures but also to a variety of intrinsic and extrinsic factors, such as pH, electrolytes, stress applied, temperature, γ irradiation, superoxide, microorganisms, and tissue type, to name a few. Among these intrinsic and extrinsic factors, the role of superoxide on the biodegradation of absorbable sutures appears to be one of the most interesting factors because of the unusually fast loss of mechanical integrity and unique surface morphology.^[35] For example, at a 0.005 M superoxide ion concentration and room temperature, the five synthetic absorbable sutures retained 20–70% of their original tensile breaking force at the end of 24 hrs as shown in Fig. 3. The bulk of the loss of tensile breaking force of these sutures occurred during the initial two-hour period. The order of tensile breaking force of these five absorbable suture materials at this relatively high superoxide ion concentration was the same as at the lower superoxide ion concentration: Monocryl[®] > Maxon[®] > Vicryl[®] > Dexon[®] > PDS II[®]. It is important to know that there would be no change in tensile breaking force of these absorbable sutures in regular buffered saline medium at 25°C for as long as days.^[9]

Upon biodegradation, absorbable sutures have shown quite interesting surface morphology and some examples are shown in Fig. 4. For example, multifilament Dexon sutures that were subjected to γ -irradiation treatment and hydrolytic degradation in buffer solution showed very regular circumferential surface cracks along the longitudinal fiber axis and had

Fig. 3 The percentage of retention of tensile breaking force of five 2/0 synthetic absorbable sutures upon 0.005 M superoxide ion-induced hydrolytic degradation at 25°C. ● - PDS; ■ - Dexon; ◆ - Monocryl; ▲ - Vicryl; ▼ - Maxon. (From Ref. [35].)

the appearance of corn-like structure (Figs. 4A and B). Upon γ -irradiation treatment and hydrolytic degradation in buffer solution, monofilament Maxon sutures, however, showed both circumferential and longitudinal surface cracks (Fig. 4C) and subsequent peeling off of these surface cracks (Fig. 4D). The appearance of moon-crater-shaped impressions of various sizes (about 10–100 μ m diameter) on a Monocryl[®] suture at a superoxide ion concentration of > 0.005 M (Fig. 4E) is unique because such circular impressions were never observed in the hydrolytic degradation of all existing absorbable sutures in a conventional buffered saline medium or in vivo. The formation of moon crater-shaped impressions on Monocryl and Maxon sutures deviates from the conventional understanding of the anisotropic character of fibers. In the reported morphological studies of all existing absorbable sutures in conventional buffer media,^[9] the most common surface morphological characteristic upon hydrolytic degradation of suture fibers is the formation of circumferential or/and longitudinal surface cracks that are consistent with the anisotropic character of fibers. It is not fully understood at this stage how superoxide ion-induced degradation could lead to such unusual surface morphology on Monocryl and Maxon sutures.

The biocompatibility of degradation products is usually not a problem because all existing absorbable sutures are made from well-known biocompatible glycolide, lactide, and their derivatives. However, biocompatibility of degradation products also depends on the rate of their accumulation in the surrounding tissues. This implies that the ability of the surrounding tissues to actively remove and metabolize degradation products is essential. Such a metabolism depends on the extent of blood circulation in the tissue. A well-vascularized tissue can remove degradation products as fast as they are released from an absorbable suture and subsequently metabolized, which can minimize tissue reactions to degradation products.

Due to their ability to release degradation products, absorbable sutures have recently been studied as a vehicle to deliver a variety of biochemicals such as growth factors to facilitate wound healing or antibiotics to combat wound infection. This new approach will increase the value of absorbable sutures and extend their function beyond the traditional role of wound closure. A typical example is Vicryl Plus which has an antimicrobial agent coating.^[10,11]

Biodegradation properties are usually examined in vitro or/and in vivo. In the in vitro environment, the most commonly used medium is phosphate-buffered physiological saline, pH 7.44 at 37°C. However, other buffers such as Tris or body fluids such as urine, bile, and synovial fluids have been used. In the in vivo environment, unstressed absorbable sutures are normally

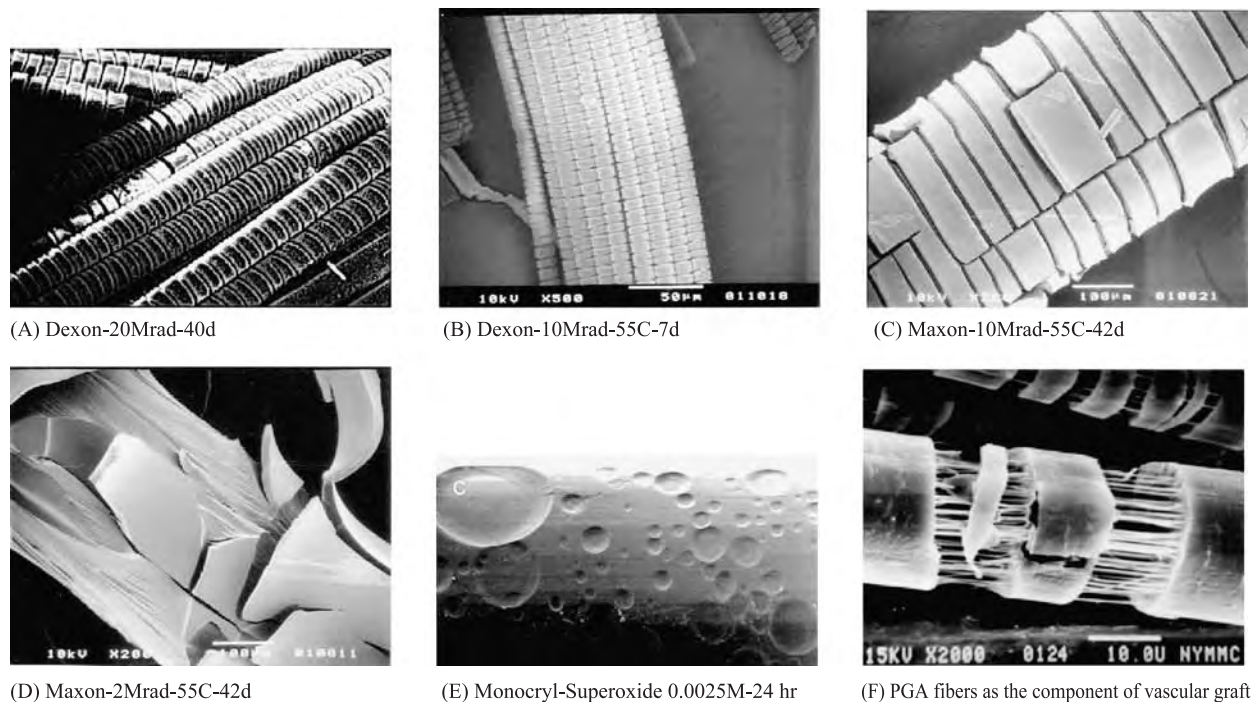

Fig. 4 Scanning electron images of degradation of some commercial absorbable sutures. (A) 2/0 Dexon after 20 Mrad γ irradiation at room temperature and 40 days in vitro in buffer at 37°C; (B) 2/0 Dexon after 10 Mrad γ irradiation at 55°C and 7 days in vitro in buffer at 37°C; (C) 2/0 Maxon after 10 Mrad γ irradiation at 55°C and 42 days in vitro in buffer at 37°C; (D) 2/0 Maxon after 2 Mrad γ irradiation at 55°C and 42 days in vitro in buffer at 37°C; (E) 2/0 Monocryl upon 0.005 M superoxide ion-induced hydrolytic degradation at 25°C; (F) Polyglycolide fibers as the component of woven vascular grafts upon in vitro hydrolytic degradation in buffer of pH 7.4 at 37°C.

implanted in rat gluteal muscle for predetermined periods of implantation. The sutures retrieved at various periods of immersion or implantation are then subjected to evaluation of their mechanical and physical properties to assess their changes with time. The degree of absorption in vivo is evaluated by the change in suture cross-sectional area, and the level of tissue reaction is assessed by a histological method and/or enzyme histochemistry.

SUMMARY

Suture materials are the most frequently used biomaterials because every wound must be closed. Suture materials are made from either natural or synthetic fibers and there is a wide range of properties of suture materials available for surgeons to choose from. Among suture properties, four properties are essential: physical and mechanical, handling, biological, and biodegradative. These properties are interrelated. The trend of current research development of suture materials is toward value-added products, such as the

incorporation of antimicrobial agents into sutures to ward off wound infection.

T

INTRODUCTION

Telemedicine or telehealth is the integration of telecommunications and information systems to support the delivery of healthcare, regardless of the patient's location. The use of sensors to collect physiologic signs and transmission of these data were hallmarks of the space program from the time of Sputnik 2 in 1957. This telemetry in space science led to critical care telemetry in standard medicine and the possibility of telemedicine. Although satellite telecommunications prompted telemedicine's genesis in the 1970s (STAR-PAHC),^[1] videoconference consultation by microwave transmission made its debut in 1955 with a psychiatric program in Nebraska.^[2] Telemedicine was also used via radio from Antarctica to Australia in the 1920s.

It is safe to state that the medical industry is changing. The advent of affordable computer technology and ubiquitous telecommunications topologies has created a new paradigm in healthcare capabilities, cost models, and challenges. The prospect of telemedicine holds the opportunity of increasing the quality and quantity of healthcare for millions of people by eliminating the barriers of distance and time.

Telemedicine need not, nor should not be, a radical change from traditional medicine. Familiar environments, existing protocols, and standard tools need to be integrated into clinical practice so clinicians and patients are encouraged with little inconvenience. The implementation of telemedicine is finding its way into the mainstream of the medical community.^[3]

OVERVIEW

To date, hundreds of funded telemedicine programs have proven to be successful in terms of increasing the quality of care. However the cost structure to support long-term and self-sustainment is still in debate.^[4-6] Studies in the area of prison telemedicine have largely

proved to be financially feasible while other areas have not.^[7,8] Ironically, the slow adaptation of telehealth in the mainstream industry is not due to the technology but rather to barriers of policies, reimbursement, and legal issues.^[9,10] Until these issues are resolved, the progression and acceptance is expected to be slow.

As clinical expertise is ferried across state lines and international borders, the need for electronic medical records becomes more apparent. With the data collection and distribution capabilities now available, the aptitude of informatics becomes plausible and a potentially powerful tool for telemedicine providing comprehensive electronic information about patients. There are many acronyms associated with names being debated, such as the Electronic Medical Record (EMR), Electronic Health Record (EHR), Computerized Patient Record (CPR), and others. The names all mean basically the same thing; although, some may imply a broader capability to include practice management capabilities such as billing. The terms stem from a variety of sources, but the Institute of Medicine is likely to have the most influence on the eventual official name—if there ever is one. The challenge remains on how the EMR will look and feel.

CLINICAL APPLICATION

Early telemedicine matured as a video-teleconferencing (VTC) through a Massachusetts General Hospital program to Logan International Airport Medical Station in 1967 and the remarkable work on Space Lab in 1983.^[11-13] The application of telemedicine has broadened from space medicine to maritime program, rural program, and support after international disasters.^[14] Telemedicine can be applied in a wide variety of medical disciplines. The technology is an enabling factor for improved clinical care.^[15]

The elements of telemedicine remain the same. For example, there must be a competent capture of data by

sensors or devices at the site of the patient. Sensors or devices may include video, audio, physiologic data, laboratory data, text, or radiographic files. Although analog data may be the source, digital readings are now almost universal with some form of compression or perhaps data interpretation at the source. Transmission can be via electromagnetic spectrum or fixed mediums such as copper or fiber optics. Various transmission technologies may interface for long distance communication—from the very slow to the very fast. Each digital phase or byte is represented as eight bits. Therefore, the speed to transfer data is a function of the number of bits measured per second. For example, to transfer a text file of 10,000 characters, which is equivalent to approximately 1500 words, with a cellular connection of 9600 bps will take just over eight seconds. A high-speed network will move it in a split second.

The data must convey an accurate depiction of the situation. The consultant must interpret, manipulate, and formulate the data with confidence and competence in the context of medical professionalism. Thereby, the consultant may ethically render a professional opinion or therapeutic plan for a patient never seen or touched. This leap of professional faith calls for consummate technical success and transparency for the consultant. The consultant response must be an action or series of actions, which can actually be carried out at the distant site. It makes little sense to recommend a drug that is not available or an operation that is beyond the training level or expertise of the practitioner. The recommendation may be in text or require effectors such as robotics. The lag time becomes critical when the consultant must await arrival of images, transmission of robotic instructions, and return of the image as altered by the robotic action. Network jitter and delays over 500 milliseconds for this segment exceeds the hand-eye coordination of surgeons.^[16] Performance of a robotic transatlantic operation by Dr. Jacques Marescaux in 2001 had a lag of only 155 milliseconds and was completely successful. Robotics solutions for Mars travelers with a 22-minute transmission—at the furthest point with our planet—is completely impractical.^[17]

Telemedicine has several components, including sensors, transmitters, responders, and effectors. In order to practice medicine in a system of telemedicine, even seamless communications cannot overcome the challenge. Medical practitioners have been implicated to human touch and uniquely personal patient interaction. In order to practice medicine in the partnership with engineers, technology, and unseen colleagues, there must be process simulators to prepare the team for competent professional performance. This may be simply familiarity with software or extensive training in a common medical language, robotics, and virtual reality. Through training, telesurgery, teleradiology, and telepathology have all seen success and look to greater ones.

TYPES OF TELEMEDICINE

Real Time

Real-time telemedicine can include a number of tools, including VTC, the plain old telephone system (POTS), Web-based chat environments, and wireless options such as Short Message Services (SMS).

Before computers were affordable and the Internet was popularized, the primary mechanism for telemedicine was VTC. While VTC matured in the boardroom of large corporations, it was being identified as a requisite component for telemedicine and for good reason. Here was an ideal solution for a physician and patient separated by great distance to interact. A call from a referring doctor to a consulting doctor using the same type of equipment corporate officers was using was a tremendous boon to the remote consult.^[18] In this modality, consults are performed by a referring physician, i.e., the location of the patient, and a consulting physician usually represents a specialty in support of the patient.

While VTC can be a powerful tool for remote consultation, the costs can be prohibitive.^[19] Dedicated hardware includes a coder-decoder (CODEC), camera, microphone, speaker, and a projection device or large-screen monitor. In addition, acquisition devices are required to provide the consulting site with additional data and images to make a diagnosis and recommendations. CODECS can be both hardware and software.

VTC facilities are not always readily available, and the equipment and technical support can be expensive to operate. VTC uses various communications capabilities such as Integrated Services Digital Network (ISDN). ISDN is a switched circuit topology that is managed by the local telecommunication company (TELCO.) These circuits behave like the traditional POTS, but, instead of routing analog signals, its signals are digital. This separate network requires installation of dedicated lines to a particular location where the CODEC is connected. The standard for videoconferencing over ISDN is H.320.

ISDN lines are available as either Basic Rate Interface (BRI) or Primary Rate Interface (PRI). Each BRI consists of a pair of 64 Kbps circuits providing 128 Kbps plus a D channel that negotiates the connection. BRIs can be configured in 128 Kbps increments. A PRI is a single 1.544 mega/million bits per second (Mbps), which is bundled as 23 BRIs plus the D channel. This channel can be fractionalized to support communications with other sites, depending on what bandwidth is available. For example, if Site A has three BRIs (384 Kbps) and it connects to Site B that has a PRI, the connection is negotiated through the D channel, and the systems agree that the highest speed they can connect is 384 Kbps. When a multipoint

conference is required, i.e., more than two participants, a specialized piece of equipment called a bridge or multipoint conferencing unit (MCU) is required. An important note, ISDN services are not available everywhere; therefore, its use depends on the capabilities at corroborating sites.

This is why significant bandwidth is required for VTC. VTC uses various compression schemes such as H.261 to minimize bandwidth requirements, even on broadband links. For example, images are sent as either 352×288 pixels, which is known as CIF, or 176×144 , which is known as QCIF. Using QCIF in 256-color mode, which requires eight bits per pixel, will require $176 \times 144 \times 8 = 202,752$ bits per frame. At 15 frames per second, this equates to $15 \times 202,752 = 3,041,280$ bits per second, which requires approximately 3 Mbps of bandwidth. Fortunately most CODECs employ other compression techniques, such as only sending the portion of the frame that changes, which is known as Deltas.

How much bandwidth is needed for clinical consultations? This is debatable and depends on the type of service, but 384 Kbps, in most cases, provides the quality for clinical application in real-time sessions.^[20] This amount of bandwidth provides full-motion video and acceptable audio. Because ISDN is billed like a normal telephone call, long distance charges accrue from the originator of the call. Also, there are initial setup fees and monthly costs for ISDN service. ISDN is often referred to as bursty bandwidth because it provides bandwidth only when needed.

By comparison, the Internet can also be a network conduit for videoconferencing. Connection to the Internet is virtually mandatory these days. ISDN is a luxury and must be justified by clinical application and participating partner sites. Since a facility is more likely to have copious bandwidth to the Internet than ISDN, videoconferencing over IP networks, which is referred to as H.323, may be a sensible option but not without challenges. The Internet uses protocols such as Transmission Control Protocol/Internet Protocol (TCP/IP) to manage data packets from one point to another. But, unlike transmission of an E-mail message, for example, which is composed and sent to a mail server to await the recipient's attention, VTC is synchronous. The packets traverse the network and are either delivered or simply expire.

In client/server environments such as the Internet, TCP is primarily responsible for transferring data over the IP network. Native to TCP are various components such as error correction and flow control—packet management. These protocols ensure that data packets arrive at their intended destination. E-mail is a good example. Data are sent in packets from one host to another. The receiving host replies to the sending host that it received the data properly or not. In the event

packets were lost or damaged in transit, the sending host retransmits the subject packets. This process is asynchronous, which means that there is no critical timing or order that the packets must be received. For most asynchronous communications, this is perfectly acceptable and preferred. However, in synchronous communications in which timing is critical such as voice over IP or videoconferencing, packet loss is extremely problematic.

IP-based VTC doesn't use TCP. It uses User Datagram Protocol (UDP) instead, which does not employ error correction. If packets are lost or damaged, they are not resent. That part of a given conversation is over. This results in dropped packets that cause dropped audio and jerky video. Another challenge presented by network topologies and real-time communications is network jitter. Jitter is the term used to describe the inconsistent flow rate of data packets over a defined path. Latency is created due to two reasons, distance and routing mechanisms. Routing mechanisms refer to the various devices that a packet must traverse to reach its destination. As packets pass through routers and other Level 3 devices, which are called hops, delays occur much like traffic at a busy intersection. This latency creates problems for synchronous communications such as image pixelization, in which portions of the image are missing or out of place, as well as audio interruptions—especially with low-bandwidth connections. More bandwidth helps because of lessened congestion, data can be compressed less, and losses that affect critical components, such as audio, are not as noticeable.^[21,22]

Nevertheless, H.323 is highly scalable, affordable, and easy to implement. As bandwidth becomes more available and affordable, H.323 will likely become more embraced.

Store-and-Forward

In many telemedicine consultation scenarios, it may be more effective—in cost, ease, and performance to use store-and-forward techniques. Examples include E-mail, File Transfer Protocol (FTP), Web services, and even the facsimile machine and documents generated by software that converts to the Group 3 fax standard. The Internet has enabled a new dimension for exchange of knowledge. TCP/IP is natively an ideal protocol for the exchange of medical data. Store-and-forward employs the asynchronous advantages of TCP/IP.

Store-and-forward is extremely useful when non-emergent conditions are addressed. Some of the most common store-and-forward applications include radiology, dermatology, pathology, and ophthalmology. The migration to EMRs will significantly increase the

viability of store-and-forward by sharing entire patient histories, current medications, allergies, laboratory values, and digital images.^[23] One area that can be used in both a real-time and store-and-forward mode is a practice called whiteboarding. Whiteboarding is accomplished over the Internet by the T.120 standard. Videoconferencing applications such as NetMeeting[®], ProShare[®], and CU-SeeMe[®] provide this function as an augment to the live video. T.120 allows you to place a selected image or part of image onto the whiteboard where each participant can annotate by using different color highlighting tools, text, or pointers. This is used in real-time modes to show a remote physician where to place a bandage, take a biopsy, or, in the case of surgical telementoring, where to—or not to—make a cut. Images can be saved as various types of formats and saved or imported into a patient's EMR for later review.

Digital images are created by a group of pixels (picture elements). Each pixel represents a single spot of color and value, which is much like the grain on photographic film. When enlarged too much, an image can lose focus because the individual pixels are noticeable. Since an image is made up of a number of these pixels, digital images can be large. This factor is one of the primary constraints in the ability to easily capture, manipulate, and transfer digital images.

However, not all pixels contain the same amount of information. With still images, each pixel is represented by a certain number of bits, and this is referred to as bit-depth. The greater the bit-depth, the more colors and values a pixel can represent. A true-color image is 24 bits, which means that, for each pixel, there are 24 bits of data or 8 bits each for red, green, and blue. A grayscale image, such as an X-ray, has only eight bits per pixel because there is no color data.

It is important to understand the concept of resolution as it applies to digital imaging if acceptable results are desired. Different devices such as scanners, printers, and cameras have different resolutions and different ways of specifying resolution. Higher resolution means more data, but it might also be a waste of space and time. Using too low of a resolution can cause the image to be unusable. There are different types of formats that have been used on the Web for years, such as Joint Photographic Experts Group (JPEG), Graphics Interchange Format (GIF), Portable Network Graphic (PNG), Tag Image File Format (TIFF), Windows Bitmap (BMP), and Digital Imaging and Communications in Medicine (DICOM), which is the standard format endorsed by the American College of Radiology.

NETWORKS AND TELECOMMUNICATIONS

There is a primary difference between traditional circuit-switched networks such as POTS and packet-switched

networks such as the Internet. Circuit-switched means that, for a given network session, a dedicated or virtual circuit is established for the parties involved. This allows for a relatively secure session, and its link is not shared. Conversely, packet-switched networks, which are akin to interstate highways, share the link and are not secure in native format. The advantage of packet-switched networks is the scalability, ease of use, and low cost.

It is important to realize that the shared network resources of the Internet make it easy to communicate with anyone in the world and there is no guaranteed level of service. Unlike a switched circuit link that is facilitated by one or more TELCOs that guarantee a certain level of service, the Internet is not managed by anyone or even few entities. It is a loose consortium of providers, carriers, and users. Therefore, it is considered a "best effort" network with no definable Quality of Service (QoS) level.^[24] The best strategy to increasing your own QoS for telemedicine applications is to increase the bandwidth of the Internet connection and a redundancy through different carriers and perhaps even different topologies.

Wide Area Networks (WANs) were once the standard for long distance data networks. Before the Internet, WANs were established by technologies such as frame relay, leased lines, or ISDN. WANs were very expensive due to the dedication of resources. Today, the Internet and telecommunications backbones and protocols such as Asynchronous Transfer Mode (ATM) have helped the Internet to become the de facto global WAN through whatever topology is appropriate for a particular facility.^[25] As the world becomes increasingly connected, access to partners around the globe becomes more prevalent. More Internet Service Providers (ISPs) and Points of Presence (POPs) provide on-ramps to the Internet by allowing more people to potentially have access to telemedicine. An example of how a telemedicine network hub and spoke system is utilized is represented in (Fig. 1).

Example Hub and Spoke Topology

Wireless cellular networks have provided telecommunications to areas that previously had none. In developed countries, copper has been the mainstay for voice and data communications. Capacity has been increased geometrically through broadband technologies, including fiber, microwave, satellites, Digital Subscriber Lines (DSL), cable, and more intelligent switching. In developing countries, terrestrial copper has been virtually skipped over in favor of cellular. The cost of implementation can be significantly lower and highly scalable, depending on radio frequency allocation. This brings us to a critical discussion known as the last mile.

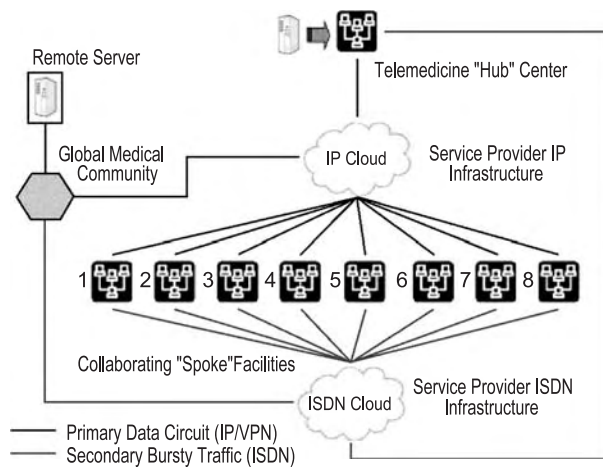

Fig. 1 Utilization of a telemedicine network hub and spoke system.

Despite these technological advances and low-cost phones, bandwidth to remote areas remains a challenge. For effective telemedicine, enough bandwidth must be available at the location of the patient, or capabilities are very limited. Although the regional POP may have a tail circuit to the Internet with capacity in the megabit range, what eventually reaches the point of care or the last mile may only be that provided by the cellular service. This also assumes the provider has a digital signal either on top of an analog wave or digital as the base. This in many cases is only 9600–19,200 bps, which is enough for relatively small amounts of data transfer but not video.

Wireless systems are generalized in terms of capacity and capabilities. They are categorized as generations (G). For example, early analog systems usually referred to as Advanced Mobile Phone Services (AMPS) were considered first generation or 1G. As digital services began to arise, such as Global System for Mobile communications (GSM) and Time Division Multiple Access (TDMA), they were referred to as 2G. Services and bandwidth continue to improve through technologies such as Code Division Multiple Access (CDMA). We are currently in a transition between 2.5G and 3G, and development of 4G is already underway.

3G services promise a quantum leap in digital capacity—on the order of 128–384 Kbps. As these capacities of bandwidth are reached, the last mile will be enabled with enough bandwidth to execute many of the telemedicine tools that will be needed to provide the quality of care that so many people desperately need.

HARDWARE

Before the Internet was popularized and desktop PCs lacked the power to handle the processing and WAN

tasks, dedicated machines running UNIX[®] workstations were needed.^[26] Of course, there are now sufficient resources on typically configured computers. Today, it is the Microsoft Windows[®] platform that is ubiquitous and, to a smaller extent, the Macintosh[®] OS. However, standard protocols and open source options such as Linux[®] may change this.

Minimum Hardware Requirements

When discussing hardware requirements, there are three areas to consider, referring sites, consulting sites, and the servers also called back ends.

The client/server modality of the Internet is ideal for the requirements of medical professionals. It is flexible, scalable, and affordable. Dedicated computers, which are used for telemedicine applications, are no longer the norm. From a commercial standpoint, telemedicine systems must be designed to utilize existing systems.

It goes without saying that the dominance of Microsoft in the personal computing market weighs heavily on the development of telemedicine. First of all, there is the issue of familiarity. People are used to the Windows environment and economies of scale have made the affordability factor low. Using the lowest common denominator for platforms and tools should help to accelerate growth in this industry. No longer will dedicated UNIX machines be required for telemedicine consultations. Beyond the specialty equipment noted subsequently, the computing and network architectures need to be what is readily available and preferably already installed.^[27,28] Purchasing and maintaining separate systems is economically unfeasible.^[29]

The needs of a site such as a remote clinic that requests consultations differs from a location that is strictly a consulting site. In some cases, the site is both. For example, a remote clinic that has a primary care physician may need assistance when diagnosing a neurological problem. A patient such as this would be better served by a virtual visit to a consulting site where a neurologist is available. A requesting or referring site usually needs more computing power and peripherals.

For consulting sites, computers need to be of average configuration, such as those that may be on your desk right now. These machines can readily access patient data presented by the referring sites. In some cases, special software may need to be installed but the push in the industry is standards compliance and browser-based applications.

Peripherals

Data, audio, and video are key components that travel over the networks, but the sources of acquisition are

T

relegated to the peripherals. During a consult, other acquisition devices besides the primary camera on the CODEC may be required. Examples include a multi-purpose portable camera that can be modified as a dermascope, otoscope, ophthalmoscope, etc. Other tools may include a digital stethoscope, ultrasound, pulse oximeter, blood pressure cuff, etc. Often, a document camera will be used to capture radiographs unless the image is already digital and can be transferred electronically. A flatbed scanner is also an affordable tool that can be useful.

Composite patient monitors such as a Propaq[®] or Criticare[®] are common in medical facilities and have data/serial ports, but, unfortunately, these devices do not yet fully support standardized output strings for sharing of data with remote sites. The IEEE 1073 Medical Information Bus standard, which has been ratified since 1994, is not yet embraced by the industry despite the fact that this standard will allow all types of medical device to fully interoperate and share vital data with remote sites.^[30]

Portable Devices

The definition of portable device has changed in recent years. For many years, the term portable device meant a cart on wheels that could be moved within a facility. These carts still exist today and are used in many cases for specialty data collection, video, or patient education.

Another more recent definition is a Personal Digital Assistant (PDA). PDAs are handheld devices such as Palm[®] computing devices or Microsoft's PocketPC[®]. These PDAs are becoming very popular, especially in medical schools where students carry and use the devices for the most basic tasks such as contacts and calendaring. But, they are increasingly embracing the applications designed for medicine.

SYSTEM ARCHITECTURE

Front-end software is the equivalent to the personal interaction of the patient and physician. For over a decade, computer users have become accustomed to the familiar Microsoft Windows OS. At least for now, this has become, in most cases, the front end for the telehealth community. Platform-independent applications such as Java that run either as applications or applets within a Web page are slowly gaining favor over applications written for a specific platform.

Back ends refer to the nomenclature associated with the data management that resides on a server. Any Web server can be considered a back end in the broadest sense but, in healthcare, a back end usually

refers to patient data from the clinical information system, which is often older and established legacy systems. Where existing clinical information systems are not available, stand-alone databases may be used for specific telemedicine practice. These back ends provide the net-enabled tools that make integrated telemedicine systems operational. This data links the participants and related services associated with the healthcare continuum.

Between the Web server and the data repository are processes called middleware. Middleware is the glue that binds the dynamic data to the telemedicine participants. The clients are permitted access to the databases, which may or may not be physically on that same server, through programming interfaces such as Common Gateway Interface (CGI)[®], Practical Extraction & Reporting Language (Perl)[®], Hypertext Preprocessor (PHP)[®], Cold Fusion[®], Java[®], and others. This business logic, as it is often referred, permits dynamic access to add, change, and delete information in a database.

Medical Informatics

There are new opportunities provided through the use of database tools that are referred to as medical informatics. Medical informatics is an emerging discipline that can be defined as the study, compilation, and implementation of structures and algorithms to improve communication, understanding, and management of medical information. As data is collected through a variety of forms and locations onto central or distributed servers, the ability to aggregate and evaluate data is of great value. There are various types of database systems available, such as flat file, Relational Database Management Systems (RDMS), object oriented (OO), hierarchical, and native eXtensible Markup Language (XML). These databases provide access to archives of medical knowledge and patient records.

Lessons learned from corporate America are beginning to take hold in the medical community. Warehoused data can be de-identified, i.e., remove patient-identifying information such as name, address, social security number, etc., aggregated, and evaluated for clinical trends or patterns. This can be manipulated in many different ways, such as to support evidence-based medicine and studies in epidemiology.

MIGRATION AND STANDARDS ADHERENCE

One of the major problems facing this industry is the interoperability of legacy systems with newly deployed, Web services.^[31] There is much debate about the

migration from paper-based record to electronic versions. To do this requires agreement by the industry on both form and function. With over 170 medical specialties and sectors such as nursing, laboratory, administrators, technicians, and physicians weighing in, the standardized EMR has an arduous path ahead. To date, at least the messaging format is largely agreed upon—XML in concert with Health Level Seven (HL7) and associated schemas.^[32]

In fact, the U.S. government has recently issued governmentwide standards for coding and sharing medical records. These standards are now mandatory for all federal agencies and stem the work of the Defense, Health and Human Services, and Veterans Affairs departments. The initiative will require agencies initially to adopt five standards:

- For messaging, the Health Level 7 standard, which includes XML, to share patient information, such as order entry, scheduling, tests and coordination of admittance, discharge, and transfer records during inpatient care.
- For ordering drugs from pharmacies, standards created by the National Council on Prescription Drug Programs.
- For systems integration, IEEE 1073 (The Medical Information Bus) to standardize how medical devices interface with computer systems.
- For diagnostic imaging, DICOM to capture, store, and share information from imaging devices.
- For laboratory records, the Logical Observation Identifier Name Codes (LOINC) to support the exchange of clinical lab results.

The legacy systems in use today use a variety of data formats such as Electronic Data Interchange (EDI), but many are proprietary in nature and not originally designed to interoperate with other systems. But, for EMRs to take hold, other issues need to be addressed. For example, who will be responsible for storing, maintaining, and hosting EMRs? Logic dictates that the common denominator is the patient. A medical encounter involves a physician(s) and the patient. It stands to reason that the patient should be empowered with control of his or her own EMR, but patients, as a whole, do not have the resources or expertise for the task. Because an EMR and its evolutionary future will require constant updates, insurance/payee information, and security components, a centralized facility such as an application service provider (ASP) or perhaps the government will need to assume the responsibility. But, is this what patients want?

Patients should be able to provide a doctor with his or her most recent and comprehensive medical history—no matter where they will be. Because all medical facilities do not necessarily have access to the

Internet or choose not to—for medical data—because of the requirements of the Health Insurance Portability and Accountability Act (HIPAA), the EMR may best be a smart card or chip the patient carries that can be easily read by any computer with a Universal Serial Bus (USB) port, card reader, or PDA. But again, if this record needs to be updated, should the patient be responsible for this? It is unlikely, and a solution needs to be found.

TRAINING AND DISTANCE LEARNING

Training and education are very important aspects of telemedicine. Telemedicine systems must be designed to be transparent to the user. The tools and interface must be highly intuitive and easy to master. Software developers straddle a difficult line in trying to provide feature-rich applications while maintaining a user-friendly environment.

Despite all efforts, the data requirements and multitude of tools required will invariably require some degree of training. In addition to the interface itself, it is recommended that those involved in telemedicine become familiar with the technology. Clinicians and even administrators can find that training in the very basics of telecommunications, data storage, imaging, and digital protocol can be a valuable augment to the people using the system. This type of training need not be exhaustive rather than a cursory overview of how it works. Training can be either live or online.

In concert with telemedicine as a clinical tool, distance learning or distance education is a complementary adjunct. The same networks that enable the host of clinical activities also provide the conduit for sharing of educational components. A good example is Continuing Medical Education (CME.) Physicians must continually keep their skill levels current, and CME is a primary vehicle for that activity. Other examples include demonstration of new technologies and even the delivery of customized modules to remote field clinicians. For example, in a remote clinic that is far from a host facility, a primary care physician cannot possibly be an expert in all areas of medicine. Yet, he or she is faced with these challenges regularly. By utilizing telemedicine consultative services, customized educational modules can be sent to address issues at hand, such as how to best handle issues like an outbreak of an infectious disease.

SECURITY

Security is increasingly becoming an integral component of telemedicine systems. Entire books are written on security and will not be addressed in detail

here. However, a few words are warranted. In the United States, HIPAA has created a stir in the medical community. Increased vigilance towards patient privacy is included in the regulations and that means increased security. This turns out to be just as much a perception issue as an actual one. As firewalls are erected and encryption is added using virtual private networks (VPNs), public/private keys and high-strength encryption algorithms, the perception is that it can still be intercepted and cracked.^[33] But, the benefits of electronic patient data and medical resources will outweigh these perceived and actual risks.^[34]

CONCLUSION

Telemedicine is a digital event that renders patient data into a simulacrum or hologram of the actual patient.^[35] The very name telemedicine feels increasingly anachronistic as we try to apply all the fabulous possibilities of informatics to the primitive videoconferences and telemetry, which initially defined telemedicine. Perhaps informatics will subsume telemedicine as a subheading. Certainly, the technology engineering, which makes telemedicine possible, is not the outcome of medical research. Telemedicine applications have called for great energy and creativity in medical science. However, the basic research in that of engineering, and it is rare that medicine is even the second or third application of basic discoveries. Medicine will continue to benefit from engineering technology that is informally applied vigorously to health issues by multidisciplinary research.

Tendons and Ligaments, Mechanical Testing Of

Richard E. Debski

Susan M. Moore

Eric J. Rainis

Musculoskeletal Research Center, Department of Bioengineering, University of Pittsburgh, Pittsburgh, Pennsylvania, U.S.A.

INTRODUCTION

The injury and subsequent repair of biological soft tissues of the human body continue to be significant problems in the fields of orthopedics and bioengineering. With the increased interest in athletic activities, severe soft-tissue injuries are becoming more prevalent in the general population.^[1] Such injuries can cause acute or even chronic instability in the diarthrodial joints of the musculoskeletal system. Given the increasing life span of humans, and the increase of incidence of injuries to soft tissues, prevention of their chronic instability is becoming more significant.

Tendons and ligaments are important structures that guide motion as well as provide stability in diarthrodial joints. Injury to these structures can lead to significant changes in joint motion and morbidity for patients. This article will focus on the biomechanics of tendons and ligaments: Section “Structural Framework” will review the structure and function of the tendons and ligaments, while section “Uniaxial Tensile Testing” will focus on uniaxial testing regimes to assess their properties. Finally, sections “Multiaxial Mechanical Testing” and “Viscoelasticity” will describe recent developments in testing techniques and their impact on computational modeling.

STRUCTURAL FRAMEWORK

Tendons

Tendons are bands of tough, inelastic fibrous tissue with closely packed, parallel collagen fiber bundles that connect bone to muscle and are composed mainly of water, type-I collagen, and cells called tenocytes. Tenocytes are specialized fibroblasts responsible for the maintenance of the collagen structure. Minor fibrillar collagens, fibril-associated collagens, and proteoglycans are present in small quantities and are critical for tendon structure. Most of the strength of tendon is because of the parallel, hierarchical arrangement of densely packed collagen fibrils.

The origin of a tendon is the region where it joins to a muscle and it inserts into bone at an enthesis, where the collagen fibers are mineralized and integrated into bone tissue. Tenocytes produce collagen molecules that aggregate end-to-end and side-to-side to produce collagen fibrils. Bundles of these fibrils are then organized by tenocytes to form collagen fibers—the primary load-bearing elements in the tissue. These fibers coalesce into macroaggregates, which are bounded by connective tissue endotendon and are termed “fascicles.” Finally, groups of fascicles are bounded by the epitendon and peritendon to form the tendon.

Ruptures and/or tears of tendons upset the balance between mobility and stability. These injuries often result in abnormal kinematics and damage to other tissues around the joint that may lead to morbidity, pain, and osteoarthritis. The incidence of tendon injury has increased over the last few decades, and it is estimated that they account for 30–50% of all injuries related to sports.^[2] Tendon injuries are typically a result of repetitive loading to the tendon, rather than traumatic loading, which is more characteristic of ligament injuries.

Ligaments

Ligaments are a sheet or band of tough, inelastic fibrous tissue with parallel collagen fiber bundles that connect bone to bone. Ligaments are composed of water and densely packed collagen fibers that run in the longitudinal direction, parallel to the axis of loading. Non-collagenous proteins such as elastin, a fibrillar protein (less than 1%), and proteoglycans are also present. The collagen fibrils in ligaments are arranged in such a way that an increase in tensile force results in the recruitment of more fibrils to help resist the increased load. This arrangement is known as a crimp pattern, which can be described as a series of springs with differing lengths in parallel (Fig. 1). The crimped nature of the fibrils serves as a guide to joint motion and provides restraint at extremes of joint motion. During normal activity, ligaments can be easily elongated to maintain normal kinematics and allow the joint to move easily and smoothly.

Fig. 1 Schematic of the crimped pattern of collagen fibers in a ligament.

With the application of higher loads, such as those found during exercise, the stiffness of the ligament increases to prevent any excessive motion in the joint. However, if the applied load exceeds the maximum limits of the ligament, as may occur during athletic events, ligament damage may occur.

Rupture or tears of ligaments can cause a joint to become unstable. These injuries often affect the kinematics of the joint and subsequently cause injury to surrounding tissues, leading to morbidity, pain, and osteoarthritis. Similar to tendon injuries, the incidence of ligament injury has also increased and is estimated to be 2 out of 1000 people in the general population per year, for the knee alone. These injuries primarily involve the medial collateral ligament (MCL) or the anterior cruciate ligament (ACL), accounting for as much as 90% of all sports-related ligament injuries.^[3]

UNIAXIAL TENSILE TESTING

What are Tensile Properties

Many researchers have examined the tensile properties of tendons and ligaments.^[4–20] The structural properties of a bone–ligament–bone complex are represented by parameters such as stiffness, ultimate load, and energy absorbed to failure that are obtained from the load–elongation curve (Fig. 2). Stiffness is simply the slope of the linear portion of the curve, ultimate load is the point at which the tissue fails, largest load achieved, and energy absorbed to failure is the area underneath the load–elongation curve from the onset of loading to the ultimate load.

Mechanical properties of a tendon and ligament substance are a measure of tissue quality and are

Fig. 2 Load–elongation curve depicting the three regions observed for tendons and ligaments: 1) toe region; 2) linear region; and 3) ultimate load.

represented by the tangent modulus, tensile strength, ultimate strain as well as the strain energy density, which are obtained from the stress–strain curve. Like stiffness, modulus is the slope of the linear portion of the curve. Ultimate stress is the maximum amount of stress achieved before failure, while ultimate strain is the strain in the tissue when ultimate stress is achieved. Finally, the strain energy density is the area under the stress–strain curve until failure.

A bone–ligament–bone complex allows for easy gripping of the bones thus minimizing any risk of slippage during testing. For this reason, it is convenient to test the mechanical properties of the tissue substance using a bone–ligament–bone complex. However, there are some instances when it is necessary to excise a tissue sample and clamp directly to the tissue substance making slippage a concern. As it is assumed that no slippage occurs during testing, one must take precautions to ensure a rigid fixation. In addition, a uniform loading distribution is assumed across the cross-section of the tissue. One method used to ensure this uniform load is to create a tissue sample with a large aspect ratio or length to width ratio. An aspect ratio of at least five is desired when performing such experiments. For an example of a typical tensile testing setup, see Fig. 3.

Testing Procedure for Structural Properties of a Bone–Ligament–Bone Complex

Structural properties can be obtained by performing a uniaxial tensile test, in which the load is measured

Fig. 3 (A) Close-up of bone–ligament–bone complex where strain markers have been placed on the tissue midsubstance and insertion sites and (B) view of experimental set-up for tensile testing.

simultaneously with the elongation. These properties depend on the geometry of the ligament in addition to the properties of the bony insertion sites. The load–elongation curve can be divided into three separate regions (Fig. 2). The first region, or toe region, has a low stiffness and is nonlinear. This behavior has been attributed to the crimp pattern of the collagen fibrils and to the nonuniform recruitment of the individual fibers. The next region is linear and has a higher stiffness, resulting from the fibers actually being stretched. The third region, or failure region, is initiated by the load at which the fibers can no longer withstand the force that is being applied to them. This point is known as the ultimate load. On additional loading, the bone–ligament–bone complex fails.

As stated previously, the stiffness is calculated using the slope of the linear portion of the load–elongation curve. However, owing to variability of the load–elongation curves between specimens, it is necessary to utilize a reproducible technique to calculate the stiffness for each specimen. One such technique is to define the stiffness as the slope of the load–elongation curve between two elongations that are within the linear region for all specimens. Another technique fits a line to the linear region of the curve and removes data points on either end until the R^2 value reaches 0.8.^[21,22] The ultimate load is defined as the maximum load achieved and the energy absorbed to failure is simply obtained by calculating the area under the curve, where the upper bound is the ultimate load. The ultimate

elongation is then represented by the elongation at failure.

Testing Procedure for Obtaining Mechanical Properties of the Tissue Midsubstance

Mechanical properties of a tissue midsubstance can also be obtained by performing a simple uniaxial tensile test. As stated above, the mechanical properties (or quality) of the midsubstance itself can be obtained by normalizing the tensile load by the cross-sectional area (stress) and by normalizing the change in elongation in a defined region of the ligament midsubstance by the initial length (strain).

A common approach to mechanical testing is to use dog-bone tissue samples instead of bone–ligament–bone complexes.^[21–23] A dog-bone sample provides a good aspect ratio and increases the chance of a midsubstance failure site, as well as ensuring a uniform load across the tissue (Fig. 5). As there is no bone present when testing a dog-bone sample, the ends of the tissue must be held rigidly by clamps. Therefore, precautions must be made to eliminate slipping of the tissue from the clamps, which is not a problem when using bone–ligament–bone complexes.

To determine the stress in the midsubstance, it is crucial that the cross-sectional area is obtained for the midsubstance. There are two types of techniques used to obtain the cross-sectional area of the tissue: contact

and noncontact.^[10,24,25] Contact methods include the use of molding techniques, digital vernier calipers, and area micrometers.^[17,26] These techniques introduce error, as they either assume a rectangular cross-section or force the tissue into a rectangular cross-section.^[14,27–29] To minimize these errors, there has been a recent push toward noncontact methods for obtaining the cross-sectional area. These techniques include the shadow amplitude method,^[30] the profile method,^[10] and the use of a light source.^[31] Another technique that is utilized is a laser micrometer system.^[32,33] This method has been shown to be highly accurate and reproducible, and the reconstructed shapes match histologic sections quite well. A new laser-reflectance system has also been developed to measure cross-sectional shape and area of soft tissues with a concave surface.^[34]

Several methods also exist to measure the strain in the midsubstance of the tissue. Again there are contact^[35,36] and noncontact^[5,37,38] methods that can be used. An example of a contact method is a differential voltage reluctance transducer. This device can be used to calculate the strain by suturing two metal probes on the surface of the tissue, and based on the distance those probes move, strain can be calculated.^[35,36] Because contact methods may alter the properties of the tissue owing to deformation, there has been a large push toward noncontact methods. More specifically, optical tracking is being used, because it requires no direct contact with the specimen. When using optical tracking, two or more markers are drawn or fixed to the surface of the tissue by means of Verhoeff's stain,^[5] elastin stain,^[37] or reflective tape^[38] to serve as gauge lengths. Camera systems are used to record marker motion, and the distance between the markers can be expressed as a function of the gauge length, corresponding to the strain in the tissue.^[4,39–41] As stated above, the tangent modulus of the tissue is calculated using the slope of the stress–strain curve. This can be performed using the same methods described in section “Testing Procedure for Obtaining Mechanical Properties of the Tissue Midsubstance” to calculate stiffness. To calculate ultimate strain and tensile strength, the strain and stress at the point just before failure is used, respectively.

Factors Affecting Tendon and Ligament Properties

There are several factors that affect the tensile properties of tendons and ligaments including hydration, temperature, strain rate, age, and orientation. The *in vitro* environment has profound effects on ligament behavior. Maintenance of specimen hydration is of primary importance to the study of soft tissues.

Temperature has also been shown to be important,^[13] although to a lesser degree. Increases in temperature from 2°C to 37°C resulted in a decrease in stiffness and a decrease in areas of hysteresis. These factors have led many investigators to immerse their specimens in a physiologic saline bath in which the pH and temperature are closely regulated.^[6,12,22,42,43]

The tensile properties of ligament are only affected minimally by strain rate. Two groups (3.5 mo old and 8.5 mo old) were used in a study of the rabbit femur–MCL–tibia complex (FMTC), with elongation rates of 0.01%/sec to over 200%/sec, corresponding to 0.008 and 113 mm/sec. For the young group, the structural properties of the FMTC and the mechanical properties of the MCL substance in the prefailure range were found to increase by approximately 300%, which was minimal considering that the strain rate had been increased by several decades. The older group followed similar trends, but the increases were even smaller. Regardless of the strain rate, however, the entire younger group failed by tibial avulsion, while the older group failed by ligamentous disruption either at midsubstance or near the tibial insertion.^[44] Although clinical injuries occur at much faster strain rates, much experimental work is performed at slow rates, based on the limitations of the testing equipment. These findings^[44] imply that age of the animals, rather than strain rate, is a much more important factor when performing such tests.

Age has been shown to have varying effects on ligaments and tendons. The significance of aging has been investigated in the rabbit MCL at 3, 5, 6, 12, 36, and 48 months of age. The tensile properties of the MCL remained relatively constant up to 12 months, with a slight decline at 48 months. The structural properties of the ACL from young donors (ages 22–35 yr) were also found to be significantly higher than those of older donors. The stiffness and ultimate load are also higher in the younger donors, by more than threefold.^[14] Age has similarly been shown to have an effect on the properties of the glenohumeral capsule.^[20] On the other hand, no significant differences were found between two different age groups (29–50 yr and 64–93 yr) of the human patellar tendon when comparing ultimate strength. The ultimate strengths for the younger and older group were 64.7 ± 15 and 53.6 ± 10 MPa, respectively.^[45]

Because bone–ligament–bone complexes are non-uniform in geometry and shape, the direction of applied force and the initial position of the ligament are important for its load–elongation behavior. Applying the force in the direction of anatomical loading allows a greater proportion of the fiber bundles to be loaded. In a study on young human femur–ACL–tibia complexes (FATC), paired specimens were studied with one knee being tested along the anatomic axis of the

Fig. 4 Collagen fiber of the long head of the biceps tendon (A) aligned along the longitudinal axis of the tendon and axillary pouch of the glenohumeral capsule (B). White dashes indicate average local alignment of the fibers while the gray scale indicates the variability of the fiber alignment in that location.

ACL and the other along the tibial axis.^[33] In the anatomic orientation, the natural insertion angles of the ACL were maintained, allowing for a uniform load distribution across the ligament, whereas for the tibial orientation, the insertion angles were not maintained, resulting in a nonuniform load and thus a higher number of insertion site failures. The stiffness and strength for the FATC's tested in the anatomic orientation were significantly greater than those in the tibial orientation. Similar results have been observed for the FATC of the porcine, canine, and rabbit models.^[13,46]

A more recent study^[47] has analyzed the effects of multiple freeze–thaw cycles on the tensile properties of the rabbit MCL, an issue originally examined by Woo et al.^[5] The results showed that careful postmortem freezing for up to three months did not significantly alter the structural properties of the bone–ligament–bone complex and the mechanical properties of the ligament midsubstance. This finding is very important as many biomechanical tests of soft tissues are generally done after a period of postmortem storage by freezing.

MULTIAXIAL MECHANICAL TESTING

Ligament and Tendon Anisotropy

The mechanical response of an isotropic material is independent of the direction of loading. However, ligaments and tendons have demonstrated anisotropic behavior. Thus, their mechanical response is dependent upon the direction of loading. A special case of anisotropy is transverse isotropy, indicating an axis of material symmetry exists, which causes the mechanical response to be independent of the loading direction in

the plane transverse to this axis (i.e., isotropic in the plane transverse to the axis of material symmetry).

Tendons and ligaments are considered transversely isotropic materials. This is owing to the fact that traditional ligaments (i.e., ligaments that primarily experience uniaxial loading) and tendons such as the MCL of the knee and the long head of the biceps tendon have a preferred collagen fiber alignment^[38,43,48] resulting in an axis of material symmetry. The preferred alignment for such ligaments and tendons is along their longitudinal axis such that loads are transmitted between bones or between bone and muscle along their length. More recently, it has been shown that the capsular tissues such as the glenohumeral joint capsule may not necessarily have a distinct preferred collagen fiber alignment.^[49] Using the small angle light scattering technique,^[50] Debski et al.^[49] determined the local average collagen fiber direction of the long head of the biceps tendon and

Fig. 5 View of the posterior capsule illustrating the orientation of the dog-bone-shaped (midsubstance 12.5 mm × 2.5 mm) transverse and longitudinal tissue samples with respect to the posterior band (PB-IGHL).

Table 1 The mechanical properties for transverse axillary pouch and longitudinal axillary pouch tissue samples (mean \pm SD)

	Modulus (MPa)	Ultimate stress (MPa)	Ultimate strain (%)	Strain energy density (MPa)
Transverse ($n = 10$)	5.4 ± 2.9^a	0.8 ± 0.4^a	23.5 ± 11.5	10.8 ± 8.5
Longitudinal ($n = 10$)	14.8 ± 13.1	2.0 ± 1.0	33.3 ± 23.6	21.1 ± 15.4

^aSignificant differences ($p < 0.05$) in modulus and ultimate stress were detected. Transverse and longitudinal refers to those tissue samples taken perpendicular and parallel to the longitudinal axis of the tissue, respectively.

that of the axillary pouch of the glenohumeral capsule (Fig. 4). For the long head of the biceps tendon and the axillary pouch, the percentage of the tissue where 50% of the fibers were oriented within 25° – 45° of their local average direction was $61.6 \pm 15.2\%$ and $23.2 \pm 8.5\%$, respectively. Although the axillary pouch did not demonstrate a clear axis of material symmetry, it is important to note that the behavior of this tissue is still anisotropic as demonstrated in a recent study of its bidirectional mechanical properties.^[22] Differences in the ultimate stress and tangent modulus were detected between tissue samples tested in two perpendicular directions (Table 1).

As ligaments and tendons are anisotropic materials, constitutive models that mathematically describe their behavior under loading conditions are much more complex than the simple constitutive model of an isotropic elastic material (i.e., $\sigma = E\epsilon$). Many researchers have successfully used transverse isotropy to describe the behavior of tendons and ligaments.^[11,51–60] The physical interpretation for transversely isotropic symmetry is that of a matrix reinforced with a single fiber family whereby the matrix properties, fiber–matrix interaction, and fiber–fiber interactions give rise to the material behavior.^[58] Therefore, it has recently been advocated that to sufficiently characterize the three-dimensional material behavior of tendons and ligaments, it is necessary to collect experimental data on the multiaxial quasistatic and viscoelastic properties of these tissues.^[58] It should be noted that multiaxial testing has also been commonly performed on other soft tissues such as heart and vascular tissues.^[61–64]

Multiaxial Testing

Bidirectional mechanical testing

The simplest form of multiaxial testing is determining the bidirectional properties of soft tissues whereby the properties are determined in two perpendicular directions via simple uniaxial tensile tests. The two directions of interest are the axis of symmetry (i.e., axis collagen fibers are aligned along) and the direction perpendicular to this axis. These two perpendicular directions are of interest, as results from these

experiments, along with knowledge of the collagen fiber arrangement, can then be used to justify describing the tissue as transversely isotropic.

Testing Procedure. As tendons and ligaments do not insert into bone or muscle in the direction perpendicular to their longitudinal axes, it is necessary to harvest tissue samples from the ligament such that clamps can be used to grip the tissue itself. To maintain a good aspect ratio, dog-bone-shaped tissue samples are therefore harvested from the midsubstance of the tissue (Fig. 5).^[21–23] Thus, only the mechanical properties of the ligament substance, and not the structural properties of the bone–ligament–bone complex, can be determined with this testing configuration. As was discussed previously (see section “Testing Procedure for Structural Properties of a Bone–Ligament–Bone Complex”), one assumption for a uniaxial test is that the tissue sample is uniformly loaded. Thus, it is necessary to maintain an aspect ratio of at least five. The mechanical properties of the tissue can be determined in the two perpendicular directions once the cross-sectional area and strain are determined (see section “Testing Procedure for Obtaining Mechanical Properties of the Tissue Midsubstance”). Statistical differences between the two perpendicular directions demonstrate that the tissue is anisotropic.

One limitation to this testing methodology is that the interfiber and transfiber bonds between the collagen fibers may have been broken when the tissue samples were excised from the midsubstance. Moreover, while the dog-bone-shaped tissue sample makes it possible to uniformly load ligaments or tendons with complex geometry, it is important to understand whether or not the tissue is hetero- or homogeneous, as the location that the tissue sample is harvested from may affect the resulting properties. An additional limitation is that this methodology does not evaluate the tissue’s response to shear loading. Understanding the response of tendons and ligaments to shear and incorporating this response into constitutive models may be necessary depending on the functional role of the tissue and the loading conditions to be modeled.

Recent Studies. Bidirectional mechanical tests have recently been performed on the MCL of the knee^[23]

and on the axillary pouch^[21] and posterior regions^[22] of the glenohumeral joint capsule. For the MCL, the ability of three different constitutive models to describe its behavior was evaluated. Thus, dog-bone-shaped tissue samples were harvested in the directions parallel and perpendicular to the longitudinal axis of the MCL. A load to failure test was performed on each of the tissue samples, and a nonlinear regression was performed to determine the material coefficients for three different constitutive models.^[16,65] All three models were able to describe the behavior of the MCL along its longitudinal axis; however, only one of the three models provided a good description of the MCL's behavior in the direction perpendicular to the longitudinal axis. These comparisons are extremely valuable, as finite element models are being increasingly used to describe the stress and strain distributions of soft tissues under clinically relevant loading conditions.^[59,66–68]

Within our research center, bidirectional mechanical tests have also been used for the glenohumeral joint capsule.^[21,22] In these studies, dog-bone-shaped tissue samples were harvested from the axillary pouch and posterior region in the directions parallel and perpendicular to the longitudinal axes of the thickenings of the glenohumeral joint capsule. A load to failure test was performed; the ultimate stress and strain, tangent modulus, and strain energy density were determined in the two perpendicular directions. Unlike traditional ligaments such as the MCL, the differences in the mechanical properties of the two perpendicular directions were not as apparent. Results for the axillary pouch, MCL of the knee, and other ligaments are shown in Table 2.^[22] While a significant difference in the ultimate stress and tangent modulus was found, no differences were detected in the ultimate strain and

strain energy density. The ratio of the tangent moduli (axillary pouch, 3.3 ± 2.8 ; posterior capsule, 4.8 ± 4.2) was an order of magnitude less than the ratio for the MCL^[30] of the knee,^[23] a ligament that has been successfully modeled as transversely isotropic.^[57–59,71] While it is clear that the glenohumeral joint capsule is anisotropic, before utilizing a transversely isotropic constitutive model to describe the behavior of the glenohumeral joint capsule, the use of this model should be validated using a more complex multiaxial testing scheme that includes shear loading.

Shear loading

A more complex multiaxial testing scheme that includes shear loading may be necessary to appropriately evaluate the ability of various constitutive models to describe the behavior of some tendons and ligaments such as the glenohumeral joint capsule. Additionally, evaluating the response of tendons and ligaments to shear loading will allow further elucidation into the functional role these soft tissues play in joint mobility and stability, respectively.

Testing Procedure. Recently, Weiss, Gardiner, and Bonifasi-Lista^[58] have described a testing procedure for ligaments that utilizes shear loading to determine the coefficients of a constitutive model. Rectangular-shaped tissue samples are harvested such that the preferred direction of collagen fiber organization is parallel to one axis of the rectangle. The initial width, height, and thickness of the tissue sample are then recorded. Using a materials testing device, the tissue sample is first preconditioned via a sawtooth displacement profile applied for 10 cycles. The shear

Table 2 Summary of data reported for the axillary pouch, MCL of the knee, interosseous ligament of the forearm, hip capsule, and the cruciate ligaments of the knee

Tissue type	Tangent modulus (MPa)	Ratio of tangent modulus	Ultimate stress (MPa)	Ultimate Strain (%)
Transverse axillary pouch ^[22]	5.4 ± 2.9	3.3 ± 2.8	0.8 ± 0.4	23.5 ± 11.5
Longitudinal axillary pouch ^[22]	14.8 ± 13.1		2.0 ± 1.0	33.3 ± 23.6
Transverse medial collateral ligament	11.0 ± 3.6	30	1.7 ± 0.5	11.7 ± 0.9
Longitudinal medial collateral ligament (knee) ^[23]	332.2 ± 58.3		38.6 ± 4.8	17.1 ± 1.5
Transverse interosseous ligament	1.1 ± 1.6	385	0.1 ± 0.1	N/A
Longitudinal interosseous ligament (forearm) ^[69]	431.3 ± 321.3		52.7 ± 33.5	
Anterior longitudinal axillary pouch ^[9]	30.3 ± 10.6	N/A	5.5 ± 2.0	15.1 ± 5.7
Posterior longitudinal axillary pouch ^[9]	41.9 ± 12.5		5.6 ± 1.9	9.9 ± 5.3
Longitudinal hip capsule ^[70]	Range 76–286	N/A	Range 2.0–6.0	Range 6.2–25.3
Average of anterior and posterior cruciate ligament and lateral collateral ligament ^[8]	345 ± 22	N/A	36 ± 3	15 ± 1

strain rate used for the MCL was 1.3%/sec with a strain amplitude of $\tan(\theta) = 0.4$ based on the measured width of each tissue sample (Fig. 6). Data from the 10th cycle can then be used when determining the parameters of constitutive models.^[57] The clamp reaction force and the crosshead displacement of the materials testing device are continuously recorded during testing. The applied shear strain can then be computed using the tissue samples initial dimensions and crosshead displacement measurements.

Owing to the inhomogeneous deformation during shear loading, a parameter estimation technique^[58] can then be used in conjunction with the finite element method to estimate the parameters for the specified constitutive model. Using this combined approach, the experimental shear loading is simulated using the finite element method, and the parameters of the specified constitutive model are iteratively adjusted until the force–displacement behavior of the finite element predictions match that of the experimentally collected data.

The methodology described above requires that the tissue samples harvested are planar with a relatively uniform thickness and fiber orientation. For many tendons and ligaments, this sort of geometry does not exist. Moreover, this method is dependent upon the optimization algorithm implemented for the parameter estimation. Therefore, it is important to validate the estimated parameters by using them to predict the results of an additional loading condition.

Recent Studies. A combined experimental and computational approach has been used to determine the

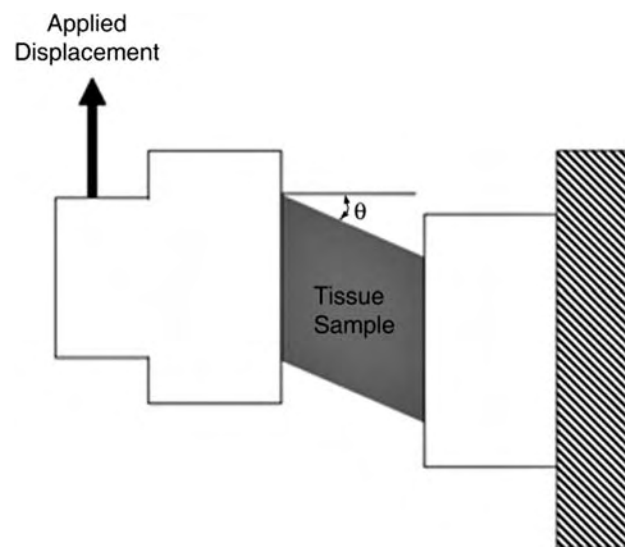

Fig. 6 Schematic illustrating θ , which is determined from the initial clamp-to-clamp length of the tissue sample and the applied displacement.

parameters for a transversely isotropic hyperelastic constitutive model^[58] of the MCL of the knee [Eq. (1)].^[57]

$$W = F_1(\tilde{I}_1, \tilde{I}_2) + F_2(\tilde{\lambda}) + U(J) \quad (1)$$

The functions F_1 and F_2 represent the matrix and fiber family strain energies, respectively and compose the entire deviatoric response of the material. An exponential matrix strain energy was utilized based on preliminary data. \tilde{I}_1 and \tilde{I}_2 are the deviatoric invariants of the right deformation tensor, and $\tilde{\lambda}$ is the deviatoric local fiber stretch. $U(J)$ governs the dilational response of the material.

Using the shear testing protocol described above, experimental force–displacement curves were obtained. The finite element method was then utilized to simulate the experiments. Subsequently, a nonlinear parameter estimation technique coupled with the finite element simulations optimized the parameters of the constitutive model based on the sum of squares difference of the force–displacement curves from the experimental data and finite element model. The nonlinear optimization program was successfully able to minimize the difference between the experimental and finite element force–displacement data for all of the tissue samples tested with R^2 values that were greater than 0.995 in all cases. Therefore, this combined experimental and computational approach was a good method by which the parameters of constitutive models can be determined. Additionally, no sensitivity to changes in the starting values for the constitutive model parameters was detected indicating that an exponential matrix strain energy was appropriate for the human MCL of the knee.

VISCOELASTICITY

Experimental Models

Viscoelastic materials such as tendons and ligaments^[72] are those that have viscous as well as elastic properties. Thus, both time- and history-dependent properties such as hysteresis, creep, and stress relaxation are displayed. This behavior is because of the interactions between their constituents (e.g., proteins, ground substance, and water). A material displays hysteresis when the loading and unloading curves do not follow the same path owing to internal energy dissipation. Creep is also displayed by tendons and ligaments as they elongate over time under a constant load. Finally, stress relaxation is displayed, with a decline in stress observed over time under a constant elongation. Physically, viscoelastic properties play an important role in tendon and ligament function by allowing

relaxation to occur during walking or jogging or by helping to prevent fatigue failure. Therefore, understanding the viscoelastic response of tendons and ligaments has important clinical significance. For example, to select the best graft material to replace a ruptured ligament, such as the ACL of the knee, it is important to select a material that has the same functional range as the ligament being replaced.

Testing procedure

Experimentally, these viscoelastic properties are evaluated using several standard methodologies that apply either a tensile^[15,19,42,45,73,74] or shear load.^[58] Tissue samples are prepared, preconditioned, and the force, stress, strain, and cross-sectional area are determined as was described previously in sections “Testing Procedure for Obtaining Mechanical Properties of the Tissue Midsubstance” and “Factors Affecting Tendon and Ligament Properties,” respectively. However, the loading conditions used to determine the viscoelastic properties differ from those used to determine the failure properties of the tissue samples (i.e., ultimate stress, ultimate strain, and strain energy density).

Hysteresis is evaluated by loading and then unloading the tissue sample. The area of hysteresis is obtained by subtracting the area under the curve obtained during the unloading of the tissue sample from the area under the curve obtained during the loading of the tissue sample. As an example of an experimental protocol used to test the rabbit MCL, one study subjected the tissue samples to 10 cycles of loading and unloading between 0 and 1.0 mm of extension at 1.0 cm/min.^[15] Using this experimental design, the decrease in the amount of hysteresis between the first and tenth cycle could then be compared.

Creep can be evaluated with either a static load or by cyclically loading the tissue sample. For example, a study investigating creep of the rabbit MCL^[75] applied a 14 MPa stress to the tissue samples and held the resulting load constant for 20 min to evaluate static creep. For cyclic creep, the tissue samples were cycled 30 times at 1 Hz between the tare stress and 14 MPa of stress. The amount of creep is obtained by subtracting the elongation achieved when the load is initially applied from the elongation that results after holding the tissue sample at that constant load for the specified time. Using this experimental protocol, the ligament length increased by approximately 10%.

As with creep, the amount of stress relaxation can be determined during either a static elongation or while cycling between two levels of elongation. For example, the static stress relaxation of the human patellar tendon in the toe and linear regions has been

investigated.^[45] The tendon was stretched at 100 mm/min to a stress level of 1 MPa and 4 MPa, respectively, and held at the resulting elongation for 15 min. A 30-min recovery period was allowed between tests. For cyclic stress relaxation, the tissue samples were cyclically extended between the two elongations for 15 cycles at a rate of three cycles per minute. Using this experimental protocol, a decrease in stress of approximately 50% was observed.

The elongations or loads used during tests for hysteresis, creep, and stress relaxation are all selected such that the tissue samples do not approach failure. Thus, the magnitude of the elongations and loads used to determine viscoelastic properties must first be determined from preliminary load-to-failure data.

Computational Modeling

Quasilinear viscoelastic theory

Quasilinear Viscoelastic (QLV) theory was developed by Dr. Y. C. Fung.^[76] The QLV model has been widely used to describe the viscoelastic properties of tendons^[77,78] and ligaments^[79–82] as well as many other soft tissues. The theory makes the assumption that the elastic and time-dependent relaxation functions can be combined in a convolution integral. This results in a one-dimensional general viscoelastic model as shown in Eq. (2).

$$\sigma(t) = \int_{-\infty}^t G(t - \tau) \frac{\partial \sigma^e(\varepsilon)}{\partial \varepsilon} \frac{\partial \varepsilon}{\partial \tau} d\tau \quad (2)$$

Using experimentally collected data, the coefficients of the QLV constitutive model can be derived. With the tissue-specific coefficients, the tendon or ligament behavior under other loading conditions can be predicted.

Recent advances

Recently, three issues regarding the QLV theory have been of interest:^[74,75,81,83,84] 1) application of parameters obtained during stress relaxation experiments to the prediction of creep behavior; 2) the assumption that the relaxation function is only dependent upon time and not strain level; and 3) the assumption that a step change in strain is applied, which is not possible experimentally.

To address the first issue, Thornton et al.^[75] obtained the parameters for the QLV theory using stress relaxation and creep experiments at low stresses for the rabbit MCL. These parameters obtained for both types of experiments predicted different behaviors. Dr. Y. C. Fung also noted that this may occur when using the

QLV theory as it is applied to certain tissues and has stated that he believes that creep is fundamentally more nonlinear, and may in fact not obey the quasi-linear hypothesis.^[76]

For the rat MCL, the rate of creep has been shown to be dependent upon stress level and that the rate of relaxation is dependent upon strain level.^[74] However, this is not admitted in QLV theory. Therefore, at least for the rat MCL model, QLV may not be appropriate when predicting the viscoelastic response over several strain levels. Instead, it has been suggested that the modified superposition method^[85] be utilized. Moreover, to account for this limitation, an analytical expression capable of determining the QLV parameters under an incremental strain history has been developed.^[84] Thus, an incremental strain history can be applied to tissue samples experimentally and the amount of stress relaxation across several strain levels can be utilized to determine a representative amount of relaxation.

Finally, the time-dependent stress relaxation of a tissue is normalized by the stress at the time of a step input of strain in the QLV theory. However, experimentally this is impossible and results in error when determining the coefficients. An improved method to analyze the stress relaxation of tissues following a finite ramp time based on the QLV theory has recently been published.^[81] With this method, the convoluted QLV constitutive equation was simultaneously curve-fit to the ramping and relaxation portions of the data. As both the ramping and the relaxation portions are considered, an instantaneous ramp time is no longer necessary. While this has been evaluated previously,^[86,87] the advantage of this new study is that extremely long ramping times are now possible. Therefore, this adaptation to the traditional QLV theory allows for a great deal of experimental flexibility.

CONCLUSIONS

This article has presented a broad review of the history of mechanical testing of tendons and ligaments, as well as more recent research. Expertise in evaluating the biomechanical properties in tendons and ligaments has been continually evolving with advances in technology. These advances include noncontact strain and cross-sectional area measurements of tissue samples. In addition to assessing the biomechanical properties of tendons and ligaments using traditional uniaxial experiments, there has been a recent interest in performing multiaxial experiments to gain a greater understanding of the function of tendons and ligaments. These experiments can provide a wealth of knowledge regarding the anisotropic nature of tendons

and ligaments and are extremely useful when establishing the parameters of constitutive models. The QLV theory has also been applied to the study of tendons and ligaments. While this theory is an extremely powerful analytical tool, it is important for researchers to understand the limitations and assumptions of such a model to ensure that their application is appropriate.

Subject-specific modeling of diarthrodial joints and their surrounding tissues has been gaining popularity. Thus, evaluating the biomechanical properties of tissue samples under uniaxial or multiaxial loading conditions on a subject-specific basis may be necessary for these models to adequately predict the tensile, shear, and/or viscoelastic response of these tissues. Furthermore, there exists a need to assess the ability of various constitutive models to predict the response of tendons and ligaments to applied loads or displacements. This demonstrates the importance of using multiaxial mechanical tests in conjunction with computational methods as a means for establishing the parameters of constitutive models.

T

INTRODUCTION

Blood coagulation is initiated by the disturbance of the hemostatic balance following injury, inflammation, endothelial dysfunction, or contact with an artificial surface and involves significant interplay between activation of the enzymatic and cellular processes, adhesion of blood cells, their aggregation, and hemodynamics. Clotting on the inner wall of blood vessels is the major cause of cardiovascular diseases such as myocardial infarction, stroke, and deep vein thrombosis. The formation of homotypic and heterotypic aggregates of activated platelets and neutrophils and their adhesion through selectins, GPIb, and integrin-mediated pathways enhances thrombin generation and subsequent fibrinogen polymerization under coagulating flow conditions. At the same time, cell adhesion and aggregation, typically requiring cell activation, are also influenced by proteins of the blood coagulation cascade.

In addition to platelets, leukocytes and erythrocytes have roles to perform in thrombosis; how they interact with platelets under coagulating flow conditions to stimulate and enhance thrombotic processes has been less well understood. This article seeks to highlight how individual platelets and neutrophils, neutrophil-platelet interactions, and interactions of erythrocytes with these cells activate and promote thrombosis following contact of blood with a defined surface. We intend to provide a fundamental review relevant to biomaterial thrombosis and inflammation-coagulation crosstalk.

COAGULATION BIOLOGY

The Reaction Cascade

Distinct from biomaterial thrombosis, the tissue factor pathway of the coagulation cascade is activated as blood comes in contact with tissue factor following vessel-wall injury. Upon contact with blood, tissue factor forms a complex with endogenous factor VIIa that catalyzes the activation of factor X to Xa. After Xa is formed, it binds factor Va released from platelet

stores. The prothrombinase complex (XaVa) on platelets activates prothrombin to thrombin, which cleaves fibrinogen to fibrin monomer. Fibrin monomer polymerizes to form fibrin polymer, which is cross-linked by thrombin-activated factor XIIIa.

The coagulation cascade can also be triggered on the contact of blood with the subendothelium tissues or an artificial surface. This pathway, known as the contact (or intrinsic) pathway of coagulation, involves formation of factor Xa from a series of reactions initiated by factor XII activation on artificial surfaces. Once formed, factor XIIa can activate prekallikrein to kallikrein to amplify factor XIIa formation. Factor XIIa then activates factor XI to XIa, which, in turn, activates factor IX to IXa. Activated platelets participate in the assembly of the intrinsic tenase (IXa/VIIIa) and prothrombinase (Xa/Va) complexes by providing anionic phospholipid binding sites for coagulation proteins. Following an initial production of minuscule amounts of thrombin through the tissue factor pathway, factor XI may be activated to XIa on activated platelets by thrombin to trigger the intrinsic pathway in the absence of the upstream contact pathway proteins, factor XII, prekallikrein, and high molecular weight kininogen.^[1] To amplify coagulation, thrombin can activate factor V and factor VIII (to Va and VIIIa), and factor Xa can activate factor VII and factor V (to VIIa and Va). By releasing factor V, which may even be partially active,^[2] activated platelets contribute to prothrombinase complex formation for an amplified production of thrombin.

While considerable interplay exists between extrinsic and intrinsic pathways (e.g. TF: VIIa activation of factor IX) and the two pathways are not independent, the concept of TF-dependent and non-TF-dependent initiation of factor Xa production remains an important distinction. Formation of factor Xa is generally viewed as the rate-controlling step in thrombin production.

Platelet Function

Platelet activation, adhesion, and aggregation play a major role in coagulation events. Platelets can be

activated by pathological high shear flow ($>3000\text{ s}^{-1}$) or by agonists (e.g., adenosine diphosphate (ADP), thrombin, thromboxane, collagen) released or produced as a result of coagulation reactions or exposed to the blood. The full activation of the platelets involves shape change and release of ADP, as well as activation of glycoprotein IIb/IIIa receptors. The aggregation of platelets is mediated through fibrinogen crossbridging of GPIIb/IIIa and von Willebrand Factor (vWF) interactions with GPIb α -IX-V (i.e., GPIb) and GPIIb/IIIa. Once adherent, platelets can recruit other platelets from flowing blood through fibrinogen crossbridging of GPIIb/IIIa and vWF interactions with GP IbIX and GP IIb/IIIa. Fibrinogen binds to GPIIb/IIIa in a specific, saturable manner via the dodecapeptide sequence $\gamma_{400-411}$ on the D domain of fibrinogen. Upon platelet activation, GPIIb/IIIa receptors undergo conformational changes to become competent receptors for soluble fibrinogen and plasma proteins such as vWF. Fibrinogen binds to GP IIb/IIIa receptors (about 50,000 binding sites/platelet) with a dissociation constant (K_d) $\sim 0.1\ \mu\text{M}$.

The platelet GP IIb/IIIa-fibrinogen interaction is not fully understood and important questions remain concerning the interaction of resting platelets with surface-immobilized fibrinogen. Resting platelets do not appear to bind to adsorbed fibrinogen during short-lived ($<50\text{ m sec}$) collisions with fibrinogen-coated beads in a shear flow.^[3] However, in whole-blood flow over fibrinogen-coated surfaces, the fibrinogen may be sufficient to capture free-flowing, resting platelets at low shear rates via the $\gamma_{400-411}$ but not Arg-Gly-Asp (RGD) sequences in the carboxy terminus of the α -chain of fibrinogen. These differences may be due to: 1) more favorable cell adhesion mechanics due to wall-directed red blood cell (RBC) particle forces; 2) low-level activation near the wall from RBC-released ADP; 3) differences in contact-area development and force mechanics of doublet formation in suspension flow versus cell-wall interactions; 4) surface-mediated accumulation over several minutes of ~ 0.1 to 1% of activated platelets in drawn anticoagulated blood; and/or 5) surface-dependent conformational changes of adsorbed fibrinogen. Does GPIIb/IIIa-dependent platelet capture to a growing thrombus require platelet activation? This is a fundamental issue in the dynamics of thrombus growth. The measurement of probabilities of capture, firm arrest, and detachment as a function of interaction time often requires high temporal resolution exceeding that of standard video microscopy. Given the potential for multivalent interaction of polymeric vWF to bind GPIb on resting platelets by accumulating monovalent interactions of micromolar affinity, it also remains unexplained why vWF does not aggregate resting platelets under normal flow. Enhancement of vWF

function at various shear rates might be a result of alteration in soluble vWF structure or aggregation state; the GPIb avidity state; and/or the collisional mechanics of doublet formation, a hydrodynamic threshold effect, as in Finger et al.^[4] and Lawrence et al.^[5] Doggett et al. observed that a critical amount of flow above 70 s^{-1} is needed for platelet GPIb binding to recombinant vWF-A1 domain.^[6]

Neutrophil Function

The neutrophils may participate in coagulation by various potential mechanisms. While neutrophils may promote blood coagulation by the deencryption of cell-surface tissue factor^[7] or the transfer of tissue factor to platelets through microparticles,^[8] they may also release proteases that activate platelets^[9] or bind factor X via Mac-1 (CD11b/CD18).^[10] Neutrophil elastase may take an active role in the deencryption of tissue factor in the plasma by cleaving tissue-factor pathway inhibitor (TFPI),^[11] and this deencrypted tissue factor may become associated on the surface of platelets^[12] to promote fibrin formation.

In the baboon femoral arteriovenous shunt Dacron graft model,^[13] monoclonal antibody GA6 against P-selectin reduced indium-labeled leukocyte accumulation by 60% over a 2 hr time frame. GA6 Fab2' fragment reduced leukocyte accumulation by 80% over 2 hr. Anti-P-selectin had no effect on platelet accumulation in the Dacron graft, but dramatically reduced fibrin accumulation by 70%. A marked reduction of fibrin deposition by anti-P-selectin was seen as early as 5 minutes after the initiation of flow. The authors indicated that monocyte and leukocyte expression of tissue factor might be the cause of this increased fibrin deposition. This explanation does not explain the dramatic reduction of fibrin accumulation by anti-P-selectin compared to control at 5 minutes, because expression of tissue factor requires gene activation, transcription, synthesis, and display—a sequence of events that results in elevated tissue factor on monocytes only after 20 minutes. Neutrophils may elevate the production of thrombin at the site of the clot via cross-sectional effects for enhanced platelet capture, tissue factor expression, Mac-1 binding of factor X, the release of proteases such as elastase and cathepsin G, or the display of anionic phospholipid for coagulation pathway assembly. The relative roles of these potential pathways are not fully understood at various flow conditions.

Neutrophil homotypic interactions

Neutrophils present L-selectin on the tips of the microvilli. ICAM-3 and L-selectin are present on

resting neutrophils in a competent state for binding. Both L-selectin and ICAM-3 are shed rapidly following neutrophil activation. Upon activation, only about 10% of displayed Mac-1 and LFA-1 is active. LFA-1 (CD11a/CD18) binding to ICAM-3, as well as Mac-1 (CD11b/CD18) binding to an unknown receptor, can facilitate integrin-mediated homoaggregation at low shear rates between 100 and 400 s⁻¹. Above 100 s⁻¹, L-selectin plays an important role in fMLP-stimulated neutrophil homoaggregation. The collision efficiency increases with shear rate to a maximum of $\epsilon=0.4$ at 400 s⁻¹ and then declines to $\epsilon=0.15$ at 3000 s⁻¹.^[14] This is consistent with observations of CD62P,E,L-mediated rolling displaying a maximum with shear stress, likely due to shear or stress-mediated delivery of microvilli to the rolling contact area^[5] or cellular deformation at high flow. Direct imaging of the neutrophil rolling contact area has been achieved^[15] to indicate the role of neutrophil membrane deformation and membrane tether formation in regulating adhesion to P-selectin. Similarly, increases in neutrophil membrane rigidity can affect P-selectin-PSGL-1 bond cluster lifetime due to reduction in microvilli extension.^[16]

Platelet–neutrophil heterotypic interactions

Recently, the laboratory of Yale Nemerson demonstrated that an inhibitor of tissue factor can greatly reduce blood clotting on purified collagen surfaces lacking tissue factor.^[7] This data strongly supports the role of blood-borne tissue factor that is potentially in a cryptic state on neutrophils but is exposed upon activation. Other non-tissue factor mechanisms of neutrophil activation of blood clotting have been described but not prioritized quantitatively. Apoptotic neutrophils or activated neutrophils can display anionic phospholipids, detectable by annexin V binding, which may serve as a cofactor in coagulation factor assembly. Due to the massive size of the neutrophil surface, a few activated neutrophils may be potent catalytic participants in platelet accumulation.^[17]

Elastase is known to cause exposure of GPIIb/IIIa on platelets by surface proteolysis.^[18] Similarly, cathepsin G can activate platelets. Yamamoto also noted the prothrombotic tendency of leukocytes in coagulation assays that was antagonized by the neutrophil protease inhibitor, eglin C.^[19] They noted that the procoagulant tendency of activated leukocytes outweighed antiplatelet effects due to NO production or arachidonic acid metabolite exchange with platelets. Neutrophil cathepsin G can also activate factor X bound to Mac-1.^[10] The competition and kinetic efficacy of factor X, fibrinogen, and fibrin-binding Mac-1, as well as the prevailing levels of cathepsin

G or elastase under flow conditions, remain largely unquantified from a kinetic point of view.

Coagulation and fibrin deposition under flow

De Groot et al.^[20] used a calibrated staining assay to measure deposition of peroxidase-labeled fibrin on endothelial cell matrix (containing tissue factor) from heparinized whole blood. They found that fibrinopeptide A generation was not a function of shear rate at 300 or 1300 s⁻¹. Fibrin deposition to the surface was greater at 300 s⁻¹ than at 1300 s⁻¹. Fibrin monomer (fibrinogen des-A) concentration was greater in the perfusion fluid at 1300 s⁻¹. In this study, the perfused blood was anticoagulated with heparin, which may emphasize the role of fibrin-bound thrombin that is resistant to heparin-mediated inhibition. The impaired fibrin polymerization at high shear was suggested to be due to increased removal of the monomer from the surface, but the physical hydrodynamics of this are poorly understood. This study is in contrast to a study with nonanticoagulated whole blood perfused over partially denuded rabbit aortas where platelet and fibrin deposition both increased with shear rates up to 1500 s⁻¹.^[21] Fibrin deposition and its shear dependency are highly sensitive to the presence or absence of cellular contributions and prevailing anticoagulation conditions. Neutrophil adhesion to preformed endothelial matrix and fibrin under shear flow was studied recently by Kuijper et al.^[22] Although neutrophils can adhere to fibrin via Mac-1 (CD11b/CD18) at shear stresses up to 20 dynes/cm², soluble fibrinogen inhibited the interaction. Fibrin-mediated steric hindrance of neutrophil attachment to TNF- α -treated endothelium was noted by Kirchofer et al.^[23] As a bulky structure, it is possible that fibrin can prevent selectin interactions with endothelium that would normally facilitate rolling and subsequent firm adhesion.

A potential role for red-blood-cell adhesion in thrombosis

Palabrica et al.^[13] noted that anti-P-selectin appeared to reduce, through an unknown mechanism, the content of red blood cells on a Dacron-graft thrombus as indicated by scanning electron microscopy of the clot surfaces. This observation raises the issue of RBCs binding to clots or activated leukocytes. The RBCs help push platelets to the reactive wall, as well as leak ADP under high-shear conditions. While numerous studies have looked at thrombospondin and CD36-dependent red-blood-cell adhesive dynamics during sickle cell anemia, malaria, and diabetes, little is known about the adhesive interaction of normal RBC

during thrombosis. Treatment of healthy RBC with $2\ \mu\text{M}$ a23817 and $0.5\ \text{mM}$ CaCl_2 causes the loss of lipid asymmetry in up to 40% of the RBC as indicated by phosphatidylserine (PS) exposure detectable by FITC-annexin V binding.^[24] In their work, CD36 was not detected on ionophore-treated normal RBC. PS exposure by RBC is sufficient for expression of procoagulant activity, as well as alternative complement pathway activation as indicated by C3b deposition.^[25] It has been shown that PS on RBC was sufficient for the binding of RBC to endothelial matrix or purified thrombospondin. Interestingly, even normal RBC could bind immobilized thrombospondin at a level \sim ten-fold greater than RBC binding to albumin. This suggests that RBC-binding thrombospondin may be important in the adhesion of normal RBC to activated spread platelets that release thrombospondin and display CD36. Platelet-released thrombospondin is an important mediator of platelet aggregation via a CD36-dependent mechanism. A role for platelet-RBC interaction in sickle cell disease has been reported to be partially mediated by thrombospondin.^[26] Platelet-RBCs are routinely observed (and ignored) in flow cytometry of anticoagulated whole blood. RBC captured in the early thrombus may display PS due to alternative complement pathway activation, and thus become procoagulant and adhesive for platelet thrombospondin. These mechanisms may be especially operative at low-shear rates if binding is extremely weak and transient.

Complement System/Activation

The complement pathway also plays a role in biomaterial function, thrombosis, and biomaterial infections. Bacterial killing in coagulating blood involves numerous interactions among coagulation factors, platelets, neutrophils, bacteria, and the complement system. Infections in coagulated blood present an important class of clinical complications in the context of artificial biomaterials, infective endocarditis, mechanical and bioprosthetic heart valve endocarditis, and wound healing. Yet, little is known about the role and dynamics of various biochemical or biological participants in regulating bacterial survival during blood coagulation. Through the classical or alternative pathway, complement-based lysis of bacteria depends on the generation of C3b and C5b on bacterial surfaces, thus triggering the formation of the membrane attack complex (C5b-9). The classical pathway is calcium and magnesium-dependent, while the alternative pathway is magnesium-dependent. Gram-negative bacteria such as *Escherichia coli* are potent activators of the alternative pathway. Also, C3b and iC3b act as opsonins; C3b binds neutrophil complement receptor

CR1, while iC3b (but not C3b) binds neutrophil CR3 (Mac-1) and CR4.

Early work on platelet activation and aggregation in the presence of complement has demonstrated that thrombin can act on the platelet surface as a low-activity C3 convertase and high-activity C5 convertase. In solution, thrombin cleaves C3 (presumably at the Arg₆₉-Ala₇₀ bond) to produce fragments roughly the size of C3a and C3b that have no anaphylatoxin or hemolytic activity, respectively. Thrombin can very rapidly cleave C5 to a C5b-like fragment and a C5a-like fragment that lacks chemotactic activity unless further digested by thrombin for 16 hr. In fact, levels of anaphylatoxin antigens C3a, C4a, and C5a are ten-, four-, and 60-fold higher, respectively, in freshly prepared serum (from whole blood maintained for 30 min at room temperature in glass tubes) than in EDTA-treated plasma, demonstrating that coagulation can activate complement. However, this level of generation of C3a, C4a, and C5a in serum represents only a \sim 3 to 10% conversion of C3, C4, and C5. Also, thrombin can cleave C9 to C9a and C9b, which remain associated without loss of hemolytic function.

BIOMATERIAL THROMBOSIS

Fibrin Formation by Adherent Neutrophils

Implantation of biomaterials is generally followed by adsorption of plasma proteins such as albumin, fibrinogen, vWF, and vitronectin onto the artificial surface. Neutrophils, via Mac-1 (CD11b/CD18), can adhere to immobilized fibrinogen. The regional neutrophil density can increase by an inflammatory response that may even be triggered by biomaterial-adsorbed fibrinogen.^[27] Once adherent, neutrophils can mediate the capture of flowing neutrophils near the surface via a L-selectin-PSGL-1 (P-selectin glycoprotein ligand 1) mechanism.

Our studies have shown that under venous flow conditions, individual surface adherent neutrophils can promote fibrin deposition in the presence of the intrinsic coagulation protein factor XIIa.^[28] On the perfusion of platelet-free plasma (PFP) over fibrinogen-adherent neutrophils at a wall shear rate (γ_w) of $62.5\ \text{s}^{-1}$, dense fibrin deposition in close proximity to the neutrophils, especially downstream of each cell, was observed (Fig. 1A). The time required for this fibrin deposition on neutrophils was prolonged by 40 to 50 min by inhibition of factor XIIa with corn trypsin inhibitor (CTI), demonstrating the role of contact pathway in this fibrin accumulation around neutrophils. Fig. 1B illustrates no fibrin formation at $t = 35\ \text{min}$ in the presence of CTI.

Fig. 1 XIIa-dependent fibrin formation around neutrophils. As recalcified citrated PFP was perfused over surface-adherent neutrophils at a shear rate of 62.5 s^{-1} for 20 min, dense fibrin deposition was observed around each neutrophil, especially downstream of each cell (A). No fibrin was formed even at $t = 35$ min in the presence of CTI (B). Fibrin accumulation was attenuated when either cathepsin G inhibitor (C) or elastase inhibitor (D) was present in the PFP being perfused over neutrophils (also treated with the matching inhibitor). Flow is from right to left.

One of the mechanisms through which individual fibrinogen-adherent neutrophils promote fibrin deposition is capture of short fibrin protofibrils flowing in recalcified plasma in contact with in-vitro surfaces. This mechanism may involve Mac-1 (CD11b/CD18)-mediated capture and, to a much lesser extent, capture by nonspecific cross-sectional capture effects that is analogous to particle capture by a sphere under flow. However, fibrin capture is not the sole process responsible for fibrin deposition. In addition to blockade of Mac-1 and inhibition of XIIa, the inhibition of either one of the two neutrophil proteases, cathepsin G and elastase (Fig. 1C and 1D), also attenuated fibrin formation around adherent neutrophils.^[28] This demonstrated that fibrinogen-adherent neutrophils can promote FXIIa-dependent thrombin generation and subsequent fibrin formation in a platelet-independent manner through pathways mediated by the released proteases elastase and cathepsin G.

The reduction in fibrin formation by either the blockade of Mac-1, inhibition of XIIa, or inhibition of either one of two proteases, cathepsin G and elastase, may be attributed to the suppression of prothrombinase formation (factor Xa and factor Va) on the neutrophil surface (Fig. 2). Because cathepsin G has been found to activate Mac-1-bound factor X,^[10] decline in factor Xa levels can be expected by inhibition of cathepsin G or the blockade of Mac-1.

Fig. 2 Procoagulant activity on the neutrophil surface. Individual neutrophils may enhance coagulation in a platelet-independent manner through prothrombinase formation on the neutrophil surface. Abbreviations: fbg, fibrinogen; CTI, corn trypsin inhibitor; XIIa, factor XIIa; X, factor X; Xa, factor Xa; Va, factor Va; II, prothrombin; IIa, thrombin; N*, activated neutrophil.

Moreover, inhibition of elastase (or cathepsin G) may suppress factor V activation by these proteases,^[29] resulting in reduced levels of factor Va. Inhibition of factor XIIa would reduce the formation of the prothrombinase complex (XaVa) by reducing XIa and consequently IXa and then Xa production.

While blockage of Mac-1 attenuated fibrin formation on neutrophils, it is difficult to distinguish fully the role of Mac-1 on fibrin capture versus its role in thrombin formation, because Mac-1 binds fibrin(ogen) and factor X to the neutrophil.^[10] Since neutrophils can bind high molecular-weight kinogen (which can bind prekallikrein and factor XI), as well as factor XII,^[30] antibodies against CD11b/CD18 will clearly interfere with fibrin binding but may also attenuate pathways leading to Xa and thrombin formation on the neutrophil surface. Also, factor XIIa is a known activator of neutrophils, and CTI would be expected to attenuate kallikrein-mediated release of elastase by neutrophils exposed to recalcified plasma.^[31]

In the absence of platelet deposition and red-cell motion, fibrin accumulation over neutrophils in the presence of contact activation was inversely correlated with wall shear rate.^[28] The density of fibrin deposited around each neutrophil at a wall shear rate of 250 s^{-1} was significantly lower than that at a wall shear rate of 62.5 s^{-1} . Under the conditions present in these experiments, an increase in flow rate may decrease the time available for interaction between the Mac-1 receptors and the complementary fibrin domain or enhance the off-rate of binding. Alternatively, dilution

T

effects of key factors (e.g., Va, Xa, or thrombin) may be enhanced at high flow. Under physiological conditions, the presence of red cells and their motion would considerably influence coagulation. Their presence would increase the collision frequency of cells with the wall to enhance platelet aggregation and platelet deposition, respectively. Additionally, rouleaux formation would support vessel-wall adhesion of neutrophils through their outward displacement under flow.^[32]

Neutrophil Enhancement of Platelet-Dependent Coagulation

Platelets can adhere to plasma proteins immobilized on biomaterials through the same mechanisms that are involved in their adhesion to the vessel wall. However, unlike collagen, fibrinogen provides a surface onto which platelets can spread, but do not transform into fully procoagulant structures on their own. Our results have shown that adherent neutrophils can interact with fibrinogen-adherent platelets to turn them into activated procoagulant structures.^[28] As platelet-free plasma was perfused over a neutrophil-coated surface, a platelet-coated surface, and a surface coated with both neutrophils and platelets, dense fibrin deposition was observed only on the latter surface suggesting that neutrophil-platelet aggregation and adhesion can have profound roles in promoting coagulation under venous flow conditions even in the presence of factor XIIa-inhibition by CTI. This fibrin formation was reduced by specific peptide inhibitors against elastase and cathepsin G, indicating that the interaction of neutrophils with platelets to facilitate fibrin formation is mediated through these neutrophil proteases.

As we compared fibrin formation on fibrinogen-adherent neutrophil-platelet cell mixtures to that on collagen-adherent platelets (no neutrophils), we found the amounts of fibrin deposited to be equivalent (Fig. 3); neutrophils on a fibrinogen-coated surface had enhanced platelet-dependent fibrin formation to the levels supported by platelets alone on a collagen surface. Because fibrinogen-adherent platelets, unlike collagen-adherent platelets, are not fully activated procoagulant structures, these observations demonstrated that neutrophils, even in the absence of collagen, can activate platelets on their own and subsequently turn them into fully coagulating structures.

Rather than being localized on and near neutrophils, the formed fibrin deposited uniformly over the entire platelet surface of the flow chamber. This observation suggests that neutrophil-promoted fibrin formation on platelets is a consequence of some intercellular signaling event and/or catalysis of coagulation biochemistry between neutrophils and

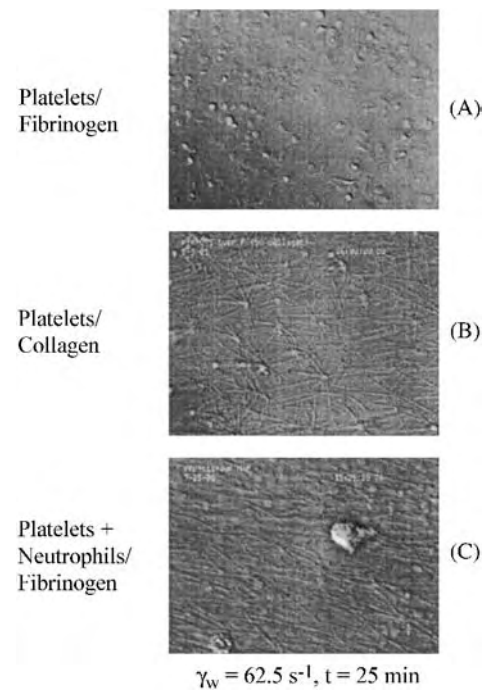

Fig. 3 Neutrophil promotion of fibrin formation in a platelet-dependent manner. On the perfusion of PFP at a shear rate of 62.5 s^{-1} for 25 min, while collagen-adherent platelets (B) supported more fibrin formation than fibrinogen-adherent platelets (A), neutrophils enhanced fibrin formation on fibrinogen-coated platelets (C) to levels supported by collagen-adherent platelets.

platelets that is mediated by elastase/cathepsin G. Several pathways exist by which neutrophils may trigger thrombin production and subsequent fibrin formation in a platelet-dependent manner, including: 1) elastase^[33] or cathepsin G^[9] enhancement of activation of spread platelets; or 2) elastase/cathepsin G cleavage of plasma zymogens such as factor V^[29] and/or X.^[10] While mechanisms of P-selectin-mediated adhesion under flow are eliminated in these studies, P-selectin-dependent platelet-neutrophil signaling did not appear to play a role in the process. We have also found that among the two neutrophil proteases, cathepsin G has a more potent role in enhancing platelet dependent coagulation.^[34] A coupled activity by both cathepsin G and elastase is not a prerequisite to achieve full activation of fibrinogen-adherent platelets; neutrophil cathepsin G alone can fully activate platelet-dependent coagulation. Moreover, platelet activation is the dominant mechanism through which cathepsin G turns fibrinogen-adherent platelets procoagulant. Using fluorimeter assay, the burst time (t_{50} , the time to reach 50% conversion of a fluorogenic thrombin substrate) for thrombin generation was measured to quantify the effect of elastase and cathepsin G on coagulation.^[34] While the addition of cathepsin G to PRP reduced the peak thrombin

Table 1 Effects of cathepsin G and elastase on thrombin generation

Environment		Burst time (t_{50}), min ^a
PRP, CTI	No protease	53 ± 1
	Cathepsin G (100 μM)	18 ± 1
	Elastase (100 μM)	53 ± 19
	Cathepsin G + Elastase	17 ± 1
PFP, CTI	Cathepsin G + Elastase	> 120

PRP=platelet-rich plasma, PFP=platelet-free plasma; CTI (corn trypsin inhibitor) to inhibit factor XIIa from the contact system.

^aData shown represent the means ± S.D. of the observations.

generation from 53 min to 18 min, the addition of elastase did not make a difference (Table 1).

The addition of phosphatidylserine/phosphatidylcholine vesicles (PSPC) alone to CTI-treated platelet-free plasma produced little thrombin, indicating that mere phosphatidylserine exposure during platelet activation is not sufficient for coagulation of the plasma.^[34] When neutrophil elastase was added to PFP containing PSPC, thrombin generation was also minimal. However, a detectable level of slow thrombin production was observed when cathepsin G or elastase/cathepsin G was added to PFP/CTI containing PSPC. These observations demonstrated that the presence of a negatively charged phospholipid surface is not sufficient to initiate coagulation. Cathepsin G is cationic and the slight increase in thrombin levels on addition of PSPC supports the view that cathepsin G-mediated cleavage of coagulation factors on a negatively charged surface may help support, in a secondary role, cathepsin G-mediated platelet activation. In comparison to cathepsin G-enhanced thrombin generation in PFP containing PSPC, a five times higher thrombin production in PRP (presence of platelets) indicated that a platelet has additional means, beyond merely presenting negative phospholipid, through which it responds to cathepsin G stimulation. These results were in agreement with studies by Sumner et al.,^[35] which show that PS exposure does not correlate with factor Xa or thrombin production on platelets and suggest that surface participants other than PS are involved in coagulation.^[36] Whereas display or release of active tissue factor by neutrophils^[7,8] to induce coagulation is possible, tissue factor did not appear to have a role in this process.^[28,34]

Adhesion of Normal Erythrocytes

While it is known that sickle and infected erythrocytes can directly adhere to the endothelium, a common

Fig. 4 Erythrocyte capture by activated platelets and neutrophils. As washed red cells were perfused over collagen-adherent platelets (A) or fibrinogen-adherent fMLP-treated neutrophils (B) at a wall shear rate of 50 s^{-1} , firm adhesion of red cells (arrows) was observed.

assumption is that normal red blood cells are passive during coagulation events and become entrapped in fibrin. We have examined capture and adhesion of normal erythrocytes to surface-adherent neutrophils and platelets under low-flow conditions as a mechanism of RBC accumulation distinct from passive entrapment within fibrin fibers.^[37] As washed erythrocytes were perfused over collagen-adherent platelets at a wall shear rate (γ_w) of 50 s^{-1} for 5 min to investigate the interactions between erythrocytes and platelets under flow, many events of red cell capture, transient tethering, and/or firm adhesion (Fig. 4A) to platelets were observed. To examine the dependence of erythrocyte adhesion on platelet activation, erythrocyte adhesion on collagen-adherent platelets was compared to that over fibrinogen-adherent platelets. The density of red cells captured was four-fold higher on collagen-adherent platelets, demonstrating that red-cell adhesion to platelets at depressed venous flow conditions is regulated by the platelet activation state. Moreover, red-cell adhesion to fibrinogen-adherent platelets that had been directly stimulated with the GPVI agonist convulxin was 2.7-fold higher than to unstimulated fibrinogen-adherent platelets.^[37] This verified the role of platelet activation in mediating these red-cell adhesion events.

Experiments in which potential mediators of these interactions, such as P-selectin, CD36, GPIb, GP IIb/IIIa, TSP, or vWF, were blocked by antibodies demonstrated partial roles for CD36 and GPIb in adhesion of red cells to activated platelets.^[37] When fibrinogen (3 mg/ml) was added to the red cells prior to their perfusion over platelets, cell adhesion was significantly blocked. This demonstrated that at physiological concentrations, fibrinogen plays a protective role in preventing red-cell adhesion to collagen-activated platelets. Red-cell adhesion to platelets was Ca^{2+} - or Mg^{2+} -dependent.

When washed red cells were perfused over fibrinogen-adherent neutrophils at a wall shear rate of 50 s^{-1} for 5 min, a few transient adhesion events were

observed between red cells and fibrinogen-adherent neutrophils. However, when neutrophils were activated with N-formyl-Met-Leu-Phe (fMLP), the number of pausing events and firmly adherent red cells (Fig. 4B) to these activated neutrophils dramatically increased. fMLP caused a sixfold increase in RBC adhesion to neutrophils. Erythrocyte adhesion to fMLP-activated neutrophils at depressed venous flows, unlike RBC adhesion to collagen-activated platelets, was not blocked by soluble fibrinogen. Adhesive interactions between erythrocytes and activated neutrophils were found to be mediated by Mac-1 (CD11b/CD18). One of the receptors on the red cell was detected to be ICAM-4 (LW blood group). Blocking antibodies against CD36 or TSP did not show any effect. Consistent with β_2 -integrin function, the adhesion of erythrocytes to activated neutrophils was markedly inhibited by EDTA.

From adhesion assays conducted at $\gamma_w = 25, 50, 75$ and 100 s^{-1} , we observed that the number of adherent red cells to collagen-adherent platelets decreased as the shear rate increased.^[37] These observations indicate that the RBC adhesion to platelets is significant only at depressed venous flow conditions (below 100 s^{-1}). Similarly, RBC adhesion to fMLP-treated neutrophils was inversely correlated to shear rate, and it was significantly reduced at γ_w above 100 s^{-1} .

While it is known that vascular compression devices help prevent deep vein thrombosis (DVT), the molecular mechanisms by which they do so have been unclear. Our observation that firm adhesion of red cells to platelets and neutrophils is efficient at shear rates below 100 s^{-1} may explain this phenomenon. Reduced shear rates can allow red-cell adhesion to the cells adherent to inflamed venular endothelium causing occlusion and pain. Vascular compressions may lead to a slight increase in blood movement and wall shear rate and shear stress, which, as explained previously, may impede erythrocyte capture and/or reverse adhesion and subsequent vasoocclusion, thus providing DVT prophylaxis to the patient.

CONCLUSION

Adherent neutrophils, being more concentrated at sites of inflammation, have a considerable impact on biomaterial thrombosis. Fibrinogen-adherent neutrophils are sufficient to initiate and amplify coagulation on a biomaterial surface in the presence of activated XIIa. Additionally, the effects of neutrophil-platelet interactions, which primarily occur during adhesion and heterotypic aggregation, on subsequent fibrin formation have been reviewed in a system that decouples flow-regulated adhesion events from flow-regulated coagulation biochemistry. Inflammatory processes,

causing neutrophil or platelet arrest and activation on an activated endothelium or a biomaterial surface, can be followed by receptor-mediated capture of red blood cells under low flow conditions. In addition to biomaterial thrombosis, these events may be clinically relevant in situations devoid of collagen or tissue factor such as those involving endothelial dysfunction and neutrophil activation during deep vein thrombosis.

Tinnitus Devices

Martin L. Lenhardt

Biomedical Engineering, Otolaryngology and Emergency Medicine, Virginia Commonwealth University, Richmond, Virginia, U.S.A.

INTRODUCTION

Tinnitus is the perception of a sound in the absence of external stimulation. The tinnitus is as real to the individual as that induced by external sound. Exposure to noise, ototoxic drugs, or even aging is commonly associated with the development of tinnitus. Clinically, tinnitus is characterized as either subjective or objective. Objective tinnitus, detectable by stethoscopic examination, is generally due to peripheral vascular abnormalities and will not be the topic of this entry. Most tinnitus is subjective, that is, nonpulsatile (varying with the heart beating) and not audible by others. Approximately 75% of those affected by subjective tinnitus adapt, but for the remaining 25%, tinnitus can be severe and debilitating to the point of suicide.

Masking is the auditory phenomenon in which a sound becomes imperceptible in the presence of another sound. The closer the masker is in frequency to the tone to be masked, the less masker energy is required. Low-frequency tones can mask high frequencies if there is sufficient masker energy. This effect is termed upward spread of masking and is important in hearing aid processing algorithms. Conceptually, wearable devices could be developed that would eliminate the perception of tinnitus.

OVERVIEW

Tinnitus is characterized by subjective pitch and loudness; both parameters can be assessed by matching tinnitus to an external tone. Although the process is tedious, reliable data can be obtained. The majority of tinnitus patients pitch-match their tinnitus to frequencies above 6 kHz. Most, but not all, have mild to moderate high-frequency hearing loss.^[1] In the acute stage, tinnitus is usually associated with an insult to the ear in the form of noise trauma or ototoxic drug exposure. There is generally an association of the hearing loss frequencies and the frequencies matched to tinnitus pitch,^[2] which is usually tonal in quality but can also be matched to narrowband noise. Tinnitus is typically matched in loudness to an intensity of an external tone of about 10 dB; however, tinnitus

annoyance may be very high. In designing a device to treat tinnitus sound, its associated annoyance must be addressed. Because there is no tinnitus cure, one standard form of treatment is the use of tinnitus maskers that produce a broad band of continuous external noise that masks or partially covers the tinnitus, but which ear to fit?

Tinnitus can be perceived as being lateralized to one ear or more often perceived binaurally. What is astonishing about the perception of tinnitus in one or both ears is that the ear is rarely the tinnitus source.^[3] Tinnitus arises not in the ear but in the brain. Imaging studies have conclusively demonstrated an auditory cortical activation.^[4] In the case of lateralized tinnitus, the ear opposite the involved cortex appears to be the site of tinnitus, giving the illusion of the ear as the site of tinnitus. Thus the lateralized tinnitus perception suggests peripheral involvement as if it sounds like the tinnitus is in one ear. If the ear is the site of tinnitus, a masker should provide relief by masking according to conventional auditory theory. Because multiple neural sites are involved in generating and processing tinnitus,^[4,5] the masking picture is far more complicated.

The vast majority of potential tinnitus device users have long-term or chronic tinnitus that can also be associated with clinical depression. There may be no direct cause-effect relationship between tinnitus and depression, but rather some common biofactors may predispose an individual to both conditions. Medical treatment strategies have been multifaceted, addressing the treatment of depression and tinnitus with pharmaceuticals, maskers, and behavioral therapy. The question arises as to what treatment outcomes should be selected to measure effectiveness of tinnitus devices. Two obvious measures are device purchases and device returns.

Approximately 1 of 6 patients evaluating maskers actually purchase, and the return rate is about 50%—hardly a ringing endorsement for the technology.^[6] Conventional tinnitus maskers address the initial symptom, but appear not to address the core complaint of tinnitus patients, the annoyance. The irritation, aggravation, and frustration associated with the tinnitus must be addressed in neural tinnitus prosthesis design. More than masking is needed.

HISTORY OF MASKING

The application of acoustic masking to tinnitus is attributed to the pioneering work of Vernon^[7] and his colleagues at Oregon Health Sciences University in the mid 1970s. Vernon readily acknowledges Jean-Marie Gaspar Itard as the first to apply the concept of acoustic masking to tinnitus around 1825. Itard suggested sitting by a green-wood fire; its hissing and popping would mask high-frequency tinnitus, whereas seasoned wood would produce a roar for masking lower-pitched tinnitus. Furthermore, Itard recognized that the sound of falling water is a very effective masker. Thus the principle of frequency-specific masking for tinnitus was known for a century and a half before the availability of wearable technology.

Vernon^[7] was also aware of the use of hearing aids to mask or suppress tinnitus in some patients, and hearing aids could potentially be fitted with masking circuits, thus functioning as both hearing aids and maskers. The first wearable tinnitus devices resembled behind-the-ear hearing aids and were manufactured by Zenith. The hearing aid microphone was removed and replaced with a broadband noise circuit. Early models produced a steady broadband sound, whereas the output of later models was matched to the tinnitus frequency and some even employed phase cancellation techniques. This entry will detail the evolution of such devices from simple maskers to instruments essential in comprehensive tinnitus management.

Conventional masking refers to the phenomenon of the perceptual elimination of one sound in the presence of a second tone. Typically, the masker and the sound to be masked must be similar in frequency content to keep the power requirements low. This was very important during the initial phase of device development in the 1970s because battery life was far more limited than it is today. Frequency matching of masker and maskee is based on efficiency in inner stimulation. The inner ear is effectively divided into critical bands of filters. If the masker and maskee fall within the same band, masking is accomplished with very little energy. The filtering capability of the basilar membrane of the inner ear is maximized when an externally applied tone falls within the same critical band associated with the tinnitus sound. If masking frequencies are systematically varied from low to high, the resulting values of masking are what is termed a psychophysical tuning curve, which is similar to what would be expected from an eighth (auditory) nerve afferent fiber associated with that critical band.^[8-10]

Unfortunately, masking of tinnitus appears to be quite different from conventional psychophysical masking. Investigators^[11,12] using maskers of varying bandwidths have shown that tinnitus is not masked as a tone in many subjects. Instead, a wide range of

frequencies typically provides roughly equivalent masking. These wide tuning curves suggest that tinnitus is not processed as if it were a pure tone. Somehow the tinnitus and the masker interact in the central nervous system. This was the first evidence that suggested tinnitus masking may have a central origin and that tinnitus itself is possibly generated centrally. This conclusion is reinforced by the phenomenon of contralateral masking; in some patients, masking noise presented to the contralateral ear is as effective as noise presented to the ipsilateral ear, so the interaction of tinnitus and masking noise must be at some point in the auditory pathway where there is binaural interaction.^[9] Evidence was mounting that tinnitus masking involves the nervous system and therefore a device that provides central masking was needed.

The observation that the frequency spectra of the masker are not always important in providing masking in some cases is compounded further by the observation that tinnitus can be masked by noise not containing any of the tinnitus frequencies. Kitajima et al.^[13] found that when a narrow band of noise around the tinnitus frequency had been removed (notched noise), masking was as effective as a very narrow band of noise covering the tinnitus frequency. This suggests that tinnitus can be masked by sounds higher or lower than the tinnitus frequency.

Determining which ear to fit with the masker, given the ambiguity of the effects of central masking, i.e., contralateral masking being as effective as ipsilateral masking, can be solved using bone conduction. Bone conduction involves placing the transducer on the skull, thereby efficiently oscillating the inner ear fluids. Bone conduction is a means to deliver broadband sound as part of a masking and habituation tinnitus therapy treatment.^[14] Bone conduction stimulates both ears because there is little attenuation across the head in the audiometric frequencies.^[15] Johnson and Hughes^[16] showed that, because the central neurological processes underlying tinnitus, correlated noise presented simultaneously to the two ears may be more effective at tinnitus suppression than two separate maskers in the ears.

Masker fitting is complex in regard to tinnitus; nonetheless, masking is recognized as an effective therapy.^[17] Masker effectiveness is often based on continuation of masking after the masker is removed, a perception of quiet termed residual inhibition (RI). RI is frequently evoked but is variable in duration ranging from seconds to weeks.^[18,19] A report that only 15 minutes of masking resulted in RI for the entire day encourages masker use. Clearly the RI is a neural phenomenon.^[20] The dependence of RI on masker characteristics such as center frequency, bandwidth, intensity, duration, and stimulating parameters are still not well understood, nor are the mechanisms for the

wide variability in RI for individuals. Thus there is considerable experimentation in both the selection of the type of masking sound and the delivery method employed in an attempt to maximize RI. Four types of maskers that have been shown to have importance in modern tinnitus treatment are electrical stimulation, acoustic masking, vibration masking, and high-frequency/ultrasonic masking.

TRANSDERMAL ELECTRICAL STIMULATION

Tinnitus is present in many severely hearing-impaired and totally deaf patients^[21] with the incidence as high as 87%.^[22] Because many severely hearing-impaired people seek hearing improvement by means of a cochlear implant that stimulates the nerve fibers in the absence of sensory cells, a logical measurable outcome of implantation procedure is the assessment of electrical stimulation on tinnitus. In some cases pre-operative electrical stimulation is applied to the cochlear wall to determine if the nerve fiber population can be activated by the implant. The electrical stimulation of the cochlear wall is in the region of high-frequency coding since it is the most accessible, i.e., nearest to the middle ear. Electrical stimulation of the cochlear wall can suppress tinnitus in 69% of the deaf patients. Cochlear implantation is not as effective, completely suppressing tinnitus in only 35% of the deaf patients and partially suppressing it in 42%. Residual inhibition for several hours after deactivation of the implant is possible.^[22] These findings suggest that activation of the nerve, including the high-frequency fibers, suppresses tinnitus and provides RI.

Years before the availability of cochlear implants, a form of transdermal electrical stimulation was explored to treat tinnitus. Transdermal electrical stimulation is applied by electrodes placed on the preauricular and postauricular regions and on the two mastoids (see Fig. 1). Electrical stimulation consisted of slowly varying tones between 0.2 and 20 kHz multiplied by a 60-kHz carrier (full amplitude modulation). This approach literally passed the audio frequencies under the skin via external electrodes placed on both mastoids. Electrical stimulation in this mode provided 60% positive success in suppressing tinnitus.^[23] An additional study^[24] revealed that in 50 patients tested, 14 (28%) obtained relief that met the criterion of a reduction in the tinnitus of 40% or more, with RI usually extended for several hours. Further, there was only one positive response in the placebo trial; nonetheless, the authors concluded electrical transcutaneous stimulation was not practical. A more powerful randomized, double-blind crossover study resulted in a reduction in tinnitus severity in only two of 20 patients with the active device and four of

Fig. 1 Headset with electrodes for transdermal electrical stimulation for tinnitus treatment. High frequencies were modulated on an ultrasonic carrier with the device (Theraband) capacitive coupled to the head during stimulation.

20 patients with the placebo device.^[25] In a large series of 500 patients treated with electrical stimulation twice weekly for a total of six to ten visits,^[26] 53% reported a significant benefit, defined as an improvement of at least two points on a 10-point scale of tinnitus intensity. Despite some positive and some ambiguous results, the transdermal electrical stimulation device was withdrawn from the market. This was unfortunately premature because electrical stimulation in the form of FDA-approved cochlear implants would provide the physiological rationale for transdermal tinnitus treatment. The transdermal stimulation provided additional design value in regard to demonstrating that high-frequency stimulation is possible without distortion associated with air conduction hearing. Although not specifically recognized at the time, high-frequency stimulation is an essential element in modern masking and treatment of high-frequency tinnitus.

ACOUSTIC MASKER DESIGNS

Masking a low-level high-pitch tinnitus percept at first does not seem to be a formidable task. If, for example, tinnitus is matched to an 8-kHz tone, delivering a tone or narrow band of noise to the cochlea at 10 dB above threshold should accomplish the predictable masking. Assuming that the tinnitus patient prefers the masking to the presence of tinnitus, providing a tinnitus masker should be the obvious simple solution. Surprisingly, about one-third of the tinnitus patients report no masking even if the masker is at very high intensities. One-third report masking with frequencies much different in frequency from their pitch match and only one-third respond as predicted from classical auditory masking theory. It appears that tinnitus masking

involves other processes different from classical masking that likely involve different pathways in the brain.

The first approach in developing an acoustic masker was to select a form of stimulation that would be effective in the majority of cases, and the logical candidate was broadband noise. The concept of masking an internally generated sound with an external sound didn't occur to researchers in the field until the 1970s. Dr. Jack Vernon, the pioneer in tinnitus masking,^[17] relates his experience with a physician suffering tinnitus who, when standing in one location near a water fountain, declared his tinnitus had disappeared. The sound of falling water was replicated in the laboratory and the synthetic waterfall was found to be effective as a masker of tinnitus. The challenge was to incorporate that masking sound into a wearable device.

The faucet test, as it were (I can't hear you while the water is running), is an excellent means of getting a preliminary assessment on the maskability of tinnitus. Water-generated noise is an outstanding source of almost flat and full-spectrum noise (Fig. 2). Synthetic water noise, essentially white, was the first masking stimulus incorporated into wearable and desk-version maskers and it is still used today.

The logical candidate for a personal wearable masker was a modified hearing aid. A prototype wearable noise generator was evaluated by Vernon's group in 1974. Although the circuit was capable of wide-frequency response, the high-frequency output was limited by the driver characteristics (<3 kHz) of the hearing aid. In the digital realm, a white noise chip will provide full high-frequency content, but the miniature speaker limits high-frequency fidelity. Most maskers are limited to about 6 kHz of effective output,

Fig. 2 Spectrum of running water from a faucet. The value of -70 dBV corresponds to 80 dB SPL (C) at one meter. The flat spectrum extending into the ultrasonic frequencies is the reason this sound is effective in initial tinnitus masking.

which is not surprising in that the middle ear resonance is about 3 kHz and its high frequency rolls off at about 26 dB/octave. Additionally, most tinnitus sufferers have high-frequency hearing loss placing increased intensity demands on high-frequency maskers, which can result in distortion and possible device rejection. The goal of wearable synthetic waterfalls proved difficult to obtain with conventional hearing aid technology. (See *Hearing Mechanisms*, p. 702)

FM MASKING

There are alternative choices to wearable maskers; desktop maskers and pillow maskers are available that generally provide a broad range of acoustic masking but are also limited in the high frequencies by their transducer response. A mistuned FM radio can provide white noise amplified through a high-fidelity speaker system. Although the mistuned radio advice has often been offered to tinnitus sufferers, its general utility and long-term acceptance is low. There persists the occasional report of a tinnitus sufferer able to fall asleep only while sitting in front of a full-volume television producing white noise after station sign-off.

PERSONAL STEREOS

Vernon readily appreciated that wearable maskers of mid-1970 vintage had intrinsically limited high-frequency response, acknowledging that patients report their tinnitus matches frequencies above 6 kHz. Vernon recorded higher frequencies on cassette tape, creating a type of desk-based masker for home use. The high-frequency response of most cassette players was usually about 16 kHz, but again the limiting element was the response of personal earphones, even some rated to 20 kHz. The high-frequency response of the stereo earphones varies by construction. An example of a relatively inexpensive set versus high-fidelity earphones is depicted in Fig. 3. The high-fidelity earphones (right panel) can extend the frequency response to a degree. Even with exact reproduction, wavelengths above 14 kHz and canal dimensions interact, depending on individual geometry, resulting in cancellation of some high frequencies.

With the advent of relatively inexpensive compact disks (CD) and players, high-frequency masking could be achieved by a "maskman." Digital sampling rates of 44.2 kHz are commonly used in CD recording that extend the frequency range to about 20 kHz (anti-aliasing filters limit the upper frequencies). Nonetheless, the concept of a wearable maskman never achieved popularity in spite of being a much cheaper alternative to tinnitus maskers.^[27] Perhaps wearable

Fig. 3 Frequency response of an inexpensive headset (left panel) and high-fidelity earphones (right panel). Overall response is similar in the low and mid frequencies and not that different at 16 kHz. Ear canal acoustics, middle ear mechanics, and sensory hearing loss all contribute to inefficient high-frequency audibility by air conduction.

maskers and stereos were providing more high-frequency output, but full high-frequency fidelity is not obtainable. The need for full treble in tinnitus treatment has been demonstrated only in the past few years. It is the lack of high frequencies delivered to the ear that may determine the success of tinnitus masking; however, some other central factor must be involved in tinnitus persistence.^[28] For these reasons, alternative vibration-based maskers were developed.

VIBRATION MASKERS

There is one report^[29] in the literature of 60% success in tinnitus relief using low-frequency vibration as a form of acoustic masking in a small sample of patients. The approach was exploited by De Mino,^[56] who developed a vibrating rod that is applied to the skin behind the ear (mastoid area). The stimuli consisted of a 60-Hz fundamental with adjustable harmonics up to 1000 Hz. The device (Aurex3) provides air-conducted, bone-conducted, and tactile stimulation and received FDA approval [510(K)] for tinnitus masking. The device was not well accepted, possibly due to cosmetic reasons. It was assumed that the acoustic energy delivered by bone conduction was the principle feature related to successful masking; however, the key effect may not have been auditory at all.

The somatosensory system has been shown to have inputs into the auditory system as low as the first synapse in the dorsal cochlear nucleus. Stimulation of the muscle body behind the ear (postauricular muscle) results in inhibition in the dorsal cochlear nucleus.^[30] The tinnitus inhibition effect is not due to air-conducted hearing, as removing the transducer from the muscle eliminated the effect. Light touch is also ineffective, suggesting that touch or refocusing

attention is not the responsible mechanism. Thus it appears that the Aurex3 may be effective when the vibrating rod stimulates the postauricle muscle and not the ear directly. The salient point is that if tinnitus can be modified by a sensory system different from audition, it is clear that complete masking may require multisensory stimulation such as by sound and muscle vibration.^[31] Tinnitus inhibition via the somatosensory system provides fast immediate relief, but there is no RI. In contrast, very-high-frequency vibration has no tactile component and can provide long-term tinnitus relief. High success in masking tinnitus and producing RI was reported with low-frequency ultrasound (20–40 kHz) delivered through bone conduction.^[32] Lenhardt et al.^[33] demonstrated that hearing through bone conduction can extend up to about 100 kHz.

HIGH AUDIO AND ULTRASONIC BONE VIBRATION MASKERS

A new trend in tinnitus treatment is the use of very-high-frequency maskers, including ultrasound, delivered by bone conduction.^[18,32] Masking and long-term inhibition may involve inducing neuroplastic changes in the brain. The bone conduction application of either high audio frequencies (10–20 kHz) or ultrasound (20–100 kHz) provides binaural high-frequency stimulation for high-pitched tinnitus masking, a requirement recognized by Vernon decades ago.

The principle obstacle in delivering high frequencies to the head was the development of a suitable transducer. An aluminum ceramic (PZT) bimorph with a resonance frequency of about 40 kHz in air was designed to stimulate the head from 5–45 kHz. There are multiple transducer resonances, which are compounded with head resonances,^[22] making calibration

a challenge. Nonetheless, the transducer is light and comfortable and has a relatively flat frequency response when mass-loaded to the head.^[18]

Bone conduction calibration standards are not available for high audio and ultrasonic frequencies. Reference can be made to calibration procedures based in part on bone-anchored measurements for some frequencies,^[34] but ultrasonic bone conduction standards do not exist.^[35] The transducer can be placed on a water surface in a small tank, assuming brain and water impedances are similar.^[36] This approach provides reliable results using a high-frequency hydrophone, but provides no exact measurement of the energy acting in the ear in that the boundary condition of skin and bone are ignored in this approach. Alternatively, acceleration can be measured and this proves to be the best method of calibration.

High-frequency accelerometers have impedances closer to bone than to brain. Using acceleration (m/sec^2), the hearing threshold for bone conduction can be referenced as -30 dB relative to $1 \text{ m}/\text{sec}^2$ from 0.25 to 6 kHz . This reference is applicable to higher frequencies, including ultrasound. A standard point of measurement is 1 gravity unit (g) rms, or $9.81 \text{ m}/\text{sec}^2$.^[37] One g is also the U.S. Occupational Safety and Health Administration (OSHA) hearing protection reference for body-coupled ultrasound.^[38]

Tones or narrow bands of noise can be applied to the head as ultrasonic bone conduction tinnitus maskers. This would simply be a variation on acoustic maskers, but the delivery method would be bone conduction. However, if the masker is similar in pitch and intensity to the patient's tinnitus, most patients would reject the substitution of just one annoying sound for a masker. If, however, the sound stimulus has an attention-focusing temporal quality, e.g., music, rejection is rare.

Thus if music or similar sound is multiplied by a high-frequency or ultrasonic carrier and the carrier and

lower sideband are canceled, a high-frequency patterned stimulation will result. Patterned auditory stimulation in the high audio range (10 – 20 kHz), using bone conduction, has been shown to be an efficient means of high-frequency tinnitus masking.^[18] It differs from the conventional masker in that little of the sound overlaps the range of reported tinnitus (Fig. 4, right panel). In this technique, amplitude-modulated and processed music is presented through a bone conduction transducer at a low-level 12 -dB sensation level that is 12 dB above threshold, for periods of 30 – 60 minutes (Fig. 4, right panel). The goal is to induce changes in the central nervous system mechanisms of tinnitus, resulting in long-term inhibition.

In the case of high-frequency bone-conducted stimulation, not all patients with a similar profile experienced immediate masking; in fact, immediate masking is generally a positive predictor of long-term relief. The overall percentage of tinnitus relief was 60 – 70% .^[18] If the masker is shifted into the ultrasonic range, tinnitus relief is also reported.^[32] Ultrasound, as will be discussed later, maps onto the high audio area of the inner ear, so both high audio and ultrasonic stimulation have similar sites of peripheral and central action.

HOW IS ULTRASONIC HEARING POSSIBLE?

Reports that humans can hear ultrasound have appeared more than a dozen times over the last half-century.^[33] Dr. Roger Maass detailed the phenomenology of ultrasonic hearing, perceptible only as bodily (bone conduction) vibration, with pitch characterized as similar to audiofrequencies in the 10 – 15 kHz range, and with crude frequency discrimination. Maass further reported some deaf subjects could also hear ultrasound at high levels. These observations were

Fig. 4 The high-audiofrequency tinnitus device (UltraQuiet™) consists of a piezoceramic aluminum transducer, a compact high-frequency amplifier, and a playback system (left panel). The vibratory output of the device is depicted in the right panel. The suppressed carrier is at 16 kHz . Filtering limits the upper sideband energy to 20 kHz . Peak energy is in the region of brain resonance to utilize natural amplification.

T

confirmed, and speech discrimination in deaf subjects was verified using modulated ultrasound.^[33] By means of magnetoencephalography, it has been determined that the primary auditory cortex is active in ultrasonic hearing in normal hearing subjects, activating sites associated with very-high-frequency hearing.^[39] A lower-frequency cortical site for ultrasound for the deaf was observed, the significance of which will be discussed later in regard to neural plasticity.^[40]

When ultrasonic energy is applied to the head, some form of demodulation occurs. The site of the demodulator could be any place, in that only some form of half-wave rectification induced by a non-linearity is required. However, the pitch of ultrasound suggests the site must have a resonant frequency above 10 kHz. A potential candidate for the ultrasound demodulator is the brain itself. The calculated brain resonant frequency, assuming a homogenous fluid-filled spherical model,^[41,42] using the formula:

$$F = c/2\pi r$$

where F is the fundamental frequency of the sound generated by the sphere, c is the velocity of sound in brain tissue (1460 m/sec),^[41,42] and r is the sphere radius, and assuming a 7-cm head radius, is 13.4 kHz. Neglected in the model are the skull and skin, together acting as a boundary condition. A higher resonant frequency^[41] of $F=15.6$ kHz would be predicted with the boundary condition. Because the brain is not truly spherical, the exact brain resonant frequency is probably a value between the free and boundary states. Individual brain resonant frequencies are likely to fall between 11 and 16 kHz, with the exact value determined by skull geometry.^[15]

If the brain is set into vibration by ultrasound, the sound produced by brain resonance will propagate to the ear via fluid channels. The most likely fluid channel is the cochlea aqueduct that allows direct fluid communication with the brain via the cerebral spinal fluid.^[43-45] If the brain—and not the skull—is vibrated, auditory nerve discharges verify the brain-ear mechanism. Transcranial ultrasonic Doppler imaging has given additional support to brain demodulation. Patients report hearing a high audio sound, much like tinnitus, when the beam is focused in the center of the brain, but the sound disappears when the beam is focused on the ear.^[46]

The position (P) of maximal stimulation of each frequency on the basilar membrane can be calculated using a formula devised by Fay:^[47]

$$P = \frac{\log_{10}[\text{fHz}/.008 \text{ fHz max}] + 1^*}{2.1}$$

where P is the proportion of base to apex on the basilar membrane, fHz is the frequency of interest, and fHz max is the maximal audible frequency by air conduction in young adults.

Further, the position (P) on the basilar membrane is determined by:

$$P = 1 - P \times \text{cochlear length (31.5 mm)}$$

The positions on the basilar membrane for brain resonance would fall between 1.5 mm from the base of the cochlea for 16 kHz to 3.9 mm for 11 kHz. These data clearly support the hypothesis of physical demodulation of ultrasound by brain resonance and the detection of this resonance in the base of the cochlea. The spherical model data also support the theory that ultrasound, regardless of its frequency, stimulates an area on the basilar membrane that codes the fundamental resonant frequency on the brain. Further, ultrasound is a method to deliver high-frequency tinnitus masking.

APPLICATIONS OF ULTRASONIC TINNITUS MASKERS TO THE DEAF

With progressive high-frequency hearing loss, pitch perceptual range collapses. Ultrasonic thresholds also increase with the degree of high-frequency hearing loss.^[33] Presumably, the increased ultrasonic energy increases the displacement spread on the basilar membrane toward the apex, thus accounting for the observation that the ultrasonic pitch is related to the highest frequency detectable by air conduction. In the case of severe deafness, with ultrasonic thresholds approximately 30 dB above normal, insufficient surviving hair cells exist in the apex to detect the basilar membrane motion. Lenhardt et al.^[33] argued that the saccule may be stimulated in the case of severe deafness. Assuming that maximal displacement of the basilar membrane is at the place corresponding to the brain's fundamental frequency, bulk inner-ear fluid displacement, permitted by compliant oval and round windows at very high intensities (100 SL+), could conceivably create fluid flow in the saccule, not unlike the Tullio effect.^[48] The very short cilia of saccular hair cells, not mass-loaded by gel or otoconia^[49] in the striola region, are likely fluid velocity-sensitive. Stimulating the saccule—an organ having input into the auditory pathways in mammals^[50]—may explain ultrasonic detection in the deaf. Treating tinnitus in severely deafened individuals with ultrasound has not been systematically studied, which is surprising due to the high incidence of tinnitus in this population^[21] and the lack of alternatives to implant electrical stimulation. An ultrasonic tinnitus masker is commercially available.

Fig. 5 Pulsed pattern bone-conduction stimulation with a high-audiofrequency device (left panel) and an ultrasonic device (right panel). The high-audio stimulation is double sideband, whereas the ultrasound is full amplitude modulation. Calibration reference is vibration in acceleration re: 1 m/s².

NEURAL PLASTICITY AND CORTICAL REMAPPING; THE MISSING ELEMENT IN TINNITUS DEVICE DESIGN

Traditional acoustic maskers have been available for more than a quarter century, yet masking only, when it occurs, seems insufficient for long-term tinnitus treatment. The compelling evidence for central processing in tinnitus suggests maskers must be designed to also address how the brain responds to tinnitus.

Conventional wisdom until very recently was that the adult human brain is hard-wired. Imaging studies have confirmed considerable cortical plasticity after sensory loss. That is to say, the brain is dynamic and it adjusts for loss in the peripheral sense organs. In monkeys,^[51] the tonotopic map (frequencies laid out spatially in the neuroaxis preserving the spatial coding in the ear) reorganized months after cochlear deafening. The deprived area of the cortex reorganized and became responsive only to intact areas of the cochlea. What this means is that the brain hears only those frequencies transduced by the ear. If stimulation ceases in a particular frequency region, the neurons in the brain sensitive to the damaged peripheral region change their frequency response.

Tinnitus is usually associated with hearing loss and hence cortical reorganization. Muhnickel et al.^[52] explored the reorganization of the auditory cortex in tinnitus using magnetoencephalography, and found a marked shift of the cortical representation of the tinnitus frequency into an area adjacent to the expected tonotopic location. There was also a strong positive correlation between the strength of the tinnitus and the amount of cortical reorganization. Plastic changes in the auditory neural axis in severe tinnitus, particularly in the auditory cortex, may play a role in the continued perception of tinnitus by adding salience to the experience.^[53,54] In tinnitus patients the tinnitus

frequency area expands to more than twice the size. Aberrant tinnitus neural reprogramming can possibly be reversed by increasing high-frequency stimulation (i.e., with frequencies above the tinnitus frequency), for auditory learning in primates has indeed been shown to expand the frequency map,^[52,55] suggesting external stimulation can change the brain. High-frequency stimulation (high audio and ultrasound) has been shown to not only mask tinnitus but also produce varying degrees of residual inhibition.^[18,32] The spectra of these masking stimuli are depicted in Fig. 5.

Tinnitus maskers have evolved from just broadband noise generators to brain stimulators essential in comprehensive tinnitus management. The next generation of devices will be smart systems with capacities for multisensory and multimodal stimulation, likely providing greater relief (RI) for a condition that will only increase in prevalence with an aging population.

Tissue Engineering

François A. Auger

Lucie Germain

LOEX, Hôpital du Saint-Sacrement du CHA, and Department of Surgery, Laval University, Quebec City, Quebec, Canada

INTRODUCTION

There is little doubt that tissue engineering is a revolutionary addition to the therapeutic armamentarium of medicine. The dilemma of adequately repairing either failing or traumatized organs has been looming larger as patients either become older or are in dire need of grafts. Compounding some of the intrinsic problems of transplantation is the chronic shortage of tissues and organs. Tissue engineering allows the hope of a regular creation of spare parts for the human body. This is a most significant approach to reconstruct, replace, or repair organs in a way that could not be foreseen 25 years ago.

Reconstructive medicine is, in a way, not a very recent concept. If one stays away from punctilious definitions, one of its forms, reconstructive surgery, has been practiced for quite some time, with a surge of development after the Second World War. In 1970s, the development of microsurgery allowed distant tissue transfer and reimplantation.^[1-5] Since then, the introduction of various biomaterials has allowed vast and diversified types of reconstruction of the human body. Vascular grafts and prosthetic articulation are two prominent examples.^[6]

However, tissue engineering does open a radically new chapter in reconstructive medicine, for it is now deemed possible to reconstruct in the laboratory human living tissues and organs for either *in vivo*, *ex vivo*, and even *in vitro* applications.^[7-13] This new domain of biotechnology is remarkably multidisciplinary, bringing together cell and molecular biologists, biochemists, engineers, pharmacologists, physicians, among others.

When the aim of tissue engineers is to obtain grafts for *in vivo* applications, then the biological and mechanical functions are of utmost importance. In some subdivisions of the field, one can essentially choose between the biological function, as in cell therapy, or mainly the mechanical function, such as happens with the use of tissue templates^[14] (Fig. 1).

Tissue-engineered substitutes are three-dimensional reconstructions that can be implanted into the human body, leading to rapid host integration and acceptance. These substitutes must have at least minimal biological and mechanical functions for such a reparative role.

HISTORICAL PERSPECTIVE

Even though the field of tissue engineering is relatively young, it has already enjoyed a fascinating evolution over the last quarter of a century. Tissue engineering has also been considered one of the most influential new technologies for the future of biomedicine.^[15-17]

The development of tissue engineering can be seen as having two phases. The phase of exponential development and potential application is still continuing to evolve. But it seems reasonable to also identify a second phase, brought about by a flurry of discoveries about stem cells. Even though these cells had been known of for many years and had certainly been involved in many tissue-engineered efforts, some very important aspects of embryonic stem cells were revealed. Indeed, the isolation and stable culturing of either the totipotent or germinal stem cell was a pivotal breakthrough.^[18-20] In parallel, adult stem cells were found to be much more ubiquitous and to have more lineage plasticity than previously thought.^[21]

Since 1998, these discoveries have brought a tremendous amount of energy and expectation to the field of tissue engineering and reconstruction. Indeed, their therapeutic potential since then has been estimated to be greatly enhanced.

APPROACHES TO TISSUE-ENGINEERED SUBSTITUTES

The different approaches to tissue-engineered substitutes involve deceptively few elements: cells and various natural or artificial matrices combined in such manner to obtain a tissue substitute. These tissue substitutes can then in turn be sequentially integrated to create more complex organs (Fig. 2).

Three main approaches are being utilized for tissue engineering. The first is the seeding of cells into various gels. The seminal work by Dr. Eugene Bell and collaborators has set the stage for various applications of such an approach with collagen gels.^[11] Previous work had already indicated that cells could be cultivated on different collagen gels. Furthermore, it was then shown that the incorporation within the depth of these matrices with various types of cells was possible.^[22,23]

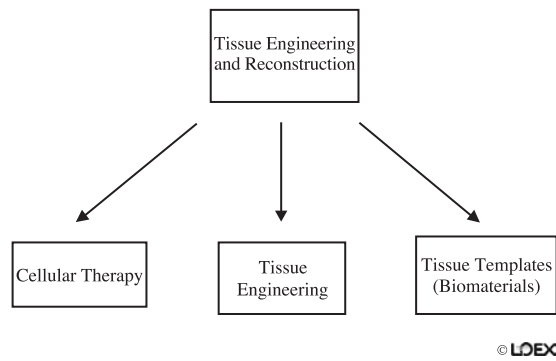

Fig. 1 Overview of the different approaches leading to tissue engineering and reconstruction.

However, the true integration of cells into gels allowed them to reorganize the surrounding matrix.^[12,24–30] A few investigators are pursuing this technology with either collagen gels or other matrix components such as fibrin.

Even though this approach allows the creation of many substitutes and can recreate excellent *in vitro* models, it has a few drawbacks. The main one is the weak mechanical resistance of the obtained substitutes. The structural integrity may be sufficient for such tissues as skin, but not so for substitutes in the vascular or orthopedic system. This problem has been addressed with some original solutions, such as glycation and magnetic alignment of the collagen fibers.^[31–33] It remains to be seen if these modifications are truly applicable to a clinical setting.

A second approach entails the seeding of cells into scaffolds. These scaffolds can be of a natural or bio-synthetic origin. The cells then thrive in the porous material and secrete various amounts of extracellular matrix depending on their nature. Much of the original concept was developed by Dr. Robert Langer's group at MIT.^[34] It also builds on the work of Dr.

Fig. 2 Simplified illustration of the components necessary for tissue engineering.

Burke,^[35,36] Dr. Yannas, and Dr. Odile Damour,^[37,38] with the creation of sponge-like structures from mainly collagenous material. Most of the MIT work has centered around synthetic scaffolds such as PGA [Poly(glycolic acid)],^[34] There have been countless modifications and additions to the different types of synthetic materials used over the last decade in this approach of tissue engineering. The obvious advantage of this approach is the immediate creation of a three-dimensional structure that already has significant structural properties. However, the intrinsic nature of most of these polymers, which are suture materials, entails slow degradation with an ensuing lowering of the pH of surrounding tissues. This leads to a slow but rather protracted low-level inflammatory process. Many groups are thus attempting to alter the chemical nature of these biomaterials for not only better tissue acceptance, but also better control over the resorption time frame and acidic conditions. These efforts would inhibit the inflammatory process and ensure that the disappearance of the material is synchronous with the integration and constructive phase of the graft. How successful these attempts are will be apparent within the next few years.

More recently, the LOEX group in Canada has developed a different approach to tissue engineering. It has some roots in the very initial phases of *in-vitro* tissue reconstruction as exemplified by Dr. Howard Green with cultured epithelia for burn patient therapy,^[39] combined with many observations about the reorganization of the extracellular matrix in various substitutes. In this approach, various types of cells, mostly of mesenchymal origin, are grown in such a fashion within a culture flask that they literally embed themselves in their very own extracellular matrix. Among many factors, the addition of sodium ascorbate allows the significant appearance of the various components of the extracellular matrix. These sheets are then either stacked or rolled to obtain various tissue substitutes.^[17] The most convincing demonstration was the re-creation of a totally biological vascular substitute. The final substitute was not only three-dimensional and three-cellular, but also had very valuable mechanical and biological properties. The main advantage in this approach is the absence of extraneous collagens and any synthetic material.^[40] This method is truly close to some of the *in vivo* processes found during organogenesis *in utero*.

This team has also championed for many years the use of self-generated mechanical forces with additional mechanical stresses also applied to these substitutes. This combination not only leads to a significant *in vitro* cellular and extracellular matrix reorganization, but also achieves a most physiological final result.^[29,30] It is felt that such substitutes could be grafted with minimal inflammatory response, but also with a rather

unique state of readiness for *in vivo* integration and remodeling.

However, one must also note that this approach is time-consuming. Thus, it will demand some form of automation and acceleration of maturation time for the culture of these substitutes. On the other hand, they can be considered, at the present time, as the purest form of *in vitro* models for various physiological, pathophysiological, pharmaceutical, and toxicological studies.

CRITICAL INTEGRATIVE ASPECTS OF TISSUE-ENGINEERED SUBSTITUTES

As tissue engineering enters the clinical area in a more and more significant fashion each passing year, some very critical aspects of tissue integration must be addressed.

Two of these critical aspects, namely vascularization and innervation, have not received all the attention they deserve. This may be due to the fact that most of the efforts leading to clinically applicable substitutes centered at first on skin grafts. Then, because of their very nature, the animal experiments did not reveal the need to take into account these two important aspects of tissue integration.

In a way, this may be seen as quite surprising since reconstructive surgery devotes a lot of attention to the revascularization and reinnervation of autologous or allogeneic grafts. This is evidently less true if a graft has a nearly exclusively mechanical function such as an aortic synthetic graft or hip prosthesis. But even then some surgeons and scientists have pointed out that some biological responses to the graft should be enhanced for a better integration. As an example, the team of Dr. Zilla has extensively studied and optimized the seeding of endothelial cells on the internal side of vascular grafts.^[41] The field of tissue engineering is now much more attuned to the necessity of responding to such a challenge.

In regard to vascularization, even with a paucity of results at first, the approach of stimulating the ingrowth of blood vessels into solid organs has not been successful. Such organs rapidly, within hours or even minutes, demand blood irrigation for survival and proper function. This necessity was the basis for a new endothelialized skin substitute developed at LOEX.^[42] Drawing on clinical lessons showing that cadaver skin could rapidly take and demonstrate a capillary blood flow, the team of Dr. Auger has strived to recreate a microvascular system in the dermal component of skin substitutes. Such a design was even more plausible with understanding of the phenomenon that allows the rapid take of cadaver skin in burn patients. Inosculation, the physiological anastomosis between blood

vessels of the graft and the wound bed, was only recently clearly described in an animal model.^[43] Thus, at first using a scaffold technique, this group has combined in the dermal layer fibroblasts and endothelial cells in such a fashion that a capillary-like system was reconstituted. A series of analyses, including histology, immunohistology and electron microscopy, has shown the microvascular nature of this endothelialized skin equivalent. Furthermore, preliminary grafting experiments in animals have shown that blood flow within the graft is reestablished at a faster rate than in substitutes without a capillary-like system.^[44]

There is now a flurry of interest in such microvascularization in various soft tissues.^[45] But the next level of complexity will undoubtedly obtain for solid organs the full spectrum, from small arteries to capillaries and finally outflow small-diameter veins. This certainly is a lofty goal and will necessitate a tremendous multidisciplinary effort.

Of a less immediate nature is the matter of tissue substitute reinnervation. Too little attention has been focused on this element if the final goal is full tissue integration. Most tissues have many types of neurological receptors that play an important role in not only the biological function but also ultimately their very own homeostasis. Thus, these receptors allow the body to receive the appropriate messages, from nociception to positional information, which then translate into local and frequently systemic reactions. This loop is an integral part of the true physiological function, we are hoping for, in order for tissue-engineered organs to obtain their full potential. Not only will the appropriate neurological signals be sent by the grafted tissues, but many physiological responses will ensue or be set in motion, such as vasoreactivity, hormonal secretion, and enzymatic delivery.

Until now efforts have been mostly centered on evaluating the reappearance of the neural network in various tissues. Once again, the most studied tissue has been the skin. Early experiments have shown the level and time schedule of pain perception reappearance in the first generation of epidermal tissue grafts for burn patients.^[46,47]

Our LOEX group has now focused its observation on some reconstructed tissues such as full-thickness reconstructed skin substitutes for reinnervation after animal implantation. The results are quite encouraging.^[48] But once again the challenges will be much more complex in large solid organs with various cell types. This is even more true when there is a specialized nervous tissue within the organ with a precise physiological function, such as the cardiac pacing system.

Another layer of complexity is added when one considers secretory or filtrating organs such as the pancreas,

liver, or spleen. The successful three-dimensional arrangement of such organs is at the present time a daunting task, but the future may hold answers that are not yet foreseeable. Some investigators have targeted embryonic stem cells as an answer to such complex issues. It remains to be seen if the science of tissue engineering will ever find the right condition for such a demanding differentiation program to occur *ex vivo*.

ENABLING TECHNOLOGIES

Some technologies can be seen as being of incontrovertible value on the path to better tissue engineering. We shall review a few of them.

Tissue Morphometrics

Some scientists in the field of tissue engineering having noted the lack of quantitative and qualitative tissue values and analysis and have proposed measures to remedy this perceived shortcoming.

With an appropriate database for various morphometric tissue parameters, the science of reconstructive medicine should be more accurate and lead to better results. This ongoing effort is certainly quite interesting, and its impact should be felt in the near future according to its proponents.

New Biomaterials

The search for innovative biomaterials seems to be developing along two pathways that will probably intertwine. The first avenue is a worldwide effort, already alluded to, in searching for biomaterials that have better integrative properties. This entails a minimal inflammatory reaction to such materials combined with optimal resorption time depending on the targeted tissues or organs. One must note that inflammation will always be present since any surgical operation entails such a reaction. However, it is quite probable that the least reaction, the better in this context.

The second avenue is to attach signaling molecules to the utilized biomaterial. This can be as direct as a slow, sequential release of various cytokines or growth factors. However, the more technically sophisticated approach of adding DNA sequencing for appropriate messaging may be of high value for all those seeking to induce favorable integration of these biomaterials.^[49]

Mechanical Stimulation

In the last decade it has become quite clear that nearly all body tissues can attain a higher level of complexity

by being submitted to mechanical stimulation.^[12] Although such a concept was rather evident in the orthopedic field, where load bearing is known to be of great importance in tissue differentiation, it also turned out to be valuable for other tissues, such as blood vessels, heart valves, and skin.^[26,32,34]

Bioreactors

If one wants to combine the previous technology with any significant scaling-up process, then bioreactors are a pivotal step in tissue engineering. A great part of the answer lies not only in obtaining large amount of cells, but also exposing them to the appropriate mechanical conditions.

Furthermore, this is a critical pathway for automating at least some of the processes involved in re-creating tissue substitutes.

Gene Therapy

If the combining of DNA into biomaterial has already been proposed, one must also look at gene therapy as an additional and more permanent technology for obtaining better tissue-engineered organs.

For example, in re-creating the pancreas, at the present time a high number of Langerhans cells are necessary for an appropriate level of insulin secretion. If these cells were amenable to higher levels of secretion, this would be of great advantage in the treatment of diabetic patients.

Another example is reconstructed blood vessels with anti-atherosclerotic molecules secreted by either smooth muscle cells or endothelial cells. Here, the patient most prone to restenosis could benefit from a superior type of graft. However, this technology brings these substitutes into an entirely different regulatory environment. It may be a step that will be valuable, but the time frame of such a step is difficult to predict today.

This does not deter many groups working on various types of “universal” donor cells. Such cells, devoid of specific immunological markers, usually targeted in rejection, would allow the creation of well-tolerated substitutes. But once again, this task may entail more complexity than meets the eye.^[50]

MULTIDISCIPLINARY TEAMWORK IN TISSUE ENGINEERING

It seems to us that the best way to meet all these challenges is to combine various types of expertise that have not always been tied together in the past. Many

regional and national programs in tissue engineering are addressing this issue.

The LOEX group has always brought together a triad of specialties into its tissue engineering efforts:

- Cell and molecular biologists
- Bio-engineers
- Biomedical clinical investigators

When we set about the project of re-creating ligaments, the orthopedic surgeons declared the anterior cruciate ligament to be of the utmost clinical importance. They also gave the team a sense of alternative therapies and what additional advantages a tissue-engineered substitute should bring. This enabled the team to reach a set of biological and mechanical criteria for each substitute. This combination has proven to be quite fruitful in forging ahead with tissue engineering projects that are clinically focused. Thus, as a first step the biomedical clinical investigators help the whole team set the stage in pinning down the most significant goals to be achieved for a particular substitute. This interaction helps in determining the most acute need in tissue reconstruction for any body system. Then the cell biologists strive to reconstruct the organ or tissue with what is deemed to be the best tissue engineering approach. The pluses and minuses of each approach have already been presented and will, in a sense, dictate the best fit. One of the most crucial roles of the cell biologists at this point is to obtain the various cells necessary for the reconstruction. Their challenge is not only to find appropriate sources of cells, but also to establish efficacious extraction methods. The purity of the cells is of paramount importance if the tissue engineering effort is to be successful.

Afterward, the expansion of cells must be efficacious enough to obtain the amount of cells and the appropriate quality necessary for the reconstruction. The cell and molecular biologists will have also settled on some functional biological requirements for the tissue-engineered organs. This may be a cellular function such as the antithrombotic properties of endothelial cells or an exocrine secretory function such as insulin for pancreatic Langerhans cells.

The role of bio-engineers is also of great value. They frequently can create or refine bioreactors to facilitate and accelerate the expansion of the necessary cells. They maintain a close relationship with the biologists so that the processes are not deleterious to the cellular phenotypes and function. But usually at the inception of a project, the biomechanical engineers are in close interaction to create different types of apparatus that will induce the appropriate mechanical strains in the reconstructed tissues. These strains may appear passively or be induced by machines that, for example, bring pulsatile flow to a reconstructed blood vessel.

There is now clear evidence that such mechanical preparation is advantageous not only for the structural integrity, but also for some functions of tissue-engineered substitutes. Many cells have been shown to acquire their *in vivo* phenotype when exposed *in vitro* to strains similar to those encountered in the human body.^[12,30,34,51]

All this multidisciplinary work forms a working loop of interaction between teams. This is quite understandable, as advances in each sector have some bearing on the other members of the team.

There is also a two-step paradigm to our efforts in a given tissue engineering project. The first step, while taking into account what has been previously described, aims at recreating a three-dimensional structure that will have a satisfactory histological aspect. However, the biological and mechanical properties are not the main purpose. The team strives to demonstrate the possibility of assembling the various cells and tissues to form an organ that will have acceptable tissular organization and enough stability to maintain it in culture. The second step is optimization of the desired mechanical and biological functions. This leads to an intensive collaboration between the biologists and the engineers.

This two-step paradigm can be well observed in our own effort at recreating a tissue-engineered blood vessel (TEBV). Our first publication, using the self-assembly approach to tissue engineering, had allowed us to recreate all three layers of a blood vessel.^[40] The histological analysis revealed well-defined adventitia, media, and intima with no crossover contamination from the different cell types between layers. Furthermore, a few very important functions were shown to be present, such as incorporation of acetylated LDL by endothelial cells and antithrombogenic activity.^[51] But no vasoreactivity was noted, and the mechanical resistance was very weak. This TEBV was thus not regarded as acceptable for grafting. The second generation, utilizing the self-assembly approach, answered those pitfalls in an interesting manner. The vasoreactivity of these vessels was clearly established as their supraphysiological burst pressure settled around 2500 mm Hg.^[40,52] This is a fitting example to a stepwise road to the completion of a tissue-engineered organ *in vitro*. Thereafter the role of the clinician is of paramount importance in creating protocols for grafting these substitutes first in animals and then into the human host.

CONCLUSION

Tissue engineering has opened fascinating perspectives in the biomedical armamentarium. The astounding clinical demand for such biotechnological solutions ensures that this research domain will continue to forge ahead.

On the other hand, the road to success has also a few meanders that should be carefully addressed if this field is to keep its pace. There is a tremendous level of trepidation related to the expanding knowledge of both embryonic and adult stem cells. The question surrounding the ethical acceptability of using embryonic stem cells is already partly out of the scientists' hands. Various nations will have to define the boundaries of acceptable utilization of embryonic stem cells.

Next we will have to solve the important aspect of host acceptance of the tissue-engineered graft. There is no problem for an autologous construct; however, allogeneic grafting brings about the eventual problem of rejection. If tissue engineers want to stay clear of the immunosuppressive drug used in classical organ transplantation, new solutions will be necessary. The two main efforts have, up to now, aimed at either rendering the graft less of a target or inducing tolerance in the receiver. Here, tissue engineers are accompanied by all the transplantation community, thus heightening the possibilities of successes.

Finally, the regulatory aspect will eventually become clearer. The examining agencies in many countries are responding to these new therapies. However, the channel of communication must be well established between regulators and tissue engineers to ensure a safe but not too constraining introduction of this form of therapy into the clinical arena.

Whatever lays ahead for tissue engineering, it is already clear that this field will alleviate much suffering and improve life for many patients around the world.

ACKNOWLEDGMENTS

The authors are grateful to all LOEX investigators and their external collaborators in the development of reconstructed living substitutes by tissue engineering, and to all members of the LOEX laboratory for their kind help, advice, and technical assistance in relation to the work presented in this review. INTRODUCTION

The characterization, separation, and positioning of cells are all subjects of importance in tissue engineering. Alternating current (AC) electrokinetics, the movement of particles (including cells) in AC electric fields, can be used to do all of this—and more! To observe AC electrokinetic effects, very high electric field strengths are needed. Such electric fields are readily produced with quite small voltages using microelectrodes. Such microelectrodes are nowadays readily produced using microfabrication techniques borrowed from the electronics industries. Alternating current electrokinetic techniques are highly flexible because electrical signals are easy to control, individual electrodes can be addressed, and the direction of induced particle movement can depend on the AC frequency. The small scales at which electrokinetic devices can be produced makes AC electrokinetics particularly suitable for the manipulation and characterization of single cells and the separation of small numbers of cells. In addition, because arrays of electroactive regions are easily produced, the method is suitable for manipulating many cells simultaneously. Especially interesting for tissue engineering is the emerging use of AC electrokinetic microdevices for two- and three-dimensional (3D) patterning of cells. This could be used to create microniches and microenvironments *in vitro*.

WHAT IS AC ELECTROKINETICS?

The term AC electrokinetics describes the movement of particles, including cells, in AC electric fields.^[1–4] With its direct current (DC) counterpart electrophoresis, ultrasound, and laser trapping AC electrokinetics forms a set of physical techniques that can be used for the manipulation of cells.^[5–7] Each physical manipulation technique has its own advantages and disadvantages (Table 1). In an alternating electric field the electric field continuously changes direction, from a few times per second or less to many million times per second. Unlike electrophoresis, which occurs in DC electric fields, particle movement is not dominated by

the surface charge of the particles, but by dipole effects. A dipole is a particle in which equal but opposite electrical charges are present at two opposite sides of the particle. Dipoles can be permanent, or induced by external electric fields. How easy it is to induce a dipole in a particle depends on its polarizability. The polarizability of materials is in turn determined by their conductivity and dielectric constant (permittivity). For many materials, and cells in particular, the values of the conductivity and permittivity change with frequency. As a result, the AC electrokinetic behavior of the cells is highly dependent on the frequency used.^[2,3] At low frequencies (typically <10 kHz), polarization mechanisms dominate that are caused by the surface charge on the cell surface and the ion double layers formed on the surface. At midrange frequencies (10 kHz–100 MHz), the cell electrical properties are dominated by interfacial polarization mechanisms occurring at the interfaces between the cell membrane, the cytoplasm, and the medium. At higher frequencies, polarization of the molecules and atoms of which a cell consists dominates. The midfrequency range, at which (Maxwell–Wagner-type) polarization occurs at the interfaces of the structures that constitute a cell, is the one that is most used and studied in AC electrokinetics. Because an intact and viable cell is surrounded by a membrane barrier that has a low dielectric constant (~ 6) and low conductivity ($\sim 10^{-7}$ S/m) compared to the cytoplasm (dielectric constant/permittivity ~ 50 – 200 , conductivity ~ 0.1 S/m) and the suspending medium (dielectric constant of pure water ~ 79 , conductivity depends on the amounts of dissolved salts), a cell has very interesting dielectric properties that are highly frequency dependent (Fig. 1).

Although it is possible to observe AC electrokinetic effects using relatively large electrodes (centimeters) and large voltages (kilovolts), it is often more convenient to demonstrate AC electrokinetic effects using microelectrodes (typically 10–100 μm) and relatively modest voltages (typically 0–20 $V_{\text{pk-pk}}$).^[8,9] The added advantage of using microelectrodes is that heating effects are reduced because heat is more quickly dissipated. Microelectrodes are most conveniently made

Table 1 Comparison of different physical particle manipulation techniques*Electrophoresis*

Directional; electrodes needed; manipulation of many cells simultaneously possible; medium conductivity important; heating effects important

AC electrokinetics

Large frequency range (Hz–GHz); directional (positive and negative forces); frequency-dependent movement; separation of cells according to different electrical properties possible; conductivity affects movement; low conductivity often necessary; manipulation directly in growth medium difficult; high spatial resolution; microelectrodes needed in close vicinity of cells; high control of cell movement; possible to manipulate many cells simultaneously

Ultrasound

Standing waves; mainly nondirectional, so limited range of movements; manipulation can be done directly in growth medium; limited frequency range (typically 1–10 MHz); separation of cells according to differences in acoustic properties difficult; low spatial resolution; ultrasound sources can be placed at long distances; manipulation of many cells simultaneously possible

Optical traps (optical tweezers)

Limited range of movements; high spatial resolution; high control over cell movement; manipulation can be done directly in growth medium; laser light source can be at a long distance away from cells; possibility to manipulate many cells simultaneously limited

All techniques suffer to some extent from heating effects; these are particularly important for electrical techniques when used directly in growth medium.

using photolithography, although other techniques such as laser ablation are also sometimes used. Electrodes have been made of a variety of materials, including gold, titanium, chromium, aluminum, platinum, indium tin oxide (ITO). Electrodes of titanium and platinum tend to be more durable, while electrodes from ITO are both durable and transparent. More often than not the substrate is glass, although other materials such as plastic and silicon can and have also been used. Electrode shape determines the electric field pattern. Electrode size is typically a small number of multiples of the diameter of the particle (cell) being investigated. Structures can be made in which each electrode is individually addressed, but often electrodes are of a design in which the electrodes are connected to common bars to simplify the electrode construction process. Some designs make use of insulating layers deposited on or near electrodes to create local high-field regions. Examples of electrode designs are shown in Fig. 2. Typically, a signal generator producing sinusoidal signals is used to generate the electric fields. For some effects, for example, electrorotation (ROT) and traveling wave dielectrophoresis (DEP), sources that have four outputs, which are 90° phase shifted relative to each others are normally used.

DESCRIPTION OF DIFFERENT AC ELECTROKINETIC TECHNIQUES

A number of different AC electrokinetic techniques exist.^[1,2] Fig. 3 shows some of the techniques.

Electrostriction

Electrostriction refers to the mechanical distortion of particles in electric fields. Electrostriction of animal cells can be readily observed at high electric field strengths, and shows up as a distortion of the cell. If the electric field becomes too strong the cells can be destroyed.^[10]

Electro-orientation

Electro-orientation refers to the orientation of nonspherical particles in electric fields. At different frequencies, in strong electric fields, nonspherical cells would orient with different axes along electric field lines.^[3,11] For example, ellipsoidal erythrocytes with three different axes of rotation have been shown to orient along three different axes at different frequencies.^[11] The technique has been used in cell characterization, and could potentially be used in the creation of tissues containing oriented cells.^[12]

Normal DEP

Dielectrophoresis, also called normal dielectrophoresis to distinguish it from traveling wave dielectrophoresis, is the most studied AC electrokinetic effect. (Normal) DEP is the movement of particles in nonuniform electric fields. It has been used for cell characterization, cell separation, particle trapping, and the production of structured biomaterials, as well as bringing cells together for (electro)fusion.^[1,8,13–32] Positive and

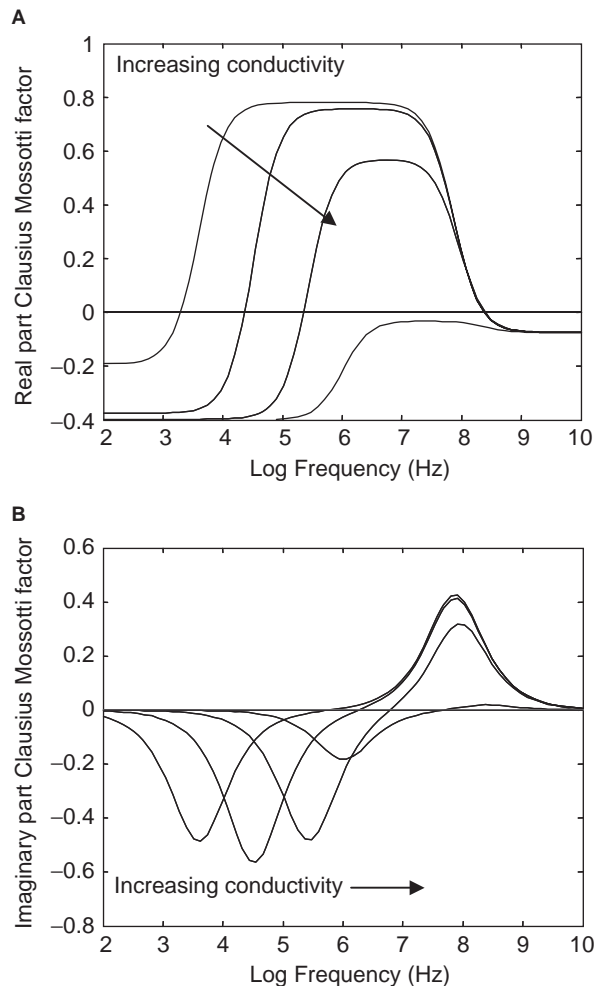

Fig. 1 Real (A) and imaginary (B) parts of the Clausius–Mossotti factor $(\epsilon_p^* - \epsilon_m^*) / (\epsilon_p^* + 2\epsilon_m^*)$ calculated for a mammalian cell using the multishell model. (From Ref. [13].) ϵ_p^* is the complex permittivity of the particle (cell), ϵ_m^* the complex permittivity of the suspending medium. $\epsilon^* = \epsilon - j\sigma/\omega$, where ϵ is the permittivity, σ the conductivity, and ω the frequency (in radians per second). $j = \sqrt{-1}$. The values for the properties of the different structures in the cell (cytoplasm, membrane) were taken as in Wang et al., except for $\epsilon_{\text{cytoplasm}} = 60$. (From Ref. [34].) Conductivity values used were 10^{-3} , 10^{-2} , 10^{-1} , and 1 S/m. The real and imaginary parts of the Clausius–Mossotti factor can in turn be used to calculate the different electrokinetic effects such as the dielectrophoretic force, electrorotation rate, etc. (From Ref. [2].) The dielectrophoretic force is determined by the real part of the Clausius–Mossotti factor. As a result, (A) clearly shows the effects of frequency and conductivity on the dielectrophoretic force.

negative DEP is possible, depending on whether particles move toward high-field regions between the electrodes (positive DEP) or away from them (negative DEP) (Fig. 4). Whether positive or negative DEP occurs depends on the polarizability of the particle relative to its suspending medium.^[9] If it is more

polarizable, positive DEP occurs, if less, negative. For animal cells to show positive DEP it is necessary to suspend the cells in low-conductivity iso-osmotic buffers. Negative DEP can be induced in low-conductivity buffers using low frequencies (typically below 50 kHz) or high frequencies (typically over 50 MHz), or at any frequency at very high medium conductivities (see Fig. 1). Especially at low conductivities and low frequencies, strong forces are exerted on the cell membrane, which, if strong enough, can disrupt cells.^[32] The low concentration of essential ions and other media components can also affect the cells adversely, and the exposure of the cells to these conditions should be kept to a minimum. At high medium conductivities the temperature of the suspending medium can be significantly increased by the applied electrical currents.^[17] It is, therefore, often necessary at high medium conductivities to limit the exposed electrode surface area, making it more difficult to manipulate many cells simultaneously.^[17] When applying electric fields over longer periods of time, hydrogen peroxide can be produced, which can affect cells adversely. Catalase can be added to the medium to overcome this problem.^[33]

Electrorotation

Electrorotation is the rotation of particles in electric fields.^[13,34] The ROT rate is dependent on the imaginary part of the Clausius–Mossotti factor (Fig. 1).^[2] Clockwise and anticlockwise rotation is possible, depending on the polarizability of the particle relative to that of the suspending medium. Although ROT can also sometimes be observed in nonphase shifted electric fields, it is best observed by applying four 90° phase-shifted sinusoidal signals to four electrodes surrounding a particle under investigation (see Fig. 3D). The technique is particularly useful for the characterization of the electrical properties of single cells. By measuring the ROT rate at different frequencies ROT spectra can be obtained, from which the electrical properties of the cell can be determined.

Traveling Wave Dielectrophoresis, Traveling Wave Devices

Traveling wave dielectrophoresis (TWD) refers to the lateral movement of particles in phase-shifted electric fields.^[35] Such phase-shifted electric fields can be produced by applying 90° phase-shifted electric fields to electrodes which are placed next to each other. By extending the electrode arrays, repeating the application of the 90° phase-shifted electric fields to every four consecutive electrodes (see Fig. 3E), railway track-like arrays can be produced, which can be used to

Fig. 2 Some examples of electrodes used for the patterning of cells. (A) Top view of a trap based on negative dielectrophoresis as used by Heida and coworkers. (From Refs. [20,21].) The system is able to trap cells by negative dielectrophoresis directly in growth medium. To prevent excessive heating, the electrodes outside the center are covered by an insulating layer. (B) Top view of an interdigitated oppositely castellated electrode system used to form cell aggregates by positive dielectrophoresis. (From Refs. [26–30].) Cells are suspended in low-conductivity buffer. (C) Top view of a parallel electrode system. (From Refs. [26–30].) Each electrode can be addressed individually, attracting cells suspended in low-conductivity buffers by positive dielectrophoresis. (D) Side view of a section through a parallel plate chamber as used by Albrecht et al. (From Ref. [25].) The top chamber is formed by an ITO covered slide, the bottom layer by an ITO covered slide, on which an electrically insulating layer of photoresist is to form local high-field regions to which cells suspended in low-conductivity buffers can be attracted by positive dielectrophoresis. Other electrode arrangements can be found in the literature. (From Refs. [19,22,23].)

characterize and separate particles, or to bring them together. Like ROT, it is dependent on the imaginary part of the Clausius–Mossotti factor.^[36]

APPLICATIONS OF AC ELECTROKINETICS IN TISSUE ENGINEERING

Alternating current electrokinetics has found the following main applications:

Characterization of Cell Properties

Typically, ROT and DEP are used to determine a cell's electrical properties. The dielectrophoretic force

and/or ROT rate is determined as a function of frequency, and a model (such as the multishell model) used to describe the relation between the properties of a cell's substructures and its overall particle electrical properties.^[13] The resulting model is fitted to the data in the dielectrophoretic or ROT spectrum to obtain the values of the different parameters. For mammalian cells, which have no cell wall, the most important substructures are the cell membrane and the cytoplasm; the nucleus and other membranous structures inside the cells only make a contribution to the cell dielectric properties if they occupy a large part of the cytoplasm. The integrity of the cell membrane is very important. The cell membrane normally has a very low conductivity and dielectric constant (permittivity) compared to the cytoplasm and suspending medium.

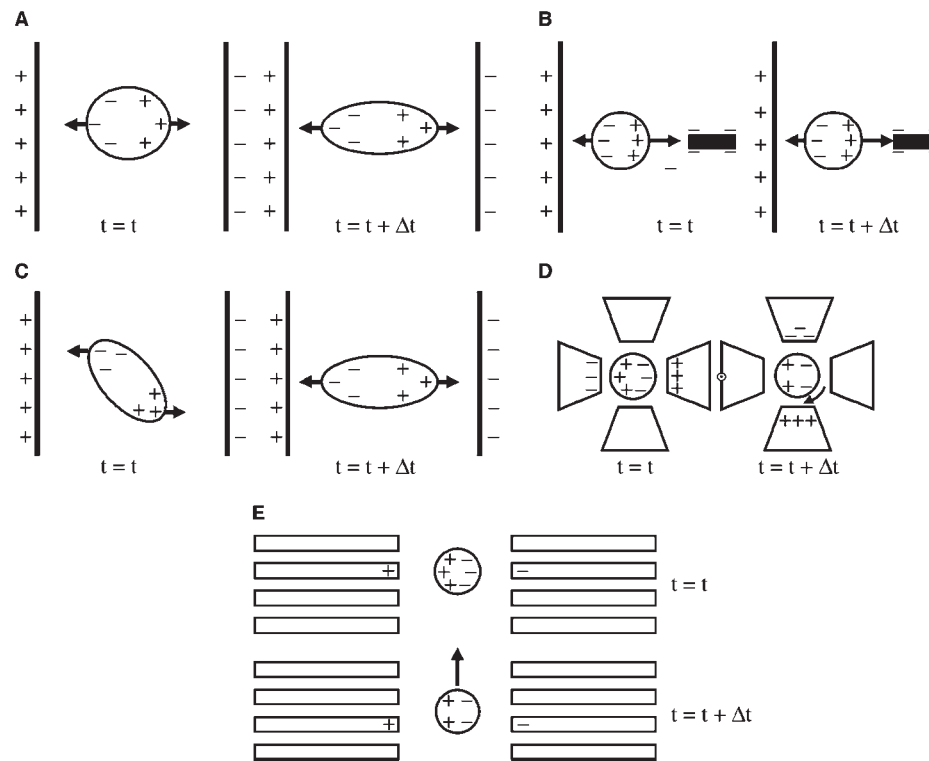

Fig. 3 Outline of the main AC electrokinetic effects. (A) Electrostriction, the distortion of particles by applied electric fields. (B) Dielectrophoresis, the movement of particle in nonuniform electric fields. (C) Electro-orientation, the orientation of elongated particles in electric fields. (D) Electrorotation, the rotation of particles in electric fields. At $t = t$ a dipole is induced in the particle. Switching the electric field at $t = t + \Delta t$ is instantaneous. The dipole induced in the particle does not disappear as quickly as the electric field is switched, and the interaction between the applied field and the remaining charges on the particle cause the particle to rotate. (E) Traveling wave dielectrophoresis. As in electrorotation, the electric field is switched from one set of electrodes to another. The interaction between the applied electric field and the dipole remaining in the particle causes it to move.

Any changes in its properties, for example, permeability, can be readily detected.^[13] The membrane capacitance is also strongly dependent on the presence of blebs and other forms of folding of the membrane.^[34] Apoptosis and necrosis are both associated with large changes in the internal conductivity and membrane properties, which lead to large differences in their AC electrokinetic behavior.^[13] Changes detected in the dielectric properties of cell during the transition from the noncancerous to the cancerous state have been associated with changes in membrane properties.^[14]

Separation of Cells

Differences in the electrical properties between cells, caused by differences in their structure and composition, lead to differences in dielectrophoretic behavior. These are sometimes large enough for their separation. Typically, in dielectrophoretic separations large arrays of electrodes of the interdigitated or interdigitated castellated type are used, covering the

bottom of a long, narrow chamber. Cells are either attracted to the electrodes by positive DEP, or pushed away to low-field regions between or above the electrodes by negative DEP. Selected cell populations are then moved out of the chamber. In dielectrophoretic field-flow fractionation the parabolic velocity profile of a fluid flowing through the chamber is used to advantage to improve the separation process and selectively move cells with different dielectrophoretic behaviors through the chamber at different speeds.^[14] In TWD no flow is needed, but the cells can be made to move to different parts of the separation chamber using the electric fields only. Typical examples of successful separations are those of dead and live cells, stem cells from nonstem cells, and cancer cells from noncancer cells.^[14]

Sorting of Cells

Dielectrophoretic forces produced by microelectrodes in a flow of suspended particles allow particles to be diverted into different streamlines, and thereby led

Fig. 4 Outline of positive and negative dielectrophoresis. The indented lines indicate the equipotential lines. Where the lines are closest, the electric field is highest. Positive dielectrophoresis (A) occurs when the particle is more polarizable than the surrounding medium. The dipole formed as a result of the polarization of the particle and the medium is aligned with the electric field, and the particle moves to high-field regions. Negative dielectrophoresis (B) occurs when the particle is less polarizable than the medium. The dipole is aligned opposite to the electric field, and the particle moves to the low-field regions. Note that for both positive and negative dielectrophoresis, when the electric field direction reverses, the induced dipole also reverses, and the direction of the net force stays the same. Thus, dielectrophoresis can occur in DC as well as AC electric fields.

into different channels. This approach could lead to miniaturized cell sorters.^[18] Microfluidic cell sorters, especially when combined with high-resolution analysis systems, could be particularly useful when handling relatively rare or valuable cells such as stem cells.^[18]

Trapping of Cells/Production of Structured Biomaterials

Alternating current electrokinetics can be used to trap (single) cells, to pattern cells on a surface, and to form aggregates of cells. The potential to use AC electrokinetics to produce tissue-like materials was first demonstrated by Pohl in 1972, who was able to trap and orient bacterial cells at an electrode surface, and then immobilize them using a concentrated aqueous solution of Pluronic.^[12] Pluronic is a block-copolymer of polyethylene and polypropylene oxide, which is fluid at 0–5°C, but sets at 35–40°C. Later, the introduction of microelectrodes led to an interest in trapping of single cells.^[17] Progress in the use of AC electrokinetics for patterning has been relatively slow, but in recent years the use of AC electrokinetics for the patterning of cells and the creation of aggregates and tissue-like materials has been receiving increasing attention.^[9,18–31]

Entrapment of the cells can be achieved with either positive or negative DEP; both methods have their own advantages and disadvantages. When positive

DEP is used, the cells are suspended in low salt buffers and attracted to high-field regions at electrode edges, typically at a frequency of 1 MHz. With negative DEP, cells are pushed into low-field regions between the electrodes. Trapping with positive DEP tends to be more rapid than trapping with negative DEP.^[24] In a typical experiment one starts with suspended cells, and uses DEP to guide cells to and trap them in specific areas on a surface. Although it is possible to continuously trap cells using an electric field only, it is often more convenient (and when using positive DEP, essential) to immobilize the cells once they have reached their destination.^[17,20,21] Sometimes cells can be made to adhere to a surface.^[19] In other cases, cells have to be immobilized in other ways. Embedding in hydrogels is used, but cross-linking is also possible.^[24,25,30] The use of hydrogels and cross-linking has the advantage that 3D physical microenvironments are created, which mimic the cell's natural microenvironment more closely than 2D systems.

The potential to use AC electrokinetics to create artificial neural networks has received a lot of attention. Heida and coworkers and other researchers have used negative DEP to create artificial neural networks by directing neural cells toward the center of a quadrupolar electrode system using negative DEP.^[20–22] It was possible to do the experiments directly in growth medium by insulating the electrode areas that were not used directly for cell manipulation, thus reducing heat production by the electric field.^[20,21] Other groups have

sought to use AC electrokinetics to pattern cells and recreate the microenvironment found in actual tissues. Matsue et al.^[31] used negative DEP to pattern cells, and subsequently immobilized them in a gel. Markx et al. used positive DEP to create multilayered aggregates of cells.^[26,27,30] By addressing individual interdigitated electrodes in an electrode array the group was able to put different cell types next to each other.^[26] Initially, the techniques were only used for microorganisms, but lately they have been adapted for use with mammalian cells.^[26,27,29,30] Cell immobilization was achieved with hydrogels or flocculating agents. Albrecht et al. have described a similar approach, using photopolymerizable PEG to immobilize cells.^[25] Instead of addressing individual electrodes, the approach taken was to pattern the cell with DEP, and then to immobilize cells in specific regions in a gel by exposing a photopolymerizable prepolymer solution through a mask, and subsequently wash away the cells and precursor in the unexposed regions. Finally, trapping of cells by DEP allows the production of large arrays of cell aggregates or even single cells, with an aggregate or cell in a specified location.^[19,25–27,29] This has many potential applications in biosensors and high-throughput analytical devices.

CONCLUSIONS

The application of AC electrokinetics in tissue engineering is still in its infancy and has to date been limited, but is likely to expand significantly in the near future. Tissues are made of specific combinations of specialized cells. Alternating current electrokinetics is unique in that it can be used for the separation of the specialized cells of which tissues are made, their characterization, as well as the actual formation of tissue-like materials. In our opinion, the layering of multiple cell types in direct contact with each other is a particularly important emerging area in AC electrokinetics. Although much early work was done with more robust microorganisms, the use of AC electrokinetics in building tissue equivalents from suspended mammalian cells is increasingly becoming a reality. The application of AC electrokinetics to building 3-D mammalian systems is particularly important because it is clear that cells placed in 3-D culture systems behave significantly differently from cells in 2-D cultures.^[37] Cells patterned using AC electrokinetics are potentially, particularly, useful for defining molecular interactions between different cell types. Aggregates of bacterial cells with defined internal architectures, made using DEP, have already been shown to be capable of responding to molecular signals and the exchange of nutrients.^[29,38] This approach may also be useful for studying the role of soluble mediators in mammalian

cells systems. Layering cells in adjacent positions could also enable the study of direct cell–cell interactions such as those mediated by adhesion molecules or ligand-receptor pairs.

Finally, while AC electrokinetics in itself is an excellent technique for manipulating cells, its usefulness could be even further enhanced by combining electrokinetic approaches with other physical manipulation techniques such as laser tweezers. For example, AC electrokinetic techniques are very suitable for the creation of cell arrays, while laser tweezers are excellent at maneuvering individual cells into specific positions. Combining the strengths of AC electrokinetics and laser tweezers in this way has many potential applications, in particular in the area of stem cell biology and the study of the stem cell microenvironment.

Tissue Engineering of Bladder

Anthony Atala

Wake Forest Institute for Regenerative Medicine, Winston-Salem, North Carolina, U.S.A.

INTRODUCTION

The bladder is exposed to a variety of possible injuries from the time the fetus develops, and may require replacement or repair. Currently, gastrointestinal segments are commonly used as tissues for bladder replacement or repair. However, gastrointestinal tissues are designed to absorb specific solutes, whereas bladder tissue is designed for the excretion of solutes. When gastrointestinal tissue is in contact with the urinary tract, multiple complications may ensue, such as infection, metabolic disturbances, urolithiasis, perforation, increased mucous production, and malignancy.^[1-4] Due to the problems encountered with the use of gastrointestinal segments, numerous investigators have attempted alternative materials for tissue regeneration and engineering for bladder replacement or repair.

MATRICES FOR BLADDER REGENERATION

Over the last few decades, several bladder wall substitutes have been attempted with both synthetic and organic materials. The first application of a free tissue graft for bladder replacement was reported by Neuhoff in 1917, when fascia was used to augment bladders in dogs.^[5] Since that first report, multiple other free graft materials have been used experimentally and clinically, including bladder allografts, pericardium, dura, and placenta.^[6-9] Synthetic materials, which have been tried previously in experimental and clinical settings, include polyvinyl sponge, tetrafluoroethylene (Teflon), collagen matrices, vicryl matrices, and silicone.^[10-13] Most of these attempts have usually failed due to either mechanical, structural, functional, or biocompatibility problems. Usually, permanent synthetic materials succumb to mechanical failure, and urinary stone formation and degradable materials lead to fibroblast deposition, scarring, graft contracture, and a reduced reservoir volume over time.

There has been a resurgence in the use of various collagen-based matrices for tissue regeneration. Fresh placental membranes have been used experimentally in dogs.^[9] Biodegradable pericardial implants were used for bladder augmentation in dogs.^[9] Functionally, the implanted bladders showed adequate capacity for up to 36 months, but grossly, they were noted to undergo

graft shrinkage. Histologically, the epithelial layer was present, but the muscular layer was absent. Bladder grafts, initially used experimentally in 1961, have been used recently by various investigators.^[6,14-16] In multiple studies using different materials as the acellular bladder graft for cystoplasty, the urothelial layer was able to regenerate normally, but the muscle layer, although present, was not fully developed.^[14-17]

Small-intestinal submucosa (SIS), a biodegradable, acellular, xenogeneic collagen-based tissue-matrix graft, has been shown to promote regeneration of a variety of host tissues, including blood vessels and ligaments. The matrix is derived from pig small intestine in which the mucosa is mechanically removed from the inner surface and the serosa and muscular layer are removed from the outer surface.

Animal studies have shown that the SIS matrix used for bladder augmentation is able to regenerate *in vivo*. Augmentation cystoplasty with SIS was performed in eight dogs, which were followed for 15 months.^[17] Preoperative mean bladder capacity was 51 ml compared to a postoperative mean capacity of 55 ml. The mean maximal voiding pressure was 52 cm H₂O preoperatively and 45 cm postoperatively. Histologically, the transitional layer was the same as that of the native bladder tissue, but as with other collagen matrices used experimentally, the muscle layer was not fully developed. A large amount of collagen was interspersed between a smaller number of muscle bundles. A computer-assisted image analysis demonstrated a decreased muscle-to-collagen ratio with a loss of the normal architecture in the SIS regenerated bladders.

In-vitro contractility studies performed on the SIS regenerated dog bladders showed a decrease in maximal contractile response by 50% from those of normal bladder tissues.^[17]

TISSUE ENGINEERING OF BLADDERS USING CELL TRANSPLANTATION

Engineering tissue using selective cell transplantation may provide a means to create functional new bladder segments.^[18] In tissue engineering, donor tissue is dissociated into individual cells, which are either implanted directly into the host or expanded in culture, attached to a support matrix, and reimplanted after

expansion. The implanted tissue can be either heterologous, allogeneic, or autologous. Ideally, this approach might allow lost tissue function to be restored or replaced in toto and with limited complications.^[18] The approach, which we have followed to bioengineer urologic tissues, involves the eventual use of autologous cells, thus avoiding rejection, wherein a biopsy of tissue is obtained from the host and the cells are dissociated and expanded in vitro, reattached to a matrix, and implanted into the same host.^[15,18–37]

The success of using cell transplantation strategies for bladder reconstruction depends on the ability to use donor tissue efficiently and to provide the right conditions for long-term survival, differentiation, and growth. We have achieved an approach to bladder tissue regeneration by patching isolated cells to a support structure, which would have suitable surface chemistry for guiding the reorganization and growth of the cells. The supporting matrix is composed of biodegradable artificial or natural polymers which can allow cell survival by diffusion of nutrients across short distances once the cell-support matrix is implanted. The cell-support matrix becomes vascularized in concert with expansion of the cell mass following implantation.

Cell Expansion

One of the initial limitations of applying tissue engineering techniques to the bladder was the previously encountered inherent difficulty of growing genitourinary-associated cells in large quantities. In the past, it was believed that urothelial cells had a natural senescence, which was hard to overcome. Normal urothelial cells could be grown in the laboratory setting, but with limited expansion. A system of urothelial cell harvest was created in our laboratory that does not use any enzymes or serum and has a large expansion potential.^[26] Urothelial cells are expanded until the desired cell numbers are obtained. Using these methods of cell culture, it is possible to expand a urothelial strain from a single specimen that initially covers a surface area of 1 cm² to one covering a surface area of 4202 m² (the equivalent area of one football field) within 8 weeks.^[26] The muscle cells are processed by the tissue explant technique and are expanded in a similar manner. We have shown that normal human bladder epithelial and muscle cells can be efficiently harvested from surgical material, extensively expanded in culture, and their differentiation characteristics, growth requirements, and other biological properties studied.^[15,26,27,29–40]

Cell Delivery Vehicles

As described initially by Judah Folkman in 1973, cells or tissue cannot be implanted in volumes greater than

3 mm³.^[41] Nutrition and gas exchange are limited by this maximum diffusion distance. If cells were implanted in volumes greater than 3 mm³, only the cells on the surface would survive, and the central cell core would necrose due to a lack of vascularity.^[41] The cell delivery vehicles we have used are designed for cell attachment and capillary infiltration to the interstitial spaces after implantation in vivo.^[15,24,25,27,29–32,34–37] In this manner, large numbers of cells can be implanted with maximal survival.

Both synthetic and natural biodegradable materials have been used as cell delivery vehicles.^[15,24,25,27,29–32,34–37] We have used resorbable biodegradable polymers, which are preferable because permanent polymers, such as silicone and Teflon, carry the risks of infection, calcification, and unfavorable connective tissue responses.^[18] The cell delivery scaffolds used experimentally in our laboratory include poly(glycolic acid) (PGA) polymer scaffolds alone and with copolymers of poly(L-lactic acid) and poly(DL-lactide-co-glycolide).^[24,25,36] These polymers have many desirable features: They are biocompatible and processible. Degradation occurs by hydrolysis, and the time sequence can be varied from weeks to over a year by manipulating the ratio of monomers and by varying the processing conditions. We have also used processed collagen derived from allogeneic donor bladder submucosa.^[15] These biodegradable matrices, both natural and artificial, can be readily modified, depending on their intended application, into a variety of shapes and structures, including small-diameter fibers and porous films, to various levels of rigidity or elasticity, and to different time sequences for degradation.

The porosity, pore size distribution, and continuity dictate the interaction of the biomaterials and transplanted cells with the host tissue. The appropriate porosity and branching pattern of the matrix results in the formation of a capillary network in the developing tissue.^[15,24,25,27,29–32,34–37] Vascularization of the engineered tissue is required to meet the metabolic requirements of the tissue and to integrate it with the surrounding host.

Formation of Bladder Tissue Ex Situ

Urothelial and muscle cells can be expanded in vitro, seeded onto the polymer scaffold, and allowed to attach and form sheets of cells. The cell-polymer scaffold can then be implanted in vivo. We have performed a series of in-vivo urologic-associated cell-polymer experiments. Histologic analysis of human urothelial, bladder muscle, and composite urothelial and bladder muscle-polymer scaffolds, implanted in athymic mice and retrieved at different time points, indicated that viable cells were evident in all three

experimental groups.^[25] Implanted cells oriented themselves spatially along the polymer surfaces. The cell populations appeared to expand from one layer to several layers of thickness with progressive cell organization with extended implantation times. Cell-polymer composite implants of urothelial and muscle cells, retrieved at extended times (50 days), showed extensive formation of multilayered sheet-like structures and well-defined muscle layers. Polymers seeded with cells and manipulated into a tubular configuration showed layers of muscle cells lining the multilayered epithelial sheets. Cellular debris appeared reproducibly in the luminal spaces, suggesting that epithelial cells lining the lumina are sloughed into the luminal space. Cell polymers implanted with human bladder muscle cells alone showed almost complete replacement of the polymer with sheets of smooth muscle at 50 days. This experiment demonstrated, for the first time, that composite tissue engineered structures could be created *de novo*. Prior to this study, only single cell-type tissue-engineered structures had been created.

Formation of Bladder Tissue In Situ

In order to determine the effects of implanting engineered tissues in continuity with the urinary tract, an animal model of bladder augmentation was utilized.^[15] Partial cystectomies, which involved removing approximately 50% of the native bladders, were performed in 10 beagles. In 5, the retrieved bladder tissue was microdissected and the mucosal and muscular layers separated. The bladder urothelial and muscle cells were cultured using the techniques described above. Urothelial and smooth muscle cells were harvested and expanded separately. A collagen-based matrix, derived from allogenic bladder submucosa, was used for cell delivery. This material was chosen for these experiments due to its native elasticity. Within six weeks, the expanded urothelial cells were collected as a pellet. The cells were seeded on the luminal surface of the allogenic bladder submucosa and incubated in serum-free keratinocyte growth medium for five days. Muscle cells were seeded on the opposite side of the bladder submucosa and subsequently placed in DMEM supplemented with 10% fetal calf serum for an additional five days. The seeding density on the allogenic bladder submucosa was approximately 1×10^7 cells/cm².

Preoperative fluoroscopic cystography and urodynamic studies were performed in all animals. Augmentation cystoplasty was performed with the matrix with cells in one group, and with the matrix without cells in the second group. The augmented bladders were covered with omentum in order to facilitate angiogenesis to the implant. Cystostomy catheters were used for urinary diversion for 10 to 14 days. Urodynamic

studies and fluoroscopic cystography were performed at one, two, and three months postoperatively. Augmented bladders were retrieved two ($n=6$) and three ($n=4$) months after surgery and examined grossly, histologically, and immunocytochemically.

Bladders augmented with the matrix seeded with cells showed a 99% increase in capacity compared to bladders augmented with the cell-free matrix, which showed only a 30% increase in capacity (Fig. 1). Functionally, all animals showed normal bladder compliance as evidenced by urodynamic studies; however, the remaining native bladder tissue may have accounted for these results. Histologically, the retrieved engineered bladders contained a cellular organization consisting of a urothelial-lined lumen surrounded by submucosal tissue and smooth muscle. However, the muscular layer was markedly more prominent in the cell-reconstituted scaffold.^[15]

Most of the free grafts (without cells) utilized for bladder replacement in the past have been able to show adequate histology in terms of a well-developed urothelial layer; however, they have been associated with an abnormal muscular layer which varies in terms of its full development.^[19,20] It has been well established for decades that the bladder is able to regenerate generously over free grafts. Urothelium is associated with a high reparative capacity.^[42] Bladder muscle tissue is less likely to regenerate in a normal fashion. Both urothelial and muscle in growth are believed to be initiated from the edges of the normal bladder toward the region of the free graft.^[43,44] Usually, however, contracture or resorption of the graft has been evident. The inflammatory response toward the matrix may contribute to the resorption of the free graft.

Fig. 1 Bladders augmented with a collagen matrix derived from bladder submucosa seeded with urothelial and smooth muscle cells (ABS + cells) showed a 100% increase in capacity compared to bladders augmented with the cell-free allogenic bladder submucosa (ABS), which showed only a 30% increase in capacity within three months after implantation. (Reproduced with permission, from Ref. [15].)

We hypothesized that building the three-dimensional structure construct *in vitro*, prior to implantation, would facilitate the eventual terminal differentiation of the cells after implantation *in vivo*, and would minimize the inflammatory response toward the matrix, thus avoiding graft contracture and shrinkage. This study demonstrated that there was a major difference evident between matrices used with autologous cells (tissue engineered) and matrices used without cells.^[15] Matrices implanted with cells for bladder augmentation retained most of their implanted diameter, as opposed to matrices implanted without cells for bladder augmentation, wherein graft contraction and shrinkage occurred. The histomorphology demonstrated a marked paucity of muscle cells and a more aggressive inflammatory reaction in the matrices implanted without cells. Of interest is that the urothelial cell layers appeared normal, even though the underlying matrix was significantly inflamed. We further hypothesized, therefore, that having an adequate urothelial layer from the outset would limit the amount of urine contact with the matrix, and would therefore decrease the inflammatory response, and that the muscle cells were also necessary for bioengineering, since native muscle cells are less likely to regenerate over the free grafts. Further studies performed in our laboratory confirmed this hypothesis.^[36] Thus, it appears that the presence of both urothelial and muscle cells on the matrices we used for bladder replacement are important for successful tissue bioengineering.

Bladder Replacement Using Tissue Engineering

The results of our initial studies showed that the creation of artificial bladders may be achieved *in vivo*; however, it could not be determined whether the functional parameters noted were due to the augmented segment or the intact native bladder tissue. To better address the functional parameters of tissue-engineered bladders, an animal model was designed which required a subtotal cystectomy with subsequent replacement with a tissue-engineered organ.^[36]

A total of 14 beagle dogs underwent a trigone-sparing cystectomy. The animals were randomly assigned to one of three groups. Group A ($n=2$) underwent closure of the trigone without a reconstructive procedure. Group B ($n=6$) underwent reconstruction with a cell-free bladder-shaped biodegradable polymer. Group C ($n=6$) underwent reconstruction using a bladder-shaped biodegradable polymer that delivered autologous urothelial cells and smooth muscle cells. The cell populations had been separately expanded from a previously harvested autologous bladder biopsy. Preoperative and

postoperative urodynamic and radiographic studies were performed serially. Animals were sacrificed at 1, 2, 3, 4, 6, and 11 months postoperatively. Gross, histological, and immunocytochemical analyses were performed.^[36]

The cystectomy-only controls and polymer-only grafts maintained average capacities of 22% and 46% of preoperative values, respectively. An average bladder capacity of 95% of the original pre-cystectomy volume was achieved in the tissue-engineered bladder replacements. These findings were confirmed radiographically (Fig. 2). The subtotal cystectomy reservoirs, which were not reconstructed, and polymer-only reconstructed bladders showed a marked decrease in bladder compliance (10% and 42%). The compliance of the tissue-engineered bladders showed almost no difference from preoperative values that were measured when the native bladder was present (106%). Histologically, the polymer-only bladders presented a pattern of normal urothelial cells with a thickened fibrotic submucosa and a thin layer of muscle fibers. The retrieved tissue-engineered bladders showed a normal cellular organization, consisting of a trilayer of urothelium, submucosa, and muscle (Fig. 3).

Immunocytochemical analyses for desmin, alpha-actin, cytokeratin 7, pancytokeratins AE1/AE3, and uroplakin III confirmed the muscle and urothelial phenotype. S-100 staining indicated the presence of neural structures. The results from this study showed that it is possible to tissue-engineer bladders that are anatomically and functionally normal.^[36]

Fig. 2 Radiographic cystograms in beagles 11 months after subtotal cystectomy without reconstruction (a), with reconstruction using a polymer without cells (b), and with reconstruction using a polymer and cell-seeded tissue-engineered organ (c). Trigone-sparing cystectomy organs retained a small-sized reservoir. Tissue-engineered neobladders showed a normal configuration and a larger capacity than the trigones grafted with polymer only. (Reproduced with permission, from Ref. [36].)

Fig. 3 Hematoxylin and eosin histological results six months after surgery (original magnification: $\times 250$). A: Normal canine bladder. B: The bladder dome of the cell-free polymer-reconstructed bladder consists of normal urothelium over a thickened layer of collagen and fibrotic tissue. Only scarce muscle fibers are apparent. C: The tissue-engineered neo-organ shows a histomorphologically normal appearance. A trilayered architecture consisting of urothelium, submucosa, and smooth muscle is evident. (Reproduced with permission, from Ref. [36].)

Fetal Bladder Tissue Engineering

The prenatal diagnosis of patients with bladder disease is now more prevalent. Prenatal ultrasonography allows for a thorough survey of fetal anatomy.

The evolution of prenatal diagnosis led to the use of intervention before birth to reverse potentially life-threatening processes. However, the concept of prenatal intervention is not limited to this narrow group of indications. A prenatal rather than postnatal diagnosis of exstrophy may be beneficial under certain circumstances. There is now a renewed interest in performing a single-stage reconstruction in some patients with bladder exstrophy. Limiting factors for following a single- or multiple-stage approach include findings of a small, fibrotic bladder patch without either elasticity or contractility, or a hypoplastic bladder.

Today's technological and scientific advances may facilitate the future prenatal management of patients with bladder disease. Having a ready supply of urologic-associated tissue for surgical reconstruction at birth may be advantageous. Theoretically, once the diagnosis of bladder exstrophy is confirmed prenatally, a small bladder and skin biopsy could be obtained via ultrasound guidance. These biopsy materials could then be processed and the different cell types expanded *in vitro*. Using tissue engineering techniques developed at our center and described previously, reconstituted bladder and skin structures *in vitro* could then be readily available at the time of birth for a one-stage reconstruction, allowing for adequate anatomic and functional closure.

Toward this end, we conducted a series of experiments using fetal lambs.^[29,30,32] Bladder exstrophy was

created surgically in ten 90–95-day gestation fetal lambs. The lambs were randomly divided into two groups of five. In group 1, a small fetal bladder specimen was harvested via fetoscopy. The bladder specimen was separated, and muscle and urothelial cells were harvested and expanded separately under sterile conditions in a humidified 5% CO₂ chamber, as previously described. Seven to 10 days prior to delivery, the expanded bladder muscle cells were seeded on one side and the urothelial cells on the opposite side of a 20 cm² biodegradable poly(glycolic acid) polymer scaffold. After delivery, all lambs in group 1 had surgical closure of their bladders using the tissue-engineered bladder tissue. No fetal bladder harvest was performed in the group 2 lambs, and bladder exstrophy closure was performed using only the native bladder. Cystograms were performed three and eight weeks after surgery. The engineered bladders were more compliant ($p=0.01$) and had a higher capacity ($p=0.02$) than the native bladder closure group. Histologic analysis of the engineered tissue showed a normal pattern, indistinguishable from native bladder at two months.^[30] Similar prenatal studies were performed in lambs with engineering of skin for reconstruction at birth.^[32]

The studies described above show that the potential for replicating this technology in humans is possible. Certainly, other tissues such as cartilage, corpora cavernosa, and bowel can be harvested and expanded in the same manner. Similar studies addressing these tissues are now in progress in our laboratory.

In addition to being able to manage the bladder exstrophy complex *in utero* with tissue engineering techniques, one could manage patients after birth in a similar manner, when a prenatal diagnosis is not assured. In these instances, bladder tissue biopsies could be obtained at the time of the initial surgery. Different tissues could be harvested and stored for future reconstruction, if necessary. A tissue bank for exstrophy complex patients could preserve different cell types indefinitely. Gene therapy could also be achieved by transfecting the cells prior to seeding and implantation.^[27]

CONCLUSION

Even though the use of bowel for bladder tissue replacement was first proposed over 100 years ago, it remains the gold standard today, despite its known problems. It is evident that urothelial to urothelial anastomoses are preferable functionally. Multiple new methods and techniques are becoming available for bladder augmentation. Most of the new techniques rely on the use of native urologic tissues, either partially or fully, in an effort to avoid the problems associated with

the use of bowel in the urinary tract. Hopefully, as experience is gained with the recent clinical and experimental approaches, a larger armamentarium of technologies and methods for bladder augmentation will become available.

Recently, functional bladder tissue has been engineered using selective cell transplantation. The approach that has been followed to bioengineer bladder tissue involves the use of autologous cells, thus avoiding rejection, wherein a biopsy of tissue is obtained from the host, the cells dissociated and expanded in vitro, reattached to a matrix, and implanted into the same host. Clinical trials using bioengineered tissues for bladder augmentation are currently being arranged.

T

INTRODUCTION

A suitable conduit for use in bypassing vessels less than 6 mm in diameter remains elusive; in recent years, attention has turned to the field of tissue engineering for potential new treatments. The focus of this article is to review some of the design criteria that have been followed in attempting to produce the first clinically acceptable tissue-engineered blood vessel (TEBV), and to highlight rate-limiting barriers to achieving this goal.

OVERVIEW

Anatomy of the Vasculature

Within the body, nutrients and gases contained in the blood are transported to the body through the vascular system, which is further subdivided into the pulmonary system (to and from the lungs) and the systemic system (to and from the rest of the body). Each of these subsystems is composed of arteries, which deliver blood from the heart to the various tissues and organs; and veins, which return blood back to the heart. Arteries are characterized as pulsatile, high-pressure, and high-flow, whereas veins are characterized as pulseless, low-pressure, and low-flow. Within the various tissues and organs, arteries and veins are separated by a microvascular network of arterioles, capillaries, and venules. Due to the varying pressures and flows in the different parts of the vascular system, the precise structure and function of the vessels differ, although the overall structure of veins and arteries is similar in many ways.

Although the wall thickness varies between arteries and veins, they are both composed of three distinct layers. The intima forms the blood contacting layer and consists of a continuous single layer of endothelial cells that is attached to a layer of connective tissue, composed mainly of elastin and other matrix proteins to form the internal elastic lamina. This layer of connective tissue separates the intima from the cell-rich media. This layer is composed of multiple layers of concentrically arranged smooth muscle cells and collagen and elastin networks. The outermost layer is the adventitia, which

is composed entirely of connective tissue, myofibroblasts, capillaries, and nerves. These three layers are most obvious in the larger diameter veins and arteries.

Clinical Need for Vascular Replacement

According to the American Heart Association, cardiovascular disease claimed nearly 1 million lives in the United States in 1996 alone.^[1] One-half of these are due to coronary artery disease, which is currently the number-one cause of death in the western world. The main cause of coronary artery disease is arteriosclerosis (hardening of the arteries), a disorder characterized by progressive thickening and hardening of the walls of the arteries, causing a decrease in or loss of blood circulation (Fig. 1). In addition, erosion or disruption of the calcified plaques within the arterial wall may trigger the coagulation cascade, resulting in thrombotic occlusion and, often, sudden cardiac death. Since the days of Alexis Carrell, the standard surgical solution to cardiovascular disease has been vascular replacement, or bypass.

The Need for a Tissue-Engineered Blood Vessel

The saphenous vein is the most widely used conduit for bypass grafting,^[2] despite its short- and long-term failure remaining a significant clinical problem.^[3] Diffuse intimal thickening occurs in all autologous saphenous vein grafts within the first year, and late failure of grafts, usually 5–10 years after implantation, is associated with intimal hyperplasia (IH) and atherosclerotic lesions.^[4] Development of intimal thickening is regarded as an unavoidable adaptation of the saphenous vein to the changed hemodynamic conditions.^[5] The process is associated with a migration of adventitial myofibroblasts and smooth muscle cells from the adventitia and media to the intima, where the cells proliferate and change from a contractile to a synthetic phenotype. This arterIALIZATION of the vessel may initially increase patency, but ultimately, intimal hyperplasia is often involved in occlusion of the vessels.

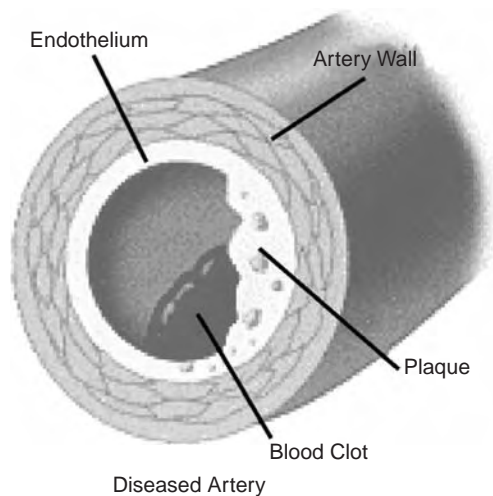

Fig. 1 Stenosed coronary artery. (From Texas Heart Institute at <http://www.tmc.edu/thi/cad.html>.)

There are limitations on alternative conduits for coronary bypass. Arterial grafts are the preferred conduits due to improved long-term patency,^[6] but they are limited due to their short size, small diameter, and availability, because many patients require multiple grafts and synthetic grafts have had only limited success, mainly in larger-diameter vessels.^[7] These clinical shortcomings in the treatment of vascular disease guided many attempts in the development of alternative bypass grafts, including synthetic grafts^[7] and grafts composed of decellularized porcine and human vessels.^[8]

The first report on the use of synthetic grafts was in 1954 when Voorhees showed the potential of using Vinyon-N cloth tubes to repair arterial defects. Subsequent investigators established the potential use of polymeric materials, like Dacron (polyethylene terephthalate), polyesters, and ePTFE (poly-tetrafluoroethylene), to form either permanent or resorbable replacements for the damaged vessels (Fig. 2). In cases where the graft can be of large diameter (greater than 6 mm), the synthetic material has been extremely effective. The main clinical problem that faces surgeons using synthetic graft materials is that they often cause severe inflammatory and thrombotic reactions. In small-diameter synthetic vascular grafts, fibrous deposition and thrombus formation will eventually lead to stenosis of the graft. To counteract such reactions, attempts were made to modify the graft materials.^[9] For example, early attempts at promoting endothelialization of synthetic vascular grafts and stents came in the form of EC seeding and sodding, or modifying the surface of polymer graft materials to promote the attachment of EC. However, successful reendothelialization of synthetic vascular grafts is still unrealized, making their use for small-diameter vascular bypass suboptimal.

Fig. 2 (A) Dacron (polyethylene terephthalate) and (B) unsealed woven polyester vascular graft. (From www.vascutek.com.)

Due to these inherent limitations on synthetic grafts, alternative strategies led to the development and use of vessels derived from either humans (allogeneic) or animals such as pigs (xenogeneic).^[10] In order to be clinically viable, such grafts must be decellularized to prevent undesirable immune responses that would lead to failure of the grafts upon implantation. Either detergent (Triton X-100 or sodium dodecyl sulfate) or nondetergent techniques (most commonly enzymatic treatments) are employed, that do not alter the structure of the tissue but could affect the performance of the graft. Although such grafts possess a structure that is initially mechanically stable, they lack a cellular component necessary for vasoactivity and antithrombogenicity. In a recent study, Conklin et al. evaluated the potential of using decellularized porcine carotid arteries cross-linked with heparin to reduce thrombogenicity.^[11] They demonstrated that when implanted in a dog model, they became populated with smooth muscle, and at 2 months, an endothelial layer was evident in the lumen. However, although successful in animal models, the use of decellularized grafts remains problematic in humans. Dardik et al. evaluated the feasibility of glutaraldehyde-treated human umbilical cord veins as grafts in humans, and most failed within 2 years.^[10] Failure of these grafts usually occurs due to late aneurysmal degradation and dilation. Similarly, studies using decellularized homologous saphenous veins for coronary artery bypass reported patency rates at 1 year of only 35%.^[8] These suboptimal patency rates highlight the limitations of using decellularized matrices for vascular applications.

DESIGN CONSIDERATIONS FOR A TISSUE-ENGINEERED BLOOD VESSEL

Many scientists working in the field of regenerative medicine feel that a tissue-engineered vascular graft

will be one of the first successful clinical applications of tissue engineering.^[12] This section highlights the criteria governing current TEBV requirements and the techniques used to fabricate them, and describes recent attempts at using such techniques.

Mimicry of Native Vascular Tissue

There are certain basic properties of the native vasculature that a successful tissue-engineered blood vessel must achieve. These can be subdivided into mechanical and biological properties.^[13] First, the vessel must be of sufficient mechanical strength to not rupture when subjected to changing blood pressures and flows. This means that any technique used to fabricate the blood vessel must result in a conduit that will function immediately upon implantation. It is also essential that the TEBV match the mechanical properties of the vessel to which it is being grafted, because compliance mismatch at the anastomosis is thought to be involved in the development of intimal hyperplasia and subsequent graft failure.^[14] From a biological standpoint, it is essential that any TEBV be antithrombogenic. Finally, a major requirement (and a major limitation) in current vascular grafts is that the vessel must be vasoresponsive in order to function under changing blood pressures and flows. To date, no vascular graft has been developed that matches the specified criteria; this is where the field of tissue engineering holds great promise.

Considerations for TEBV Fabrication

Cell source

In a recent review, Nerem highlighted cell source as one of the keys to a successful vascular tissue-engineering approach.^[13] In order to be clinically viable, any vascular tissue-engineering technique should utilize a method by which autologous cells may be easily harvested and used. Most previous studies on TEBV fabrication have used either terminally differentiated or nonautologous cells.^[15–17] The use of nonautologous cells is limited by difficulties in harvest or isolation, inability of the cells to expand, and immunorejection issues. Niklason et al. recently reported that after in-vitro expansion (as required for tissue-engineering applications), terminally differentiated cells derived from a 2-year-old human aorta were incapable of expanding into a functional tissue,^[18] emphasizing the potential limitations on autologous cells. Attempts to transfect the cells with telomerase to stimulate cell proliferation has had limited success, and would not be practical in the clinical setting within a foreseeable time-frame.

There is clearly a need for an alternative cell source for TEBV development. One such approach utilized by Julie Campbell is to use the cells present in the peritoneal cavity to form blood vessels.^[19] This new procedure involves growing tissue around an artificial tube placed inside a patient's abdominal cavity and then using the tissue to replace diseased or damaged blood vessels. Peritoneal myofibroblasts and macrophages attach to the tube and form granulation tissue composed of collagen and elastin, which is subsequently covered in a layer of mesothelial cells that express von Willebrand factor. Vessels formed in this manner have shown patency in rabbit and rat models for up to 4 months, with the constituent cells assuming a smooth musclelike phenotype with time.^[19] However, the use of such vessels in clinical trials has yet to be achieved; other cell sources must also be considered.

A second potential source of cells is stem, or progenitor, cells, which have shown great potential for use in tissue-engineering applications, and may circumvent many of the problems associated with cell sourcing. The notion that primitive progenitor cells exist in adult humans was first suggested in 1867 by Cohnheim.^[20] Bone marrow-derived progenitor cells (BMPCs) are the best-characterized progenitor cells due to the focus on treating bone marrow-associated diseases such as leukemia. Bone marrow is known to contain primitive and multipotent progenitor cells, identifiable by cell surface markers that are capable of differentiating into several different hematopoietic and mesenchymal lineages. Specifically, in-vitro conditions have been identified that stimulate the differentiation of these progenitor cells, not only along hematopoietic lineages, but also to cardiovascular cell types such as cardiomyocytes.^[21] In addition, new data are emerging that suggest that BMPCs possess the ability to differentiate to smooth muscle cells.^[22]

Noishiki and colleagues reported that ePTFE grafts treated with bone marrow had increased neovascularization^[23] and improved endothelialization after 3 weeks following implantation in a canine model, resulting in improved patency at 3 and 6 months compared to untreated grafts.^[24] More recently, several in vivo studies have shown that BMPCs can contribute to blood vessel formation within the heart after myocardial infarction.^[25] Highly-enriched hematopoietic stem cells (CD34(-)/low, c-Kit(+), Sca-1(+)) were injected into a mouse model and subsequently migrated into ischemic cardiac muscle and blood vessels, contributing to the repair of the infarction and revascularization. Furthermore, a recent study has shown that circulating bone marrow-derived progenitor cells can contribute to neointima formation after injury.^[26] In this study, a mouse model of iliac artery injury was transfused with nucleated bone marrow cells from donor mice, and after 4 weeks, the arterial lumen was obliterated by a cell-rich

neointima, with cells containing smooth-muscle α actin, approximately half of which were of donor origin. These results suggest that bone marrow-derived cells are recruited in vascular healing as a complementary source of smooth musclelike cells, and are capable of differentiation in a biomechanically dynamic environment. Although these studies suggest that *in vivo* delivery of BMPCs could be useful in cardiovascular regeneration, the intrinsic factors that govern the recruitment and differentiation of these cells are yet to be elucidated *in vitro*. Factors that must be considered relate not only to cytokine and growth factor-mediated differentiation, but also to the influence of mechanical stimuli, as the cardiovascular system is one of the most dynamic environments in the body.^[27] The primary limitation on *in vivo* differentiation is that it is impossible to control the exact biochemical and biomechanical interactions (both magnitude and history) that stimulate differentiation.

The advantages to using BMPCs are numerous. Given the potential they show for cardiovascular tissue engineering, they offer a real alternative to terminally differentiated smooth muscle. First, they may be easily isolated from a patient for whom a vascular procedure requiring cells is intended. Furthermore, BMPCs are also known to produce growth factors that promote SMC proliferation and migration. This includes vascular endothelial growth factor (VEGF), basic fibroblast growth factor (bFGF), and platelet-derived growth factor-BB (PDGF-BB). In addition, we have completed experiments that suggest that BMPCs may differentiate to a smooth muscle lineage when grown under the appropriate biomechanical stimuli.^[28] When grown under 10% cyclic strain at 1 Hz for 7 days, BMPCs upregulated smooth muscle-specific genes (namely, smooth muscle α actin and h1-calponin) (Fig. 3). Furthermore, strain caused a cessation of proliferation and caused the cells to align perpendicular to the direction of strain. Given these important new findings in combination with information already known about BMPCs, they clearly show great promise as a cell source for vascular tissue-engineering applications, and as an alternative cell source for TEBV fabrication.

Construct design

One of the main areas of focus in vascular tissue engineering is developing the optimal method of forming a tubular construct. Factors that must be considered include the ability to control the inner diameter, wall thickness, and length.^[13] Following is a summary of various approaches to forming a tubular construct.

Collagen-Based Scaffolds. Initial construct design focused on collagen as the basis for TEBV fabrication

Fig. 3 Detection of smooth muscle α actin in (A) unstrained and (B) strained cultures, and h1-calponin in (C) unstrained and (D) strained cultures. Nuclei are labeled blue and stain is red. Note that only strained cultures are positive for each marker. Arrows indicate direction of strain. Mag \times 20.

because it is the predominant extracellular matrix (ECM) protein found in native arteries. Collagen has many potential advantages. For example, it is a natural material that can be readily isolated and formed into a tubular structure.^[12] In a 1986 paper that many credit as the impetus for the vascular tissue-engineering field, Weinberg and Bell reported the production of a two-layer TEBV. This was achieved with an annular mold, and featured a medial layer containing type I collagen and SMCs, and an adventitial layer containing collagen and fibroblasts. Seeding the luminal surface of the resulting tube with EC formed the intimal layer. However, Weinberg and Bell made an important observation about the histology of their TEBV: The SMC and collagen were oriented longitudinally rather than in the predominant circumferential orientation found in native blood vessels.^[29] It is believed that this longitudinal orientation of the tissue constituents compromised the strength of the TEBV. Furthermore, circumferential alignment ensures mechanical loading of SMC in a pressurized construct, and this is thought to be imperative to maintaining SMC phenotype.^[30]

Subsequent investigators have used a molding technique similar to Weinberg and Bell's, but have attempted to increase the strength of the collagen constructs using several different approaches. First, most cell types will contract collagen gels and this has been used to the advantage of being able to compact the collagen against a mandrel^[16] that, when removed, forms the lumen of the vessel. Other techniques include cross-linking of the collagen using glycation^[31] or enzymatic methods^[32] (Fig. 4). Other studies have

Fig. 4 Effect of enzymatic cross-linking with transglutaminase on collagen construct burst strength. (From Ref. [32].)

investigated the influence of collagen concentration on the mechanical strength of TEBVs. For example, Hirai et al. demonstrated that the burst pressures of their collagen-based tubes increased with increasing collagen concentration, although they only succeeded in improving the pressure to 110 mm Hg.^[33] Subsequent attempts to organize the collagen used magnetic pre-alignment, but this worked only in constructs without a central mandrel,^[34] limiting the formation of a central lumen in the TEBV.

Although collagen gels have taken precedence in the development of a TEBV, other studies are showing the potential of native, collagen-based tissues such as small intestine submucosa used as the basis for a graft. In one approach, Huynh et al. used the submucosa derived from porcine intestine to produce an acellular graft, which showed patency in a rabbit model for 13 weeks.^[35] Other studies have shown the potential of submucosa used in combination with cells as a potential graft, with patency rates in a rat model of up to 8 weeks.^[36]

As many advantages as collagen has as a scaffold, it also confers certain limitations on the fabrication of a fully-functional TEBV. It is known that cells grown on collagen gels show a tendency to switch off collagen synthesis,^[37] and show reduced proliferation, which may be major limiting factors when vascular tissue-engineering applications require remodeling and growth within the construct. However, it is clear that collagen—either in gel or native form—shows good potential as the basis for fabrication of a TEBV.

Cellular-Based Approaches. By definition, the field of tissue engineering is based on the utilization of cells and constructs to produce functional tissues that can be reimplanted into the body.^[38] In 1998, L'Heureux and colleagues produced a TEBV that utilizes human vascular SMCs cultured with ascorbic acid to produce a cohesive cellular sheet.^[16] This sheet, as well as a similar sheet of human fibroblasts, was wrapped

around a cylindrical mandrel to produce a tubular construct with an inner SMC-based media and an outer fibroblast-based adventitia. After maturation, the tubular support was removed and endothelial cells were seeded on the lumen. The TEBV resembled a native human artery, and its histology showed well-defined intima, media, and adventitia (Fig. 5). However, although positive for smooth muscle α actin and desmin, SMC density was lower than is evident in a normal artery. A confluent endothelial layer was observed on the luminal surface, although upon implantation in a dog model, the grafts remained patent for only 7 days with significant thrombus formation. Burst strength measurements showed that the TEBVs had good mechanical properties, bursting at higher pressures than the human saphenous vein. Although limited by poor thrombogenicity, this study clearly shows the potential of forming TEBVs with good mechanical properties using a cellular-based approach.

Scaffold-Based Approaches. Although the study by L'Heureux and colleagues demonstrated the ability to generate TEBVs using a purely cellular-based approach, most vascular tissue-engineering approaches have relied on some form of scaffold—natural or synthetic—to form the basis of the graft. Many of the techniques employed in the fabrication of a tissue-engineered blood vessel revolve around mechanical integrity of the graft, (incorporation of polymer scaffolds) such that it will not rupture upon implantation when faced with arterial levels of pressures and flows or faced with cyclic deformations. Furthermore, in many vascular tissue-engineering applications, mechanical conditioning is implemented in the fabrication process, and the presence of synthetic materials allows such regimens to be applied without compromising the TEBV. The synthetic materials used as constructs have varied, ranging from biodurable materials such as Dacron to biodegradable polymers such as polyglycolic acid (PGA). Niklason et al. created a TEBV from bovine aortic SMCs and a PGA mesh.^[17] In this approach, the SMCs were seeded onto PGA tubes and then placed in a bioreactor for 8 weeks under pulsatile radial forces. The resulting TEBVs demonstrated contractile responses to pharmacological agents and contained SMCs that maintained markers of differentiation such as h1-calponin and myosin heavy chain (Fig. 6). In addition, the TEBVs showed good mechanical properties, such that they could be implanted in a porcine model where they showed patency for 4 weeks. However, long-term patency of this TEBV remains to be proved, and complications such as the production of undesirable breakdown products from the polymer scaffold must be addressed. Although the field of polymer development has evolved significantly, there remains a need to develop materials

T

Fig. 5 Organization of the TEBV developed by L'Heureux et al.^[16] (A) Macroscopic view of a mature TEBV. The vessel is self-supporting when removed from culture medium (open lumen = 3 mm). (B) Paraffin cross section of the vascular wall stained with Masson's trichrome shows collagen in blue-green and cells in dark purple. Aside from an oversized internal elastic lamina (IM = 125 μ m), the histology is similar to that of a muscular artery with a large media (M = 320 μ m) and a surrounding adventitia (A = 235 μ m). (C) Frontal view of the endothelium seeded on the IM. Cytoplasmic green fluorescence reveals cell viability, metabolic activity, and degree of confluence. Red fluorescence (DII-ac-LDL uptake) confirms cell viability and the endothelial nature of the cells. Blue fluorescence shows the characteristic von Willebrand factor expression in ECs (orange = red + green; pink = red + green + blue). Scale bar = 25 μ m. (D) The media-adventitia junction (arrows) stained for desmin (nuclei are stained blue). Scale bar = 50 μ m. (E) The adventitia double-stained for elastin (green) and vimentin (red). Scale bar = 50 μ m. (From Ref. [16].)

that exhibit both acceptable biomechanical properties and biocompatibility.^[39] Factors that must be considered include matching polymer degradation rates to ECM production and enhancing adhesion and differentiation.

Mechanical conditioning

The vascular system is an extremely dynamic environment, wherein cells in the blood vessel wall are exposed to pulsatile pressure and flow, causing cyclic deformations and fluid shear stress. In addition, in the coronary system, blood vessels are exposed to cyclic bending, twisting, and stretching due to the beating of the heart.^[40] Smooth muscle and endothelial cells respond to these stresses and strains to maintain tissue in a quiescent state.^[41]

Biomechanical stimulation also has a profound effect on cellular phenotype. It is well-documented in the literature that a loss of cyclic strain causes an alteration in SMC from contractile to synthetic phenotype, thereby causing a loss of function within the vessel.^[42] Therefore, if a TEBV is fabricated using differentiated SMCs but is then placed in static culture, it may lose its phenotypic profile. Several laboratories have focused on the design of bioreactors to apply physiological biomechanics to TEBVs. Niklason et al. employed such a system to apply 5% radial distension through inflation of a silicone mandrel (Fig. 7). When static and conditioned vessels were compared, the latter had a higher collagen content, a histological appearance closely resembling native tissue, and a burst strength of 2000 mm Hg, compared with 300 mm Hg for static controls. In addition, a study by Seliktar and colleagues investigated the effect of cyclic strain on SMC/collagen constructs over an 8-day culture period, and observed increased contraction and mechanical strength that correlates with circumferential cellular and collagen orientation.^[43] This is an interesting contrast to the observations of Weinberg and Bell, whose constructs had longitudinal cellular and collagen orientations and subsequently exhibited low burst strength. It thus appears that the application of strain not only influences cellular phenotype, but also tissue structure and matrix composition.

Although studies to date have focused on the application of circumferential strains, future studies should consider the effects of physiologically relevant mechanical stimuli. For example, if a TEBV is required for coronary bypass, then it may be appropriate to condition it with coronary-consistent cyclic stretching, bending, and twisting in addition to circumferential straining. To this end, our laboratory has developed vascular perfusion systems that allow the application of precisely controlled pressures and flows,^[40,44,45] along with cyclic stretching, twisting, and bending.

CURRENT LIMITATIONS OF TEBVs

None of the TEBV approaches to date has become clinically viable. This section discusses the major

Fig. 6 Histology of the engineered blood vessels developed by Niklason et al.^[18] (A and B) Pulsed vessel cultured for 8 weeks; (A) Verhoeff's elastin stain [original magnification (orig. mag.) $\times 20$]; (B) Masson's trichrome stain; collagen stains blue (orig. mag. $\times 100$); (C and D) Nonpulsed vessel cultured for 8 weeks; (C) Verhoeff's stain (orig. mag. $\times 20$); (D) Masson's stain (orig. mag. $100 \times$); (E and F) Pulsed vessel without medium supplementation; (E) Verhoeff's stain (orig. mag. $\times 20$); (F) Masson's stain (orig. mag. $\times 100$); (G) Scanning electron microscopy of the endothelial cell layer in an engineered vessel. Scale bar, $10 \mu\text{m}$; (H) Immunoperoxidase staining for PECAM antigen reveals an EC monolayer on the vessel lumen (orig. mag. $\times 1000$). (From Ref. [17].)

limitations of these approaches and potential strategies to circumvent them.

Clearly, the most prominent shortcomings of previously described TEBVs—whether with or without synthetic materials—is the requirement of antithrombogenicity. Within a blood vessel, the endothelial layer functions to prevent the adhesion of platelets and other blood components such as macrophages. The endothelial cells prevent such adhesions by not only acting as a physical barrier, but also by continued release of factors such as nitric oxide and von

Willebrand factor. In many of the tissue-engineered blood vessels fabricated to date, patency has been maintained for only a few days after implantation, and thrombus deposition has been evident in the endothelial layer upon explantation. Although this thrombogenicity is likely multifactorial, the fact that nonautologous cells were used in most cases highlights this as a potential limitation in vascular tissue-engineering applications. Even though nonautologous cells may be shown to be partially functional (e.g., the production of von Willebrand factor by the endothelial layer of a TEBV), they may not be fully functional. Furthermore, autologous endothelial cells isolated from, e.g., adipose tissue, also often prove to be problematic for reasons such as an inability to expand in culture, undesirable phenotypic changes, and an inability to withstand blood vessel stresses.

Another major problem in developing a TEBV is the possible mismatch of mechanical properties between graft and host artery.^[46] Such a mismatch can lead to elevated suture line stresses as well as elevated shear stress levels and turbulent flow, which can in turn lead to development of anastomotic intimal hyperplasia, the most common failure mechanism of bypass grafts. The challenge in engineering a TEBV, therefore, includes ensuring that it has biomechanical properties similar to a native artery's.

Another rate-limiting barrier to the fabrication of TEBVs is the length of time required to expand the cells, seed the constructs, and mechanically condition them. Current time frames to fabricate a TEBV are in the order of 10 to 15 weeks—clearly too long for many patients in need of bypass surgery. For any TEBV

Fig. 7 Biomimetic system for blood vessel culture used by Niklason et al.^[18] The bioreactors and fluid reservoir were fitted to provide gas exchange, and buffer flowed through highly distensible silicone tubing inserted through the vessel lumen. (From Ref. [17].)

application to be clinically successful, such fabrication times must be minimized. One potential solution may be to optimize the use of mechanical conditioning,^[43] which accelerates remodeling.

Finally, TEBVs' greatest limitation may be the lack of performance data in a clinical setting, or even in an animal model. It is important to demonstrate that the constructs have the ability to remodel and repair themselves, while resisting the development of pathologies such as thrombosis, arteriosclerosis, and intimal hyperplasia.

CONCLUSION

Treatment modalities developed to date fall short of what is required, and vascular disease remains the greatest killer in the Western world. In recent years, the design and fabrication of the TEBV has come a long way, but the challenges remain large (although not insurmountable). The significant hurdles that remain to be overcome include cell sourcing (differentiated cells vs. progenitor cells) and construct design (natural materials vs. synthetic). An area that deserves further investigation is the use of biomechanical conditioning as a means to reduce fabrication time. With improvements rapidly occurring in these areas, and with increased understanding of cell biology and biomechanics, it is likely that the first clinically acceptable TEBV will be developed in the near future.

INTRODUCTION

Tissue engineering is a new development in biomedicine, involving a series of strategies using biologically based mechanisms to repair and heal damaged and diseased tissue. The key elements include a specific living cell type (or several cell types), a material scaffold that forms a supporting structure for culturing the cells in vitro and surgical delivery in vivo to the patient, and, for the majority of mammalian cell types, a growth stimulus.

Tissue loss or end organ failure resulting from trauma or disease is a major health problem. Examples of bone-related illness include osteoarthritis, cancer, trauma, fetal defects, and metabolic disorders. Currently available methods include mechanical devices or artificial prostheses, which do not repair the tissue or organ function and do not integrate with the host tissue. In the aging population worldwide, the incidence of bone-related illness is more prevalent than ever before, and bone transplantation is a commonly required surgical procedure. In the UK there are approximately 150,000 fractures (wrist, vertebral, and hip) due to osteoporosis, with high rates of associated morbidity and mortality. In the United States bone tissue is used in over 450,000 graft procedures, and total national health care costs for these patients exceed \$120 billion per year.^[1] Hence, there is an increasing demand for developing bone augmentation strategies. Bone tissue engineering is an emerging interdisciplinary field seeking to address needs for the development of biological substitutes, by combining the principles of orthopedic surgery with basic science (such as chemistry and cellular and molecular biology) and engineering (chemical and structural), to develop strategies for the restoration, maintenance, or improvement of tissue form and function. Bone is a living structure and as such, has the ability to regenerate through a dynamic biological integration of biochemical, cellular,

and hormonal processes. However, if the lesion is above critical size, the site will not regenerate but will become scarred, leading to nonunion at the site. To restore normal function, tissue regeneration has to occur; hence new bone tissue has to be surgically introduced to bridge the defect.

OVERVIEW

There are approximately 500,000 surgical procedures performed each year in the United States that require bone substitutes. These substitutes include autografts, allografts, and synthetic materials. The autograft, which involves harvesting viable tissue from one site in the patient and transplanting it into another part of the same patient, is considered the current gold standard against which other bone transplantation choices are weighed. Commonly used autograft procedures in orthopedics include spinal fusion and the treatment of nonunion fracture, where bone is usually taken from the patient's iliac crest and used to stabilize the defect site. It has proved highly successful due to its immunological compatibility and direct transfer of osteogenic cells and osteoinductive cues. However, it has limited therapeutic potential, as donor tissue is usually short in supply, collection is painful, and there are risks of donor site morbidity and infection with the patient having two operations. Furthermore, it is highly dependent on the quality and quantity of patient bone that can be harvested. The allograft, tissue transplanted from a different donor host, provides an abundant supply of both cortical and trabecular bone; however, it can cause an immune response and potentially transmit viral diseases. In addition, its processing removes all cells and bioactive molecules, compromising its incorporation into existing host tissue. The natural skeletal repair process of fracture

healing utilizes bone-forming cells, a cartilaginous scaffold upon which the new woven bone forms, and bioactive molecules to direct the repair sequence. An ideal augmentation would be “de-novo” tissue which has the same function, structure, and mechanical integrity as the original tissue that was lost. The cartilaginous scaffold recognized and ossified by the body is porous and allows vascularization and cellular ingrowth. Hence, the vast majority of engineered approaches are based on porous scaffolds. Bone analogue materials such as porous hydroxyapatite, composites, and degradable polymers such as poly(glycolic acid) and poly(lactic acid) are also being developed. In the main, these materials may be osteoconductive in nature; few, however, provide osteoinductivity.

Bone morphogenesis is a sequential cascade with three key phases: chemotaxis and mitosis of mesenchymal cells, differentiation of the mesenchymal cells initially into cartilage, and replacement of the cartilage by bone. The natural repair mechanism of bone utilizes bone-forming cells, a cartilaginous scaffold upon which the new woven bone is formed, and bioactive molecules to direct the repair process. Tissue engineering of bone endeavors to provide some or all of these components.

CELLS

Osteogenic function is necessary for biomaterial integration into the host environment. In bone engineering there are basically four types of cells that can be used: unfractionated fresh bone marrow; purified, culture-expanded mesenchymal stem cells (MSCs); embryonic stem cells (ESCs); and differentiated osteoblasts.

Unfractionated bone marrow autotransplantation was one of the very first techniques to be used in bone tissue engineering. This was an empirical procedure and seemed ideal, as bone marrow is rich in osteoprogenitor cells and osteogenic precursors such as bone morphogenetic proteins (BMPs). The procedure involves taking bone marrow from a donor site (the iliac crest) and transplanting it into the defect site. The procedure was relatively simple, inexpensive, and did not require FDA regulation. This type of approach in a rat model has shown favourable results.^[2-5] However, limited sources and the scarcity of osteogenic cells after aging, disease, and irradiation prevented its continued widespread use.^[6,7]

MSCs are immature and undifferentiated cells that are obtained from bone marrow and the periosteum. They have the capacity for extensive replication without differentiation and they possess multilineage developmental potential, making them a powerful research tool.^[8] An important issue with respect to these cells is understanding how to induce them and

controlling their differentiation into the desired cell type. Stem cells are either pluripotent or multipotent depending on their lineage. These stem cells are able to differentiate into fibroblastic, adipogenic, reticular, and most osteogenic cells.^[9,10] They are capable of multiple passages without loss of stem cell characteristics and tend not to de-differentiate unless exposed to specific biochemical and mechanical cues, in which case they can be directionally differentiated.^[11] Furthermore, the cells can be grown in a bioreactor, which provides an ideal environment, where a permeable membrane allows gaseous exchange and the microgravity environment created by the rotation reduces flow stress on the construct and encourages the cells to remain within the construct. After a given time period, tissue regeneration is observed and the engineered tissue can be transplanted into the body and integrated in a functional manner with existing tissue.

Stem cells have the advantage that they can be harvested in small quantities to be expanded in culture and, being autologous, they present the ideal cell type. The use of stem cells, however, relies on being able to identify adult stem cells and isolate them in sufficient quantities. This can be a lengthy procedure, and in older patients, where cell numbers and proliferative capacities may be lower, this can be a limiting factor. However, development of selective monoclonal antibodies that bind to surface antigens will allow the selection of specific subsets of osteoprogenitor cells that can be used in combination with osteoconductive materials for bone formation at specific target sites. Jaiswal et al. reported passing MSCs through 30 population doublings in vitro without loss of osteogenic potential.^[12] The long-term biological effects of the stem cells at the implant site, as well as issues of cell plasticity, remain largely unknown.^[13] Hence, it can be said that stem cell technology is still in its infancy, and the long-term biological interaction of these cells with the scaffold material itself has yet to be fully elucidated.

Stem cells can be subdivided into adult stem cells and embryonic stem cells. Embryonic stem cells (ESCs) are usually isolated from the inner wall of the pre-implantation blastocysts. These embryonic cells in the early developmental stages are more proliferative and are pluripotent due to their indefinite amplification, without the risk of de-differentiation.^[14] ESCs are nonautologous, as they contain a haploid set of chromosomes from a different non-self genetic parent; hence they can be immunoreactive. However, recent advances in gene transfer, MHC manipulation, and nuclear cloning allow the formation of autologous-like ESCs.^[10] The ethics behind their use, however, remains an area of consternation—in particular the use of embryos solely for research purposes.^[15] Stem cells may have the potential to be used to generate entire skeletal tissues without the need for scaffolds.^[16]

Thomson et al. showed that embryonic stem cells (from blastocysts) can proliferate indefinitely and have the ability to become any desired cell type. These cells may induce an immune response, but again, their use presents a number of ethical problems.^[17] Much work remains to be done on the use of stem cells.

Genetically modified cells are the newest cell-based technique for bone regeneration, first described by Lieberman et al.^[18] This technique involves the genetic modification of isolated and expanded cells to produce populations of progenitor cells that over-express certain signaling molecules.^[19] For example, Breitbart et al. showed that via retroviral transduction, cells were able to express BMP-2.^[20] Musgrave and coworkers used direct adenoviral-mediated gene therapy to deliver active BMP-2 and produce bone in skeletal muscles, thus eliminating the problems associated with delivery of BMP-2 to the required site as well as the need for cell expansion.^[21] However, limitations concerning this approach involve several safety issues. The possibility of immunogenicity in vivo is a concern as is the fate of the adenoviral cells. Moreover, the oncogenic biosafety fears must be answered before potential therapeutic models can be established clinically. The major challenge will be to demonstrate bone repair in clinical models without an immunological reaction.^[22] Differentiated osteoblasts are essentially committed mesenchymal cells that have been directed down the osteogenic lineage. This has the advantage of rapid and effective repair of bone defects, as the cells are already differentiated. The main disadvantage is that they have a limited capacity for proliferation, as they are able to perform only a certain number of replication cycles before the problem of de-differentiation arises.

SCAFFOLDS

Central to the formation of new bone tissue is the role of the scaffold; this should either induce the formation

of bone from the surrounding tissue, or act as a carrier or template for implanted bone cells or other osteoinductive agents. An ideal biomaterial should be osteoconductive, osteoinductive, and porous for cellular infiltration. Furthermore, it should be biocompatible, mechanically stable with respect to the native bone, and biodegradable to prevent the presence of foreign material in the body for prolonged periods of time. Other considerations include ease of sterilization without loss of properties.

Biomaterials can be divided in cellular and acellular materials. Acellular materials are usually solid, absorbable fillers that are biodegradable, or porous scaffolds that allow bone ingrowth into the construct. Cellular materials are designed to be seeded with cells. The first acellular material was demineralized bone matrix (DBM); this had both osteoconductive and osteoinductive properties. In early studies inflammatory cells and MSCs were observed to infiltrate the DBM, and within three weeks endochondral ossification was observed.^[23] The role of the scaffold is to provide a template to define the structure of the growing tissue and ensure effective delivery of the osteogenic cells, either singly or in combination with growth factors (Fig. 1). Following implantation the scaffold provides an initial biomechanical support until the cells produce adequate extracellular matrix. Alone, they overcome the need for donor tissue in autologous bone grafts; however, their success in large bone defects is limited as they lack the osteogenic and osteoinductive properties of bone autografts and growth factors. Scaffolds in bioengineered tissues are important not only in terms of structural support for cells, but also for providing signaling cues in influencing cell proliferation and differentiation.

The success of cell-based therapies is very much dependent on the ability of the transplanted cells to be delivered and retained at the site where they are required. Based on the functional requirements of the cells, the method of delivery must be able to encourage

Fig. 1 The optimal tissue-engineered construct requires three essential elements: a suitable cell source, growth and differentiation factors, and a scaffold matrix to support the attachment, migration, and proliferation of these cells.

angiogenesis, be osteoinductive, and be biodegradable so that it can be replaced by new bone formation. Materials commonly used include ceramics, polymers, and composites. More specifically, bone tissue-engineered systems have included demineralized bone tissue, collagen composites, fibrin, and calcium phosphate. In the case of degradable polymers, it is important that scaffold degradation occur at the same rate as tissue regeneration, to ensure that only natural tissue will remain in the body. An ideal scaffold should provide cell anchorage sites, mechanical stability, and structural guidance. Numerous types of scaffolds are being investigated, with biodegradability a common characteristic. Pore size, macro- and microporosity, interconnectivity, and tensile strength are all important factors affecting physical properties as well as cell number and function.

Current approaches to bone tissue engineering involve the use of MSCs to form the three-dimensional (3-D) shape and internal architecture of bone. In order for these exogenously cultured cells to function, they need to be combined with a carrier material before implantation. This will give rise to the 3-D structure where a vascular bed can be established and also act as a supporting scaffold for the transplanted cells to differentiate. This construct with the appropriate biological growth factor can be used to effectively repair defects of critical sizes that would otherwise not heal. Gundle et al. showed that osteoprogenitor cells from humans seeded on the scaffold and given the appropriate osteogenic signaling (e.g., dexamethasone and beta-glycerophosphate) could produce bone tissue *in vivo*.^[24] Bone is made up of an extracellular matrix (ECM) consisting of a composite fibrous network of collagen within a hard matrix of calcium/phosphorus. Bone cells exist within this ECM and are responsible for its generation and remodeling. The physical communication between cells and the ECM directly and indirectly impacts cell shape and function, and these signals are all necessary cues for normal cellular activity. These actions are regulated by protein-based molecules: growth factors. Vacanti et al. reported that for cell colonies to grow into 3-D functional tissues, external cues in the form of mechanical, electrical, structural, and chemical signals mimicking the local ECM are required.^[25]

The similarity of calcium-based ceramics such as hydroxyapatite (HA) or tricalcium phosphate to bone composition and their osteoconductive properties have allowed them to be used extensively as coatings on implants. HA has been successful in increasing implant fixation integrity and has been tried with culture-expanded MSCs.^[26] Although HA is highly biocompatible, it is very brittle and is mechanically too weak to take full compressive loads. It has been shown that the lack of completely interconnected pores, lack of

osteoinductivity, and slow resorption leads to sub-optimal results where only bony ingrowth is observed on the porous surfaces instead of true bone regeneration.^[27]

Pore size is important in determining cellular ingrowth, growth factor release, and vascularization. Opinions on pore size vary; Burg et al. have suggested an optimal pore size between 200 and 400 μm .^[28] Pineda et al. however, have claimed that pore sizes up to 200 μm in polyester membranes achieve the best bone ingrowth.^[29] The porosity of the scaffold has a significant effect on its mechanical integrity, and a compromise is necessary between this and its biological activity. Scaffold macroporosity is a critical factor in cell migration and bone matrix elaboration *in vitro*. In addition, angiogenesis has to occur and could be achieved by incorporating angiogenic factors into the scaffold. Ceramic-based cellular techniques have shown the greatest promise, in particular HA-based constructs, in the fabrication of sintered porous hydroxyapatite (SPHA).^[30] This material consists of repetitive sequences of concavities and is intrinsically osteoinductive without the need for growth factors. SPHA is a so-called smart material. Such materials are gene and cell activating, and it is thought that they attract BMPs and other osteogenic factors intrinsically into the material cavities by adsorption.

Three-dimensional porous structures also offer a desirable scaffold. These can be tailored to achieve a specific pore size (300–400 μm) and high interconnectivity, thus allowing a high degree of cellular ingrowth. These types of systems—for example, microsphere—have the advantage that they can be injected directly into the site and then solidify *in situ*; however, this limits their capacity to be shaped for a specific site.^[31] Other materials, such as polymers, are being tested as potential scaffolds; examples include blends of starch with cellulose acetate poly(lactic acid) and ethylene vinyl alcohol and poly(caprolactone), poly(glycolic acid) (PGA), and poly(lactic-co-glycolic acid) (PLGA). Variable processing methods have been used depending on the desired porosity, degradability, and other properties. This allows them to be tailored to specific applications depending on the mechanical properties and the degradation kinetics required. The one disadvantage of these polymers is their lack of mechanical competence in load-bearing bone applications. Surface-eroding polymers such as poly(ortho-esters) may be advantageous in load-bearing applications as only the surface of these materials degrades, leaving the bulk of the material to provide mechanical strength and reducing the risk of implant failure.^[32] Degradation kinetics applies to all biodegradable biomaterials and leads to a number of changes in both the polymer surface and the local environment.^[33] A further consideration of degradable materials is the constant change in surface topography and energy, both of

which have an effect on cell attachment and proliferation. For example, nanotopography has been shown to improve cell proliferation rates on polymer-based materials, whereas surface energy has been shown to effect cell adhesion to surfaces and even their orientation.^[34]

A more adaptive scaffold could be achieved if it could be made responsive to the mechanical environment in which it is placed. Work in the literature has indicated that mechanoreceptive stimulation of cells can be achieved by incorporating slow-release agonists in the polymer scaffolds. Biomimetic materials aim to provide a biological scaffold to promote integration of host bone with implanted cells and growth factors. For example, it has been shown *in vitro* that mechanically active scaffolds, where a voltage-gated calcium channel inhibitor is integrated into PLLA with a cyclically loaded environment, can increase collagen type I expression and increase matrix production.^[35] This work is in an early stage and has not been performed *in vivo*, where the mechanical stimuli will be more randomly distributed across the material.

ECM would seem to be the most natural scaffold, since its composition adapts depending on the site and physiological requirements of the host tissue. Furthermore, it contains all the necessary proteins for cell adhesion (fibronectin, laminin), proliferation, and differentiation, as well as those required for structural support such as collagen and GAGs. *In vivo*, ECM has been shown to be rapidly biodegradable and transient in terms of functionality.^[36] The major disadvantage of ECM, however, is its limited supply.

A greater understanding of biomineralization has initiated developments in biomimetic materials fabricated according to biological principles and processes of self-assembly and self-organization. Biomimetic materials are being developed whereby the desirable properties of natural, biodegradable, and ceramic-based techniques are combined. For example, arginine-glycine-aspartic acid (RGD) sequence peptides have been incorporated onto scaffold surfaces to increase cell adhesion, proliferation, and biocompatibility.^[37] RGD is the minimal amino acid sequence needed to promote cell adhesion and is found in many ECM proteins. Hrkach et al. have prepared comb-like graft copolymers with lysine or aspartic acid side chains, which have demonstrated increased cell attachment compared to unmodified surfaces.^[38] Another promising approach has been the use of supercritical fluid technology in the development of porous biodegradable scaffolds.^[39] This technology does not involve solvents or thermal processing, thus allowing growth factors to be incorporated into the scaffold at construction. Other bioactive particles such as HA could also be incorporated; this would overcome the problem of mechanical competence.

The synthesis of complex inorganic forms that mimic natural structures offers exciting avenues for the chemical construction of macrostructures and a new generation of biologically and structurally related bone analogues for tissue engineering.^[40] Although these appear to offer attractive possibilities, biomimetic scaffolds require clinical evaluation, with little known about their immunoreactivity, biocompatibility, and effects on stem cell fate and host osseointegration of such constructs.

SIGNALING MOLECULES

Growth factors (GFs) are proteins secreted by cells that act as signaling molecules on the appropriate target cell to carry out a specific function. They act as a cellular communications network and influence critical functions such as cell proliferation, matrix production, and differentiation of tissues. They have been shown to play a significant role in bone and cartilage formation, fracture healing, and the repair of other musculoskeletal tissues. The advent of recombinant proteins has resulted in considerable interest in their use as therapeutic agents in the treatment of skeletal injuries and disease. A GF may have effects on multiple cell types and may induce several different cellular responses in a variety of tissues. Once a GF binds to a target cell receptor, it induces a ligand-receptor interaction. This induces an intracellular signal transduction system to the nucleus and results in a biological response. These interactions can be very specific, with a specific GF binding to a single cellular receptor, or complex, with one or more GFs binding to one or more receptors in order to produce an effect.

A number of GFs have been shown to be expressed during fracture healing; these include transforming growth factor- β (TGF- β), bone morphogenetic proteins (BMPs), fibroblast growth factor (FGF), platelet-derived growth factor (PDGF), and insulin-like growth factor (IGF). Osteoinduction is therefore mediated by numerous growth factors, and on this basis, it is thought that these GFs may have potential use as therapeutic agents in bone healing and tissue engineering. Hauschka et al. showed that osteogenesis is in part due to the combination of actions of several growth factors acting at specific stages in the different cells.^[41] Bone is rich in many growth-stimulating factors, but the most important group is the TGF- β superfamily, of which the BMPs are the most significant. There are 15 BMPs (BMP-2–BMP-16) which are known to regulate bone formation via stem cell recruitment, proliferation, and differentiation. The biological action of BMPs are mediated via specific BMP receptors. There are two types of BMP receptors, type I and type II, which are serine/threonine protein kinases.

These kinases are enzymes that phosphorylate proteins called Smads and activate them. The active Smads are then translocated to the nucleus, where they participate in the transcriptional regulation of the expression of genes involved in cartilage and bone formation.^[42]

BMPs have been extensively studied and used in clinical trials with variable success depending on the mode of delivery.^[43,44] Human BMPs are difficult to obtain and purify from bone donors, and BMP-7 (also known as OP-1) and BMP-2 are currently synthesized via recombinant technology. BMPs have already been successful in trials in vivo. It has been shown using native human BMP that they have potential in the treatment of established nonunions and spinal fusions.^[45] The importance of BMPs in fracture healing was demonstrated by Bostrom et al. when they were localized to fracture callus.^[46] Einhorn et al. showed that injection of rhBMP-2 into a standard fresh-fracture model can accelerate healing, which was achieved two weeks earlier than in the controls.^[47] Evidence for its proposed use in tissue-engineered bone was provided by the study of Wang et al., who showed that BMPs caused commitment and differentiation of multipotential stem cells into osteoprogenitor cells.^[48] Wozney et al. was also able to show new bone formation using BMPs.^[49] Extensive work by Ripamonti using BMP-7 has shown that it elicits heterotopic bone formation and complete healing of 25 mm-diameter critical-sized defects in primates in 90 days.^[50] In another study, Johnson and Urist used BMPs to lengthen femoral nonunion fracture.^[51]

Recombinant BMP-2 has been extensively used for in vitro and in vivo studies and has been shown to induce cell differentiation and form endochondral bone in ectopic and heterotopic locations.^[52] Although BMPs are at the forefront of reconstructive orthopedic surgery,^[53] there are difficulties in integrating them into a drug delivery system. Purified BMPs are hydrophilic and, when incorporated in the body, tend to disperse rather than act locally. Hence to slow the release down, they need to be complexed to a carrier. This adds a further problem in that proteins are immunogenic.

The osteoinductive capacity of BMPs has been extensively demonstrated in preclinical studies, and the efficacy of BMP-2 and BMP-7 for the treatment of orthopedic patients is now being evaluated clinically.^[54]

Much remains to be known about the cascade of growth factors necessary for tissue regeneration. Growth factors are species and dose dependent and require careful targeting within the host environment. Large bone defects can be repaired only if scaffolds are able to cause ingrowth of host tissue into the structure and become fully integrated with the adjoining tissue. A major problem, however, is that these GFs require a carrier that will allow their release in a controlled manner. Kaplan et al. showed that too low a dose

resulted in poor bone formation with reduced mechanical strength, while high doses may inhibit osteogenesis or lead to bone growth at sites outside the graft boundaries.^[55] These factors are easily diffusible and have a short half-life.

Scaffold-based drug delivery is important, with numerous promising studies well advanced. However, it is limited by conflicting requirements of scaffold and drug delivery needs. For example, microgeometry is important in BMP-induced osteogenesis.^[56] A large pore size promotes vascularization and osteogenesis but also causes greater drug release; the hydrophobicity of a scaffold ensures gradual biodegradation and mechanical competence but binds the drugs less readily. Many novel drug delivery systems which can control drug release kinetic externally are being developed. Smart polymers utilizing hydrogels, alginate, and gelatin microspheres, which are responsive to thermal, mechanical (ultrasound), and pH stimuli, are being investigated.

CONCLUSION

Orthopedic surgery has evolved over the last 25 years from the age of resection, reconstruction, and replacement to the age of regeneration. Bone tissue engineering provides a means of evolving therapies using the body's own cells. The requirements include a scaffold that is immunologically inert and allows the incorporation and release of osteoinductive proteins. Furthermore, it should allow cellular ingrowth with angiogenesis occurring in a timely fashion within the scaffold construct in order to restore proper function. The complex problem of the scaffold is one of the main limiting factors, and the interaction of stem cells with biomaterials still requires a greater understanding. Although some progress has been made in this field, bone tissue engineering is still in its infancy. A basic understanding of the spatial and temporal distribution of cells and growth factors necessary for osteogenesis remains to be developed. Modern technologies like molecular cloning and gene therapy may further enhance the ability of BMPs to play an important role in the clinical practice of the 21st century. The clinical application of bone-engineered constructs has the potential to greatly improve the treatment of conditions requiring bone repair. Enhancing our understanding of these factors will assist in the development and use of engineered systems in orthopedic applications.

INTRODUCTION

Hematopoietic stem cell cultures have generated intense clinical, commercial, and academic interest due to their potential applications in cell-based therapies, such as genetic, cellular, tissue engineering, transfusion support, and immunotherapy. Furthermore, the increasing therapeutic applications of mesenchymal stem cells (MSCs) in gene therapy, bone marrow (BM) transplantation, and tissue engineering exploit current knowledge in molecular biology and biomaterial science^[1] and have greatly expanded the potential of therapeutic use of BM-based stem cells. However, numerous problems remain to be addressed and new methodologies are needed for the well-controlled and reproducible culture of clinically relevant numbers of hematopoietic stem cells (HSCs), MSCs, and their derivatives. This article will focus on the BM micro-environment, its complex three-dimensional (3-D) structure, and its role in hematopoiesis. In addition, we will review the culture parameters critical for the *ex vivo* hematopoietic cell cultures, aiming at developing clinically desirable “designer transplants.”^[2]

HEMATOPOIESIS AND BONE MARROW

Hematopoiesis is a three-stage continual process consisting of the proliferation, commitment, and differentiation of the hematopoietic cells. It takes place in the BM, which is located in the medullary cavity of bone. In normal adults, the BM produces approximately 2.5 billion red blood cells, 2.5 billion platelets, and 1 billion granulocytes per kilogram of body weight per day, the rate of production adjusting to actual needs and varying from nearly zero to many times normal.^[3] All blood cells are derived from a common precursor, the HSC (Fig. 1). Self-renewal of the HSC ensures maintenance of the stem cell pool and hence continuous blood formation throughout life. Commitment of the HSC to differentiation is the first

step in a series of cell divisions through which specialization and differentiation along a single lineage occur resulting in the production of mature blood cells. Within the three stages of hematopoiesis, extensive expansion and maturation occur; it has been proposed that a single HSC is capable of more than 50 cell divisions to generate up to 10^{15} cells.^[4]

Bone marrow is a complex tissue with an elaborate architecture that contains the hematopoietic cells and the supporting stroma consisting of reticular cells, osteocytes, adipocytes, the vascular endothelium, and the extracellular matrix (ECM).^[5] Hematopoiesis is regulated by the hematopoietic inductive micro-environment (HIM), a concept that was introduced in the 1960s to explain the restriction of adult hematopoiesis to the BM.^[6] The HIM (Fig. 2) consists of the stromal cells, which through their intimate physical contact with the hematopoietic cells, the ECM, and the growth factors (GF) they secrete, create this unique 3-D structural and biochemical micro-environment that regulates, through positive and negative factors, the survival, proliferation, and differentiation of the HSCs. In vivo the HIM supports and regulates hematopoiesis, which takes place in spaces surrounded by BM sinusoids that form a 3-D spatially designed microvascular network.^[7] The stroma, composed of endothelial cells that line the marrow sinuses, adventitial reticular cells, macrophages, and adipocytes,^[8] liberates GFs in the immediate environment.^[9] Marrow stromal cells, originally examined because of their critical role in the formation of the HIM, have come to center stage with the recognition that they are the source of the stem/progenitor cells of skeletal tissues. Recent data have also suggested an unexpected plasticity of marrow stromal cells in that they may be able to differentiate into neural tissue or muscle.^[10]

The ECM is a rich heterogeneous carpet of a broad class of macromolecules such as proteoglycans or glycosaminoglycans, adhesive proteins such as fibronectin and laminin, and collagen (types I, III, and IV).^[11]

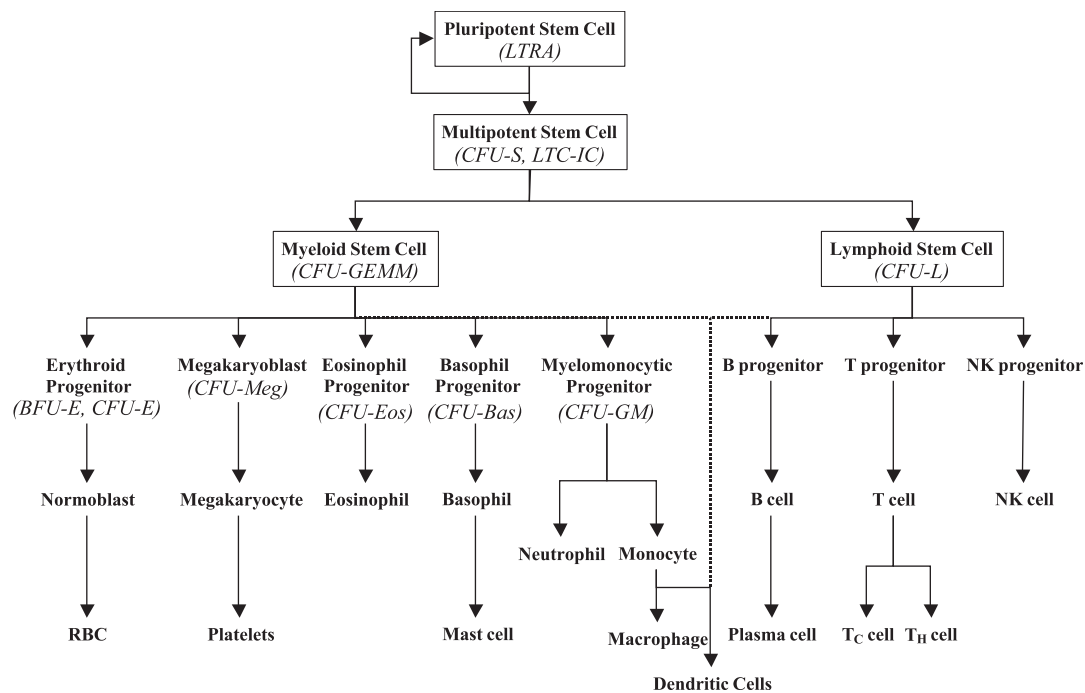

Fig. 1 The hematopoietic system hierarchy, including stem and progenitor cell assays. Hematopoiesis is a three-stage process, which includes proliferation, commitment, and differentiation. LTRA: long-term repopulation assay; CFU-S: colony-forming unit-spleen; LTC-IC: long-term culture-initiation cell; CFU-GEMM: CFU-granulocyte/erythrocyte/macrophage/megakaryocyte; CFU-L: CFU-lymphocyte; CFU-Meg: CFU-megakaryocyte; CFU-Eos: CFU-eosinophil; CFU-Bas: CFU-basophil; CFU-GM: CFU-granulocyte/macrophage.

Collagen fibers of types I and III are produced by fibroblasts and provide the structural framework for the HIM.^[3] Laminin and fibronectin contain the universal attachment peptide, RGD, and bind hematopoietic cells to collagen and GFs. Proteoglycans may also bind GFs and modulate hematopoiesis.^[3] The ECM plays an important role in hematopoietic regulation by localizing cytokines and hematopoietic cells to specific 3-D microenvironmental niches,^[3] thus establishing different HIMs through binding of

particular cell lineages to distinct ECM components^[12-14] and providing scaffolding that lends support and cohesiveness for the marrow structure. For example, the ECM modulates cell maturation by selectively binding to erythroid^[14] and granulocyte precursors.^[13] The ECM may also determine cell adhesion and homing.^[8] For example, CD34⁺ cells have multiple adhesion receptors^[3] enabling them to attach to cellular and ECM components within the marrow.^[15] These receptor-ligand interactions permit close cell-cell or

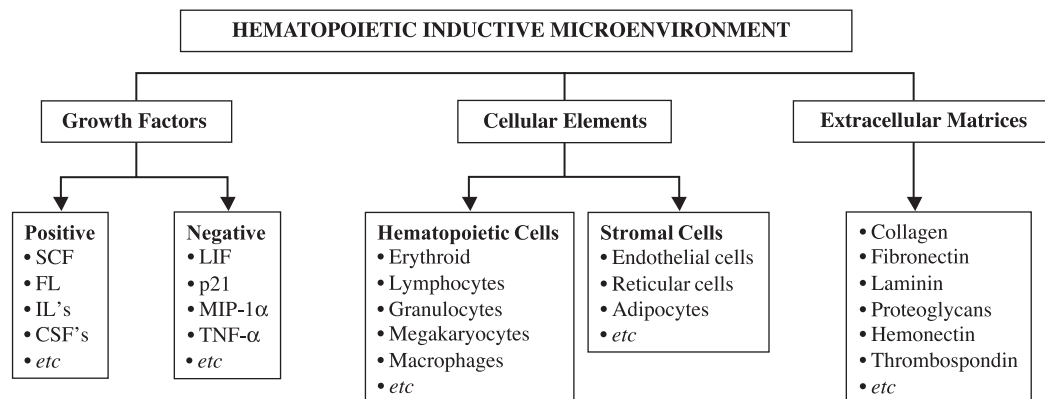

Fig. 2 The components of the hematopoietic inductive microenvironment. SCF: stem cell factor; FL: flt-3 ligand; ILs: interleukins; CSFs: colony-stimulating factors; LIF: leukemia inhibitory factor; p21: protein 21; MIP-1 α : macrophage inflammatory protein-1 α ; TNF- α : tumor necrosis factor- α .

cell-matrix interactions and are essential both for the retention of stem cells and for their maturation and development.^[9,16]

A model for hematopoietic regulation has been proposed according to which rare niches within the HIM specifically promote the self-renewal of HSCs.^[17] Space within each niche acts as the limiting factor for stem cell renewal. When sufficient numbers of self-renewing divisions have occurred and the niche is filled with stem cells, the excess cells are pushed into a neighboring niche, which fosters the production of differentiated progeny by these cells. Eventually, mature blood cells exit the marrow space and enter the blood circulation. These selective microenvironments may be due to the presence and/or absence of positive and negative GFs, as well as to concentration gradients created by membrane-bound cytokines that may instruct HSCs to differentiate or remain quiescent.^[18,19] The cellular and molecular natures of each niche remain to be determined. Development of culture systems recapitulating these specialized microenvironments in vitro may help verify the niche concept and reveal the niche requirements.^[20]

CULTURE PARAMETERS

The BM culture system supports in vitro hematopoiesis, which can be influenced by culture parameters including pH, local oxygen concentration, the composition and concentration of GFs, the supply of nutrients, and the cellular and molecular surrounding of the cells.^[21] Due to the heterogeneous cell population with a wide range of maturation stages, defining optimal culture parameters for ex vivo expansion of hematopoietic stem and progenitor cells is challenging. The effort can be further complicated by the complex kinetics, transient nature, and intricate interactions among culture parameters.^[22]

Culture Media

Traditional media for hematopoietic cultures contain xenogenic supplements such as fetal calf and horse sera (at a total of 25% v/v) or bovine serum albumin, usually supplemented with a cocktail of cytokines.^[23–25] Serum has a number of potential advantages for culture performance: serving as a source of essential nutrients, hormones, and GFs, and protecting the cell against damage.^[26] The presence of serum in hematopoietic culture media has also been shown to influence the induction or enhancement of various cytokines^[27,28] and to contribute to the growth and survival of hematopoietic progenitor cells.^[25] However, serum contains a wide array of proteins that may interact

with cell signaling components and alter the physiological/physiochemical properties of the culture. Serum supplementation in the cultures of CD34⁺ BM cells facilitates greater expansion of granulocytic and monocytic lineages due to the presence of transforming growth factor- β (TGF- β),^[29] which inhibits the expansion of erythroid and megakaryocytic lineages.^[30–32] Furthermore, serum additives are problematic for clinical applications due to the risk of contamination by infectious agents and foreign proteins and the lack of well-defined and standardized media composition.^[33] For these reasons, low concentrations (1–2%) of autologous serum or plasma have been used to substitute for animal sera for supporting the expansion of hematopoietic cells in culture.^[34,35]

A number of serum-free media have been developed, which, when supplemented with the appropriate cytokines, support the ex vivo expansion of HSCs and hematopoietic progenitor cells (HPCs).^[33,36–41] In a direct comparison, serum-free media enhanced the clonogenic potential of human BM CD34⁺ cells whereas serum-containing media enhanced total cell expansion.^[41] Serum-free media are generally considered suitable for stroma-free cultures because serum aides the growth and maintenance of the stromal layer,^[42] and serum-free media do not support the attachment of an adherent cell layer to the surface of the tissue culture dish, even after pretreatment of the culture surface with poly-D-lysine, collagen, or fibronectin.^[36]

Growth Factors

Hematopoiesis is regulated by a large number of GFs (cytokines), primarily the interleukins (ILs) and colony-stimulating factors (CSF), with multiple and overlapping functions (Fig. 3).^[43] HSCs and HPCs are thought to express most cytokine receptors, yet they are selective in the cytokines to which they respond.^[44] Growth factors have been used to stimulate or potentiate the proliferation of stem or progenitor cells in the various lineages (Table 1). A key feature of a typical hematopoietic culture medium is the combination of cytokines it delivers to the cells and how the concentrations of these cytokines are maintained over time, both influencing the cumulative response obtained.^[45]

Fig. 3 Regulation of hematopoiesis by cytokine networks.

Table 1 Examples of cytokines with stimulating action on hematopoietic cell proliferation

Cell type	Cytokines
B-cell	IL-7, SCF, IL-2, IL-5, FL
T-cell	IL-2, SCF, FL
NK-cell	IL-2, IL-12
Erythroid	Epo, SCF, IL-3
Megakaryocyte	TPO, CSF, LIF, Epo, IL3, IL-6, IL-11
Neutrophil	G-CSF, SCF, GM-CSF, M-CSF, IL-3, IL-6
Eosinophil	IL-5, GM-CSF
Basophil	IL-3, SCF
Macrophage	M-CSF, GM-CSF, IL-3

Abbreviations: NK-cell: natural killer cell; IL: interleukin; SCF, stem cell factor; FL: flt-3 ligand; Epo: erythropoietin; TPO: thrombopoietin; CSF: colony-stimulating factor; LIF: leukemia inhibitory factor; G-CSF: granulocyte-colony stimulating factor; GM-CSF: granulocyte/macrophage-colony stimulating factor; M-CSF: macrophage-colony stimulating factor.

Cytokine receptors belong to three main families: the tyrosine kinase receptors, the hematopoietic GF (or cytokine) receptors, and the gp130 receptor.^[45] c-kit, the receptor for stem cell factor (SCF),^[46] and flk-2/flt-3, the receptor for flt-3 ligand (FL),^[47] are examples of the tyrosine kinase receptors. Both are expressed on very primitive hematopoietic cells and are implicated in the regulation of early stages of hematopoiesis.^[48–50] Ligands for the cytokine receptor family include IL-3 and thrombopoietin (TPO), both of which are active on primitive progenitors. IL-3 is required, along with SCF and flt-3 ligand, to maximize the expansion of human long-term culture-initiating cells (LTC-ICs) from CD34⁺/CD38[−] cells isolated from BM.^[51] TPO supports the proliferation and long-term maintenance of primitive hematopoietic progenitors and repopulating HSCs when used in combination with other stimulatory cytokines.^[52,53] The gp130 receptor family includes receptors for IL-6, IL-11, oncostatin-M, and leukemia inhibitory factor (LIF). IL-6 has direct proliferative effects on hematopoietic cells and interacts synergistically with other GFs to stimulate myeloid proliferation.^[54] IL-11 is produced by stromal cells and has been found, in synergy with SCF and flt-3 ligand, to stimulate the ex vivo expansion of adult murine stem cells.^[55] The addition of LIF to purified CD34⁺/Thy-1⁺ cells on a murine BM-derived stromal cell line caused the expansion of these cells, which in synergy with other GFs such as IL-3, IL-6, SCF, and granulocyte/macrophage-colony-stimulating factor (GM-CSF) resulted in a 150-fold expansion of cells retaining the CD34⁺/Thy-1⁺ phenotype.^[56]

Although most studies have focused on hematopoietic-related cytokines, novel factors, not originally identified as a result of their effects on hematopoietic cells, have been investigated. Bone morphogenetic proteins (BMPs) can modulate the proliferation and differentiation of primitive human hematopoietic cells (CD34⁺/CD38[−]/Lin[−]).^[57] Recently, the addition of the Notch ligand, Jagged-1, to cultures of primitive progenitor cells induced the survival and expansion of repopulating HSCs.^[58] Aside from growth-promoting cytokines, a number of growth-inhibitor cytokines, such as TGF- β , macrophage inflammatory protein-1 α (MIP-1 α), and tumor necrosis factor- α (TNF- α), have been shown to affect hematopoiesis.^[44] Although the role of the growth-inhibitory cytokines in vivo is not known, in vitro production of inhibitory proteins may be one reason for the transient expansion observed in many cultures.^[2] In long-term cultures, TGF- β is responsible for the quiescent state of the progenitor five to seven days after the last medium exchange.^[59] Similarly, addition of MIP-1 α to cultures prevents cells from cycling.^[60] Hence, addition of MIP-1 α and platelet factor-4 to IL-3-containing cultures of human hematopoietic cells resulted in the preservation of LTC-ICs for at least eight weeks.^[61]

Inoculum Density

Long-term hematopoietic cultures have demonstrated the influence of seeding density, GF supplements, and the rate of medium exchange on progenitor output.^[62] Consideration needs to be given not only to cell density, but also to the composition of stem, progenitor, and accessory cells, as well as the combination and concentration of GFs in the medium.^[63] A number of reports have examined the effect of inoculum density on the ex vivo expansion of human hematopoietic cells using static cultures. Koller et al.^[64] demonstrated that high seeding density cultures of BM mononuclear cells (MNCs) (e.g., 5×10^5 cells/well) resulted in higher total cell and colony-forming cell (CFC) numbers, whereas lower seeding densities (e.g., 5×10^4 cells/well) led to higher cell expansion and greater depletion of CFCs. Similarly, Poloni et al.^[65] demonstrated that decreasing the seeding density from 3×10^4 to 1.5×10^3 cells/ml enhanced total cell and progenitor expansion by up to 20-fold and 3-fold, respectively, while maintaining the LTC-ICs. The effect of preformed stroma on culture performance and its relation to seeding density was also examined.^[64] It was demonstrated that when BM MNCs were cultured at sufficiently high seeding densities (e.g., 5×10^5 cells/well), the culture became stroma-independent in terms of LTC-IC maintenance and expansion. On the other hand, when the seeding density of MNCs was lowered

T

(e.g., 5×10^4 cells/well), their behavior greatly resembled cultures of CD34-enriched and stroma-free cells, with greater variability in culture output and dependence on accessory stromal cells.

Studies on the rate and net expansion of LTC-ICs and CFCs in stirred suspension bioreactors have also exemplified the dependency on seeding density, with the highest cell density ($0.1\text{--}1 \times 10^6$ cells/ml) of BM MNCs resulting in a significant net expansion of primitive HPCs.^[62] The typical inoculum range reported has been in the order of $1\text{--}3 \times 10^6$ MNCs/ml and $0.5\text{--}1 \times 10^4$ CD34⁺ cells/ml.^[62,64,66,67] However, the range can vary depending on the culture system, the use of preformed stromal “feeder” layer, or the use of scaffolds. Therefore, it is important that individual laboratories determine the initial inoculum concentrations that generate optimal cell-outputs of the desired cells from a given starting population under specific experimental conditions.

Feeding Schedule and Culture Duration

The *in vivo* BM microenvironment has a perfusion rate of $0.1 \text{ ml/cm}^3/\text{min}$,^[68] wherein hematopoietic cells are subjected to continuous feeding of nutrients and the removal of metabolic wastes. To mimic such an environment, various feeding strategies have been employed in the cultivation of hematopoietic cells.^[66,69–73] The major role of medium exchange is to overcome the limitation of growth^[69] due to the depletion of substrates and the accumulation of the metabolic by-products such as lactate that result in a drop in culture pH,^[74] and growth inhibitory substances. Mass transfer limitations of oxygen can also restrict cell expansion.^[62,64,75] In static cultures, especially at high cell densities of BM MNCs in the presence of preformed stroma, frequent medium exchange enhanced the cell and colony-forming unit-granulocyte/macrophage (CFU-GM) outputs.^[64] Perfusion systems offer several advantages over static cultures in terms of automated, continuous, and controlled medium exchange. Perfusion cultures of peripheral blood (PB) MNCs or CD34⁺ cells have demonstrated an increase in LTC-IC numbers in comparison to static cultures^[66] and have been shown to enhance the expansion of total and CFCs.^[73] Finally, perfusion cultures have the added advantage over frequently-fed static cultures in that during feeding they do not result in the depopulation of nonadherent cell fractions and they require less handling.^[66]

The duration of hematopoietic cultures is especially relevant for clinical applications. In CD34⁺ *ex vivo* expansion from mobilized peripheral blood (MPB), a two-phase growth was observed with a pre-CFU phase during the first 7–10 days and a phase past day 10 where CFU-GM decreased and mature myeloid cell

numbers increased.^[76] Many clinically relevant studies have reported a decrease in progenitor production during days 12–15 of culture, probably due to inadequate feeding protocols and high cell concentrations, indicating that expansion in static liquid cultures should be limited to 7–14 days.^[77] However, several preclinical studies have reported continuously increasing levels of expansion of all hematopoietic lineages for several months.^[78]

pH

Hematopoietic cultures, unless controlled, experience varying pH with time. Hence, the *ex vivo* expansion of hematopoietic cells is affected by gradients in pH^[79] that may alter cell physiology, receptor expression,^[80,81] and cell differentiation.^[80–87] The optimum extracellular pH is dependent on the hematopoietic cell lineage,^[80–87] with enhanced proliferation of phytohemagglutinin-activated T cells at pH 7.0–7.2, accelerated erythroid differentiation at pH 7.6,^[82–84] optimal formation of CFU-GM at pH 7.2–7.4,^[82] and enhanced differentiation, polyploidization, and apoptosis of megakaryocytes at pH 7.4–7.6.^[86] PB-derived macrophage progenitors (CFU-M) appear to be more sensitive to acidic pH than granulocytic progenitors (CFU-G), yet cord blood (CB)-derived progenitor cells are more resistant to pH variation in methylcellulose cultures.^[82] Expression of cell surface receptors, which mediate cell adhesion and signal transduction, is also pH-dependent. For example, the receptor for granulocyte-colony-stimulating factor (G-CSF) is expressed optimally at pH 7.22,^[80] whereas expression of the IL-2 receptor is optimal at pH 7.0.^[81]

Oxygen Tension

Oxygen tension affects the growth of hematopoietic progenitor cells,^[88–90] and increases the responsiveness of cells to cytokines^[90,91] and the ability of these cells to produce cytokines.^[92] The concentration of oxygen within the microenvironment is more important than the gas phase oxygen level.^[8] *In vivo*, BM oxygen tension is between 10 and 50 mm Hg.^[8,88] *In vitro*, low oxygen concentration (2–7%) enhances the size and number of hematopoietic colonies in semisolid cultures,^[88,89,91,93–95] and the optimal expansion of human BM CFU-neutrophil, macrophage, and eosinophil progenitors (CFU-C), burst-forming unit-erythroids (BFU-E), and multipotential progenitors (CFU-mix) occurs at 7% O₂.^[88] The production of progenitor and mature cells is likewise dependent upon oxygen tension,^[88–91,95,96] with the formation of CB BFU-E favored in hypoxic conditions (1%), whereas cultures

exposed to 20% oxygen produced mature erythrocytes.^[89] Similarly, the size and number of CFU-megakaryocytes (CFU-MKs) was enhanced at low oxygen tension (5%), whereas high oxygen tension (20%) enhanced CD41⁺ megakaryocyte generation, high ploidy, proplatelet formation, and apoptosis.^[96] This *in vitro* situation may resemble the *in vivo* situation, where megakaryocyte maturation and platelet production occur adjacent to the BM sinus, which is exposed to venous pO₂ (8%). In contrast, early progenitors and stem cells reside in the core of the bone marrow hematopoietic compartment (BMHC), where the average concentration of O₂ is 1–5%.^[97]

Stimulation under low oxygen tension can, in part, be attributed to the increased responsiveness of the cells to cytokines^[90,95,96,98] and to the production of hematopoietic GFs.^[92] Thus, oxygen tension may regulate the production of erythropoietin (Epo) by macrophages^[92] as well as the formation of CFU-erythroid (CFU-E) and BFU-E by altering the sensitivity of these colonies to Epo.^[91] Therefore, there may exist an optimal oxygen tension based on the cytokines used and on the developmental state/potential of the cells.

In vitro, the availability of oxygen depends on culture configuration, cell density, and gas-phase oxygen tension.^[42] At early stages of culture, low oxygen tension is sufficient for the production and maintenance of progenitor cells. As cell numbers increase, oxygen becomes a limiting factor. Depending on the culture system used, oxygen may be maintained within the system by increasing gas-phase oxygen tension, agitation rates, or perfusion rates. However, increasing the gas-phase oxygen tension to overcome the increased demand due to increased cell density can result in oxygen toxicity. Increased feeding and the use of perfusion are preferred alternatives to oxygenation because they do not result in cell damage.^[95] The generation of reactive oxygen intermediates, as a consequence of cellular metabolism and the accumulation of neutrophils, macrophages, and mature myeloid cells, results in the progressive decline of progenitor cell production.^[91,99] To reduce oxygen toxicity in response to high oxygen tension, antioxidants, such as reduced glutathione, vitamin E, and 2-mercaptoethanol,^[88,91] as well as scavengers of hydroxyl radicals and hydrogen peroxide, such as mannitol and catalase, may be used.^[99]

CONCLUSIONS

The success of clinical stem cell transplantation depends on the supply of sufficient numbers of high-quality repopulating HSCs. In addition, a number of clinical strategies that combine HSC with

accessory and mesenchymal stem cells are being examined. Although significant progress has been made in characterizing the factors that govern hematopoiesis, *ex vivo* expansion of hematopoietic cells appears to be a technique still in its infancy. Nevertheless, the *ex vivo* expansion of hematopoietic cells for clinical use may hold potential.

The operational control of hematopoiesis *in vitro* presents a challenge in terms of the cell source and type, culture system, culture medium, and operating conditions.^[22] Even slight deviations in the culture parameters can affect the final cell output. Factorial and composite designs may be utilized to increase the efficiency of investigations on the effects of stimulatory (or inhibitory) factors and culture parameters on hematopoietic culture systems, and to reveal unexpected interactions that would otherwise be missed by conventional analyses.^[100,101] The ultimate challenge in developing successful *ex vivo* HSC expansion processes, however, lies in devising convenient assays that faithfully reflect the homing, function, and repopulating activities of stem cells in human subjects.

INTRODUCTION

Following the development of a stroma-dependent long-term murine bone marrow culture system by Dexter and colleagues,^[1] conventional bone marrow cultures have been on flat two-dimensional surfaces of tissue culture dishes. This methodology has been adapted for human long-term bone marrow culture.^[2] The major challenge for the *ex vivo* expansion of hematopoietic stem and progenitor cells is to provide a suitable culture environment that would support the expansion of clinically relevant cell numbers of the desired cell type(s) from relatively small donor samples.^[3]

STROMAL SUPPORT

There are two main approaches for *in vitro* hematopoietic cultures, namely, stroma-free and stroma-dependent. For clinical use, stroma-free cultures are more easily standardized and maintained.^[4] However, stroma-based cultures can facilitate a 600-fold expansion of human cord blood (CB) CD34⁺ cells and the enhanced expansion of colony-forming unit cells (CFU-Cs) and cobblestone area-forming cells (CAFCs).^[5,6] They can also provide a more physiologically relevant microenvironment to the hematopoietic stem and progenitor cells. Stromal feeders have also been used to support the retroviral transduction of autologous hematopoietic stem cells (HSCs)^[7] and to purge contaminating leukemic cells from chronic myelogenous leukemia (CML)^[8] and acute myelogenous leukemia (AML)^[9] autografts *ex vivo*. An advantage of using autologous feeders is that the graft intended for clinical applications will not be contaminated with allogeneic or xenogeneic feeder cells.^[4] However, *ex vivo* hematopoietic support may be defective due to exposure of the stroma donor to chemotherapy and radiation prior to harvest of the

autologous stroma feeders^[10] or due to inherent defects in the stromal cells as a result of the disease.^[11] To circumvent these potential problems, murine or human stromal feeder cells have been cloned from other sources.^[4]

STATIC CULTURES

Different devices have been developed to facilitate *ex vivo* hematopoietic culture, including vessels for static cultures and bioreactors (Table 1). Static culture systems, such as well-plates, T-flasks, or gas-permeable blood bags, are the most widely used devices.^[12,13]

Gas-permeable polypropylene bags provide a closed and easily manipulated system for the expansion of cells for clinical applications. In these systems, an optimal seeding density of 5×10^4 bone marrow (BM) CD34⁺ cells/ml or 1×10^4 CB CD34⁺ cells/ml in serum-free medium and a 14-day culture period resulted in the expansion of total cells, CD34⁺ cells, clonal progenitors (CFU-granulocyte/macrophage [GM] and burst-forming unit-erythroid [BFU-E]), and long-term culture-initiation cells (LTC-ICs).^[14] An increased seeding density induced the production of granulocytic cells with terminal differentiation, but the overall extent of cell expansion decreased.^[15] In contrast to flask cultures, gas-permeable blood bags do not support the development of stromal cells. Despite their widespread applications, static cultures are limited to relatively low-density cultures with low total cell output.^[12,13] The drawbacks of the blood bags include the difficulties in monitoring and control, the need for repeated handling during feeding, and the limited surface area available for growth and expansion of cells.^[13]

Bioreactor culture systems were developed to overcome the limitations of static cultures. They enable better control of culture parameters and automated feeding strategies, allowing a hands off operation and

Table 1 Summary of the culture systems used for cultivation of hematopoietic stem and progenitor cells

Culture system	Comments	Ref.
Static	<ul style="list-style-type: none"> Well-plates, T-flasks, or gas-permeable blood bags Lack of on-line monitoring and control for dissolved oxygen and pH Lack of support for automated feeding/exchange of culture medium 	[12,13]
Suspension (Stirred bioreactor)	<ul style="list-style-type: none"> Provision of a well-controlled, closed, and reproducible environment Cell-cell and cell-matrix interactions are not reproduced Generation of shear stress through agitation Easy scale-up 	[25,31]
Perfusion		
Hollow-fiber	<ul style="list-style-type: none"> Continually perfused culture medium Shear-free environment Spatial inhomogeneities for oxygen, pH, nutrients, and metabolites Difficulty in monitoring and controlling the culture environment Scale-up difficulties Hematopoietic cell expansion questionable 	[25]
Perfusion chambers	<ul style="list-style-type: none"> Continually perfused culture medium Relatively homogeneous bulk culture medium Support the formation of a stromal layer if desired Support higher expansion of LTC-IC numbers for both MNC and CD34⁺ cultures Problem with over diluting endogenously-produced factors Medium-intensive culture system Scale-up not straightforward due to the system geometry Problems with monitoring and control of the environment near cell periphery Clinical application (Aastrom Biosciences) 	[16–19,22,23,28]
Airlift	<ul style="list-style-type: none"> High cell density growth Supports the formation of stromal cells on fiberglass beads Adverse effects such as bubble shear and breakage caused by gas sparging Lower expansion of hematopoietic cell culture compared to static control 	[25,58]

Abbreviations: LTC-IC: long-term culture-initiating cell; MNC: mononuclear cell.

lower risk of contamination,^[3,16] and are able to support high cell densities and accessory cells. One such bioreactor system (Aastrom Biosciences, Ann Arbor, Michigan), which is an automated perfusion system, has obtained market approval from the Food and Drug Administration in the United States and a CE (Conformite Europeenne) mark in Europe.^[17,18]

PERFUSION CULTURES

Perfusion bioreactors have been developed to continually replace culture medium, thus removing any harmful metabolites and maintaining a constant supply of growth nutrients. However, care must be taken not to over-dilute endogenously produced soluble stimulatory compounds^[19] or to mechanically damage

the cells. Perfusion bioreactors have also been used to analyze the consumption and production of growth factors and the relationship of these parameters to specific cell production.^[20] Changes in the schedule of the medium perfusion may influence growth factor secretion by stromal cells.^[21] This suggests that it may be possible to provide culture conditions in which the stroma is maintained in a state that supports hematopoiesis but negates the need of growth factor supplementation. Perfusion bioreactor systems have been shown to support the expansion and maintenance of LTC-ICs and colony-forming cells (CFCs).^[16,17,22,23] Currently, at least three types of perfusion bioreactor systems have been reported, namely, the flatbed perfusion system,^[16,17,22] the grooved-bed perfusion system,^[23,24] and the hollow-fiber system.^[25]

Flatbed perfusion systems contain culture chambers that are inclined with the outlet above to reduce the removal of nonadherent cells during perfusion. The chambers are designed to maintain low laminar flow.^[22] They have been used to expand mononuclear cells (MNCs) in which a stromal layer developed^[16] or CD34-enriched cultures on preformed stroma.^[26] To facilitate stromal cell attachment, medium flow is started after a 24-hour initial period without perfusion.^[17] Nonadherent cells are harvested by aspirating the medium, whereas adherent cells are removed after trypsinization.^[17] The flatbed perfusion systems have been shown to facilitate the expansion of all types of human hematopoietic progenitor cells (HPCs) and HSCs from BM, CB, and mobilized peripheral blood (MPB).^[22,27] A 20–25-fold expansion of unselected human BM MNCs and a 10–30-fold expansion of CFU-GM over a two-week culture period^[16] have been observed. A BM aspirate of 10–15 ml can produce 3 billion cells in total and a 7.5-fold expansion of LTC-ICs.^[17] On preformed stromal cells, a 7-day culture of CB MNCs can support an 11-fold expansion of CFU-GM, a 2.5-fold expansion of BFU-E, and a 2.4-fold expansion of CFU-mix.^[22] Harvesting half the cell population every 3 to 4 days may further enhance the expansion of adult human bone marrow MNCs in perfusion bioreactors.^[28] Hence, when supplemented with cytokines and under optimized conditions, flatbed perfused bioreactors support expansion of LTC-ICs and CFU-GM, suggesting that adult-sized grafts from CB and MPB can be obtained. These culture systems are being evaluated in clinical trials, and initial results advocate that human repopulating stem cells can be preserved.^[4,29]

Grooved-bed perfusion bioreactors facilitate stroma-free cultures and hold more potential for clinical applications. The chambers are designed with multiple microgrooves, 200 μm across and 200 μm deep, separated every 200 μm . Because the microgrooves are perpendicular to the direction of flow, a higher perfusion rate (2.5 ml/min) can be accommodated, compared with the flatbed reactor, without disruption of the cells. However, the cells are isolated from the main convective flow of the medium, which creates inhomogeneities in concentration and presents difficulties in the monitoring and control of the cellular microenvironment.^[24] Grooved-bed perfusion bioreactors have supported the expansion of CFU-GM (19.4-fold) and can maintain LTC-IC (64% of input after a 15-day culture)^[23,24] from MPB MNC as well as from CB.

Hollow-fiber perfusion bioreactors offer a shear-free environment for cell proliferation and have been investigated for their potential applications in the expansion of HSCs.^[25] The bioreactor employed by Sardonini et al. had a 1.0-ft² fiber surface area with an

extracapillary space of 12 ml, which was seeded with 4.4×10^7 MNCs. Medium was perfused into the hollow-fiber cartridge at a rate of 50 ml/min. In contrast to the continuous flatbed and grooved-bed perfusion culture systems, the hollow-fiber bioreactor showed no observable expansion of hematopoietic cells when compared to the control (static) cultures.^[25] In addition, hollow-fiber bioreactor systems present inherent difficulties in scale-up because the spaces between the fiber modules are not kept constant, resulting in fluctuations in oxygen transfer and difficulties in monitoring of the culture.

STIRRED SUSPENSION CULTURES

Stirred culture systems are well characterized and widely used for the culture of both microbial and mammalian cells. They provide a well-controlled, closed, and reproducible culture environment and are superior to most static and perfusion systems for sampling ease, data collection, and control of culture parameters. Furthermore, stirred bioreactors could be advantageous for clinical applications in terms of the scale anticipated for clinical cultures.^[30] BM MNCs have been successfully propagated in serum-containing stirred culture systems;^[25,31] MPB and CB MNCs and CD34⁺ cells have been propagated in both serum and serum-free stirred cultures.^[13] Natural killer cells isolated from peripheral blood mononuclear cells have also been cultivated in stirred culture bioreactors.^[32] However, since hematopoietic cells are relatively sensitive to shear, low shear rates are required to avoid physical damage,^[13,25,31] altered expression of surface markers and cytokine receptors, and changes in cellular metabolism.^[33] Although macrophages tolerate suspension, fibroblasts and endothelial cells are unlikely to perform properly in stirred cultures.^[34] Therefore, agitation could have a profound effect on the type of cells that will expand and the extent of this expansion. Since suspension culture systems do not mimic the complex three-dimensional (3-D) microenvironment found in BM, it is not clear if extensive stem cell self-renewal can be sustained in the stirred culture. Expansion of cell numbers in such stirred systems can be achieved by the addition of microspheres that provide a scaffold for HSCs.^[25]

THREE-DIMENSIONAL CULTURES

Whereas *in vivo* hematopoiesis is regulated by cell-cell, cell-matrix, and growth factor interactions, most *ex vivo* culture systems have focused on the addition of cytokines alone and, hence, are insufficient to promote optimal blood cell development and retain long-term

generative capacity.^[35,36] Traditional stroma-dependent culture systems are not designed to enhance cell-cell and cell-matrix interactions or to create a spatial distribution of stromal and hematopoietic cells that mimic the *in vivo* 3-D configuration. Novel 3-D culture systems (Table 2) have been developed based on the hypothesis that growth in 3-D culture may more faithfully replicate the *in vivo* marrow hematopoietic inductive microenvironment (HIM) required for self-renewal and differentiation of stem and progenitor cells.^[37-48] We developed a long-term bone marrow culture system using porous microspheres as scaffolding to support 3-D growth configuration.^[40,41] Highly porous scaffolds used in these systems allow high-density cell growth across a higher specific surface area than the conventional static (monolayer) culture, thus creating a spatial distribution of stromal and hematopoietic cells.^[49] This spatial distribution facilitates the localization and delivery of cells and growth factors to the desired sites on the scaffolds and mimics the biological and mechanical function of the extracellular matrix (ECM).^[50] Furthermore, the interconnecting pores enable the dispersed cells to rearrange into functioning tissue units.^[48]

The scaffolds used for bone marrow tissue engineering applications are either naturally derived materials, such as macroporous collagen carriers,^[41,51] or synthetic polymers, such as porous polyvinyl formal (PVF),^[48] nonwoven polyethylene terephthalate (PET),^[49] porous biomatrix (Cellfoam™),^[45] tantalum-coated porous biomaterial (TCPB),^[44] porous gelatin microspheres (CultiSpher G),^[43] nylon filtration screen,^[37-39] polyester nonwoven fiber disks,^[52,53] and cellulose porous microspheres.^[40]

Macroporous collagen carriers have been used for the cultivation of CB CD34⁺ cells in coculture with the murine cell line S1/S1 in a fixed-bed reactor with continuous perfusion.^[51] The collagen microspheres supported the development of the murine stromal cell line, which produced ECM proteins. This system resulted in 100-, 114-, and 6.4-fold increases in MNCs, CFU-GMs, and CAFs, respectively. Research on synthetic polymers (in static culture systems) includes the use of collagen-coated nylon mesh as a template to grow BM cells, maintaining multilineage differentiation but with declining CFU numbers.^[37-39] A PVF resin has been utilized as a 3-D scaffold for the proliferation and differentiation of murine BM cells,^[48] which resulted in enhanced cellular proliferation and increased number of CFUs in the presence of growth factors and in the absence of preformed stroma. Nonwoven polyethylene terephthalate fabric^[49] has been used to simulate the marrow microenvironment for the expansion of CB progenitor cells. Such cultures enhanced cell-cell and cell-matrix interactions and allowed the 3-D distribution of

stromal and hematopoietic cells. In the presence of exogenous cytokines, 62.1-, 7.0-, and 6.0-fold increases in total cells, CD34⁺, and CFUs were obtained, respectively. Human BM CD34⁺ cells have also been cultured on inert Cellfoam™,^[45] which resulted in enhanced colony formation and LTC-IC in both cytokine-supplemented and cytokine-free cultures when compared with plastic cultures (using either preformed stroma or fibronectin-coated plastic well-dishes). A comparison between polyester nonwoven disks (Fibra cel) and porous cellulose carriers using mouse bone marrow showed that the weekly output of total hematopoietic cells increased at week 3 in the culture using polyester nonwoven disks along with the proportion of progenitor cells (BFU-E and CFU-GM) after week 1 in contrast to the output of the porous cellulose carriers.^[53] A tantalum-coated porous scaffold has been shown to improve retroviral transduction and maintain hematopoietic progenitor cells.^[44,54] This scaffold, in the absence of exogenous cytokines, supported up to a 1.5-fold expansion of BM CD34⁺ cells as well as a 6.7-fold increase in CFUs.^[44]

We have developed packed-bed bioreactors, both continuous and batch-fed, that use porous collagen or cellulose microspheres to grow both murine and human BM cells.^[40,41] These cultures supported multilineage differentiation in the absence of exogenous growth factors and a 3-D growth configuration that mimicked that of BM *in vivo*. In the presence of cytokines, including erythropoietin (Epo), this system supported extensive erythropoiesis when compared with a traditional flask culture under lower, more physiological concentrations of Epo,^[40] indicating that the culture system better mimics the HIM *in vivo* and is a more physiological marrow model. Furthermore, CultiSpher G microspheres, coated with preformed BM stroma have been used in a stirred tank culture system for the expansion of CB MNCs in the presence of exogenous cytokines.^[43] This system supported 7.7-, 23.3-, and 9.6-fold increases in total cells, CFU-C, and CD34⁺ cells, respectively, as compared to the static control after a 12-day culture period. Distinct hematopoietic islands were observed on the scaffolds, indicating the localization and compartmentalization of the progenitor cells.

Biodegradable porous scaffolds can be prepared in different ways.^[55-57] Wang et al. manufactured and evaluated bioactive and biodegradable materials and scaffolds, both porous or nonporous,^[42] and found that incorporation of bioceramic particles in the biodegradable polymers would render the composites bioactive and enhance their ability to induce the formation of bonelike apatite on their surfaces. These biodegradable porous materials may be employed for hematopoietic cell culture.

Table 2 Summary of the 3-D scaffolds used for the growth and expansion of HSCs and HPCs

Scaffold	Experimental condition	Comments	Ref.
Porous polyvinyl formal (PVF)	Culture system: static Surface treatment: type I collagen Porosity: 90% Pore size: 130 μm Cytokines: IL-3, IL-6, Epo, SCF	<ul style="list-style-type: none"> • Cell expansion without a preformed stroma • Increased cell proliferation efficiency • Increased CFUs and HPCs 	[48]
Nonwoven polyethylene terephthalate (PET) fabric	Culture system: static Surface treatment: hydrolysis step to improve adhesion Porosity: 85% Pore size: 10–60 μm Cytokines: TPO, Flk-2/flt-3 ligand	<ul style="list-style-type: none"> • Supports CB stroma development, which does not contain adipocytes (compared to BM stroma) • Increase in total cell number and CFUs in the absence of GFs. • Enhanced long-term expansion in the presence of GFs • 62.1-, 7-, and 6-fold increase in total cells, CD34⁺, and CFUs in the presence of GFs 	[49]
Porous biomatrix (Cellfoam™)	Culture system: static Surface treatment: tantalum, fibronectin, and collagen Porosity: 90% Pore size: not reported Cytokines: none and IL-3, IL-6, SCF, Flk-2/Flt-3 ligand	<ul style="list-style-type: none"> • Increased CFUs and LTC-ICs in both cytokine-free and cytokine-containing cultures compared with 2-D cultures 	[45]
Tantalum-coated porous biomaterial (TCPB)	Culture system: static Surface treatment: tantalum and fibronectin or collagen Porosity: 90% Pore size: not reported Cytokines: none	<ul style="list-style-type: none"> • No preformed stroma requirement • 1.5- and 6.7-fold increase in HPCs and CFCs, respectively • Supports progenitor viability and multipotency 	[44]
Nylon filtration screen	Culture system: static Surface treatment: collagen Porosity: not reported Pore size: 210 μm Cytokines: none	<ul style="list-style-type: none"> • Supports stroma development • Supports multilineal differentiation and proliferation of immature cells. 	[37–39]
Polyester nonwoven disks	Culture system: static or stirred Surface treatment: not reported Porosity: not reported Pore size: not reported Cytokines: none	<ul style="list-style-type: none"> • Supports stroma development • Increase in weekly output of total hematopoietic cells in wk 3 	[52,53]
Porous gelatin microspheres (CultiSpher G)	Culture system: stirred flask Surface treatment: not reported Porosity: not reported Pore size: not reported Cytokine: IL-3, IL-6, SCF	<ul style="list-style-type: none"> • Preformed stroma • 7.7-, 23.3-, and 9.6-fold increase in total cells, CFU-C, and CD34⁺ cells compared to static control • Distinct hematopoietic islands were observed 	[43]
Porous cellulose microspheres	Culture system: packed-bed bioreactor Surface treatment: not reported Porosity: 95% Pore size: 300 μm Cytokine: none or IL-3, Epo, SCF, GM-CSF, IGF-I	<ul style="list-style-type: none"> • Supports 3-D growth configuration • Supports multilineal differentiation • Supports erythropoiesis in the presence of GFs 	[40,41]

(Continued)

Table 2 Summary of the 3-D scaffolds used for the growth and expansion of HSCs and HPCs (*Continued*)

Scaffold	Experimental condition	Comments	Ref.
Macroporous collagen carriers	Culture system: packed-bed bioreactor Treatment: not reported Porosity: 85% Pore size: 50 μm Cytokine: IL-3, SCF, TPO, Flt-3 ligand	<ul style="list-style-type: none"> • Supports preformed stroma development and ECM production • 100-, 114-, and 6.4-fold increase in MNCs, CFU-GMs, and CAFCS 	[51]

Abbreviations: IL: interleukin; Epo: erythropoietin; SCF: stem cell factor; GFs: growth factors; CFUs: colony-forming units; HPC: hematopoietic progenitor cell; CB MNCs: cord blood mononuclear cells; TPO: thrombopoietin; BM: bone marrow; LTC-IC: long-term culture-initiating cell; CFCs: colony-forming cells; CFU-C: CFU-neutrophil, macrophage, and eosinophil progenitor; GM-CSF: granulocyte/macrophage-colony-stimulating factor; IGF-1: insulin-like growth factor-1; CFU-GM: CFU-granulocyte/macrophage.

Although the use of a scaffold provides greater surface area for cell attachment than the two-dimensional monolayer culture systems and enhances spatial cell-cell and cell-matrix interactions, several issues, including those of scale-up, monitoring, and sampling, remain to be addressed.

One other bioreactor configuration used for the expansion of hematopoietic stem and progenitor cells was the airlift packed-bed bioreactor system, which was designed with a central draft tube.^[25,58] The annular region of the bioreactor was packed with fiberglass disks with a mean diameter of 13.5 μm and a surface area of 109 cm^2 , which were used to establish preformed stroma designed to mimic the *in vivo* environment. The medium was circulated upward through the draft tube by gas sparging and then downward through the packed bed of stacked fiber disks. A 0.5-L system resulted in the total production of 3.6×10^8 BM cells over an 11-week culture period. However, the fiberglass disks did not simulate the natural marrow microenvironment, and adverse effects of bubble shear and breakage caused by gas sparging further hindered cell expansion.^[58]

CONCLUSIONS

The engineering of optimal hematopoietic cell culture systems will require the design of culture systems that mimic the *in vivo* self-regulating bone marrow environment, operate under reliable and reproducible conditions, and offer a broad spectrum of possibilities for different culture strategies as well as the cultivation of various cell types—from stem cells to differentiated cells for gene, cellular, and tissue therapies. Furthermore, the requirement for good manufacturing practices (GMP) compliance of *ex vivo* expanded HSCs for clinical application involves the development of suitable, closed culture systems that can be easily controlled and monitored.

INTRODUCTION

An estimated 269,000 new cases of breast cancer were diagnosed in women in 2005.^[1] Breast cancer is the most frequently diagnosed cancer in American women, accounting for approximately 31% of new cancer cases yearly.^[1] Breast cancer poses an enormous threat because of the high concentration of local blood and lymphatic vessels through which cancer can metastasize. The actively differentiating epithelial cells that line the breast ductal structures are responsive to hormonal changes and thus are susceptible to mutation during cell division cycles.^[2] Upon formation of epithelial-derived breast carcinomas, women have several treatment options, including radiation therapy, chemotherapy, hormonal therapy, and surgery, the latter involving the removal of a tumor and a surrounding margin of normal breast tissue. Management of breast cancer is often a multistep process, generally consisting of primary, neoadjuvant (presurgical), and adjuvant (postsurgical) therapies. Neoadjuvant therapies, which may be local or systemic, have been used successfully to shrink tumors prior to removal, whereas adjuvant treatments provide a mechanism of targeting and eradicating malignant cells residing at surgical margins or cells that have metastasized. Although the use of neoadjuvant therapies does not affect patient survival outcome, increased use of such therapies is correlated with an increase in the lumpectomy rate. These treatment methods have been proved effective as preventive therapies in high-risk patients to avert tumor recurrence or disease of the contralateral breast.^[3] The removal or partial removal of a breast by way of mastectomy or lumpectomy can be taxing, physically and psychologically; nevertheless, because of the effectiveness of surgical tumor removal, lumpectomies and mastectomies are almost always part of a treatment regimen.

Following surgical tumor removal, women may select among a variety of reconstruction procedures. Because of the complications associated with current reconstruction methods, researchers are investigating methods to restore tissue function and aesthetics permanently with biological substitutes.

The discussion of the role of tissue engineering and biomaterials to breast cancer applications in this article is threefold. First, the development of a breast reconstruction procedure using biocompatible and biodegradable materials could result in the development of an implant that can stimulate the regeneration of host adipose cells and fill a soft-tissue void in the breast. With successful implantation and cellular control, permanent biological restoration of adipose tissue can be achieved using autologous patient cells. Second, the use of these materials as drug-delivery vehicles could lead to prevention of tumor recurrence in the breast. Last, the construction of *in vitro* engineered breast tissue has the potential to aid in cancer research and drug testing by providing a model in which concurrent cellular processes that lead to tumor growth and metastasis may be monitored.

CURRENT TREATMENT AND RECONSTRUCTION OPTIONS

Breast cancer treatments are multifaceted and vary widely from patient to patient. Most treatment plans, however, consist of surgical tumor removal coupled with presurgical or postsurgical therapies. The two major types of surgeries are lumpectomies and mastectomies. A lumpectomy is often preferred by patients because unlike a mastectomy, which results in the loss of form and function due to a high degree of soft-tissue removal, a lumpectomy is a breast-conserving surgery. To help patients cope with the psychological, emotional, and physical aspects of a mastectomy, breast reconstruction procedures are widely performed. Two primary categories of breast reconstruction methods exist: prosthetic and autologous.

Prosthetic Methods

Prosthetic or acellular methods of reconstruction include breast prostheses and breast implants, and tissue expansion devices followed by the insertion of implants. Breast prostheses are custom-molded to be

worn outside the body and thus are not permanent corrections of breast defects. Furthermore, prostheses can limit the physical activities of patients and may give breasts a distorted appearance.

Permanent alloplastic implants are constructed from a silicone shell filled with either silicone or saline. The first step in implant reconstruction (if it is not carried out immediately following tumor removal) is the expansion of the skin and muscle in the breast region. An expander is placed under the chest muscle, and saline is added gradually over the course of weeks or months until the skin and muscle have stretched sufficiently for the implant to be placed. Implants, generally placed within 6–8 months of initial tissue expansion, often require replacement after several years, and with them come a series of possible complications, including bleeding, fluid collection, and capsular contraction due to scarring and fibrosis. Additionally, there is a low level of concern that implants can obstruct mammographic images and potentially prevent detection and diagnosis of recurring tumors.^[4]

Autologous Methods

Traditional autologous methods often consist of the use of flaps of tissue removed from the abdomen, back, or buttocks that are transferred to the defect site to reconstruct the breast mound. Autologous donor tissue can remain coupled to its original blood supply, or it can be completely excised and subsequently reattached to the vascular network in the breast region. Complications of autologous flap procedures include scarring, infection, and donor-site morbidity.^[5] Soft-tissue transplants similarly can be used to fill tissue voids following tumor removal. Adipose tissue can be removed from a fatty region of the body and transplanted by way of injection to a defect site. The concept of autologous fat transplantation is logical in that fatty tissue is replaced with fatty tissue, but the use of this technique has not been consistently successful in practice. Unfortunately, adipocytes are frequently damaged as a result of harvesting methods such as liposuction. These damaging effects, in addition to poor vascularization and integration of the transplanted tissue, often lead to rapid resorption of more than 50% of the original graft volume and eventual deformation of the transplant site.^[6]

To minimize the effects of cellular and tissue resorption, researchers have more recently focused on developing cellular scaffolds, where cells are seeded onto an absorbable template or scaffold. The scaffold is designed to induce cell growth and to absorb in the body gradually once implanted, paralleling tissue growth. The scaffold material provides a surface to

which the cells attach and therefore diminishes the likelihood of cellular resorption. The selection of cell type and cell source and the design of the optimal scaffold material are the subjects of many research programs.

BREAST RECONSTRUCTION AND TISSUE ENGINEERING

Significant improvements have been made over the past decade in current prosthetic and autologous reconstruction procedures with regard to aesthetics and ensuing complications. Tissue engineering practices, however, have the potential to provide patients with a minimally invasive reconstruction alternative that will render current complications obsolete. A permanent, biologically based restoration of breast tissue will also preclude the need for multiple surgeries and recovery time. Current methods for breast reconstruction typically involve invasive medical procedures that can be costly and, at times, ineffective in achieving the desired shape, size, texture, and volume of the natural breast tissue. So that the patient avoids pain, scarring, and recovery time associated with multiple procedures, tissue engineering strategies are being investigated.

Anatomy of the Breast

The framework of the breast, shown in Fig. 1, is comprised of three major tissue types: glandular, fibrous, and adipose. Among these highly innervated tissues is a local network of blood and lymphatic vessels. Also contained within the breast are 15–20 lobes that branch into smaller lobules and that have individual excretory ducts, also known as lactiferous tubules. Lobes are connected by the fibrous tissue of the breast and are separated by intervals of adipose tissue. The volume of the breast is composed primarily of adipose tissue. The fundamental unit of adipose tissue is a fat lobule, which consists of approximately 10^2 – 10^3 mature adipocytes. Comprised of mostly ductal and lobed structures, the mammary glands are the major functional units of the breast and are embedded in a layer of contractile epithelial cells.^[7]

Cellular Components of Adipose Tissue

Adipose tissue is a highly specialized connective tissue that serves to insulate and cushion the body. The principal cellular component of adipose tissue is a collection of lipid-filled cells known as adipocytes, which are adhered to a collagen fiber matrix. Other cellular components of adipose tissue include

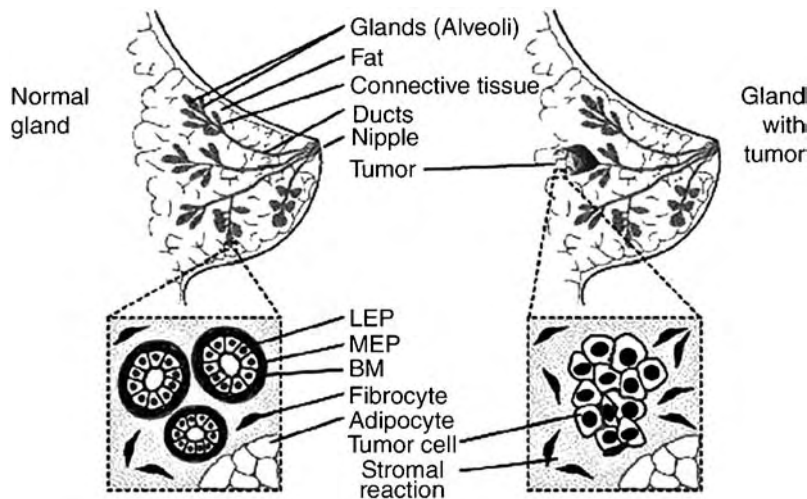

Fig. 1 Structure and 3-D model of mammary gland. Luminal epithelial cells (LEP) forming the acinus are regulated by homotypic interactions with neighboring luminal cells, by heterotypic interactions with myoepithelial cells (MEP), and by interactions with the basement membrane. The bilayered structure is surrounded by a complex basement membrane and a stroma comprised of stromal extracellular matrix, fibroblasts, and adipocytes, as well as nerves, blood, and lymphatic vessels (not depicted). This structure is disrupted in tumors.

fibroblastic connective tissue cells, leukocytes, macrophages, and preadipocytes (committed precursor cells that, while accumulating lipid, will differentiate into mature adipocytes; the classic, mature adipocyte found in the white adipose tissue of the breast has one large fat vacuole and a sliver-shape nucleus located against the perimeter of the cell). Although white adipose tissue is not as highly vascularized as its brown counterpart, each fat cell in the white adipose tissue construct is in contact with at least one capillary, which provides a vascular network for continued growth of the tissue. As a result, the vascular cells that make up this network are of great significance to adipose tissue engineering.

Cell Sources

As noted earlier, several problems are associated with the use of autologous adipose tissue transplantations, including migration of the fat graft tissue, destruction of adipocytes during harvesting methods, and tissue resorption due to insufficient revascularization. One possible solution to these problems may be the use of preadipocytes rather than mature adipocytes or autologous adipose tissue. Preadipocytes are mesenchymal adipocyte precursor cells that are committed to becoming mature adipose cells. The fusiform shape of preadipocytes is maintained throughout the proliferation process until growth-arrest initiates the onset of differentiation or maturation. Cells in the differentiation stage begin to accumulate triglycerides, transform into a more spherical morphology, and begin to express genes typical of mature adipocytes. A differentiation-inducing medium containing insulin, dexamethasone, and 3-isobutyl-1-methylxanthine (IBMX) can accelerate *in vitro* phenotypic changes.^[8]

It has been shown that preadipocytes more readily survive transplantation conditions than do mature adipocytes.^[9] For this reason, a supply of preadipocytes is now needed for use in studies and research in the areas of tissue regeneration. Research assessing the use of stem cells in producing adipose tissue has become increasingly common. Because fat tissue located in different areas in the body behaves differently, it is likely that a ready supply of cells that displays characteristics of multipotency (i.e., cells that can give rise to numerous mature cell types) will be needed. Stem cells not only provide, in theory, an unlimited supply of cells, but also increase the ability of researchers to define and control cellular processes.

One of the basic requirements for the development of suitable tissue replacements is an adequate source of viable cells to be used for tissue production. Cell types that have the potential to be used for repair and regeneration include mature cells obtained directly from a patient and stem cells (adult or embryonic). Adult stem cells are located in niches of the body—specifically in the brain, bone marrow, mammary tissue, gums, and intestines, among others. Marrow stromal or mesenchymal stem cells, which arise from haematopoietic (blood) precursor cells, are capable of differentiating into osteoblasts, chondrocytes, and adipocytes. The use of mature cells obtained from the patient minimizes the need for immunosuppressive therapy postimplantation; these cells are differentiated and committed to a specific cell type, however, and thus provide little potential for further proliferation. Embryonic stem cells, on the other hand, are by definition a population of cells that can be harvested from the inner cell mass of a blastocyst (16-cell mass) and are capable of providing replacement cells for a specific differentiated cell type. Embryonic stem cells are different from other cell types due to two primary distinguishing characteristics. First, embryonic stem

cells are capable of self-renewal in long-term cultures. Second, embryonic stem cells have the potential to differentiate into numerous specialized cell types when exposed to a variety of epigenetic factors.

Scaffold Constructs

Scaffolds used in tissue engineering may be implanted either by surgical incision or by injection. The materials used for constructing the scaffolds, whether they are implanted or injected, must possess several essential properties. These materials should be biocompatible, biodegradable, easily manufactured and sterilized, easily managed during surgical procedures, and capable of guiding the differentiation, migration, and proliferation of cells. Additionally, they should possess mechanical properties similar to those of natural tissue and have nontoxic byproducts. To allow adequate cellular growth, the construct design should be porous to allow the permeation of nutrients and waste products in and out of the construct. Thus, the size of the scaffold should also be taken into consideration, not only with respect to the method of implantation, but also with respect to cellular nourishment and mass transport through the scaffold.

In Vitro Studies

All cells in the human body exhibit an identical genotype—that is, they carry the same genetic information within their nuclei. Epigenetic regulators such as cell–extracellular matrix interactions, cell–cell interactions, growth factors, electrical stimuli, and physical force are

all responsible for cellular expression of a specific phenotype. Therefore, it is crucial to understand the environmental factors responsible for cellular processes and protein production so that *in vitro* culture systems can adequately mimic the *in vivo* environment. Though static culture conditions remain important stepping stones, dynamic bioreactors are becoming more prominent in the laboratory because they better simulate *in vivo* flow, pressure, and diffusion characteristics.

Prior to implantation of scaffolds, it is important to conduct *in vitro* studies to understand how material properties and surface chemistry affect a specific cell type. The response of preadipocytes when seeded on a 2-D polystyrene surface, for example, drastically differs from the response when seeded on 3-D spherical surfaces.^[8] Through scanning electron microscopy (SEM) images, shown in Fig. 2, significant differences in the morphology of various 3-D surfaces are observed. Lipid production, cell number, cell viability, and gene expression can all be altered by the capability of adipocytes to form adhesions to surfaces and the orientation with which they do so. Consequently, material characterization techniques are important so that gene expression can be predicted and better controlled. Among the most common material properties to consider are denaturation and melting temperatures, molecular weight, chemistry, polydispersity index, stiffness, surface roughness, viscosity, and microscopic structure.

Cellular response of adipose precursor cells can also be influenced by stimuli existing in co-culture systems. It has been shown, for example, that the presence of MAC-T cells (normal bovine mammary epithelial cells)

Fig. 2 Preadipocyte culture on poly(lactide) (PL) and gelatin microcarriers. (A) Scanning electron microscopy (SEM) image of PL bead surface. (B) SEM image of 3T3-L1 cells attached to PL beads. (D) SEM image of gelatin microcarrier surface. (E) SEM image of 3T3-L1 cells attached to gelatin microcarriers. in vitro inhibits the differentiation of D1 (murine marrow stromal stem cells) into adipocytes, even in the presence of an adipogenic differentiation inducer.^[10] It has been hypothesized that pH changes in culture medium resulting from proliferation of MAC-T cells are responsible for reduced lipid formation.

CURRENT ADIPOSE TISSUE ENGINEERING STRATEGIES

One proposed strategy for engineering adipose tissue is through the isolation of preadipocytes and endothelial cells, procured through enzymatic digestion of fat obtained from patients during liposuction or biopsy.^[9] A microvascular network is formed by the capillary endothelial cells, and this network and the preadipocytes are cultured with the appropriate growth factors on a polymeric scaffold.^[6] The scaffold would be implanted into the patient to fill the defect site; in the case of breast tissue reconstruction, the cellular scaffold would be placed in the breast envelope. Ideally, as the scaffold gradually absorbs, the preadipocytes would grow, proliferate, and eventually mature into adipose tissue. In a study conducted by Patrick and associates, differentiation of preadipocytes into mature adipocytes was demonstrated using *in vitro* cultures of preadipocytes harvested from the epididymal fat pads of Sprague-Dawley and Lewis rats.^[11] Adipocyte production was identified through the use of histological staining and fluorescence labeling, and the cells, seeded on polylactide-based scaffolds, were viable for extended periods postimplantation. Modifications to this scaffold-guided form of breast tissue regeneration have been proposed as well. In a patent issued to Vacanti and associates, a hydrogel polymer solution used as an injectable polymer is suggested rather than the use of the typical scaffold construct.^[12] Burg and coworkers have suggested the concurrent use of absorbable tissue expanders to create more space for the implantation of cellular scaffolds and to allow the serial development of breast tissue in large defects.^[13]

In another study, Cui and coworkers assessed steroid-induced adipogenesis of a multipotent mesenchymal stem-cell line obtained from mouse bone marrow.^[14] The bone-marrow cell line, cloned from mouse bone-marrow stroma, was treated with the steroid dexamethasone, which caused the cells to produce vesicles that contained triglyceride and to express adipocyte lipid binding protein (aP2), a gene that is expressed in mature fat cells. The results of the study indicated that the dexamethasone, which was applied at varying concentrations and for varying lengths of time, stimulated the differentiation of cells in bone-marrow stroma into adipocytes and the accumulation of fat in the marrow itself, suppressing differentiation into

osteoblasts. Further investigation into the properties of this steroid and its effect on stem cells and their production of adipose tissue, along with investigation of the other methods for adipose tissue engineering, could lead to a more efficient method of regenerating tissue for breast reconstructions.

To date, *de novo* lipogenesis in animal models has been minimal, and it has not yet been determined whether the presence of fat tissue in an implant region is due to migration of preadipocytes via induction by growth factors [i.e., basic fibroblast growth factor (bFGF)] or a result of proliferation of implanted precursor cells.^[15] Cell labeling prior to implantation may be a necessary next step to better understand the proliferative capacity of implanted cells and their capability to form new fat tissue.

DEVELOPMENT OF INJECTABLE COMPOSITE SYSTEMS

Early efforts to engineer breast tissue were limited due to insufficient vascularization of scaffold materials and the inability of larger scaffolds to fill defect sites properly. As an alternative to the common synthetic materials used for scaffold production, natural injectable materials—including collagens, alginates, and gelatins—have been suggested for use in breast tissue reconstruction. Injectable scaffolds have adaptable geometries; when injected collectively, they are able to conform to an infinite amount of defect shapes and sizes, and they require minimally invasive surgical procedures for implantation. Additionally, injection of collective groups of scaffolds allows the incorporation and timed release of bioactive molecules in specific scaffolds, provides support for anchorage-dependent cells, allows mass and fluid transfer between scaffolds, and allows the inclusion and tailoring of individual scaffolds to accommodate multiple cell types. Natural scaffolds degrade into natural metabolites and provide biologically familiar surfaces to which cells will readily attach; they are quickly remodeled in the body, however, usually in an unpredictable manner. Synthetic materials, by contrast, while not providing the familiar surface, can easily be processed to provide the appropriate mechanical properties and degradation times. Thus, a combination of natural and synthetic materials of injectable size can provide an optimized device for breast reconstruction.

Both preadipocytes and adipocytes are anchorage-dependent cells that must be seeded on an appropriate scaffold surface that provides traction for cell differentiation and proliferation to occur. Because preadipocytes and adipocytes are generally function limited when embedded directly in a gel, an injectable composite system has been proposed and tested.^[16] In this system, cells are

seeded on biodegradable beads of an injectable size to create cell carriers; then these cellular constructs are mixed with a hydrogel delivery medium, resulting in a composite that may be injected into a patient through a syringe at the defect site. Hydrogel-based microspheres can be constructed with an electrostatic bead generator to facilitate ejection through a small-gauge needle. Synthetic beads, such as those comprised of polylactide, can be fabricated using an oil-in-water emulsification process. Cell-seeding protocols can be carried out following the harvest, separation, and expansion of preadipocytes. After fat tissue is removed from the host animal in a biopsy procedure, cells can be isolated following a collagenase digestion process during which extracellular matrix proteins are removed. Cells are expanded in 2-D, polystyrene culture vessels, with the intention of preventing terminal differentiation of preadipocytes; at confluency, cells can be seeded on injectable scaffolds. The scaffolds and delivery medium will then degrade over time as the implanted cells proliferate and form new tissue. The most advantageous aspect of this technology is that these injectable devices require a minimally invasive surgical procedure, effectively eliminating any additional trauma a patient will have to undergo following cancer treatment. Further studies are required to define parameters fully regarding cell seeding densities that will provide optimal conditions for inducing *de novo* adipogenesis and sustaining long-term viability of fat tissue.

LARGE-ANIMAL MODEL SELECTION

Before any of these tissue engineering technologies may be applied to human medicine, they must be evaluated within appropriate animal models. Several researchers have demonstrated the ability to regenerate adipose tissue to repair soft-tissue defects in small animals, such as rats and mice. Halberstadt and coworkers have also demonstrated the feasibility of adipose tissue regeneration using an ovine model.^[17] Further investigation of this technology within a large animal that has biological characteristics comparable with those of humans is required, however. An animal model's mammary-tissue anatomy and physiology must be similar to those of humans, and the animal must be large enough to display similar mass transport and diffusion rates.^[18,19] The size of the animal is also important because a selected area for implantation of cellular constructs must be large enough to ensure space for sufficient replication of *in vivo* experimentation. Last, the life span of the selected model should be long enough to allow extensive studies during the relevant phase.

Bovine animal models have been used in the evaluation of tissue engineered devices for breast tissue

reconstruction.^[20,21] The bovine mammary gland and the normal human breast have a similar anatomical structure and tissue type. Histologically, bovine mammary tissue is more similar to that of humans than is the mammary tissue of traditional animal models, such as mice and rats. Ductal structures in the human and cow, for example, are surrounded by relatively dense stromal tissue, unlike the ducts in the mouse, which are almost completely enclosed by adipocytes. Regarding injectable tissue engineered constructs, the dairy cow could serve as a more clinically relevant animal. A larger defect site that would more closely resemble those that follow lumpectomies could be mimicked in the bovine model. Likely, large defects will require a slow progression of *de novo* adipogenesis to allow for neovascularization and integration with host tissue. This can be achieved using a system of serial injections that a smaller, traditional animal model could not likely support. If fat tissue can be engineered during a series of injections, problems related to mass transport, maturation and integration of newly formed tissue, and inflammation can be minimized.

FUTURE AREAS OF DEVELOPMENT

Drug Delivery

Further development of adipose tissue engineering strategies for breast tissue reconstruction may lead to more complex systems that incorporate therapeutic components. Studies have shown that common adjuvant therapies, both systemic and localized, greatly reduce the risk of tumor recurrence, for example.^[22] Since 1985, mortality rates in the United States have declined approximately 8%, largely due to better use of adjuvant therapies.^[23] Tumors can recur, stemming either from cells that were not removed during surgical treatments or from those that have metastasized. Currently, the majority of women opt for lumpectomy (breast-conserving surgery) because this procedure maintains the appearance of the breast. This surgical method may not result in a cancer-free surgical margin, requiring the sacrifice of additional breast tissue.^[24] Despite resection to cancer-free margins, local recurrence remains an issue. Thus, the incorporation of antitumor agents with implantable breast tissue engineering devices that can complement traditional adjuvant treatment regimens may further aid in minimizing local recurrence.

Current adjuvant treatments include chemotherapy, radiation therapy, and hormonal therapy. Polychemotherapeutic treatments consist of a series of systemically administered drugs. Currently, 100 different types of drugs are used for chemotherapy.^[25] The target of a chemotherapeutic drug is a rapidly dividing cell.

Unfortunately, drugs cannot always differentiate between normal and tumorigenic cells; thus, a balance must be met to destroy cancerous cells while preventing extraneous side effects. Most drugs target cells in the M (mitosis) or S (DNA synthesis) phases of the cell cycle when cells are actively dividing, as opposed to the resting phases (G_0 , G_1 , G_2) of the cell cycle.

Like chemotherapy, radiation therapy acts on cells that are actively dividing in the M and S stages of the cell cycle. Unlike chemotherapy, however, radiation therapy is not administered systemically but is used to treat localized regions of the body. Post-mastectomy radiation therapy (PMRT) practices have changed over the years. Generally, PMRT is administered only to women at high risk for tumor recurrence. This risk includes tumors that are originally 5 cm or larger, tumors that are affixed to the skin or chest wall, and tumors whose surgical margins test positive for residual cancer. Furthermore, PMRT is often used in conjunction with polychemotherapeutic treatments. There are several categories of radiation, all with specific energies and applications.^[26] Some common types of radiation include high-energy photons from radioactive sources, electron beams, protons, and neutrons. Radiation is administered as either external beam or internal radiation, external beam being the most widely used. Toxicity associated with radiation therapy includes fibrosis of the treated area, color changes, and (rarely) persistent discomfort. These and other toxicities are usually confined to the area of treatment.

Hormonal treatments are not cell cycle dependent. Rather, the goal of hormonal therapy is to compete with estrogen for estrogen receptor binding sites or to reduce the amount of circulating estrogen.^[27] Therefore, hormonal therapies are given only to patients whose tumor cells express estrogen receptors. The primary advantages of hormonal therapies are that they have relatively low toxicity and result in an approximately 50% decrease in risk of recurrence. Tamoxifen is the most widely used hormonal therapy. Tamoxifen blocks estrogen receptor sites and thus prevents a pathway leading to estrogen-regulated genes that contribute to cell proliferation. The duration of tamoxifen treatments is optimal at about 5 years postsurgery. Common side effects of this treatment include estrogen withdrawal-related hot flashes and vaginal bleeding, as well as depression, headache, insomnia, and dizziness.^[26] Recent evidence has demonstrated that aromatase inhibitors such as arimidex have a better toxicity profile and modest improvement in efficacy.^[28]

The ability to deliver drug-loaded devices with minimally invasive techniques to the breast locale could lead to prevention of systemic drug circulation and toxicity to healthy tissues. It is believed that the physiological changes that occur in most cancerous

tissues can actually facilitate the positive effects of drugs delivered to the area. The “leaky vasculature” that results from increased angiogenesis works synergistically with poor lymphatic transport to allow for better drug retention and potency in the tumor region.^[29] In fact, gold-coated polymeric nanoshells have been tailored to respond to specific wavelengths of light such that they may be injected into the vasculature, allowed to “leak” into the tumor area, and then heated via the external application of light. Such “homing” devices and timed-release polymeric drug delivery systems are frequent subjects of research investigations; few studies have assessed such systems as components in tissue engineered devices, however.

3-D *In Vitro* Testing Systems

Tissue engineering strategies may also be employed in the development of *in vitro* breast tissue models that have potential for use in testing of drug therapies and vaccines.^[10] With these models, researchers can also study the physical and chemical interactions that occur among cells and matrix components to better understand the progression of transformed epithelial cells into tumors and the ultimate metastasis of tumor cells. Thus, methods of breast tissue engineering may be useful in the treatment and prevention of breast cancer. Using 3-D breast tissue systems, breast cancer cells and normal human mammary cells can be observed in a variety of relevant conditions to deduce why variations in subsequent cellular processes and matrix mechanics lead to cancer progression and, thus, what therapies will be useful in prevention as well as a cure.

CONCLUSION

Several critical challenges remain before breast tissue regeneration can be put to practical use. First, more basic tissue engineering methods and procedures must be developed. Without suitable biomaterials, cell supplies, and methodologies for producing the needed tissue, the breast tissue engineering process cannot be completed. Along with obtaining a sufficient supply of cells, it must be determined whether stem cells are in fact the best source for cells, and if so, the most clinically and scientifically sensible stem cell retrieval site must be ascertained. Additionally, the controversies that currently surround the use of stem cells, particularly embryonic stem cells, must be resolved before the research can proceed in an efficient manner. Other challenges include perfecting the engineered adipogenesis process. The use of preadipocytes has yielded positive results, but there are still unanswered questions—for example, how one can identify whether the

preadipocyte cells do in fact form mature adipocytes, and how one can determine what characteristics truly affect the performance of the preadipocytes during the adipogenesis process (i.e., do cells from different locations in the body respond the same way to culturing techniques?). Other challenges include the formation of functional glandular and tubular structures, the use of coculture environments, and the integration of the implanted tissue with the host vasculature. Ideally, the investigation of these ideas will one day result in a precise, clear-cut method for breast tissue regeneration that will eliminate the need for painful and invasive reconstruction, and restore the aesthetics and function of the breast.

Tissue Engineering of Cardiac Muscle

Wolfram-Hubertus Zimmermann
Thomas Eschenhagen

*Institute of Experimental and Clinical Pharmacology, University-Hospital
Hamburg-Eppendorf, Hamburg, Germany*

INTRODUCTION

Cardiac tissue engineering might offer new solutions for the treatment of heart disease. Ideally, tissue engineered heart muscle could be utilized to replace diseased myocardium and thereby refurbish the heart with contractile elements. To achieve this goal, engineered heart muscle should exhibit structural and functional properties of native myocardium, particularly synchronous contractions and active force development should be present. Additionally, *in vitro* designed heart muscle constructs must have the propensity to integrate into the tissue architecture *in vivo*, remain vital, and contract synchronously with the host myocardium. From a clinical perspective, engineered heart muscle must be autologous or at least allogeneic to avoid immunorejection and should not induce a significant inflammatory response. Further, issues of arrhythmia induction and potential thrombogenicity of graft materials have to be considered. In this article, we will give an overview of current methods in cardiac muscle engineering. Issues that we feel are critical for cardiac muscle engineering in general and specifically for clinical applications will be discussed.

METHODS IN CARDIAC TISSUE ENGINEERING

Pioneering experiments in cardiac regeneration were performed by Bader and Oberpriller in the late 1970s.^[1] In their study, partial regeneration of injured newt ventricles was observed after autologous implantation of minced myocardium. However, grafted tissue fragments remained morphologically and functionally separate from the native myocardium. Recently, the regenerative capacity of ventricular myocardium was demonstrated in zebrafish.^[2] In contrast to amphibians and fish, mammals do not exhibit a similar regenerative capacity. However, survival of engrafted tissue fragments from fetal myocardium of rats and humans could be demonstrated for up to 65 days *in situ*.^[3]

Lately, studies to regenerate myocardium in mammals have been expanded by true tissue engineering approaches (Table 1).^[4-13] Alginate, polyglycolic acid (PGA), and collagen have been utilized as scaffold materials to construct heart muscle. Different groups

including our own demonstrated that cardiac myocytes from neonatal rats and embryonic chicken can be reconstituted to three-dimensional (3-D) cardiac tissue-like constructs. Animal studies indicate that engineered heart muscle can survive and remain contractile *in vivo*. Importantly, the door to potential clinical applications has recently been opened by the demonstration that autologous bovine cardiac myocytes can be derived from fetal tissue generated by somatic nuclear transfer and can be used for cardiac tissue engineering.^[14]

Three principally different strategies have been employed to engineer heart muscle constructs: 1) seeding of solid matrices with cardiac cells; 2) mixing of cardiac cells with initially liquid extracellular matrix components; and 3) stacking of cardiac myocyte monolayers (Fig. 1).

Cell Seeding on Solid Matrices

Langer and Vacanti pioneered the field of matrix-based tissue engineering in the early 1990s.^[15] Seeding of preformed matrices offers intriguing perspectives for tissue regeneration *in vivo*. Ideally, matrix constructs can be formed in every shape and size and potentially even as whole organs. Cell seeding would then vitalize these nonvital matrices to yield biomaterial with organotypic properties. Successful application of this concept has been reported for the reconstitution of cartilage, bone, liver, intestine, and urologic tissues.^[16] In cardiovascular tissue engineering, the construction of artificial valves and vessels has been quite successful, and ongoing preclinical trials in large animal models will decide whether or not clinical studies are warranted in the near future.^[17,18] Unfortunately, utilization of preformed matrices to engineer myocardium has been rather disappointing so far. Mainly, lack of contractile function, poor tissue morphology, and size limitations have been setbacks in the field. Several reasons might account for the failure of the classic tissue engineering approach in cardiac muscle engineering: 1) Engineered matrices resemble diffusion barriers and limit nutrition and oxygen supply in thick constructs (> 100–200 μm); 2) currently employed scaffolds appear not to promote the organization of

Strategies in cardiac tissue engineering. Various scaffold materials have been employed as solid and sometimes preformed matrices, or as initially liquid matrices that contain solubilized extracellular matrix components. Solid matrices serve as an attachment substratum and guidance for the growth of seeded cells, whereas cell entrapment in liquid matrix-cell mixtures is assumed to promote the intrinsic capacity of neonatal rat cardiac myocytes to organize spontaneously into a three-dimensional contractile tissue.

cardiac cells in 3-D cardiac muscle constructs in vitro; 3) differentiation of cardiac myocytes in preformed matrices does not proceed to an adult phenotype; and 4) contractile function and actively developed forces of tissue constructs are modest or not detectable.^[4,7–10] The hope is that chemical or physical modifications of solid matrices will result in optimized scaffolds for cardiac muscle engineering.

Liquid Cell Matrix Mixtures

Solubilized scaffold material has been used as an alternative approach in cardiac muscle engineering by our group.^[5,6,12,19] The principle of this method is that neutralized collagen type I and extracellular matrix proteins (matrigel) are mixed with isolated heart cells from neonatal rats. After being cast in circular molds with a central Teflon rod, this liquid reconstitution mixture entraps the cardiac myocytes in a 3-D geometry and coalesces to strongly contracting and well-differentiated ring-shaped engineered heart tissue (EHT). Large 3-D constructs can be generated by merging several single EHTs. The following factors have been found to be crucial for EHT construction: 1) batch-controlled collagen type 1 from rat tail; 2) matrigel (only in rat EHT);^[3] 3) horse serum (10%) and chick embryo extract (2%);^[20] 4) culture under

mechanical load;^[19] 5) a circular geometry rather than lattices; and 6) utilization of mixed heart cell populations. Under these conditions, strongly contracting (up to 3 mN) and morphologically highly-differentiated muscle constructs can be engineered. Myocytes within EHTs form a network of interconnected myocyte strands throughout the EHT (diameter of ~1 mm).^[12] Single myocyte strands reach a diameter of 20–200 μm . This size limitation is likely to be caused by an oxygen diffusion deficit in thick reconstituted muscle strands. Similar limits in tissue oxygen diffusion have been observed in isolated heart muscle strips.^[21] Despite the possible oxygen diffusion limitation in single reconstituted muscle strands, we could not observe a spatial preference of myocyte strands within EHTs. This indicates that the loose matrix in contrast to the dense myocyte strands does not constitute a significant diffusion barrier in EHTs. Another aspect that indicates normoxic conditions is the high degree of cardiac myocyte differentiation and an organotypic organization in EHTs. This is supported by ultrastructural analysis of cell volume fractions and sarcomere organization of cardiac myocytes in EHT.^[12] Interestingly, myocyte differentiation surpassed the degree of differentiation that was found in neonatal rat myocardium, indicating the importance of 3-D growth possibilities and matrix factors for cardiac myocyte development. Beside the development of a differentiated cardiac myocyte strand network, EHTs exhibit cardiac organoid structures formed by nonmyocytes (e.g., endo- and epicardial surface lining and primitive capillaries).

Stacking of Monolayers

An alternative nonmatrix-based method in cardiac tissue engineering has been developed by Shimizu and colleagues.^[11] This method utilizes single detached cardiac myocyte monolayers in a stacked culture format. Resulting cardiac myocyte sandwiches developed diffuse connexin 43 junctions within the construct. Further, synchronized contractions were observed in vitro and after subcutaneous implantation in vivo. A potential advantage of this technique might be the possibility of stacking monolayers of different cell types and thus reconstituting an organoid tissue construct composed of all cell species that make up the myocardium.^[22] In line with this reasoning, addition of endothelial cells might facilitate the induction of vascularization, and fibroblasts may increase the stability of engineered constructs by producing extracellular matrix. Yet, it would be anticipated that size limitations do also apply to the sandwich culture format. Maximal thickness of four layer constructs has been reported at 70 μm (four monolayers). Whether

T

Fig. 1 Different strategies in cardiac tissue engineering. (I) Seeding of solid/preformed matrices with cardiac myocytes;^[1,5-7,13] (II) mixing of liquid, not preformed extracellular matrix components, with cardiac myocytes;^[2,3,12] and (III) stacking of detached cardiac myocyte monolayers^[11] have been employed as main approaches in cardiac tissue engineering. Contractility of muscle constructs can be characterized by isometric force measurements *in vitro*. Subsequently, contractile heart muscle constructs with defined mechanical properties may be used for cardiac regeneration *in vivo*. FT: force transducer.

this technique will be suitable to construct thick viable cardiac grafts (> 200–300 μm and eventually up to several millimeters) remains unclear.

SCAFFOLD MATERIALS IN CARDIAC TISSUE ENGINEERING

A broad range of synthetic polymers such as polyglycolic acid and biomaterials such as alginate, collagen, or gelatine have been employed in the aforementioned tissue engineering approaches (Table 1) and have been extensively reviewed elsewhere.^[16] In general, scaffold materials should be nontoxic, biodegradable, and biocompatible.

Synthetic Polymers

Synthetic polymers have following advantages: 1) Chemical properties are defined; 2) batch-to-batch variations can be reduced to a minimum; 3) geometry can be chosen as required; 4) negligible immune responses are expected; and 5) chemical modifications allow bonding of bioactive compounds that might facilitate survival, differentiation, or angiogenesis *in vitro* and *in vivo*. On the one hand, synthetic polymers are by nature unphysiological. Conceptually, synthetic materials serve initially as an attachment substratum and should guide cell growth but are to be replaced by a physiological matrix over time. On the other hand, biodegradation of synthetic polymers can induce

inflammatory responses to the original material or byproducts of its degradation. Changes in local pH, foreign body reactions, and secretion of inflammatory cytokines may cause unwanted side effects.

Biomaterials

Biomaterials are naturally occurring extracellular matrix components that can be chosen according to the desired application. Yet, the physiological complexity of extracellular matrix composition makes it difficult to mimic an organ-specific environment. Therefore, it is not clear whether biomaterials as currently employed serve a more specific purpose than synthetic scaffolds. Biomaterials may have an advantage of inducing only mild inflammatory responses *in vivo*. On the other hand, the composition of biomaterials strongly depends on the isolation procedure and exhibits batch-to-batch variations. The varying content of extracellular matrix components and growth factors might exert desired and undesired effects on tissue formation that are difficult to define. Additionally, utilization of biomaterials may be associated with the risk of infectious disease transmission.

Choosing the Right Scaffold for Cardiac Tissue Engineering

In cardiac tissue engineering, the choice of scaffold material, with regard to its physical properties, might represent a more crucial issue than in other approaches

in tissue engineering, including artificial cartilage, bone or skin, and organs with a mostly humoral or detoxifying function such as pancreas or liver. On the one hand, scaffold materials in cardiac tissue engineering would have to withstand tremendous mechanical stress *in vivo*. On the other hand, engineered cardiac constructs must remain flexible and extensible at the same time. Importantly, physical matrix properties should not compromise cardiac myocyte contractility and allow transmission of contractile force via the matrix.

It is apparent that none of the currently employed materials or approaches offers an ideal solution. Whereas chemical and physical modification of scaffold materials might yield further optimized matrices, alternative approaches exist. One is to use scaffolds that are derived from intact organs of donor animals by chemical decellularization and then repopulated with host-derived cells. This approach is currently employed in tissue engineering of heart valves. Additional approaches are to utilize liquid matrix protein mixtures that may not serve as attachment substratum but maintain a favorable growth milieu for cardiac myocytes and thus promote spontaneous cardiac organogenesis, or to avoid scaffold material completely.

As outlined earlier, our own approach is based on the concept of self-organization of isolated cardiac myocytes into cardiac tissue in a primarily liquid growth milieu. The propensity of cardiac myocytes from neonatal rats to reorganize into cardiac tissue structures *in vitro* has been demonstrated.^[7] A main requirement for successful EHT construction is to maintain a high cardiac cell density in a defined volume of concentrated collagen/matrigel and thus allow for an intimate cell–cell contact. During 10–14 days in culture, EHTs undergo extensive remodeling. This includes changes in matrix structure and composition as well as in cell differentiation and organization (Fig. 2). As observed in monolayer cultures, embryonic chick or neonatal rat cardiac myocytes start to spread, redifferentiate, and contract spontaneously in EHTs. In contrast to monolayers, cell growth occurs in three dimensions. Over time cardiac myocytes organize to highly differentiated interconnected muscle strands and develop cell–cell contacts via fascia adherens, gap junctions, and desmosomes. Additionally, nonmyocytes within EHTs remodel and partially replace the extracellular matrix (fibroblasts, macrophages), forming a complete epi- and endocardial surface lining (endothelial cells, smooth muscle cells, cells of leukocytotic origin) and primitive capillaries (endothelial cells).^[12] Thus, our data support the notion that cardiac cells from embryonic chick and neonatal rats have the intrinsic capacity to form new cardiac tissue, and that this process is merely stimulated and directed by the collagen/matrigel-containing environment. A disadvantage of this approach is that

geometric shape and size cannot be controlled as easily as when employing preformed fabricated scaffolds. A compromise is the use of different casting molds and the merging of several ring-shaped EHTs to larger patches. An advantage of EHTs is that stretch devices can be utilized to allow culture under defined mechanical load. The importance of stretch/load has been substantiated by our recent findings that contractile force, morphology, and tissue formation of EHTs can be markedly improved by phasic stretch.^[19] In contrast, when EHTs are left unloaded during culture, they quickly retract, exhibit thickening of the matrix, and stop beating.

CELLS IN CARDIAC TISSUE ENGINEERING

Reconstruction of viable myocardium after a large myocardial infarction in humans will require approximately 1 billion cardiac myocytes.^[23] Hence, success in cardiac tissue engineering will critically depend on the availability of large quantities of, ideally, autologous cardiac myocytes. Unfortunately, cardiac myocytes withdraw from the cell cycle before or shortly after birth. This precludes the use of biopsy material for cardiac myocyte propagation. Whether strategies to induce cell cycle reentry can resolve this limitation remains to be elucidated.^[24] Embryonic and adult stem cells might represent an alternative to primary cells.^[25,26] Despite the proof of embryonic stem cell differentiation into cardiac myocytes and some evidence for adult stem cell transdifferentiation, enthusiasm is limited because cardiac lineage (trans) differentiation appears to be a rare event. The key questions involve: 1) means to upscale the yield of cardiac myocyte differentiation from embryonic stem cells; 2) factors that induce transdifferentiation of adult stem cells; and 3) factors that induce terminal differentiation of stem cell-derived cardiac myocyte. Other problems associated with (embryonic) stem cells are tumor formation and immunorejection. Tumor formation might be a question of cell dose and the proportion of remaining pluripotent stem cells in transplanted cardiac cell populations. Whether depletion of remaining multipotent stem cells can resolve this issue remains to be demonstrated. Immunorejection might be controlled by utilization of a primarily autologous cell source (adult stem cells), tolerance induction,^[27] or nuclear somatic transfer to generate cells of the recipient's genotype.^[14] Intense basic research is necessary to find answers to these questions before advancing into the clinic.

Another issue that might be important for cardiac tissue engineering is the cellular composition of cardiac grafts. Physiologically, endothelial cells, fibroblasts, smooth muscle cells, neural cells, and leukocytes

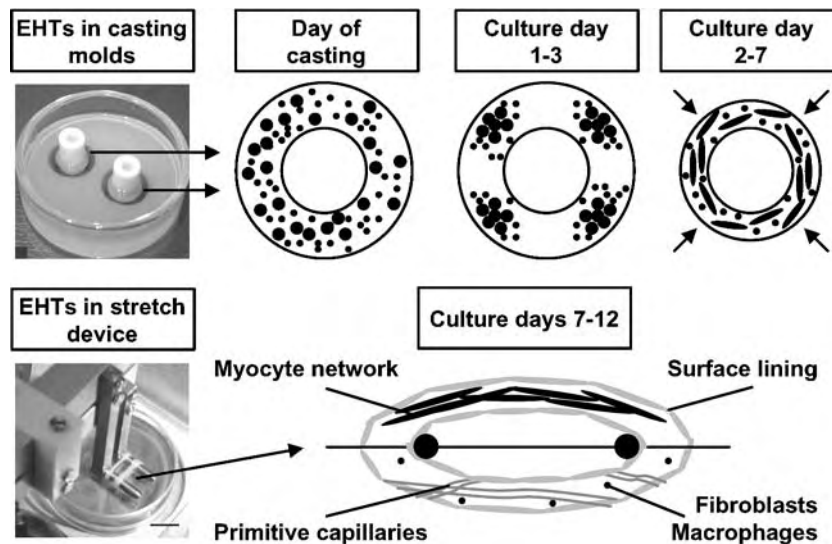

Fig. 2 Engineered heart tissue (EHT) development. Original photographs depict EHTs in casting molds (culture days 0–7) and in a stretch device (culture days 7–12). Initially, heart cells from neonatal rats are entrapped in a liquid collagen/matrigel mixture. Cell clustering and spontaneous contractions of clusters are observed on culture days 1–3. At the same time, EHTs start to coalesce around central Teflon spacers; cardiomyocytes elongate, and begin to form a synchronously contracting muscle network (culture days 2–7). Subsequently, EHTs are subjected to phasic strain (culture days 7–12) to further improve tissue formation and contractility. Formation of organoid structures is summarized in the bottom sketch: Cardiac myocytes develop a dense myocyte network throughout the entire EHT. Nonmyocytes reconstitute primitive capillaries and a surface lining composed of endothelial cells, smooth muscle cells, and cells of leukocytotic origin. Fibroblasts and macrophages are scattered throughout the EHT and contribute to matrix remodeling by synthesizing extracellular matrix proteins and sequestering cell debris.

constitute about 70% of the total cell number in the working myocardium.^[22] Thus, cardiac muscle engineering is more likely to be successful if various cardiac cell species are being considered and brought together in a physiological context. *In vitro* studies have demonstrated the role of nonmyocytes in cardiac development and function.^[28] Whether nonmyocytes will be beneficial in cardiac tissue engineering remains to be clarified. This notion is supported by preliminary studies from our laboratory. When EHTs were constructed from a native heart cell rather than from a purified cardiac myocyte population, contractile force was markedly improved. Presently, the exact contribution of each single cell type to tissue formation is under investigation.

FUNCTIONAL REQUIREMENTS

Conceptually, most cardiac muscle engineering approaches aim at improving systolic function of diseased ventricles. We believe that to achieve this goal, engineered heart muscle needs to be fairly differentiated, to beat in synchrony, to feature systolic and diastolic properties of native myocardium, to develop sufficient contractile force, to have a critical size, and

to have the propensity to integrate into the host tissue architecture. In fact, noncontractile cardiac grafts have been implanted and have improved diastolic properties.^[9] This was explained by a beneficial effect on scar remodeling and prevention of aneurysm formation in infarcted hearts. Yet, systolic properties were not changed in this study.

So far, strong synchronous contractions have, to our knowledge, been shown only for stacked monolayers and EHTs (Table 2). Another study that employed cell seeding of preformed matrices has also described synchronously contractile muscle constructs, but systolic and diastolic contractile properties were markedly inferior to the aforementioned methods.^[8] Besides absolute contractile forces, an important parameter of contractile function is the ratio of systolic (twitch tension; TT) and diastolic force (resting tension; RT). Physiologically, the TT/RT ratio of healthy cardiac muscle is > 1 , even at modest inotropic stimulation. This ratio is lower in diseased hearts as a consequence of fibrotic remodeling of the myocardium. EHTs develop a TT of > 2 mN with a TT/RT of > 3 under maximal inotropic stimulation with calcium. Monolayer stacks develop comparable TT but RT has not been reported.^[11] In cell-seeded collagen fleeces, the TT/RT ratio was apparently low, indicating a high

Table 2 Reported contractile properties of tissue engineered heart muscle

	TT (mN)	RT (mN)	TT/RT

Zimmermann et al., 2002	0.75±0.11	0.15±0.02	5

Systolic force (twitch tension; TT) and diastolic force (resting tension; RT) were measured under isometric conditions^[2,3,5,12,19] or in vivo.^[11] If possible, TT/RT ratios were calculated from available data. Nd: not determined.

matrix rigidity.^[8] High passive diastolic forces, on the one hand, could have a beneficial effect on scar remodeling and possibly prevent ventricle enlargement and aneurysm formation. On the other hand, they may contribute to increased myocardial stiffness in vivo and thus would have to be considered as rather detrimental. Systematic implantation studies will have to examine this issue.

PRECLINICAL IN VIVO APPLICATIONS

Studies to test the feasibility of cardiac muscle constructs as graft material have been performed almost exclusively in rats.^[9–11,20,29] So far, most studies have addressed issues of in vivo survival, maintenance of electrical activity, and contractile function in healthy animals. Grafting was performed subcutaneously,^[10,11] into the peritoneal cavity,^[20] or on beating hearts of healthy rats.^[29] The question of in vivo survival is not trivial because implanted muscle constructs are not immediately connected to the host vasculature and must be nurtured by diffusion until vascularization of implants has occurred. Despite this apparent caveat, different groups have shown that engineered cardiac muscle constructs do survive in vivo and retain their electromechanical activity.^[9–11,20,29] Presently, it is unclear if and to what extent cell death occurs immediately after implantation of cardiac grafts as a consequence of hypoxia or reduced nutrient supply. Vascularization of implants has been reported to occur rather fast and thus might rescue surviving cells. In EHT implants, survival of well-organized cardiac muscle has been observed predominantly in close vicinity of new ingrown vessels. Here, grafted cardiac myocytes showed ultrastructural evidence of terminal differentiation and were indistinguishable from native cardiac myocytes.^[29] Additionally, ingrowth of well-organized nerve bundles

composed of myelinated and nonmyelinated nerve fibers was observed in EHTs. So far, we have not analyzed the origin of the nerve bundles and whether innervation has any functional consequences.^[29] Contractile function of grafted EHTs has been observed for at least eight weeks in vivo, and ongoing grafting studies will shed light on the consequences of EHTs for the function of infarcted hearts.

Important issues for cardiac muscle grafting are inflammation and immune responses. Although a transient inflammation caused by the surgical intervention cannot be completely avoided, additional inflammatory responses to scaffold materials or its degradation products may be minimized by optimizing the physical and chemical properties of scaffold materials, by using autologous biomaterials, or by avoiding scaffold material altogether. Immune responses in recent grafting studies have been controlled by utilization of nude rats^[11] or immunosuppression.^[29] A new and exciting, but technically challenging and ethically questionable, approach is to utilize autologous donor animals that have been developed by nuclear cloning.^[14]

CONSIDERATIONS FOR CLINICAL APPLICATIONS

Predictions on the future of cardiac muscle engineering in practical medicine remain necessarily speculative at present. We believe that the principal techniques of graft construction are likely to be resolved. However, identification of a suitable cell source for human applications will remain a key issue. Whether embryonic stem cells from presently available lines, adult stem cells, or ethically controversial nuclear cloning approaches will offer a perspective remains to be shown. As mentioned earlier, all of these approaches are hampered by a low cardiac myocyte yield, the potential of tumor formation, and, in the case of adult stem cells, the remaining uncertainty about true transdifferentiation versus cell fusion or simple phagocytosis.^[30] Other areas of intense research will be the risk of arrhythmia induction by spontaneously depolarizing cells, inflammation, immune responses, vascularization, functional integration, thrombogenicity of graft material, and tumor formation. Some of these caveats might be addressed by electrical pacing of implanted constructs, utilization of purely autologous scaffolds and cells; integration of vessels in cardiac constructs in vitro; bonding of factors that improve cell survival, differentiation, and function; utilization of nonthrombogenic scaffolds; and stringent cell purification when stem cell-derived cardiac myocytes are employed.

Eventually, all approaches in cardiac regeneration have to be compared to standard treatment. Potential advantages of cardiac tissue engineering for cardiac regeneration might be: 1) Grafting of cardiac constructs would resemble a causal therapy; 2) graft design can be performed according to patients' needs; 3) functional and structural properties of cardiac grafts can be controlled prior to grafting; 4) surgical grafting of engineered heart muscle is likely to prevent washout of cells as it occurs in simple cell implantation; and 5) it would ideally allow for true replacement of a ventricle wall, reconstruction of congenital malformations, and possibly construction of a complete heart, although, the latter aspect is, at least in our view, rather unlikely to be achieved with currently employed strategies. A first step to advance presently employed approaches would be to provide proofs for the concept of cardiac regeneration in small animal models and subsequently in large animals such as pigs, sheep, or dogs.

Tissue Engineering of Cartilage

J.N. Amritha De Croos

Rita A. Kandel

Bioengineering of Skeletal Tissues Team, Mount Sinai Hospital, Toronto, Ontario, Canada

INTRODUCTION

Articular cartilage is a unique tissue found at the articulating ends of bones whose functions are the distribution of applied load to the underlying subchondral bone and to provide, along with the synovial fluid, a low-friction interface between the contacting surfaces in the joint.^[1] As cartilage does not have a blood supply, it relies on the surrounding synovial fluid for nutrition. As well as being avascular, it has neither a lymphatic supply nor neural innervation. Adult articular cartilage has a limited ability to spontaneously heal when damaged by trauma or disease. A variety of reasons for this lack of reparative response have been postulated, including the inability of chondrocytes to migrate into the site of injury, the avascular nature of cartilage, and the absence of a fibrin clot scaffold into which the cells can migrate.^[2,3] However, other factors may also influence the repair process as chondrocytes have been shown to be able to reconstitute at least part of their extracellular matrix (ECM) in vitro as well as in vivo with the appropriate treatment.^[4,5] The morbidity, pain, and limitation of movement that arises as a result of joint disease are significant problems for both the individual and the health care system. Arthritis affects some 40 million Americans, or 15% of the US population.^[6] And, with an aging population, this number is only expected to increase. There is a great need to develop new approaches to treat damaged cartilage, especially focal defects or during the early stages of arthritis.

Currently, replacement of an articulating joint with a synthetic prosthesis represents the optimal treatment for end-stage joint disease. Primary hip replacements placed since the late 1980s have shown reasonable success rates. However, even apparently successful implants have their limitations as failure rates of up to 20% have been reported after 10–20 years.^[7–9] To circumvent the problems associated with the use of prostheses, several biological treatments have been developed to repair focal cartilage defects.^[10] One of these involves the transplantation of osteochondral plugs that have been obtained from donor sites within the same joint into a defect site (osteochondral transfer/mosaicplasty). Several plugs are usually required to repair a single defect that may be several centimeters in

diameter. The major disadvantages of this approach are the resulting donor site morbidity (i.e., a hole remains in the donor site) and difficulty in placing the plugs congruent with the joint surface. The long-term success of this technique is also questionable.^[1,10] Alternatively, large articular shell grafts (articular cartilage with subjacent thin layer of bone at least 1 cm in thickness) have been utilized with success, but as these are allografts they are limited in supply and can be associated with disease transmission.^[11] Perforation (microfracture) of the subchondral bone has also been used to induce cartilage repair. However, as this response is a result of ingrowth of cells from the bone marrow this treatment results in fibrocartilage repair, rather than hyaline cartilage, and as it does not have the necessary load-bearing capability it will degenerate over time.^[12]

As all of the above treatments have limitations, current investigations have focused on developing strategies to replace damaged tissue with tissue-engineered cartilage as an alternative, novel therapeutic approach. Tissue engineering emerged in the late 1980s and has as its goal the regeneration of tissue using biomaterials and/or cells.^[13] This approach has been investigated intensively, and there is now proof of concept to support cell-based regeneration of tissue.^[14–16] However, there are still some limitations, and the goal of current research related to tissue engineering of cartilage is to identify the conditions that will result in the formation of tissue that approximates in vivo cartilage and will be suitable to use in repairing joint defects. This tissue could also be used as a model to study articular cartilage development and disease mechanisms, and for in vitro testing of new therapeutic agents. This review will provide a summary of the characteristics and composition of native articular cartilage, an overview of the methods used currently to bioengineer cartilage, an approach to evaluate the bioengineered cartilage, and a discussion of the problems associated with generating tissue in vitro.

ARTICULAR CARTILAGE: COMPOSITION

Chondrocytes are the cellular component of articular cartilage, which synthesize, secrete, and organize ECM

molecules. Chondrocytes make up about 10% (or less) by volume of cartilage.^[17] An important feature of chondrocytes is that they are isolated from each other and surrounded by abundant ECM. This matrix prevents cell migration likely contributing to the limited repair potential of cartilage. For a review of chondrocytes, their function, and origin, see Ref. [18].

In humans, articular cartilage has a high (60–80% of wet weight) water/fluid content and varies in thickness from 2 to 4 mm depending on the location in the joint. The ECM makes up about 20–40% of the wet weight of articular cartilage and consists predominantly of proteoglycans (15–30% of dry weight) and collagens (50–70% of dry weight).^[17,19] Glycoproteins and other non-collagenous proteins make up approximately 15–20% of the dry weight.^[17,19] Aggrecan is the main proteoglycan found in articular cartilage. Aggrecan monomers bind to hyaluronan, an interaction stabilized by link protein, and form large aggregates that are distributed throughout the collagen network. Smaller proteoglycans such as biglycan, decorin, and fibromodulin can bind to other components of the ECM, contributing to matrix stability. The predominant collagen is type II, but collagen types V, VI, IX, X, and XI are also found, but to a lesser extent. Type I and III collagens originally not thought to be a component of articular cartilage have also been detected in small amounts. Proteoglycans are hydrophilic and entrap water, allowing articular cartilage to withstand compressive forces. The collagen fibers constrain the proteoglycans and provide the tensile strength required by cartilage.

As well, there are numerous other non-collagenous proteins present in the ECM (see review^[20]). One such protein is cartilage oligomeric matrix protein (COMP), which has been shown to be important in sensing mechanical loading.^[21] COMP along with the other non-collagenous proteins aids in the proper functioning of articular cartilage, but is present in lower amounts than proteoglycans and collagens. The importance of these non-collagenous matrix molecules has been demonstrated by studies of knockout mice or naturally occurring mutations in matrix molecules that occur in humans. For example, individuals with a mutation in COMP develop pseudoachondroplasia, which is characterized by a lack of type II collagen fibril organization, although the role that COMP plays in collagen organization and pseudoachondroplasia is not known.^[22]

ARTICULAR CARTILAGE: ORGANIZATION

Articular cartilage can be divided into four distinct zones: A) superficial; B) middle; C) deep; and D) calcified (Fig. 1). Each of these areas has a composition

and organization that contributes to normal articular cartilage function. There is evidence suggesting that each zone plays a role in response to loading. It is possible that for bioengineered cartilage to function properly it may be necessary to reconstruct all these zones.

Superficial Zone

This zone is the upper-most layer and forms the gliding surface of the cartilage. It has a lower-water content than the deeper zones of cartilage.^[17] The collagen fibers are arranged parallel to the articular surface,^[17,23] and morphologically, the chondrocytes in this zone are flatter. The superficial zone has the highest content of type II collagen of the four zones and the lowest content of proteoglycans. Type I and III collagens have also been detected in this region. Decorin and biglycan are the predominant proteoglycans in this zone. Superficial zone protein (SZP), a proteoglycan involved in lubrication, is unique to the superficial zone at the joint–cartilage interface.^[24] The organization and composition of the superficial zone likely aids in resisting the shear stresses produced during articulation.^[17]

Middle Zone

This zone (also called the transitional, intermediate, or middle zone) is the largest of the zones in terms of thickness.^[17,23] The chondrocytes of the middle zone are spherical. The collagen fibers in the middle zone tend to be randomly oriented and surround the cell. Type II collagen content is higher than in the deep zone. Aggrecan is the major proteoglycan, and the proteoglycan content is higher in the middle zone relative to the superficial zone. The middle zone also has a characteristic protein, cartilage intermediate layer protein, that increases in amount with age,^[25] although its function is not fully characterized.

Deep Zone

In the deep zone (also called the radial zone), the collagen fibers are oriented perpendicular to the subchondral plate and cross into the underlying calcified cartilage. The radial orientation of collagen fibers contributes to the compressive resistance characteristic of this zone and allows a stronger adherence of the articular cartilage to the subchondral bone.^[26] The chondrocytes can be aligned in columns perpendicular to the subchondral plate. These cells retain some of the properties of hypertrophic-like chondrocytes, which

(B) Photomicrograph of human articular cartilage and subchondral bone following formalin fixation, decalcification, and paraffin embedding (hematoxylin and eosin, magnification $\times 25$).

include expression of alkaline phosphatase and type X collagen.^[27]

Just below the deep zone is the tidemark, which is the interphase between the deep zone and calcified layer. The tidemark is known to contain crystals of calcium salts and hyaluronan but otherwise is poorly characterized.

Calcified Layer

Just below the deep zone is the calcified layer that consists of hyaline cartilage that has undergone mineralization. During development the cells of the calcified layer are active but become quiescent in adult cartilage. This zone anchors the hyaline cartilage to the underlying subchondral bone and is involved in the transmission of forces across the joint. The calcified layer stiffness is less than bone most likely because of the arrangement of collagen fibers.^[28] The elastic modulus, which is a measure of the stiffness of the tissue, is approximately 0.32 GPa, which is an order of magnitude greater than the non-mineralized hyaline cartilage but is an order of magnitude less than bone.^[28] It has been hypothesized that this stepwise transition in stiffness is very important for the proper functioning of cartilage and distribution of forces across the joint and is often not considered for tissue bioengineering articular cartilage.

In summary, the goal of tissue engineering cartilage is to generate articular cartilage that will function similarly to the native tissue and to do so may require regeneration of cartilage with all of these zones. It is well known that repair of cartilage defects with fibrocartilage, which does not have the organization and

composition of hyaline articular, will degrade over time with weight bearing as it does not have the necessary load-bearing capability.^[10]

ARTICULAR CARTILAGE: FUNCTION

Articular cartilage is important for smooth, painless articulation. The tissue is constructed to allow for this. The superficial zone is organized, as described above, to support this function. As well, chondrocytes in this region (superficial zone) produce a factor (lubricin or SZP) that is critical to proper cartilage function.^[24] Cartilage tribology is not well understood and likely is important for tissue-engineered cartilage.

Cartilage is exposed to a variety of static and cyclic loads and can sustain loads that compress the cartilage as much as 45% (with contact pressures up to 14 MPa).^[29,30] The mechanical properties of the cartilage can vary depending on its composition and location in the joint. When cartilage is loaded, for instance, during walking there is an initial increase in pressure which squeezes the fluid out of the solid matrix,^[23] however, the exudation is affected by the relatively low fluid permeability of the ECM. The subchondral bone and the surrounding adjacent cartilage confine the cartilage serving to restrict mechanical deformation.^[31] As the fluid is expressed, the ECM of the superficial layer and to some extent the upper middle (transitional) zone consolidate, the chondrocytes in this zone will undergo compressive deformation, and the cartilage experiences an increase in the negative charge density because of the fixed proteoglycans as well as an increase in osmotic pressure. Given the high (60–80%) water content of articular

cartilage, the compressive strains can be substantial.^[17] The compressive forces are resisted by the solid phase and the fluid pressures. In addition, the rolling action of joint surfaces produce cyclic tensile strains that are tangential and outside the contact area of articular cartilage.^[32] Tissue-engineered cartilage must be able to withstand these forces. However, what is not known is the minimal mechanical properties the tissue should have to ensure that the tissue-engineered cartilage will function properly over the long term.

Loading of articular cartilage is also important for nutrition and cartilage health. As mentioned above, cartilage is avascular and alymphatic and therefore relies on diffusion of nutrients from the synovial fluid. Mechanical loading facilitates water/fluid movement and thus distribution of nutrients to the chondrocytes embedded in the ECM as well as removal of waste products from the tissue. It has been shown that *in vitro* cartilage tissue formation is improved when there is unrestricted exchange of nutrients and/or solutes that may explain in part the positive effect of forming cartilage in bioreactors observed under many experimental conditions.^[33,34]

ARTICULAR CARTILAGE: CELL SIGNALING

As chondrocytes are surrounded by ECM (and are not in contact with other cells) they perceive changes through effects on molecules in the matrix and translate those signals into gene and protein changes (Fig. 2). Thus, tissue-engineered cartilage that does not have the appropriate composition when subjected to weight bearing could activate a chondrocyte response that would potentially result in either tissue degradation or production of abnormal matrix molecules. The end result would be degradation of the bioengineered cartilage. Much research has focused on the cell surface molecules involved in the signaling process activated by matrix molecules.^[35,36] Integrins, one such molecule, are transmembrane proteins made up of an alpha and beta subunit, which function as receptors for extracellular matrix molecules such as collagen. Integrins also contain a cytoplasmic tail that interacts with the actin cytoskeleton, and this allows for outside-in signaling by the extracellular matrix.^[36,37] Other membrane surface receptors found in chondrocytes such as CD44 and annexin V (anchoring CII) are also involved in signaling and act through a pathway different than that used by integrins.^[35]

After activation of cell surface receptors, the signal is conducted inwards through secondary messengers. Regulation of cellular function is then exerted by transcription factors that are induced by these environmental cues and can enhance or inhibit transcription of

a gene. Generally, transcription factors are phosphorylated at certain protein residues by kinases such as mitogen activated protein kinases (MAPK). Once phosphorylated, the transcription factor undergoes a conformational change that allows it to bind to a DNA consensus sequence and regulate transcription.^[38] Recent studies have highlighted the mechanosensitivity of the MAPK p38, extracellular-signal-regulated kinase (ERK)1/2, and stress activated protein kinase/cjun amino terminal kinase (SAPK/JNK) in cartilage explants.^[39] Apart from the MAPK, there are other pathways that may play a role in chondrocyte signaling such as the RhoA/RhoA kinase (ROCK) pathway.^[40,41] This cell-signaling pathway involves RhoA, a small G-protein in the Rho family that regulates cell morphology via actin cytoskeleton reorganization in response to extracellular signals. The RhoA/ROCK pathway has not been well studied in articular cartilage, but it has been shown that chondrocyte cytoskeleton changes involved both integrins and association with RhoA.^[37] The sensitivity of the chondrocyte to its environment emphasizes the importance of selection of the appropriate material on which to grow the chondrocytes as well as the need to generate cartilage with the appropriate composition.

T

APPROACHES TO TISSUE ENGINEERING CARTILAGE

Tissue engineering of articular cartilage can be performed using a variety of strategies that can be divided into three categories as shown in Fig. 3. Tissue formation may occur *in vitro* or *in vivo* depending on the approach selected.

Cells

In this approach, cartilage repair is encouraged by placing a large number of cells in a defect. To accomplish this, the patient's cartilage is harvested, and cells are isolated and grown in monolayer culture (2D) to expand the number of chondrocytes [Fig. 3(A)]. The cells are then transplanted into a cartilage defect under a flap, which can be either periosteum or a collagen membrane and which serves to confine cells in the defect (autologous chondrocyte implantation).^[10,14–16] Alternatively, the cells can be seeded onto the membrane prior to implantation.^[42] The contribution of these cells in repairing is somewhat controversial. Although a recent study showed that the cells remain in the defect,^[43] it is possible that the mesenchymal cells from the periosteum and/or the underlying bone marrow (as the subchondral bone can be breached during the procedure) may also

Fig. 2 Integration of cell signaling in chondrocytes. Changes in the ECM are perceived by receptors, such as integrins, on the cell surface. These signals are relayed inwards through secondary messengers ultimately resulting in gene and protein changes.

contribute to the repair as histological studies have documented the presence of fibrocartilage repair in many of these defects. This treatment is useful in alleviating pain but is not without its disadvantages.^[15] As the resulting tissue is at least partially fibrocartilage it may not remain intact over the long term. More recently, it was shown in a goat model that there was a loss of bone underlying the implant, which could negatively impact on implant survival and have long-term effects on joint function because of the altered biomechanics.^[44]

The benefits of growing cells in a 2D monolayer are that it is easy to manipulate, to expand cell number, and to treat cells with exogenous growth factors or other forms of stimulation when compared to cells grown in 3D culture. However, a major limitation of this approach is maintenance of the chondrocyte phenotype. Chondrocytes grown in monolayer at low density and/or after several passages will dedifferentiate. If this approach is to be used for tissue engineering, then monolayer conditions need to be identified that allow for expansion of the number of chondrocytes while retaining phenotype as well as maintenance of phenotype after transplantation of these cells.

Scaffolds

In this approach, tissue engineering cartilage entails the use of scaffolds. Scaffolds [Fig. 3(B)] are typically porous materials that may be untreated or coupled to chemicals, growth factors, oligonucleotides, silencing RNA oligonucleotides, plasmid DNA, or peptides with the goal of stimulating cell attachment and/or ingrowth as well as matrix accumulation.^[45] They may or may not (cell-free scaffolds) be seeded with cartilage-forming cells and either are placed directly into defects and the cartilage forms *in vivo* or the cell-seeded scaffold is grown in culture to form cartilage prior to implantation (see reviews^[45-48]). The porosity of the scaffold is important to facilitate cell permeation (*in vitro*) or ingrowth (*in vivo*, if necessary) and matrix accumulation as well as mass transport of nutrients into and waste products out of the tissue. Scaffolds can be made from a variety of materials ranging from naturally occurring materials such as collagen or silk to synthetic polymers such as polylactic acid.^[45,49] These scaffolds can be made in a variety of ways including standard solvent casting particulate leaching foam methods, melt molding, electrospinning, and solid freeform fabrication.^[45] They can be formed with

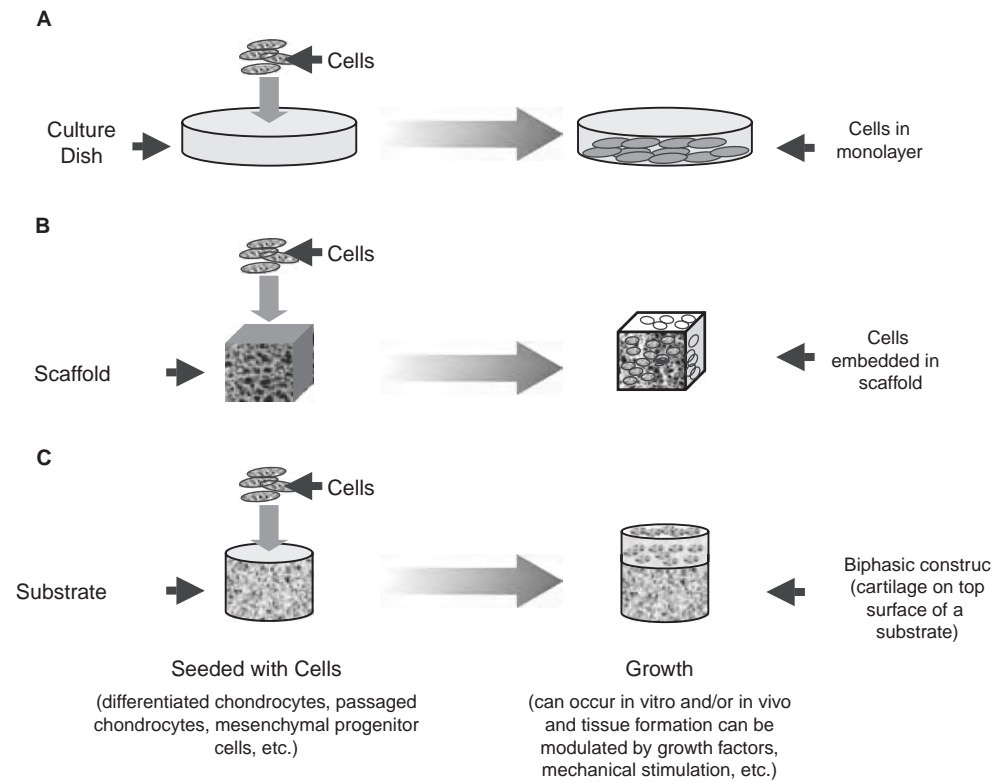

Fig. 3 Schematic of the three main methods that are used to tissue engineer articular cartilage. The duration of the culture period can vary considerably between all three methods; (A) Cells grown in monolayer are expanded and then harvested. The cells can be placed into articular cartilage defect; (B) Tissue-forming cells are seeded into a 3D scaffold. Cartilage may be generated in vitro or in vivo; and (C) Cartilage is formed on the top (the intended articulation) surface of a substrate. One example of this approach, and demonstrated in this figure, is to place chondrocytes on the substrate and cartilage tissue is allowed to form in vitro. The biphasic construct has a cartilage layer integrated with the top subsurface of the bone interfacing component. This composite construct can then be transplanted into a full thickness cartilage defect.

variable percent porosity and pore sizes ranging up to the micron size and in various physical forms such as a fleece or hydrogel. Much attention is now being directed toward the suitability of nanomaterials for cartilage tissue engineering.^[50] As well, design of “smart” scaffolds is also of great interest. For example, polymeric carriers can be created that have pH-sensitive membrane destabilizing activity to enhance delivery of biomolecules but are able to switch conformation with changes in pH so that they are not toxic to the cell^[51] or alternatively cross-linking oligopeptide metalloprotease substrates into 3D networks together with integrin-binding domains to create a condition that favors cell ingrowth.^[52] It would appear that some of the major benefits derived from growing chondrocytes in scaffolds are the 3D structure, which provides a setting conducive to the maintenance of cell phenotype, initial mechanical strength, and enhancement of cell retention in a defect.

Studies have shown that material geometry, pore size, and composition can affect the matrix molecules

produced by the chondrocytes, which could result in part from the interactions of chondrocytes with the material. To properly form articular cartilage it is necessary to ensure that the appropriate scaffold is selected as it is necessary to establish the conditions that will stimulate cells to produce the appropriate matrix molecules to ensure proper cell signaling and thus proper cartilage function. This includes selecting a material whose surface chemistry and roughness favors cell attachment and proper cell morphology (spread but not flattened with cortical actin distribution), which facilitates maintenance of chondrocyte phenotype, has an architecture that allows for formation of cartilage tissue with the organization described above, and has a degradation rate that matches the rate of tissue formation and does not incite an inflammatory reaction when implanted. Unfortunately, it appears that identification of optimal scaffold properties must be determined experimentally for each material developed.

Although most materials used are biodegradable, there are reports of non-biodegradable scaffolds, such

T

as agarose gels, that have been used with some success. Although cells seeded into agarose are distributed uniformly, their phenotype being maintained and can be injected into defects, the agarose can induce a giant cell foreign body response, suggesting that there are potential problems with its use.^[53]

There are several limitations in using scaffolds for cartilage repair. At present when cell-seeded scaffolds are allowed to form tissue *in vitro* prior to implantation the resultant tissue is of inferior quality with low collagen content and a fraction of the mechanical properties when compared to *in vivo* cartilage.^[54-57] This may be because of the absence of weight bearing during tissue formation, which is known to effect gene expression and matrix synthesis and can enhance nutrient diffusion. However, other factors such as scaffold breakdown can affect tissue formation. For example, as poly-L-lactic acid or its copolymer poly D,L-lactic glycolic acid degrade they release lactic acid, resulting in an acidic environment that can inhibit collagen synthesis by the cells and/or disrupt proteoglycan aggregation.^[58,59] As well, identifying the optimal scaffold for cartilage tissue engineering is still the subject of numerous investigations.

Substrates for Forming Biphasic Constructs

A third approach for cartilage tissue engineering is to generate biphasic constructs composed of a cartilage tissue phase overlying a substrate phase that serves as the bone interfacing component ("osteochondral-type" or biphasic constructs) [Fig. 3(C)]. Similar to scaffolds, substrates are porous and usually biodegradable, and can also be coupled to chemicals or biomolecules. However, it differs from scaffolds in that the cells or tissue is placed on the top surface and not seeded

throughout the substrate, and the regenerated cartilage is anchored to the intended articulation surface of the substrate. The substrate both supports cartilage formation and facilitates fixation after implantation by ingrowth of bone into the pores. An important characteristic of this substrate is that it is fully porous or the chondrocytes will not form cartilage.^[60] As well, the size and organization of the pores is important as they must allow for fluid flow but not allow (or severely restrict) cell infiltration throughout the full thickness of the substrate. The substrates have been made from many of the natural and synthetic materials utilized for scaffolds. However, as these are bone interfacing they must have sufficient strength for weight bearing, and so ceramics, processed bone, mineral reinforced polymers or collagen, and coral are used more commonly as substrates.^[10,61-63]

The cartilage component can be formed in several ways. Cartilage-forming cells can be seeded into a scaffold that is then affixed to the substrate either by sutures^[62] or by an adhesive such as fibrin glue,^[63] or if the substrate is a polymer by a concentration gradient of material properties.^[64] Alternatively, the cells can be placed directly on the top surface of the substrate. The biphasic construct can then be implanted, and cartilage tissue forms *in vivo*, or they can be grown in culture and cartilage allowed to form prior to implantation. An example of the latter approach entails the use of the ceramic porous calcium polyphosphate (CPP), which has mechanical properties approximating cancellous bone.^[65] Articular chondrocytes are placed on the intended articulation surface of the substrate, and as the cartilage forms *in vitro* the tissue integrates with the top subsurface of the scaffold (Fig. 4). The cartilage tissue that forms contains type II collagen and large proteoglycans similar to native cartilage.^[57] There are several potential benefits in using this type of biphasic

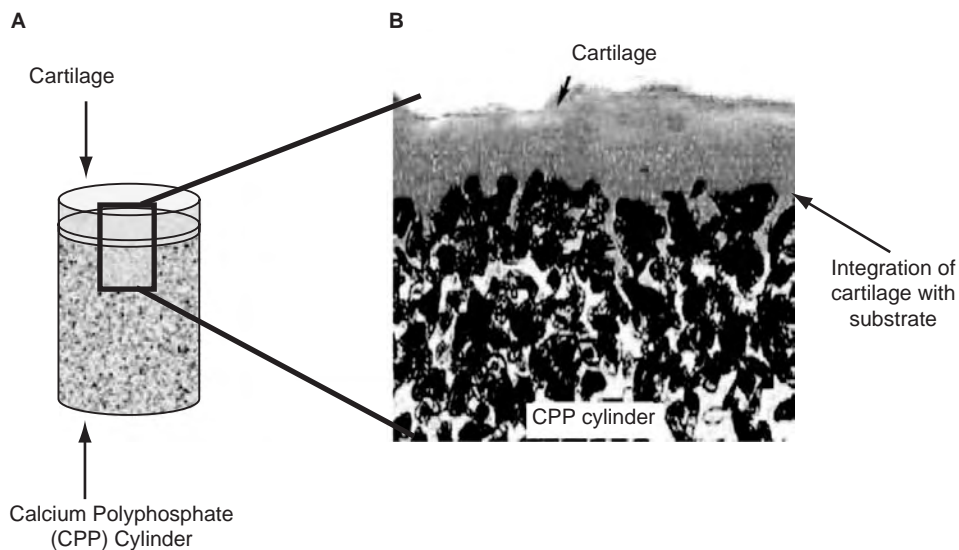

Fig. 4 An example of articular cartilage formed *in vitro* on a biodegradable substrate. (A) Diagram of the biphasic construct. (B) Photomicrograph of the histological appearance of the eight-week old cartilage grown on the surface of a porous CPP cylinder after formalin fixation and processing in Spurr resinTM.

construct to repair focal cartilage defects. Cartilage grown on substrates has the potential to form a stratified structure that more closely resembles native tissue. As the cartilage is already formed, lateral integration with the adjacent host cartilage is possible immediately upon implant insertion. As the substrate (CPP) is porous, bone can grow into pores not filled by cartilage after implantation, resulting in secure implant fixation. The CPP is biodegradable and will ultimately be replaced by bone, and as the biomaterial is made of calcium and phosphate the breakdown products do not incite an inflammatory reaction.^[65,66] However, similar to cartilage formed in scaffolds, the cartilage tissue and the cartilage–substrate interface formed after four weeks in culture have only a fraction of the mechanical properties of native tissue.^[57,67]

METHODS TO ASSESS BIOENGINEERED CARTILAGE

As there are many ways to tissue engineer cartilage, it is necessary to evaluate whether the approach under development generates cartilage with the appropriate qualities. Assessment of bioengineered cartilage can be done either following *in vitro* growth if appropriate or after implantation into the defect. Some of the methods that can be utilized are described below.

Pre-transplantation Assessment

Initial tests of the suitability of a biomaterial involve evaluation to determine if the material is toxic to chondrocytes. The 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrasodium bromide (MTT) assay, which measures mitochondrial activity, can be used to quantify cell viability. Live–dead assay (Molecular Probes) and confocal microscopy allow for visualization of the cells as well as quantification of the number of dead cells. Cellularity can also be determined using Hoechst dye binding assay to quantitate DNA content.^[68] Scanning electron microscopy is suitable to evaluate cell shape. Light microscopical examination is necessary to determine if cartilage tissue has formed and whether it approximates the appearance of *in vivo* tissue. Fig. 4 shows the histological appearance of the cartilage formed by chondrocytes seeded on top of a substrate. The type of molecules and their distribution in the tissue can be determined using immunohistochemical staining with antibodies reactive to the different macromolecules. The total amount of proteoglycan and collagen accumulated can be measured using biochemical assays (dimethylmethylene blue assay for glycosaminoglycans to estimate proteoglycan content^[69] and chloramine-T/Ehrlich's assay for

OH-proline to estimate collagen content).^[70] As treatment of cells with growth factors or other methods of stimulation can elicit a change in extracellular matrix synthesis these effects can be evaluated by semi-quantifying newly synthesized macromolecules and changes in gene expression.

Post-transplantation Assessment

After transplantation, histological evaluation should be used to assess the morphology and integration of the regenerated cartilage. As well, this will allow determination of the host response to the implant. If the tissue has formed *in vivo*, then it is necessary to characterize the tissue and confirm that it has the composition of hyaline cartilage and not fibrocartilage. The mechanical properties of the implant should be determined and compared to the native cartilage. This can also be evaluated *in situ* over time using arthroscopy and indentation probes.^[71,72]

MAJOR PROBLEMS ASSOCIATED WITH TISSUE ENGINEERING OF CARTILAGE

Appropriate Cell Source for Tissue Engineering Cartilage

One of the major limitations of cartilage bioengineering is obtaining sufficient numbers of chondrocytes to form enough cartilage to resurface a defect several centimeters in diameter. Although, cartilage and neonatal chondrocytes are considered immune privileged,^[73] recent studies have shown that implantation of cartilage between different species can incite an immune response that can compromise the implant.^[74] This suggests that xenogeneic sources may not be an option to obtain tissue. Development of transgenic pigs with “humanized” tissues has the potential to be an alternative source of cells, but this is still in the experimental phase because of the risk of viral disease transmission from pigs to humans. Current investigations into ways of preventing infection, such as RNA silencing, may prove successful, and in the future “humanized” animals may be able to provide chondrocytes or even cartilage for implantation. Thus, the major focus has been on developing a source of autologous cells. There are several ways to approach this.

Differentiated chondrocytes

To acquire chondrocytes, cells are isolated from cartilage obtained from around the defect or from a non-weight-bearing region. However, as only small amounts of tissue can be harvested a limited numbers

of cells are obtained, and as the individual gets older (+40 years) this problem is exacerbated as cell yield appears to decrease with age.^[75] In addition, cells from older individuals appear to be less robust in their ability to synthesize and accumulate extracellular matrix as determined by agarose gel culture studies.^[76] It has also been shown that chondrocytes obtained from arthritic cartilage, as may surround a joint defect, produce less extracellular matrix.^[75] There have been numerous investigations into culture methods that will allow for reliable expansion of chondrocyte number by cell proliferation while still preserving chondrogenic potential such that the cells can redifferentiate to chondrocytes under the appropriate conditions. Another approach to circumvent this problem has been to induce redifferentiation of the cells after the cell number has been expanded. This has been done by harvesting the cells from monolayer culture and then growing them under 3D conditions, at high cell density or on a material such as alginate.^[77] An alternative approach has been to harvest cells after growth on alginate and then culture them scaffold free on filter inserts to form tissue (the alginate-recovered-chondrocyte or ARC method).^[78]

Stem cells

Stem cells and progenitor cells are present in most if not all adult tissues and could serve as a source of cells. Stem cells give rise to progenitor cells and retain the capability of self-renewal. Progenitor cells can proliferate, have a limited capacity for self-renewal, and have the potential to differentiate. For example, mesenchymal stem cells (MSCs) can differentiate toward osteoblasts, chondrocytes, and adipocytes. MSCs, although initially identified in bone marrow, have since been isolated from a variety of tissues including periosteum, cancellous bone, cartilage, and even adipose tissue.^[79] The number of progenitor cells in a tissue is small (0.001–0.01% of nucleated cells in marrow)^[80] and varies from individual to individual and is influenced negatively by increasing age and presence of disease.^[81] Most of the work is focused on MSCs, and their role in tissue engineering is preliminary in part because of our limited understanding of the biology of these cells and because the markers used to separate out these cells from a mixed cell population have not been well defined for each subset. However, MSCs after expansion and seeding into a scaffold are able to differentiate toward chondrocytes under the appropriate culture conditions (see review^[81]). MSCs have also been used to repair cartilage defects with promising results,^[81,82] however, the cells can differentiate toward bone and cartilage. The use of MSCs avoids potential donor site morbidity that can

result from the harvesting of autologous cartilage, and as they escape immune surveillance, allogeneic cells could potentially be used.

An alternative to placing MSCs directly into a defect is to implant a scaffold that has been modified to stimulate MSC in situ to proliferate and migrate into the scaffold.^[83] Progenitor cells present in the superficial zone of cartilage may be particularly susceptible to this type of stimulus.^[10,84] As well, injection of stem cells into the knee joint has resulted in homing of cells to damaged cartilage and may be another mode of delivery of these cells to a defect.^[85]

Improving the Quality of Bioengineered Cartilage

Despite the development of potentially suitable biomaterials for tissue engineering, there still remains the problem that the articular cartilage generated in vitro does not mimic native cartilage in terms of composition, organization, and mechanical properties. There are several tactics that show promise in improving the quality of the tissue formed.

Mechanical stimulation

Under physiological conditions articular cartilage in vivo is exposed to complex loads and it has been shown that cartilage development and maintenance is regulated by these forces. Several studies have demonstrated that loading chondrocytes in a controlled manner in vitro leads to improved tissue formation with better physical properties. For example, Waldman et al. (2003) demonstrated that intermittent application of either cyclic compressive or shearing forces (400 cycles, 1 Hz) increased the amount of cartilage that formed and improved at least twofold both the load-bearing capacity and stiffness compared to unstimulated tissues formed on the CPP ceramic substrate.^[86] This would suggest that formation of tissue in the appropriate mechanical environment could be used to influence the quality of the cartilage that forms.

Growth factors

Addition of media supplements such as insulin-like growth factor I, osteogenic protein 1, and/or transforming growth factor- β (TGF- β) can improve the quality of in vitro-formed cartilage by stimulating production of specific matrix molecules.^[87,88] It may be that the addition of TGF- β coupled with mechanical stimulation may be an appropriate way to improve extracellular matrix accumulation.^[88]

Subpopulations of chondrocytes

Studies in our laboratory have shown that the quality of the cartilage formed *in vitro* can be influenced by the zone of the native cartilage from which the chondrocytes were obtained to establish the cultures.^[89] Chondrocytes obtained from the deep zone of cartilage accumulated more extracellular matrix and formed tissue that was thicker than that formed by cells harvested from full thickness or the mid/deep zones of articular cartilage. However it was the tissue formed by the mid/deep zone cells that had the best mechanical properties.^[89] This suggests that the use of chondrocyte subpopulations may be an interesting approach for tissue engineering. A study by Klein et al. demonstrated that it is possible to generate cartilage tissue *in vitro* by layering the cells from different zones in an appropriate sequential manner from deep to superficial to mimic the architectural features of the *in vivo* tissue.^[90] The stratified tissue although deficient in physical properties had a protein distribution similar to native tissue.^[90] Furthermore, using subpopulations will also allow for formation of tissue-engineered cartilage with a deep mineralized zone to recreate the soft tissue (cartilage) –hard tissue (bone) interface critical to proper cartilage function.^[89] So it may be advantageous to use chondrocyte subpopulations to modulate the composition and mechanical properties of the regenerated tissue.^[89,91]

CONCLUSIONS

There has been much research in tissue engineering of articular cartilage for joint repair. Current studies are aimed at improving the quality of tissue generated. However even when the optimal conditions to bio-engineer cartilage are developed there will be other problems to overcome such as integration of the repair tissue with the surrounding recipient tissues (cartilage and/or bone) after implantation and ensuring its long-term functionality *in vivo* under weight-bearing conditions in a “hostile” environment likely containing cytokines and metalloproteases because of the underlying cartilage damage.

ACKNOWLEDGMENTS

Owing to page constraints, we have been limited in the number of references that could be included, but we wish to acknowledge the many contributors to this field. As well, we thank all the students, fellows, and technologists in the Kandel, Pilliar, and Grynepas laboratories for the stimulating discussions and their

hard work, as well as CIHR, The Arthritis Society, and NSERC for their support.

INTRODUCTION

The cornea is the transparent barrier between the eye and the environment. Tissue-engineered corneas are currently developed to replace wounded or diseased corneas. Various experimental applications are also foreseen for these tissues reconstructed in vitro by tissue engineering. This article covers the first human corneas reconstructed by tissue engineering from normal human cells and the different models used for the production of human and animal corneas in vitro. Corneal injury and the activation of the complex wound-healing mechanisms are also addressed. Finally, we will attempt to provide the reader with a brief look toward the future of corneal tissue engineering, including the challenges that lie ahead as well as the potential experimental and clinical applications of this field.

CORNEAL TISSUE RECONSTRUCTION

Living tissue reconstruction rests mainly on a good choice of cells and biomaterials because these components will affect the quality of the final product. The ideal cell source should provide cells with extensive proliferation potential and appropriate differentiation

abilities. Stem cells possess such characteristics. After isolation and culture, cells can be combined with biomaterials to produce three-dimensional constructs.

Cell Source

The corneal epithelium is a transparent mucous tissue composed of a nonkeratinizing-stratified squamous epithelium (Fig. 1) comprising five cell layers centrally and up to 10 peripherally. It is surrounded by a small transitional zone, the limbus, and by the conjunctiva. The latter will not be discussed further since this nontransparent tissue represents a different type of epithelium containing goblet cells that cannot restore a normal central cornea. Corneal cells from the basal layer are polygonal and become more flattened in the suprabasal layers. All cells are nucleated. The stromal tissue underlying the epithelium as well as the basement membrane varies according to the three regions of the cornea. The limbus and conjunctiva are highly vascularized. In contrast, blood vessels are absent in the central cornea. However, endothelial cells form a monolayer underlying the stroma in this region. This cell layer is very important as it is involved in the maintenance of corneal transparency by regulating its

Fig. 1 Organization of the corneal epithelium and its interaction with basement membrane components. The stratified corneal epithelium is depicted along with the Bowman's layer and the most outer part of the corneal stroma. The enlarged section of the basal corneal epithelial cells illustrates how membrane-bound integrins bridge the components of the ECM (for instance, laminin, fibronectin, collagen IV, and collagen VII) to the actin filaments through their interaction with cytoskeletal elements (talin and α -actinin). Formation of functional focal adhesion structures also requires the participation of other cytoskeletal components such as tensin, vinculin, and paxillin. The end result of integrins clustering at the cell membrane and the stabilization of their intracellular connection with actin filaments through the selective use of these cytoskeletal elements is the formation of an adhesive junction that can withstand stable attachment of the cell to the ECM. (Taken from Ref. [6] with permission.)

degree of hydration. Therefore, the central and limbal cornea comprise three cell types: epithelial cells, fibroblasts (also called keratocytes), and endothelial cells. The first step of living tissue engineering is determining the best cell source for tissue reconstruction, the ideal source being able to regenerate the tissue for a lifetime as well as producing a differentiated progeny. Then, tissue engineering requires the isolation, culture, and expansion of each cell type on plastic substrates before three-dimensional tissue reconstruction.

Epithelial cells

The corneal epithelium is a self-renewing tissue in which the balance between proliferation and differentiation

maintains the homeostasis. However, the stem cells, ultimately responsible for repopulating the cornea, are not uniformly distributed on its surface. They are restricted to the limbus, the transitional zone surrounding the central cornea.^[1] They migrate in a swirling circular movement to the basal layer of the central cornea and then move through the suprabasal compartment toward the corneal surface.^[2] All cells from the central cornea express the keratin pair, K3/K12, which is typical of terminal differentiation of the corneal epithelium.^[3] Despite this keratin expression, cells from the basal layer of the central cornea can proliferate, but only for a limited number of divisions; they are transitional cells and not stem cells. In contrast, basal cells do not contain K3/K12, but express K19 in the region containing stem cells, the limbus.^[4-6] Interestingly, this keratin is expressed in stem cells of the skin.^[7] Keratin

19 was shown to possess distinct assembly properties and to form narrower filaments *in vitro*. Thus, keratin 19 may impart unique properties to the basal cells expressing it.^[8]

Human epithelial cells can be isolated from the central cornea or from the limbus by dispase digestion. They are cultured with the method originally described by Green for the clonal growth of skin keratinocytes.^[9] The coculture with an irradiated fibroblasts feeder layer in a medium containing growth factors allows expansion of corneal epithelial cells *in vitro*.^[10,11] In addition to the promotion of epithelial cell growth, the presence of irradiated fibroblasts limits the outgrowth of human fibroblasts that may have been isolated with the epithelial cells. The high concentration of calcium in the culture medium sustains cell differentiation and allows the formation of desmosomes essential to the production of a multilayered epithelium.

In culture, human epithelial cells form colonies that are several layers thick. The proliferative cells are located at the edge of the colonies, in the basal layer where they attach to the plastic substrate. The differentiated cells can detach from the plastic substrate and leave the basal layer to form the suprabasal layers where cells are bound to their neighbors by desmosomes. Therefore, cultures performed under these conditions contain a mixture of epithelial cells with various differentiation levels. The behavior of K19 positive limbal cells in culture remains to be

determined. Interestingly, cells isolated from the limbus grow much better in culture than cells from the central cornea, suggesting that stem cells are preserved in culture. Cells from the central cornea have a short lifetime in culture as they can barely be subcultured. In contrast, limbal cells can be subcultured for several passages (up to seven passages, depending on the donor). Moreover, cells isolated from the central cornea present morphological characteristics consistent with their low proliferative potential. They form small colonies containing large cells with a low nucleus-to-cytoplasm ratio, indicating that they are differentiated. In contrast, limbal cells produce large colonies consisting of small cells that possess a high nucleus-to-cytoplasm ratio (Fig. 2). These characteristics are typical of less differentiated cells.

The lifespan of primary cultured human corneal epithelial cells varies with the donors. This variation has been correlated with expression of the transcription factors of the Sp1 family.^[12] Therefore, the expression of Sp1/Sp3 might represent a good predictor for selecting human corneal epithelial cell cultures that are most likely to proliferate, stratify, and differentiate properly when used for the production of reconstructed corneal substitutes.

Within the limbus, a higher colony-forming efficiency is attributed to cells that have been isolated from the superior and temporal quadrants compared to cells from nasal or inferior limbus,^[13] indicating that

Fig. 2 Phase contrast micrographs of epithelial cells isolated from limbus cultured on plastic substrate with irradiated mouse 3T3 fibroblasts (A), corneal stromal cells (B), and bovine (C) or human (D) corneal endothelial cells. Note that limbal epithelial cells form large colonies of small cells surrounded by irradiated fibroblasts. Magnification = $\times 70$.

biopsies should preferably be taken from these two former sites. The preferential localization of stem cells in the superior quadrant is consistent with a better protection against environmental and mechanical injuries provided by the eyelids in this region.

Keratocytes

Human corneal keratocyte cultures can be established from the corneal stroma that is left after dispase digestion and removal of the epithelium and endothelium. Stromal explants are seeded in DMEM (Dulbecco–Vogt modification of Eagle’s culture medium) supplemented with 10% fetal calf serum and antibiotics. Stromal cells are subcultured in the same medium and undergo more than nine passages. In this culture medium, stromal cells adopt a fibroblastic morphology after subculturing (Fig. 2).

Alternatively, human corneal keratocytes can be obtained either after digestion of bare corneal stroma with collagenase or from stromal cell contamination in epithelial cell cultures by changing the culture medium for keratocyte culture medium. Epithelial cells are lost in subcultures because this medium is not adequate for their proliferation.

Endothelial cells

As opposed to the other corneal cell types, mature human corneal endothelium has a very limited capacity of division under normal conditions. However, these mesothelial cells, arrested in the G1 phase of the cell cycle, have retained a proliferative potential, as indicated by positive reaction against cyclins D, E, and A.^[14] As with epithelial cells, incubation in a dispase solution allows the endothelial sheet to separate easily from the underlying stroma. The endothelium is grown in a 1:1 combination of medium M199: Ham’s F12 supplemented with fetal calf serum, ascorbic acid, insulin, transferrin, penicillin, and gentamicin.^[15] Under these conditions, we were able to grow corneal cells from very young donors (2 or 3 years old). On the other hand, endothelial cells from adult corneas are more difficult to grow in culture. Alternatively, DMEM, supplemented with fetal calf serum, endothelial cell growth supplement, penicillin, and gentamicin, may be used to culture bovine endothelial cells (Fig. 2).

Clinical Application of Corneal Epithelial Cells Cultured on Fibrin Gels

The expansion of corneal epithelial cells in culture was applied for the treatment of patients suffering from conjunctivalization following chemical burn of the

cornea.^[16] Corneal cells harvested from an intact portion of the limbus from the contralateral eye were expanded in culture as described earlier. After the primary culture, cells were seeded on an acellular fibrin gel and cultured until confluence. The grafting of cultured epithelium resulted in a permanent corneal epithelium and the improvement of the visual quality for the patients.^[16] These results indicate that stem cells are conserved in cultures and remain functional after grafting.

Corneal Tissue Reconstruction Using Collagen Gels

The collagen gel model allows the production of living corneal tissue comprising both the reconstructed stroma and epithelium. This model was first optimized for skin.^[17,18] The reconstructed stroma is produced by mixing stromal cells with collagen. The epithelium is obtained by culturing corneal epithelial cells on the mature reconstructed stroma (Fig. 3).

Several models have been produced *in vitro* using animal corneal cells. Animal models with two or three reconstructed layers (endothelium, stroma, and epithelium) were produced with rabbit or bovine cells. Zieske et al. (1994) used rabbit corneal epithelial cells over rabbit stromal keratocytes included in a collagen gel with or without an underlying layer of immortalized mouse corneal endothelial cells.^[19] Minami et al. (1993) reported another model with the three cell types of bovine origin.^[20] The following paragraphs present the first model reconstructed from normal human corneal stromal and epithelial cells.

The first step is producing the reconstructed stroma. Corneal stromal cells are mixed with bovine type I collagen, adjusting the pH to 7.4. The mixture is then poured into a petri dish containing an anchorage ring and incubated 1 h at 37°C for gelation. Alternatively, bovine collagen can be replaced by human type I and type III collagen to produce an entirely human substitute.^[11] The addition of a filter paper ring allows the anchorage of the gel to prevent the inevitable contraction of floating collagen gels that is proportional to the cell number and inversely proportional to collagen concentration.^[11] The anchorage was designed to keep a constant surface area and to reduce the thickness without interference of the peripheral filter paper with the cells. The collagen gel produced by this process contains dispersed living stromal cells. The reconstructed stroma, (Fig. 4) resembles the corneal stroma, but the Descemet’s and Bowman’s membranes are absent in this first model of normal corneal cells.

The production of the epithelium was initiated by cultured epithelial cells from the limbus. They were chosen because of their greater proliferative potential. They are seeded on mature reconstructed stroma

HUMAN CORNEA RECONSTRUCTION BY THE COLLAGEN GEL METHOD

(4-day culture in stromal cell culture media). With the addition of epithelial cells, the culture medium is changed for epithelial cell culture media, which contains EGF, insulin, hydrocortisone, cholera toxin, and serum.^[11] Under these conditions, epithelial cells attach to the reconstructed stroma and uniformly cover it. After 3 days of culture submerged in the medium, it forms a multilayered epithelium with a basal layer containing cuboidal cells. Cells become elongated as they progress into the suprabasal layers (Fig. 4). The cultures can be raised at the air-liquid interface to promote epithelial cell differentiation, as shown for reconstructed skin,^[21,22] and later used for reconstructed cornea.^[6,19,20] Obviously, human or bovine endothelial cells may be seeded over this stromal equivalent covered with epithelial cells. The medium is changed afterward to a 1:1 mixture of epithelial and endothelial medium.^[23] In an animal model, the addition of endothelial cells under a collagen matrix improves differentiation of corneal epithelium as well as the distribution of keratocytes within the gel.^[19]

The resulting reconstructed cornea presents a translucent macroscopic aspect (Fig. 3). The thickness of the reconstructed epithelium was found to be close to that of normal corneas upon histological examination (Fig. 4).

Corneal Tissue Reconstruction Using Collagen Sponges

Another method to produce artificial corneas was described by Griffith et al.^[24] It takes advantage of

natural or synthetic polymers as a scaffold to seed cell lines of transformed human cells for the production of a tissue.^[24,25] Collagen-based polymers are cross-linked with glutaraldehyde or other cross-linkers to produce a sponge into which virally transformed keratocytes are seeded. The addition of transformed corneal endothelial and epithelial cells leads to artificial corneas that presented functional properties as shown by a decrease in transparency following their response to chemical wounding.

Corneal Tissue Reconstruction by the Self-Assembly Approach

The self-assembly approach constitutes a truly new concept for tissue engineering. We have originally designed it to reconstruct tissues in a manner akin to the embryonic development phenomenon, which would result in the creation of living substitutes as similar as possible to their physiological *in vivo* counterparts. Indeed, in this approach, cells produce their own extracellular matrix and organize it into a structured three-dimensional network. Addition of the adequate cell types results in the production of complex tissue with the expected histological, mechanical, and functional properties, as was previously demonstrated by our group for blood vessels and skin.^[21,26] There is no need for providing exogenous collagen or synthetic material.^[21] The vascularization system can also be reconstructed, as demonstrated by the formation of a

Fig. 4 (A) Masson's trichrome staining of reconstructed human stroma produced with bovine collagen. Note the presence of keratocytes and extracellular matrix. Masson's trichrome staining of reconstructed human corneas produced with human collagen (B) and normal human cornea in situ (C). capillary-like network in our skin construct.^[27] This promising new technology is now applied for the reconstruction of human cornea^[28,29] and results in a transparent tissue (Fig. 5). In this model, the stromal cells produce a dense matrix (Fig. 6B). Moreover, the epithelial-mesenchymal interactions lead to the formation of a complete basement membrane with all expected ultrastructural components (lamina lucida, lamina densa, hemidesmosomes) (Fig. 6A).

WOUND HEALING

Corneal Injury and Activation of the Wound-Healing Mechanisms

One major aim in developing a tissue-engineered human reconstructed cornea is its use as a corneal substitute for those individuals afflicted with severe corneal wounds. Corneal wounds, either superficial with damage limited to the epithelium or extensive with defects of basement membrane and stromal lamellae, account for approximately 37% of all visual disabilities and 23% of medical consultations for ocular problems in North America. Severe recurrent and persistent corneal wounds are most commonly secondary to recurrent erosion, mild chemical burns, superficial herpetic infections, neuroparalytic cornea, autoimmune diseases, and stromal ulcerations due to viral or bacterial infections or to severe burns (reviewed in Reim et al., 1997).^[30] Many of these corneal wounds and scarring diseases persist for weeks and months or else recur frequently and can progress to corneal perforation. Those eyes that survive perforation will eventually develop corneal scars, which will compromise vision and may also alter the mobility of the globe and conjunctiva.

The use of techniques for refractive surgery such as excimer laser photorefractive keratectomy (PRK), automated lamellar keratoplasty (ALK), and laser in situ keratomileusis (LASIK) has become popular worldwide. Individual patients have shown an aggressive wound-healing response with excessive myopic regression and severe corneal haze after PRK as well as a severe form of lamellar keratitis after LASIK.^[31] Stromal keratocytes, together with epithelial cells, are also likely to play a critical function in defining the visual outcome of refractive surgery. Corneal injury also induces a series of phenotypic changes, ultimately resulting in the transformation of stromal keratocytes into a fibroblastic cell type that shares characteristics of myofibroblasts. This transformation process and the subsequent physiological activity of these cells ultimately determine the final outcome of refractive surgical procedures.

Fig. 6 Transmission electron microscopy of reconstructed human skin tissue by the self-assembly approach, showing the presence of the basement membrane between the stroma and the epithelium (A), and the extracellular matrix organization including the typical pattern of collagen bundles (B).

Wound healing in the cornea is a complex process that requires the formation of scar tissue as well as the restoration and maintenance of the transparency of the cornea. Healing of the ocular surface is closely related to the regeneration of the corneal and conjunctival epithelia. Tissue repair obviously requires cell migration, proliferation, and adhesion. Cell adhesion and migration in turn depend on the synthesis and assembly of the extracellular matrix (ECM). The ECM is a complex, cross-linked structure made up of various proteins such as fibronectin (FN), laminin (LM), collagen, and vitronectin. It organizes the geometry of normal tissues through cell-cell and cell-ECM adhesion. Both FN and LM are adhesion proteins identified as potential wound-healing agents because of their cell-attachment, migration, differentiation, and orientation properties. Cells bind the different adhesion proteins with membrane proteins better known as the integrin superfamily of receptors, which recognizes the RGD tripeptide that is shared by many adhesion proteins. These integrins bridge the cytoskeletal elements of cells to the ECM and thus promote cell-ECM and cell-cell interactions (Fig. 1).

Integrin Expression in Normal Cornea and in Wound Healing

Integrins are now recognized as the main class of cell adhesion receptors for the various components of the

ECM. Therefore, the patterns of integrin expression of human corneal substitutes must be very similar to normal human cornea in order to save its many adhesive and migratory characteristics. The integrin superfamily contains at least eight types of receptor subfamilies, which differ from one another only by the nature of their β subunit. To date, 18 α and 8 β integrin subunits that can heterodimerize into more than 25 known integrin receptors have been described.^[32] Both the ECM and integrins collaborate to regulate gene expression associated with cell growth, differentiation, and survival. Therefore, the interactions between ECM and integrins exert profound influences on these major cellular programs by altering, through a number of signal transduction pathways, the transcription of genes. The binding of ECM components, such as FN, with their corresponding integrin receptors is known to trigger the activation of different intracellular signaling mediators. For example, the activation of the MAPK signal transduction pathway is of particular interest because it links integrin-mediated signaling to transcriptional regulation of genes, which are crucial for cell growth and differentiation through the activation of distinct transcription factors such as ELK, c-Jun, c-Myc, ETS, and Sp1. These factors play pivotal roles in controlling the transcription of genes required for the cellular programs mentioned earlier.

Many integrins have been identified in the corneal epithelium including alpha subunits $\alpha 2$, $\alpha 3$, $\alpha 4$, $\alpha 5$, $\alpha 6$, αv , and $\alpha 9$, and beta subunits $\beta 1$, $\beta 4$, and $\beta 5$ (for a review, see Elnor and Elnor, 1996).^[33,34] The increase of FN and LM expression in corneal wound healing was postulated to be coordinated with the expression of their corresponding integrin receptors, $\alpha 4\beta 1$ and $\alpha 5\beta 1$ (recognized as the major FN receptors), as well as $\alpha 6\beta 4$ and $\alpha 6\beta 1$ (LM receptors) (for a review, see Refs. [35,36]). For instance, the integrin $\alpha 5\beta 1$ was shown to be present during corneal wound healing after radial keratectomy and $\alpha 6$ was detectable around the entire cell up to the leading edge of the migrating epithelium. The use of a debridement wound model in the mouse cornea clearly provided evidence that the expression of both $\alpha 6$ and $\alpha 9$, as well as that of $\beta 4$, is closely associated with wound healing, resulting in a significant increase in the level of expression of these integrins at both the mRNA and protein levels (Ref. [37] and the cited references therein). The appearance and disappearance of $\alpha 5$ and $\alpha 6$ integrin subunits are thus well coordinated with FN and LM in the cornea.

Extracellular Matrix Components: Expression in Normal and Healing Cornea

In the unwounded rat eye, FN was observed by immunohistological staining at the level of the corneal

epithelium basement membrane whereas LM is found in the subepithelial region, the basal aspect of the basal epithelial cells and the Descemet's membrane.^[35,36] Shortly after corneal injury, the basal cells that border the injured area and stromal keratocytes start producing massive amounts of FN and its subepithelial immunohistological staining progressively decreases once the wound is reepithelialized. In corneal keratectomy wounds, the presence of LM was demonstrated along the wound bed. In addition, it was shown that scarred regions of keratoconus corneas had greater than normal staining of the epithelial basement membrane for FN and LM.^[38,39] Moreover, FN and LM are expressed at levels greatly above normal in the healing corneal stroma of alkali-burned corneas.^[40]

The expression of FN and LM was found to increase in tear fluid as well as in corneas after PRK or LASIK treatments.^[41-43] With increased postoperative time, FN levels diminished and the change in expression of $\beta 4$ became linear. It is therefore clear that FN and LM, as well as their respective receptors, are very important components of a proper regeneration and adhesion of corneal epithelium.

Integrin and Extracellular Matrix Expression in Reconstructed Human Cornea

Integrins and basement membrane components were visualized by immunohistofluorescence labeling of human cornea reconstructed by the collagen gel model because these constituents are necessary for a good tissue cohesion. The expression of the $\beta 1$, $\alpha 3$, $\alpha 5$, and $\alpha 6$ integrin subunits are detected in the epithelium, but the expression of the $\alpha 4$ integrin subunit is not.^[6,11]

The basement membrane components, laminin, type VII collagen, and fibronectin are already detectable in the reconstructed cornea after 3 days of culture. A discontinuous pattern of laminin is visualized at the basement membrane. Laminin, as well as type VII collagen labeling, is present in the cytoplasm of the epithelial basal cells, indicating an active production of ECM proteins. Fibronectin is also present at the epithelium-stromal junction in addition to its detection within the stroma.^[11]

FUTURE CHALLENGES AND APPLICATIONS

Future Challenges

The biggest challenge in the tissue engineering of reconstructed human cornea is to combine the improvement of the models while conserving transparency. All components of the cornea—the epithelium, the stroma, and Bowman's and Descemet's membranes, as well as the endothelium—are organized to allow light to pass

through. The corneal epithelium with its relative thinness, the absence of cornified cells, and the smooth and linear junction that contributes to its transparency has been reproduced in vitro by tissue engineering with human^[11,24] and animal^[19,20,44] cells. The absence of blood vessels in the cornea facilitates its reconstruction in vitro.

The stroma represents a greater challenge because its transparency is due to the particular organization of its collagen fibers. The keratocytes oriented parallel to the collagen fibers form lamellae, which are superposed with others in a regular order. The collagen in each lamella is perpendicular to one of the adjacent lamellae. The uniform diameter and regular spacing of the fibers, in which proteoglycans play a role, also contribute to the transparency of the stroma. Further characterization of the ultrastructural features and the extracellular matrix composition of the reconstructed stroma will be necessary. The reconstructed cornea could be used as a model to evaluate the extent to which mechanical stimulation and matrix constituents (proteoglycans) are necessary for a particular stromal organization.

The Bowman's membrane is composed of randomly oriented delicate collagen fibers and is therefore less complex. The Descemet's membrane is a basal lamina elaborated by the underlying corneal endothelial cells that should reappear in vitro after the addition of endothelial cells to the reconstructed tissue.

The state of hydration of the cornea is another factor of utmost importance for its transparency. The semipermeable endothelium plays an active role in keeping the cornea underhydrated. Therefore, the addition of corneal endothelial cells to the reconstructed cornea is an important optimization step that could be accomplished because the culture of human endothelial corneal cells is possible^[45-47] and the reconstruction of corneal tissue with animal endothelial cells^[19,20,44] has been reported.

The level of optimization necessary may depend on the application foreseen for the human reconstructed cornea. The complete model with all three layers might not be required for in vitro applications such as the evaluation of the effect of mechanical forces on the extracellular matrix organization. Since the maturation and differentiation of reconstructed tissues continue after transplantation, immature tissues could be grafted for some clinical applications.

Experimental Applications

An understanding of the cellular and molecular mechanisms underlying the adhesion, migration and differentiation properties of the various cell types encountered in the cornea will lead to predictable, safe refractive surgical and visual results. The availability of

a human model will be much closer to the real in vivo tissue and would clearly represent a more appropriate alternative to the use of whole human tissues. No such human model could be exploited for this type of study until we recently succeeded in tissue engineering human corneal equivalents, which show appropriate histology and expression of basement membrane components and integrins.^[11] Corneal endothelial cells of either human or bovine origin have recently been added to this corneal equivalent.^[23] Not only are such tissue-engineered corneal substitutes valuable tools for physiological, toxicological, and pharmacological studies, but they also represent outstanding models for the study of stem cells or gene expression. This approach may be helpful to study the factors that modulate integrin expression at the promoter level such as growth factors and cytokines, as well as ECM components.

The development of a reconstructed cornea is also of great interest in industrial applications where alternatives for the Draize test are sought. This procedure evaluates the toxicity of drugs and household products by exposing the cornea of rabbits to various concentrations of the test chemical or product to determine the concentration resulting in irritation, toxicity, or alteration in transparency. The use of corneal equivalents for these tests would contribute to reducing the large number of animals required. In addition, this approach is not biased by potential intrinsic differences in the reaction of the animal compared to human. Therefore, there is a need to find alternative new methods that will result in a reduction in the use of laboratory animals. In June 2000, a new law (*directive européenne* 97/18/CEE) banished in France the use of animals in the testing of cosmetics. Promising results have been obtained with the collagen sponge model including transformed human epithelial cells, keratocytes, and endothelial cells. The chemical-induced change in transparency of reconstructed corneas is indeed a criterion of the original Draize test.^[24]

Clinical Applications

A reconstructed human cornea could be very valuable in two different clinical fields. First, a tissue-engineered reconstructed anterior cornea could be grafted for patients suffering from corneal epithelial stem cell aplasia. The loss of stem cells in the limbal epithelium may lead to functional blindness as it impedes with cell renewal leading to neovascularization, persistent epithelial defects, scarring, ulceration, and corneal perforation. The only possible cure is transplanting limbal stem cells from autologous or allogeneic tissues.^[48,49] In the short term, tissue engineering will be most advantageous when performed for lamellar keratoplasty autologous transplantation, as only a small limbal

tissue biopsy is needed because the epithelial culture can be expanded from a 1 mm² biopsy sample and transplanted on the patient.^[50] As a long-term goal for reconstructed whole cornea production, the supplementary autologous biopsy that may be required to isolate keratocytes and endothelial cells remains a challenge both technically and in terms of controlled cell differentiation.

Second, the tissue-engineered cornea might be used as a specialized living wound dressing in applications related to wound healing. The cultured tissue would not be grafted, but instead temporarily placed over the wounds to improve healing. Under these circumstances, healing is initiated by the patient's own stem cells remaining in the limbal cornea whereas the tissue-engineered cornea protects the wound and secretes factors that promote healing. Such a clinical application has proven useful for cutaneous wounds. Indeed, tissue-engineered epidermis, or skin, has been reported to accelerate the healing of second-degree burns or cutaneous ulcers.

Thus, the development of reconstructed cornea by tissue engineering could bring an additional and valuable therapeutic approach to the present clinical arsenal for the treatment of various corneal diseases.
