T

INTRODUCTION

The default mechanism of wound repair in the esophagus of adult mammals is scar tissue formation with stricture. Tissue engineering and regenerative medicine strategies for reconstitution of functional esophageal tissue have been largely unexplored or not reported. The clinical problems related to the esophagus, animal models of esophageal pathology, and an overview of regenerative medicine and tissue engineering principles as they relate to replacement and reinforcement of injured or missing esophageal tissue will be discussed, with an emphasis upon scaffold and cell-based approaches.

CLINICAL RELEVANCE

Congenital pathology such as esophageal atresia or acquired pathology such as esophageal cancer are currently treated by surgical resection,^[1,2] with morbidity rates exceeding 50%.^[3] Translocation of the stomach, large bowel, small bowel, and skin have been utilized in attempts to replace the resected esophageal tissue.^[4,5] The results of past and current surgical therapy have been less than ideal with high morbidity and mortality.^[6,7]

The current standard of care for esophageal cancer or Barrett's esophagus with high-grade dysplasia is esophagectomy with a "gastric pull-up," a procedure in which the stomach is shaped into a tube and mobilized through the mediastinum and anastomosed to the remaining cervical esophagus (Fig. 1).^[4] During this procedure, the blood supply to the stomach is compromised, and the resulting poorly vascularized anastomotic site has a reduced healing capacity that contributes to complications such as mediastinal leaks or strictures that hinder the normal postoperative recovery.^[7,8] Following esophagectomy with gastric pull-up, patients suffer from delayed swallowing or chest discomfort because of gastric distention within the mediastinal cavity.^[9,10] Anastomotic leakage because of dehiscence of the tissues is one of the most common complications associated with esophageal surgery that contributes to postoperative morbidity.^[11,12] Technical-related complications

such as anastomotic site leakage are considered an independent risk factor for the prognostic outcome.^[13] Another common complication related to suboptimal healing is stricture at the anastomotic site. Almost 50% of patients require one or more postoperative endoscopic dilations to treat stricture.^[12]

Non-malignant pathologies of the esophagus such as traumatic injury, fistulae, or small congenital defects would benefit greatly from effective tissue engineering approaches that could close defects without stricture and/or prevent resection of esophageal tissues with the need for an anastomosis.^[14] The mechanisms of esophageal scarring and stricture formation are largely unknown, although they are likely related to the presence of an acidic environment, proteolytic enzymes, and molecular mediators of inflammation that lead to fibroblast proliferation and contracture.^[15-19]

Esophageal stricture can be triggered by partial mucosal resection, which is a therapeutic intervention for the treatment of Barrett's disease, a preneoplastic condition that can increase the risk of developing esophageal adenocarcinoma by 50-fold.^[20,21] In the past decade, two minimally invasive approaches have yielded promising results for the treatment of Barrett's esophagus. The first involves endomucosal resection (EMR) of the affected area to remove the affected epithelium. The main limitation of this procedure is stricture formation, which, in turn, is dependent on the extent of the resection. The risk of stricture increases significantly when the segment is longer than 30 mm or when the resection involves more than three-quarters of the inner circumference of the esophagus.^[22-24] The second minimally invasive approach for treatment of Barrett's is ablation of the pathological tissue by photodynamic therapy (PDT). PDT is not as strongly associated with stricture as EMR, but the risk of perforation increases with the depth of the ablation. Complete removal of the esophageal mucosa by PDT requires several endoscopic sessions to be effective without complications,^[25] while superficial ablation of the esophageal mucosa increases the risk of leaving metaplastic glands beneath the neoe epithelium, thereby increasing the risk of recurrent disease or progression to neoplasia.^[26,27]

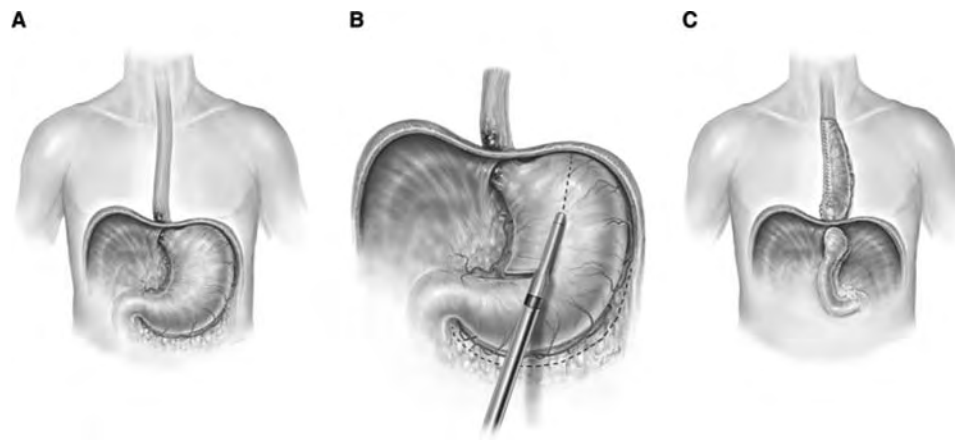

Fig. 1 Schematic of the gastric “pull-up” procedure. (A) Normal anatomy of the upper gastrointestinal tract with high-grade dysplasia in the distal esophagus. (B) The esophagus and part of the gastric fundus are surgically excised to remove the tumor. The remaining stomach is shaped into a tubular form. (C) The tubularized stomach is passed through the mediastinum and anastomosed to the remaining proximal esophagus.

These negative outcomes could potentially be mitigated by employing a tissue engineering/regenerative medicine approach for reinforcement or replacement of functional esophageal tissue.

ANIMAL MODELS

Although interactions between various cell populations and scaffold materials can be studied *in vitro*, preclinical *in vivo* studies are essential to study esophageal regeneration. Complex interactions such as cell–cell and cell–matrix interactions in the presence of inflammation, fibroblastic proliferation, and scarring that characterize the esophageal response to injury in mammals cannot be replicated in *in vitro* studies. Animal models have been used extensively in the field of regenerative medicine of the digestive tract.^[28] One of the earliest reports involved the repair of a duodenal wound with jejunal serosa using mongrel dogs.^[29] Subsequently, reconstructive strategies have been investigated for almost the entire length of the digestive tract, including the esophagus, stomach, small bowel, and large bowel.^[28,30–34] Two of the most commonly used animal models for esophageal studies are the mongrel dog and the opossum. The canine model of the esophagus is appropriate because the canine esophagus is similar to that of humans, dogs are a convenient size for surgical models, they are readily available for research purposes, and their slow growth rate and typical life span are suitable for long-term follow-up studies.^[35] Limitations of the canine model include the relatively high cost compared to rodent studies.

The other model employed in esophageal studies is the opossum. Several studies have been published, showing the similarity of the opossum esophageal

histology to that of the human esophagus, especially with regard to blood supply.^[8,36,37] Although, there are no studies using the opossum in the tissue engineering/regenerative medicine literature, it has been used as a valid model to understand the complications of gastrointestinal tract reconstruction after radical esophagectomy. Limitations with this species include size of the animal and its esophagus, availability of the animal model, and behavior of the species.

The choice of an appropriate animal model in any experimental design is very important. Factors to be considered include resemblance of the animal model to human anatomy and function, and the response to injury both in normal and pathological conditions. Misinterpretation of excellent healing capacity by certain species can lead to erroneous human clinical translation.

ESOPHAGEAL TISSUE ENGINEERING STRATEGIES

Synthetic Scaffolds

A variety of scaffold materials have been considered for tissue engineering of esophageal tissue, including synthetic and naturally occurring scaffolds, with and without the addition of cells. Recently, there have been a number of studies evaluating viability and differentiation of esophageal cells on various synthetic scaffold materials. Poly-L-lactic acid (PLLA), poly-lactic-glycolic acid (PLGA), and polycaprolactone/PLLA (PCL/PLLA), alone or surface modified with collagen and fibronectin, have been shown to support growth of esophageal cells including epithelial cells, smooth muscle cells, and fibroblasts.^[38–40] Rat esophageal organoid units isolated by digestion of normal esophageal tissue

by dispase and collagenase have been seeded onto a PLGA scaffold for implantation within the omentum of an allogeneic recipient.^[31] After four weeks, the organoid graft was removed from the omentum and used to replace a segment of the esophagus in the same animal. The result was a functional repair of the esophagus that was histologically similar to the normal esophagus, although it was significantly dilated. Staining of the cells in the organoid units with green fluorescent protein prior to implantation allowed for verification that these cells were responsible for reconstituting the esophageal tissue.

Collagen Type I Scaffolds

A large body of literature describes the replacement of the esophagus with a composite collagen matrix and silicone stent.^[41–46] This composite approach has shown moderate success when the stent is left in place for a minimum of three weeks after surgery. Prior to three weeks, the mortality rate was nearly 100% and was associated with stricture and only partial epithelialization.^[43] With longer stenting of four to six weeks, survival has been observed for as long as 26 weeks after surgery, although some stenosis and contracture were still present.^[44] The remodeled tissue consisted of longitudinally oriented collagenous tissue without smooth muscle or glandular structures. The degree of success when stenting for three weeks compared to four weeks or greater was associated with the extent of reepithelialization.^[47]

Type I collagen scaffolds have also been studied with cell seeding prior to implantation. A sheet-like construct of esophageal epithelial cells, aortic smooth muscle cells, and dermal fibroblasts seeded on Type I collagen was implanted onto the latissimus dorsi of an athymic rat.^[48] The resulting remodeled graft had a structure similar to that of normal esophageal tissue. However, the tissue was not transplanted to the esophageal location so functionality was not determined. In summary, Type I collagen scaffolds show some promise for replacement of esophageal tissue. The work with collagen-based scaffolds also emphasizes the importance of complete reepithelialization to prevent stricture formation.

Cell Sheets

A cell-based approach for tissue reconstruction has been investigated for a number of tissues, including the corneal epithelium, urothelium, and periodontal ligament.^[49–52] Cell sheets have been formed by growing cells on specially designed culture dishes, which allow an intact, confluent monolayer to be detached from the surface of the dish. As no enzymatic treatments are used, the resulting cell sheet retains the extracellular

matrix (ECM) components produced by the cells and is robust enough to be handled and delivered to the site of implantation. Although such cell sheets have shown promise for reepithelialization of the esophagus after EMR, controlled studies are forthcoming. (Yamato, M. Personal communication, 2005.)

Naturally Occurring Scaffolds

Biologic scaffolds, such as ECM, that are derived from various tissues have shown a great deal of promise for esophageal reconstruction. An *in vitro* study showed that PLLA, PLGA, and PCL/PLLA (all synthetic scaffold materials) were inferior to AlloDerm (LifeCell Corporation, Branchburg, NJ), an ECM scaffold derived from human skin, when evaluated for epithelial organization and stratification.^[38] Naturally derived ECM scaffolds have also been investigated for *in vivo* esophageal tissue engineering. Surgically created full thickness defects in the cervical esophagus measuring 5 cm in length and encompassing 40–50% of the circumference or 100% of the circumference were repaired with small intestinal submucosa or urinary bladder submucosa. Well-organized, site-specific remodeling with esophageal tissue that was fully epithelialized and contiguous with normal esophageal tissue was present by 50 days after surgery in the partial circumferential defects. However, the full circumferential defects healed with stricture within 35 days after surgery.^[53]

In a subsequent study that used an ECM composed of the basement membrane and tunica propria of the porcine urinary bladder [urinary bladder matrix (UBM)], it was shown that critically sized, full circumferential defects could be repaired with minimal stricture formation if adjacent autologous smooth skeletal muscle tissue was placed in direct apposition to the ECM scaffold at the time of surgery.^[30] The maintenance of the basement membrane on UBM provides an ideal substrate for epithelial layer development, and this, combined with the presence of skeletal muscle cells, may have facilitated the epithelialization necessary to prevent or minimize tissue contracture.^[54] Spontaneous motility of the muscle within the remodeled section was shown by esophograms and endoscopy, although the motility did not appear to be synchronous with the native esophagus. The mechanical behavior of the graft was also evaluated, and it was shown that while the biologic scaffold material was much stiffer and stronger than the native tissue at the time of surgery, the remodeled tissue approached the mechanical behavior of the normal esophagus by three months after implantation. In summary, it appears that a regenerative medicine approach that includes both ECM scaffolds and autologous muscle cells holds promise for functional esophageal replacement.

T

CONCLUSIONS

Complete replacement of the esophagus after esophagectomy and reinforcement of the esophagus after anastomosis or EMR are important clinical applications for which tissue engineering/regenerative medicine approaches hold promise. Rapid epithelialization of a graft has been shown to be essential for the development of functional tissue without stricture. It appears that the presence of parenchymal cells associated with a biologic scaffold is important for the repair of the esophagus. However, it is not clear which cell types are most important. It has yet to be determined whether it is better to introduce the cells prior to in vivo transplantation or to utilize an autologous cell source in situ at the time of surgery. In summary, tissue engineering/regenerative medicine approaches for esophageal reconstruction appear promising, but significant work remains to be done before human clinical application becomes reality.

T

INTRODUCTION

There is a tremendous demand in reconstructive and plastic surgery for suitable grafts to repair soft tissue defects. Conventional inanimate implants represent only suboptimal solutions. Fat is the natural filler tissue for soft tissue defects. Surgeons already use autologous adipose tissue grafts, but current procedures are all afflicted with different disadvantages. Tissue engineering, that is, the *in vitro* and *in vivo* generation of biologically functional tissue substitutes, provides new strategies to overcome the existing limitations. Currently, two major approaches are pursued to create new adipose tissue: the implantation of cell-containing constructs and the induction of *de novo* genesis of adipose tissue *in vivo*. Therefore, the three classical components of tissue engineering, that is, cells, scaffolds, and tissue-inducing substances, are combined in various ways. Ongoing research is furthermore focused on the crucial process of vascularization of the generated fat. Additionally, engineered adipose tissue constructs have recently been established as a model system for basic research. The model especially considers three-dimensional cell–cell and cell–extracellular matrix (ECM) interactions and is proposed to be utilized in investigations on the endocrine functions of adipose tissue and fat-related diseases, such as obesity.

BACKGROUND

Clinical Need

A transplantable and biologically functional adipose tissue graft is especially required in reconstructive and plastic surgery. It is needed to compensate various soft tissue defects, for example, after tumor resections. In 2004 alone, over 60,000 clinically indicated breast reconstructions were reported by the American Society of Plastic Surgery and in the same year over 16,000 so far commonly used breast implants had to be removed again because of incompatibilities and other

problems.^[1] Furthermore, fat equivalents are needed to reconstruct congenital abnormalities and traumatic soft tissue defects, especially large burns or chronically open wounds. Cosmetic and aesthetic plastic surgeons would also prefer a natural implant to compensate contour deformities.^[2]

Current Surgical Techniques and Their Limitations

One approach to soft tissue replacement is to use alloplastic surrogates, such as Teflon and silicone implants, or allogeneic or xenogeneic materials, such as calcium hydroxyl apatite, hyaluronic acid (HA), collagen, and decellularized tissue matrix implants.^[1,3] The greatest drawbacks of these grafts are fibrous capsule formation, allergic or foreign body reactions, suboptimal mechanical properties, distortion and migration of the implant, and long-term resorption.^[2]

Another strategy to augment soft tissue defects is to use autologous tissue, which is regarded to be the ideal implant in terms of biocompatibility, immune response, and avoidance of tissue rejection. Smaller deformities are currently treated with isolated injections of mature adipocytes. However, as lipid-loaded adipocytes are very fragile, the majority of the fat cells are mechanically damaged during aspiration or preparation. The remaining cells tend to form cysts or localized necrosis postinjection. Free fat grafts also tend to get necrotic, as vascularization of the grafts is too slow leading to insufficient oxygen supply. Poor vascularization also includes limited transport of nutrients as well as deficient removal of metabolic waste products that may also contribute to the poor survival of the transplants. Therefore, these methods have an unpredictable outcome with regard to transplant shrinkage, and repeated surgery might become necessary. To overcome the limitations of insufficient neovascularization, pedicled flaps can be used. These grafts consist of subcutaneous fat, fasciae, and, if greater stability and integrity is necessary, muscle. The

vessels of the pedicled grafts are microsurgically integrated into the preexisting vasculature. These grafts show better survival rates; however, the surgical procedure is complicated and, therefore, cost-intensive. Furthermore, the acquisition of the flap might cause severe donor site morbidity, such as hypertrophic scar formation and constricted motility of the affected area.^[2]

Origin and Characteristics of Adipose Tissue

When seeking the optimal method to engineer adipose tissue as an alternative therapeutic approach, it is necessary to be aware of the typical characteristics of fat, its natural development, and its biological functions.

There are two types of adipose tissue: brown adipose tissue and white adipose tissue (WAT). Brown adipose tissue is an organ that dissipates energy in the form of heat and represents only a small portion of the total body fat.^[4] This work focuses only on WAT, which is the sole object of the current adipose tissue engineering research. White adipose tissue is located throughout the body, but most of it is situated subcutaneously and viscerally.

On the cellular level, WAT mainly consists of lipid-loaded mature adipocytes, adipocyte precursor cells and, as it is highly vascularized, various blood cells, epithelial cells, pericytes, and fibroblasts (Fig. 1).^[4] The origin of adipocytes is still not fully understood. Pluripotent embryonic stem cells are thought to give rise to multipotent mesenchymal stem cells (MSCs).

Fig. 1 Native fat (H&E staining). Accumulation of fat droplets that coalesce to one large droplet during adipocyte cell maturation leads to the displacement of the cytoplasm and the nucleus to the edge of the cell. This morphology is described as the signet ring form. Hexagonal-shaped adipocytes are surrounded by basement membrane. Capillaries are dispersed throughout the tissue. Bar = 50 μ m. (From Ref. [5].)

Further downstream the adipocytic lineage, it has been established that the commitment of MSCs leads to unipotent adipocyte progenitor cells.^[6] On the right environmental stimulation, these so-called preadipocytes can differentiate and mature into adipocytes.^[7] Many inducing factors, signal transduction pathways, and molecular events of adipogenesis are well characterized and summarized in various reviews.^[8,9] However, there are also mechanisms in adipose differentiation that have not been fully elucidated yet, such as the contribution of cell–cell or cell–ECM interactions.^[10,11] Adipose tissue development begins during fetal development; postnatal fat growth occurs either by enlargement of differentiated adipocytes (hypertrophy) or by recruitment of new adipocytes (hyperplasia).^[4,8]

The functions of fat are to serve as filling and isolation material and as a storage organ for energy homeostasis. In recent years, fat has additionally been established to be an active endocrine and immunological organ. In particular, adipocytes secrete various cytokines, hormones, and other biochemically active molecules involved in the regulation of insulin sensitivity, glucose homeostasis, inflammation, energy balance, lipid metabolism, reproduction, and vascular homeostasis.^[12]

STRATEGIES OF ADIPOSE TISSUE ENGINEERING

The aim of adipose tissue engineering approaches is to generate fat that is equivalent to native adipose tissue with regard to its cellular and extracellular structure and composition as well as its biological functions. Furthermore, it has to be nonimmunogenic to avoid allergic reactions and tissue rejection. In addition, it is important for clinical purposes to produce tissue volumes sufficient for the intended therapeutic use and to be able to create different implant shapes. The developed fat needs to be well vascularized and it must not be resorbed over time.

To comply with these requirements, presently two major strategies are pursued that differ primarily in whether cells are transplanted or not (Fig. 2). The first approach to generate fat equivalents is to implant cell-containing constructs. Cells are isolated from the desired donor tissue and, if necessary, propagated *in vitro* until a sufficient number of cells are obtained. After seeding onto or into a scaffold that functions as cell carrier, the construct is implanted. Alternatively, the cell-carrier constructs can be further cultivated and differentiated *in vitro* and implanted at later time points. Additionally, it is possible to administer

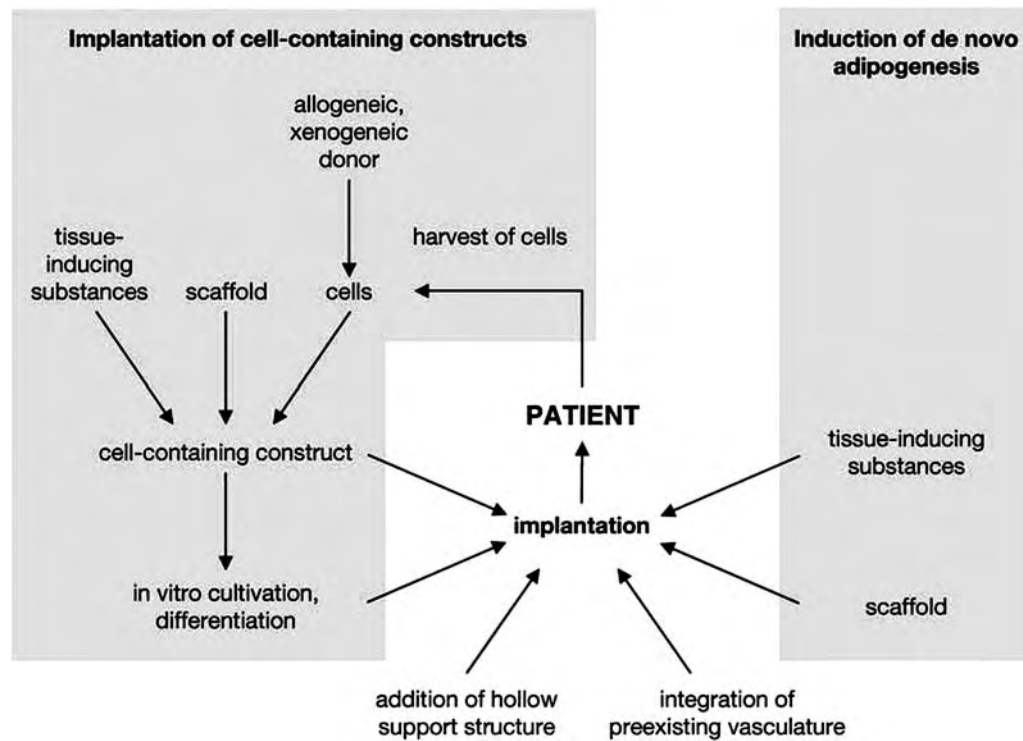

Fig. 2 Different strategies for the tissue engineering of fat. Left: implantation of cell-containing constructs; right: induction of de novo adipogenesis. The integration of preexisting vasculature and the addition of hollow support structures are options applicable in both strategies.

growth factors or tissue-inducing substances to enhance adipogenesis or also angiogenesis, either by simple injection into the recipient site or by application of a controlled release device. Furthermore, vascularization (i.e., oxygen supply, nutrient supply, and removal of waste products) can be enhanced by microsurgical integration of the preexisting vasculature.

The second strategy of fat engineering is to induce de novo adipogenesis *in vivo*. Here, only adipose tissue-inducing substances are administered. These substances then facilitate the *in vivo* development of preferably vascularized adipose tissue. Also in this case, the application of supporting scaffolds and the integration of preexisting vasculature are additional options. In comparison with the first strategy, here no cells are transplanted. This can be advantageous in future clinical applications because problems concerning the harvest and immunological compatibility of the cells would be avoided and no cost- and time-intensive *in vitro* cell culture would be necessary.

In the following chapters the main components of both strategies, i.e., cells, scaffolds, tissue-inducing substances, and vascularization, are discussed in detail; here, the corresponding adipose tissue engineering studies are only mentioned. Subsequently, an extensive

discussion of the approaches and achievements of these publications is provided.

Cell Sources

The ideal cells for the engineering of fat should fulfill the following criteria: The cells need to be autologous or, at least, nonimmunogenic. The cells have to be available in sufficient quantities either by direct harvest of enough material or by their propagation *in vitro* without the loss of their potential to differentiate into adipocytes. The harvest should be possible with minimally invasive procedures to ensure minimal donor site morbidity. Potential cell types generally can be found along the adipocytic lineage.

Mature adipocytes

As already mentioned, mature adipocytes are very fragile and easily traumatized during cell preparation. It is principally possible to maintain and propagate differentiated adipocytes *ex vivo*; however, these cultures are difficult to handle *in vitro* because of the buoyancy of lipid-loaded cells.^[13,14] The use of mature adipocytes is, therefore, not a prevalent method.^[7]

Preadipocyte cell lines

Other possible cell sources are preadipocyte cell lines, for example, 3T3-L1 and 3T3-F442A.^[5,15-17] These cells are commercially available and can easily be propagated and differentiated into adipocytes in vitro. Major drawbacks of cell lines are their aneuploid status and xenogeneic origin. A clinical use of preadipocyte cell lines is therefore unlikely. However, in contrast to primary cell sources, cell lines are reproducibly uniform in their process and status of differentiation. Therefore, they are an appropriate cell type to establish the principles of fat engineering and they are well suited for model systems in basic research.^[5,7,16,17]

Adipose-derived progenitor cells

The cell source that is currently utilized in most cell-based approaches and that is estimated most promising for clinical purposes is adipose-derived progenitor cells.^[18-27] Adipose tissue contains a cellular fraction that can be isolated by enzymatic digestion of fat tissue, optional differential centrifugation, and subsequent adherence to plasticware surfaces. This fraction of cells has been variously termed adipose-derived (adherent) stromal cells, processed lipoaspirate cells, adipose-derived (adult) stem cells, and preadipocytes.^[28] Today this cell pool is considered to be a mixture of, among others, noncommitted multipotent stem cells that can differentiate at least along all the mesenchymal lineages, and committed unipotent preadipocytes that can only differentiate into adipocytes. At the moment, no distinct markers are established, which could facilitate the strict separation between stem cells and preadipocytes. Therefore, this cell pool will be subsumed as adipose-derived progenitor cells in this work.

Adipose-derived progenitor cells are easily available from lipoaspirates or liposections. A device that combines direct harvest of lipoaspirates and isolation of cells has already been developed.^[29] A shortage of autologous donor tissue is unlikely for most patients. Furthermore, several in vivo studies support the general feasibility of allogeneic adult stem cell transplantation.^[6] Allogeneic transplantations carry the risk of immune rejection by the host and transfer of infectious agents. Nevertheless, the possible use of allogeneic cells would enable the fabrication of off-the-shelf transplants eliminating the need to perform elective liposuction to obtain autologous cells and facilitating faster treatment. Therefore, it is currently discussed whether also an allogeneic transplantation of adipose-derived progenitor cells is possible.^[28]

Adipose-derived progenitor cells have the capacity to proliferate in vitro over several passages with low

levels of senescence and with conservation of their potential to differentiate into adipocytes.^[30,31] However, it has to be considered that the self-renewing and differentiation capacity of this heterogenous cell pool may vary depending on the donor itself (sex, age, and health status) and the donor site (epididymal, mammary, subcutaneous, omentum, etc.).^[32] Fat depots at different sites of the body can vary substantially with regard to fat cell morphology and function. These differences are discussed to be not solely a result of site-specific environmental factors (nutrient availability, innervation, anatomic constraints, etc.) modulating the development of mature adipocytes but also a result of the site-specific characteristics of preadipocytes the mature fat cells originate from.^[33]

Bone marrow-derived MSCs

Whereas they have been applied in the engineering of several other tissues for years, only recently, bone marrow-derived MSCs have also been used for adipose engineering purposes in different studies.^[34,35] Mesenchymal stem cells can be isolated from bone marrow aspirates.^[6] The easiest way to separate MSCs from other cellular fractions, that is, primarily the hematopoietic fraction, is by their tendency to adhere to tissue culture plastic. Other possibilities to further purify MSCs are differential centrifugation and fluorescent activated cell sorting or magnetic activated cell sorting. However, no selective surface markers to identify the "pure" MSC have been established yet.

Bone marrow-derived MSCs were reported to have a high self-renewal potential in vitro.^[36,37] They differentiate into adipocytes in vitro and in vivo on adipogenic stimuli. Mesenchymal stem cells are discussed to be nonimmunogenic in allogeneic transplantations.^[6] In contrast to adipose-derived progenitor cells, harvest of bone marrow-derived MSCs is more inconvenient for the donor and only smaller amounts are accessible. The properties of the isolated MSC pool are also donor-dependent.

Embryonic stem cells

Embryonic stem cells have not been used for the tissue engineering of fat yet, but have to be mentioned as a possible cell source in the future. The major advantage of embryonic stem cells is their almost infinite proliferation potential and their capacity to differentiate into a wide variety of cell types, such as adipocytes.^[38,39] Ethical concerns and legal constraints limit the application and availability of human embryonic stem cells at present. Nevertheless, cells from other species, such as mouse embryonic stem cell lines, are readily available for basic research purposes.

Scaffold Materials

A scaffold can serve as a template for the desired three-dimensional shape of the engineered tissue. Current opinion favors biodegradable scaffold materials that provide initial, transient stability. The newly developed tissue, that is, the cells and secreted ECM, is responsible for the long-term maintenance. Therefore, it is necessary to adjust the degradation kinetics to the tempo of tissue development. The bulk material and its biodegradation products need to be biocompatible. Further requirements are adequate mechanical properties; very rigid scaffolds might not be appropriate to augment soft tissue defects. The surface structure and chemistry should allow cell attachment and facilitate differentiation and maintenance of the biological functions of the cells. Another very critical feature is the microarchitecture of the scaffolds. High porosity and interconnectivity are necessary to guarantee an even distribution of the cells, capillary ingrowth, and sufficient nutrient supply. A specific characteristic of adipocytes is that they enlarge to over 100 μm in diameter during maturation and potentially change their size because of their lipid storage function in energy homeostasis. Therefore, adequately large pore sizes within the scaffold have to be provided to enable full differentiation of the cells.^[22]

Synthetic materials

Possible scaffold materials include synthetic biodegradable and absorbable polymers, such as polylactic acid (PLA), polyglycolic acid (PGA), and copolymers thereof, which are Food and Drug Administration (FDA) approved and clinically widely used as sutures. Disadvantages of these materials are their acidic degradation products, which may affect cell functions and the lack of chemically reactive groups that are easily accessible for surface modifications. For adipose tissue engineering, these polymers have been processed by salt-leaching techniques or solid-lipid templating, which leads to relatively stiff scaffolds.^[18,19,34,40] Softer constructs are achieved by the use of meshes fabricated with textile technologies.^[5,16] Polytetrafluoroethylene (PTFE) is a non-biodegradable polymer that has already been used as filling material in aesthetic surgery. Polytetrafluoroethylene scaffolds proved useful to seed preadipocytes if coated with ECM proteins.^[24]

Semisynthetic and natural materials

One approach is to mimic the native cellular environment of fat cells by the use of ECM compounds naturally occurring in adipose tissue, such as collagen

or further compounds of the basement membrane. Further options are materials based on extracellular components of other tissues, such as fibrin glue or HA esters. These materials are characterized by low toxicity and, if autologous material is used, by a low inflammatory response. Furthermore, most ECM compounds can be processed into gels, which allow minimally invasive application. Drawbacks, however, include batch-to-batch variations, easy denaturation, and difficult chemical modification due to their complex structure. The relatively low mechanical stability of ECM-based scaffolds may not be a major problem in soft tissue engineering.

Collagen has been used as gels or as porous sponges produced by freeze-drying of diluted solutions.^[20,22,23] It has been reported that collagens enhance the adipose conversion of precursor cells.^[41] Major disadvantages of collagens are their potential immunogenicity and relatively high price. Matrigel is a basement membrane extract derived from Engelbreth-Holm-Swarm mouse sarcoma, which is rich in ECM. The main components of Matrigel are laminin, collagen type IV, proteoglycans, and entactin, which are all components of the basement membrane that surround adipocytes in native tissue. Furthermore, it contains different growth factors, such as platelet-derived growth factor (PDGF), transforming growth factor (TGF- β), and basic fibroblast growth factor (bFGF); however, the exact composition is not defined. Matrigel promotes cell attachment of adipocyte precursor cells, adipogenesis, and angiogenesis in vivo.^[15,42,43] However, it is still unclear to what extent this effect can be attributed to the presence and architecture of the ECM compounds or to the existence of the adipogenic and the angiogenic growth factors. It has to be noted that as Matrigel is a mouse tumor product, it does not appear appropriate for clinical purposes. Fibrin glue is already FDA approved for a variety of clinical applications and has also been used for adipose tissue engineering purposes.^[26,27,44] It can be produced from autologous blood, thereby avoiding tissue reactions. Fibrin is dissolved rapidly in vivo by proteases, but residence time can be prolonged by adjusting the process parameters during gelation and addition of protease inhibitors.^[45,46] Hyaluronic acid is highly soluble and, therefore, rapidly resorbed in vivo. But esterification of HA leads to insoluble polymers that can be easily processed into sponges or fiber meshes suitable for fat engineering.^[20,21] An advantage of HA-based scaffolds might be that degradation products of HA are known to enhance angiogenesis in vivo.^[47]

Besides ECM compounds, other biological materials, such as alginates, can be used as scaffold materials. Alginates are cheap, biocompatible, and nontoxic. But as they are strongly hydrophilic, protein adsorption is reduced. Therefore, chemical modifications, such

as the linkage of lectins or RGD-containing adhesion peptides, are necessary to enable cell–material interactions.^[25]

Growth Factors and Adipogenic Inducers

On the one hand, the scaffold itself as well as its degradation products can enhance adipose tissue development, as discussed in the previous entry. On the other hand, there are a great number of publications that identify growth factors and other biological or pharmaceutical agents that influence proliferation and differentiation of adipocyte precursor cells and adipose tissue development. In some cases, the studies come to contradictory results, most probably because of the fact that different cell lines and primary cell types have been studied under diverse culture conditions. A summary of growth factors and adipogenic inducers that can be used for adipose tissue engineering purposes is given in the following.

One important step during the generation of cell-based constructs is the efficient expansion of precursor cells *in vitro*. Factors that enhance *in vitro* proliferation of adipose-derived progenitor cells and bone marrow-derived MSCs include insulin-like growth factors (IGF-1, IGF-2), acidic FGF, bFGF, epidermal growth factor (EGF), and PDGF; TGF- β 1 is reported to stimulate the proliferation of adipose-derived progenitor cells, but inconsistent results exist concerning the growth of MSCs.^[29]

In vitro adipogenesis of adipose-derived progenitor cells and bone marrow-derived MSCs can be induced by administration of a hormonal cocktail typically composed of insulin or IGF-1, a glucocorticoid (corticosterone, dexamethasone, hydrocortisone, etc.), and cAMP or an agent increasing intracellular cAMP levels, such as phosphodiesterase inhibitors (isobutylmethylxanthine and forskolin).^[8] Furthermore, agonists of peroxisome proliferator-activated receptor gamma (PPAR γ), a key transcription factor during adipogenesis, also can be used either alone or in combination with the mentioned hormonal cocktail to induce adipogenesis. The PPAR γ agonists include thiazolidinediones (rosiglitazon, troglitazon), indomethacin, and prostaglandins of the D and J series that have recently been found to be natural ligands of PPAR γ .^[48] Growth hormone and thyroid hormone have been reported to enhance adipogenesis of preadipocyte cell lines, but they have no or even a negative effect on the differentiation of primary precursors.^[8] The influence of bFGF on adipogenesis is controversially discussed. Basic FGF has been considered to inhibit adipogenesis of preadipocyte cell lines and primary adipose-derived progenitor cells.^[8] However, recent studies have shown a distinct increase of

adipogenesis of MSCs when bFGF was administered.^[34,49] Most of the knowledge about adipogenic inducers has been gained *in vitro*. The physiological relevance of the inducing hormones is still not fully clear. Nevertheless, administration of IGF-1 and insulin can induce *de novo* adipogenesis *in vivo* and prolong survival of newly generated or transplanted mature adipose tissue.^[50,51] *In vivo* application of bFGF also induces *de novo* adipogenesis.^[23,26,42,50,52] However, it is unclear whether bFGF has a direct adipogenic effect or adipogenesis is triggered through neoangiogenesis. (For a more detailed discussion of the relation between adipogenesis and angiogenesis, see the next entry.) Besides the search for inducing agents, the way of *in vivo* application has to be considered. Several of the aforementioned studies revealed that simple injection of the substrates is less effective than application of devices that enable the controlled release over a defined and adjustable period of time.^[23,42]

Vascularization

As already mentioned above, vascularization is a crucial requirement for adequate development and long-term survival of engineered adipose tissue. Fat is a highly vascularized organ with every adipocyte attached to at least one capillary. Moreover, the metabolism of adipose tissue is even higher than that of muscle, if normalized to the amount of cytoplasm. Thus, it is reasonable that adipose tissue easily gets necrotic in avascular areas.^[2] Furthermore, fetal and adult adipogenesis is spatially and temporally closely related to angiogenesis.^[53,54] Both processes are coordinated via an intensive cross-talk between endothelial cells and adipocytes. Endothelial cells secrete various soluble and matrix-bound factors which promote proliferation as well as differentiation of adipose-derived progenitor cells; one of these factors has been identified as acidic FGF.^[55–57] Platelet-derived growth factor is also found to be involved in the cross-talk, as it is secreted by endothelial cells and enhances adipose precursor cell proliferation.^[29,58] In turn, established adult adipose tissue modulates angiogenesis via several secreted factors, such as vascular endothelial growth factor (VEGF), angiopoietin-1, and others.^[53,59]

Different strategies are pursued to enhance vascularization of the engineered adipose tissue. One approach that has been adopted from surgical procedures is the integration of preexisting capillary structures into an implanted scaffold.^[52,60] The vascular pedicle provides initial oxygen and nutrient supply and is the origin for sprouting capillaries. Another strategy is the administration of angiogenic growth factors, such as VEGF and bFGF, which recruit

endothelial cells and their precursors and enhance sprouting of new vessels.^[26,42,50,52] Effects of growth factors might be improved via a prolonged application by the use of controlled release devices or gene transfer. Vascularization can also be achieved by transplantation of endothelial cells, which then form vascular networks within the newly formed tissue.^[27]

CURRENT APPROACHES AND ACHIEVEMENTS

In Vitro Studies

In vitro cultures have been used for different purposes in adipose tissue engineering. Several researchers utilized in vitro studies to explore the suitability of new scaffold materials with regard to their interaction with cells. von Heimburg et al. seeded adipose-derived progenitor cells onto different sponges consisting either of collagen or of HA benzyl esters (HYAFF[®] 11) of various degrees of esterification and different pore sizes.^[21,22] In analog studies, it was shown that adipose-derived progenitor cells adhere also to the salt-leached PLGA scaffolds or PTFE scaffolds.^[18,24] The latter have to be coated with ECM components to enable cell attachment; fibronectin turned out to be more effective than albumin and collagen. Furthermore, all of these studies proved that the precursor cells differentiate into adipocytes and develop a mature phenotype within the scaffold. Hong et al. established that also human bone marrow-derived MSCs are capable of differentiating into mature adipocytes in a three-dimensional context.^[35] However, none of the aforementioned studies could show in vitro formation of coherent tissue.

Other studies aimed at engineering mature adipose tissue in vitro. Neubauer et al. seeded bone

marrow-derived MSCs onto PLGA scaffolds.^[34] On repeated hormonal induction, MSCs matured into adipocytes; administration of bFGF significantly enhanced adipogenesis. After 4 weeks of cultivation tissue-like structures with mature unilocular adipocytes could be detected at least in the outer areas of the scaffolds, whereas isolated immature, multivacuolar adipocytes were observed in the inner parts. So far only one approach achieved the development of coherent adipose tissue in vitro.^[5] Constructs consisting of 3T3-L1 preadipocytes and PGA nonwoven fiber meshes were cultivated over 5 weeks in vitro. Cells differentiated into mature adipocytes exhibiting the typical signet ring form and the constructs developed into coherent fat pads histologically comparable to native adipose tissue (Fig. 3A).

In Vivo Studies

Implantation of cell-containing constructs

The first study conducting the implantation of cell-containing constructs to engineer adipose tissue was presented by Patrick et al.^[18] Adipose-derived progenitor cells seeded onto salt-leached PLGA scaffolds were subcutaneously implanted into rats. After 5 weeks, clusters of vascularized adipose tissue had developed within the implant with remnants of scaffold material dispersed throughout the construct. Further in vivo investigation revealed that the implants as well as the newly formed adipose tissue were completely resorbed after 4 mo.^[19] As this time point correlated with the degradation kinetics of the scaffold material, the engineered tissue was probably absorbed when the supporting structure broke down. In comparable studies, von Heimburg et al. used HYAFF

Fig. 3 Adipose tissues engineered with different strategies (H&E staining). (A) Coherent fat pads generated in vitro. Preadipocytes (3T3-L1) were seeded onto PGA nonwoven fiber meshes, hormonally induced, and further cultivated for 5 weeks. Bar = 50 μ m. (B) Formation of adipose tissue (lower part of the image) in the subcutis of BALB/c mice 6 weeks after implantation of collagen sponges incorporating human adipose-derived precursor cells and gelatin microspheres containing 1 μ g of bFGF. Bar = 300 μ m. (C) De novo formation of adipose tissue (lower part of the image) in the subcutis of BALB/c mice 15 weeks after implantation of Matrigel mixed with gelatin microspheres incorporating 0.1 μ g of bFGF. Bar = 150 μ m. (From Refs. [5,23,42].)

sponges, HYAFF nonwoven fiber meshes, and collagen sponges as cell carriers.^[20,22] Scaffolds were seeded with human adipose-derived progenitor cells and implanted subcutaneously for up to 12 weeks. Only within HYAFF sponges could areas of vascularized adipose tissue be detected. In contrast, implant sizes of HYAFF nonwoven fiber meshes and collagen sponges drastically decreased over *in vivo* time. The fiber meshes had collapsed during implantation; thus, the space available for preadipocyte growth and differentiation was significantly reduced. After explantation of collagen sponges, mature adipocytes were only located in the surface areas of the scaffolds. This was probably due to the fact that cells could not fully penetrate the collagen sponges because of their small pore size (40–100 μm). Another material used for the delivery of adipose-derived progenitor cells is alginate modified with a covalently bound cell-adhesion peptide (arginine-glycine-aspartic acid, RGD).^[25] Progenitor cells suspended in alginate–RGD also developed into adipose structures after subcutaneous implantation into sheep.

The application of growth factors in conjunction with cell-containing constructs can enhance *in vivo* adipose tissue formation. Human adipose-derived progenitor cells seeded on collagen sponges and implanted into the subcutis of mice for 6 weeks gave rise to adipose tissue only if bFGF was administered.^[23] Best results were achieved when bFGF was released over an extended period of time from gelatin microparticles (Fig. 3B). Yuksel et al. used PLGA/PEG microparticles to locally release insulin, IGF-1, and bFGF.^[50] All three growth factors were reported to increase the survival of transplanted diced mature adipose tissue fragments for up to 12 weeks, but bFGF led to infiltration with interadipocyte stromal tissue. Generation of adipose tissue with the help of growth factors resulted in the development of more coherent fat pads; however, also in these cases the long-term maintenance has not been established yet.

Whereas, in the studies described above, constructs were implanted shortly after cell seeding, a different approach is to implant cell-containing constructs that already have been induced and cultivated *in vitro*.^[5] Implantation of coherent fat pads, generated from 3T3-L1 preadipocytes and PGA nonwoven meshes (see previous entry) resulted in vascularization and further development of the constructs. The size of the engineered fat was maintained *in vivo* over 3 weeks, but a long-term investigation was not conducted.

The mentioned approaches show that adipose tissue engineering based on the application of cell-containing constructs is, in principle, possible with various types of scaffolds. However, volumes of the constructs were smaller than 1 ml in all cases. Furthermore, long-term survival (>6 mo) of engineered fat was not achieved or

not investigated in these studies. One important reason why newly generated fat is absorbed is the insufficient neovascularization of the constructs. Schoeller et al. showed that adipose-derived progenitor cells can develop into mature adipose tissue that persists over 12 mo if implanted into well-vascularized capsules.^[44] These capsules were formed by inducing a foreign-body reaction through implantation of silicon tubes. This study clearly points out that a sufficient blood supply is necessary for long-term survival, but it is questionable if this technique of capsule formation is clinically applicable.

Induction of de novo adipogenesis

Application of bFGF in combination with Matrigel but without the addition of any cells proved to induce de novo development of adipose tissue in different studies.^[42,43] The newly formed fat was a well-vascularized coherent tissue consisting of mature adipocytes (Fig. 3C). Long-term release of bFGF from gelatin microspheres enhanced the effect of bFGF. Matrigel and bFGF are both known to enhance angiogenesis. Further proadipogenic effects of bFGF are currently being discussed. It is not fully understood yet whether the combination of Matrigel and bFGF induces adipogenesis directly or via the development of capillary structures within the transplant. Interestingly, neither injection of bFGF nor Matrigel alone could induce de novo adipogenesis; however, there are no obvious explanations for this synergy. Despite the good quality of the de novo engineered fat, it has to be mentioned once more that Matrigel is a tumor mouse product and, therefore, not suitable for clinical applications. Besides the effects of bFGF, Yuksel et al. reported that long-term delivery of insulin or IGF-1 also induced de novo adipogenesis.^[51] Especially, coimplantation of insulin- and IGF-1-loaded PLGA/PEG microspheres led to the development of mature vascularized adipose tissue. However, similar to the studies in which cell-containing constructs were implanted, volumes generated via de novo adipogenesis also did not exceed 1 ml and no long-term study has proved the survival yet.

Implantation of synthetic hollow support structures

A recent trend in adipose tissue engineering is to implant synthetic hollow support structures consisting of silicone, PGA/PLA, or polycarbonate (Fig. 4A).^[26,52,60] These approaches take advantage of the natural characteristic of fat to fill void spaces. Furthermore, such support structures could protect the developing fat from potentially deforming forces. On the one hand, the structures were placed around

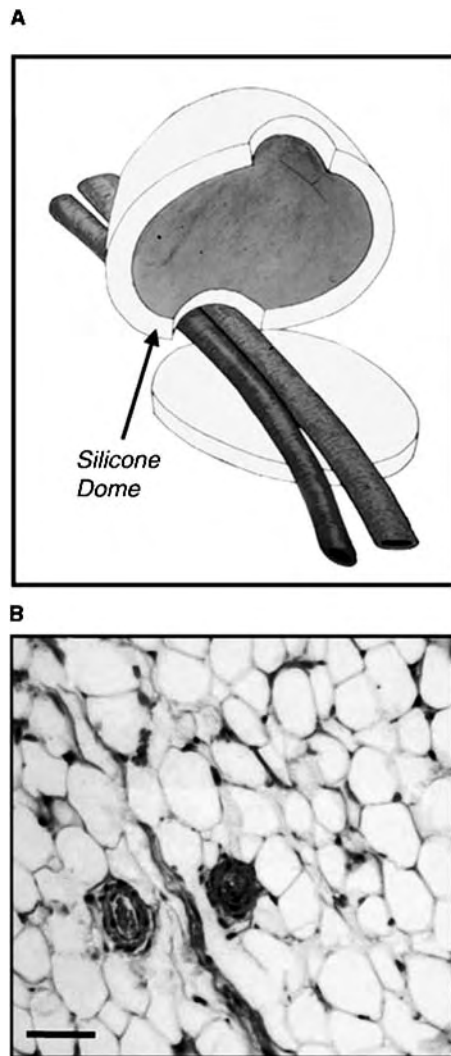

Fig. 4 Application of hollow support structures. (A) Diagram of dome-shaped construct placed around preexisting vasculature. (B) Adipose tissue engineered within a hollow silicon support structure (H&E staining). Injection of Matrigel and bFGF into the mold induced de novo formation of mature fat. Bar = 200 μm . (From Ref. [52].)

existing vasculature and filled either with Matrigel and bFGF or with fibrin, Matrigel, or PLGA.^[52,60] Invasion and differentiation of preadipocytes led to de novo adipose tissue formation within the capsule (Fig. 4B). On the other hand, injection of preadipocytes suspended in fibrin glue in dome-shaped structures also gave rise to mature adipose tissue.^[26] It was reported in a conference contribution that by this principle it was possible to generate larger adipose tissue volumes in the order of 50 ml in a pig model.^[60] However, specific procedures and results have not been further published yet. Though current results are quite promising, it has to be considered that these approaches require complex surgical procedures

during implantation; furthermore, biodegradable structures have to be developed to avoid the otherwise inevitable explantation of the support structures.

TISSUE-ENGINEERED FAT FOR BASIC RESEARCH

Besides the interest of plastic and reconstructive surgeons, fat is also the topic of research concerning obesity and related disorders, such as accelerated atherosclerosis, increased risk of thrombosis, hypertension, insulin resistance, and type 2 diabetes. Fat has been established to be an active endocrine organ involved in many important physiological and pathological processes.^[12] (See also entry “Origin and Characteristics of Adipose Tissue.”) Therefore, rapidly increasing efforts have been made to investigate the basic understanding of adipogenesis, fetal and adult adipose tissue development, and regulation of adipocyte functions. Most of the knowledge about molecular regulation of adipocytes has been acquired using two-dimensional *in vitro* cell cultures with preadipocyte cell lines, such as 3T3-L1, 3T3-F442A, or Ob-17. Two-dimensional cultures are appropriate model systems for many questions; however, they only marginally reflect the physiological environment of adipose tissue. Recent research has suggested that adipogenesis as well as regulatory or secretory functions of adipocytes are influenced by tissue inherent factors, such as cell–cell or cell–matrix interaction.^[8,53] Tissue-engineered model systems could overcome existing experimental limitations by providing three-dimensional fat constructs that partially mimic the *in vivo* environment. Recently, Fischbach et al. presented a system to develop coherent adipose tissue *in vitro* (see entry “*In vitro* studies”).^[5] This study reported several differences in adipocyte morphology and function depending on whether cells were cultivated in two-dimensional culture plates or within three-dimensional constructs (Fig. 5). Although no coherent tissue was presented, differences in adipocyte marker gene and protein expression between two-dimensional and three-dimensional cultures were also found by Kang, Xie, and Kniss, who recently established a similar model consisting of 3T3-L1 cells cultivated on fibrous PET scaffolds.^[17] A drawback of the presented models might be that immortalized cell lines have different properties from primary cells with regard to proliferation potential and differentiation capacity. However, on the other hand, the use of a cell line provides reproducible and standardized conditions. Therefore, these and other tissue-engineered systems may be used to address the relevance of interactions between adipocytes and their surroundings and may contribute to the further elucidation of the important secretory

Fig. 5 Comparison of cell and tissue development in two- and three-dimensional cell culture systems. Scanning electron micrograph images of 3T3-L1 cells grown in vitro in two-dimensional cell culture or three-dimensional tissue-engineered constructs. Cells in two-dimensional monolayers are loosely connected to each other and ECM sheets are preferentially deposited on the cell surface. In contrast, three-dimensional differentiated adipocytes are situated within a coherent environment featuring three-dimensional cell-cell and cell-ECM interactions. Bar = 20 μm . (From Ref. [5].)

functions of adipose tissue. In turn, the knowledge gained on microenvironmental characteristics can contribute to improving the engineering of biologically functional adipose tissue.

CONCLUSIONS

To date, several approaches have been investigated to engineer adipose tissue in vivo and in vitro. Different strategies have been presented including the implantation of cell-containing constructs and the de novo generation of fat. In principle, both strategies enabled the generation of fat constructs. However, there are still major questions to be solved until clinical application becomes a reality. First, methods have to be established that facilitate the long-term survival of the engineered constructs. The problem of fat implant resorption that has bothered plastic surgeons for over

almost 100 yr has not been solved satisfactorily by tissue engineers yet. This problem is closely related to the necessity to enhance early and sufficient vascularization of the constructs. Furthermore, it will become inevitable to investigate not only the histological characteristics but also the functionality of the newly generated tissue. To date, only small volumes of engineered fat have been generated. These constructs might be available for clinical purposes in the near future, such as aesthetic facial augmentations. In contrast, it will take more time until it is possible to generate fat transplants sufficient for the treatment of larger defects, for example, after breast tumor resections. Finally, similar to the situation in other tissues, it may be considered if the use of autologous material is strictly necessary or if allogeneic or xenogeneic cells and matrices may also be applicable, enabling, in the long run, the development of off-the-shelf products. Until engineered adipose tissue becomes a widely applicable alternative in plastic and reconstructive surgery, much more intensive research by clinicians, bioengineers, and life scientists is required.

Tissue Engineering of Heart Valves

Ivan Vesely

Biomedical Engineering, The Cleveland Clinic Foundation, Cleveland, Ohio, U.S.A.

INTRODUCTION

Valvular heart disease is a slow, debilitating process during which the cardiac valves become stenosed or incompetent. Unless the diseased valve is repaired or replaced with either a bioprosthesis or mechanical artificial valve, this disease eventually results in cardiopulmonary failure and death. Mechanical valves are typically constructed from pyrolytic carbon, and bioprostheses are fabricated from glutaraldehyde-tanned bovine pericardium or whole porcine aortic valves (Fig. 1). These devices, however, are imperfect. Mechanical valves are rigid, require chronic anticoagulant therapy, and can fail suddenly and catastrophically.^[1,2] The rigid construction can lead to perivalvular leaks, and the chronic anticoagulation is associated with cumulative morbidity and mortality.^[3] The rates of anticoagulant-related morbidity can be as high as 5% per year,^[4] essentially guaranteeing an untoward event within 20 years. Animal tissue valves or bioprostheses, on the other hand, are flexible and do not require anticoagulation. Unfortunately, they have poor long-term durability. The bioprostheses fail through calcification and rupture of the valve cusps,^[5] and eventually need to be replaced. Reoperation to replace a failed bioprosthetic valve, however, carries significant operative risk. When the chest is re-opened to access the heart, the adhesions between heart and thoracic cavity can cause rupture of the heart. Furthermore, removing a failed bioprosthesis is very time-consuming due to considerable tissue ingrowth into the sewing ring. This requires additional time on cardiac bypass and increases the chance of complications. Because the operative mortality to replace a failed bioprosthetic valve can be as high as 20% for the elderly,^[6,7] bioprostheses are intended to be implanted only once and should last the life of the patient. Because they last only 10 to 12 years,^[3,8-10] they are used only in the elderly who are not expected to outlive their bioprosthetic valve. However, due to their excellent short-term function and lack of long-term morbidity, bioprostheses are considered by many to be the ideal replacement heart valve. Surgeons would prefer to implant a tissue valve, but must resort to a mechanical prosthesis if patients are too young and at risk of outliving their bioprostheses. If it wasn't for their poor long-term durability, bioprosthetic valves could be used in practically all patients. At present, the

most durable of the tissue valves appears to be the allograft, a transplanted human aortic valve.^[11] Because donor human valves are in short supply, however, the majority of the tissue valves implanted are made from glutaraldehyde-tanned porcine aortic valves or bovine pericardium. Indeed, the bioprosthesis is making a strong comeback in its popularity relative to the mechanical valve. Surgeons and patients alike are becoming less tolerant of accepting the complications of anticoagulant therapy and in the United States today, more tissue valves than mechanical valves are implanted every year. Tissue valves have been recognized as the valve of choice in the United States for the majority of cardiac valve patients, in spite of their limited durability.

T

THE CURRENT PROBLEM

A more critical need for tissue valves exists for children and young adults. A large fraction of valve replacement occurs for congenitally bicuspid aortic valves that need to be replaced at an early age.^[12] Unfortunately, the implanted bioprostheses calcify in a few years in young adults, and in as little as a few months in children.^[13] A conventional bioprosthesis is therefore not an option for these patients; they must receive a mechanical valve and be placed on permanent anticoagulant therapy. Warfarin therapy requires a strict protocol of daily oral doses and periodic testing of blood coagulation at the hospital. Side effects include bruising and uncontrolled bleeding and even strokes and infarcts. This seriously decreases the quality of life of active people. Warfarin is also teratogenic and unsuitable for women in child-bearing years. These patients must therefore be on daily injections of heparin and face major complications during labor. For this smaller but very significant subpopulation of patients, current prosthetic valve solutions are simply not acceptable. There is therefore a critical need to develop better, more long-lived tissue valves that do not succumb to early degenerative failure.

Mechanisms of Bioprosthetic Valve Failure

Bioprosthetic heart valves degenerate through calcification and mechanical damage. Large calcific growths

can impede leaflet motion causing stenosis, but often result in leaflet tearing and hence massive regurgitation. For many years, calcification has been promoted as the main mechanism of valvular degeneration, with tearing thought to be secondary to calcification.^[1] Opinion has recently shifted toward recognizing that mechanical damage and calcification can be two separate processes, each with different initiators.^[5] In the current generation of porcine bioprosthetic valves, calcific degeneration appears to be a relatively minor issue, with the majority of the damage occurring strictly for mechanical reasons.^[14,15]

Role of Mechanical Damage in Calcification

Pathologic examinations of a large number of prosthetic valves with torn leaflets have shown that free-edge tears occur frequently in the absence of calcification^[16–18] in the areas that experience highly localized mechanical forces. Therefore, a purely mechanical mode of failure must also be responsible for a large percentage of bioprosthetic valve failures. The prosthetic valve cusps experience high transient stresses during valve closure, and cyclic flexural and compressive stresses during valve opening. Although it was initially believed that tensile stresses induced during valve closure were responsible for cuspal tearing, studies have shown that tissue rupture is related to flexural fatigue^[14,16,19] and the presence of compressive stresses on the inner surface of the bent tissue.^[20] Others have theorized that the cyclic compressive stressing of the valve cusps disrupts the collagen architecture^[21] and exposes calcium-binding sites believed to exist on the collagen molecule.^[22,23] This stimulates calcification, disrupts the material, and may promote further calcification.^[24,25]

Mechanical Basis for Valvular Degeneration

The relevance of mechanical degeneration to tissue engineering is the experience with aortic valve allografts. These valves are harvested from cadavers and

Fig. 1 Images of a typical mechanical valve (left) and a porcine bioprosthetic valve (right), also called a xenograft.

implanted into patients without any chemical preservation. These valves do not contain viable cells in the long term^[26] and therefore do not remodel, yet remarkably they do not disintegrate and fail rapidly. Aortic valve allografts, in fact, last longer in most patients than do glutaraldehyde-preserved xenografts, and are considered the optimal biologic valve.^[11] Not surprisingly, the mechanical properties of allograft valves are nearly identical to those of the native aortic valve.^[27,28] Their success as functional, load-bearing, biomechanical devices results not from chemical stabilization like the bioprostheses nor from an ability to repair and remodel like other tissues in the body, but rather from their inherent structural strength, durability, and fatigue resistance. Allograft valves are therefore durable only because they have the appropriate microstructure and mechanical properties.

AORTIC VALVE CUSP MICROSTRUCTURE AND MICROMECHANICS

Aortic valve cusps consist of three layers of morphologically distinct tissue: the fibrosa, spongiosa, and ventricularis^[29] (Fig. 2). Toward the aortic surface is the fibrosa, consisting mainly of collagen fiber bundles arranged primarily in a circumferential direction; that is, running from commissure to commissure. Starting at one commissure, these fiber bundles spread out into a somewhat isotropic mesh near the belly of the cusp, then combine again into clearly visible bundles toward the opposite commissure (Fig. 3). The ventricularis consists mainly of sheet elastin with some collagen arranged in a highly folded manner. It is much thinner than the fibrosa and does not have the rough surface topography. Separating the fibrosa and ventricularis is the very loosely organized spongiosa, consisting of collagen, elastin, and glycosaminoglycans (GAGs). The GAGs bind water readily and give the spongiosa a gelatinous, watery consistency. The specific function of the spongiosa is not yet well understood but is believed to be a buffer zone that enables the localized movement and shearing between the fibrosa and the ventricularis during loading and unloading. The spongiosa may also act as a reservoir for GAGs, which impart viscoelasticity to the valve material. The ridges on the fibrosal surface of the leaflet are not simply the relief formed by large collagen fiber bundles, but rather the radial folding of the fibrosa.^[30] When separated from the ventricularis, the fibrosa spontaneously flattens out and lengthens by 30%. The corrugations in the compressed fibrosa are maintained by virtue of its attachment to the ventricularis, which is under tension.^[31] When this tension is relieved, the ventricularis shrinks by 10%.^[32] The complex morphologic differentiation

Fig. 2 Diagram of a cutaway through the central portion of a valve cusp (left), and a histologic image (right) showing the three major layers.

between the principal layers of the valve cusps suggests that the fibrosa, spongiosa, and the ventricularis perform specific functions.

Indeed, the mechanical properties of the fibrosa and the ventricularis are quite different. When the aortic valve cusps were carefully dissected to separate the layers and the fibrosa and ventricularis tested separately, it was found that the fibrosa has a much lower radial extensibility than the ventricularis.^[30] This was indeed surprising because the two layers extend simultaneously during valve closure. We subsequently determined that the fibrosa is so extensible in situ (up to 60% strain) because of its naturally folded configuration. Because the fibrosa elongates following separation from the ventricularis, its loading curve is missing the long, unfolding region that it would normally exhibit. Similarly, the ventricularis appears more extensible when tested alone, because it is no longer preloaded in tension. Subsequent studies have reconstructed the load transfer that occurs from the ventricularis to the fibrosa during valve closure and confirm that the unique mechanical properties of the aortic valve cusps result in part from the multilayered nature of the cusp and the folded configuration of the fibrosa.^[33]

Aortic Valve Collagen

As a whole, the aortic valve cusp is made up of 55% collagen and 5% to 13% elastin,^[34,35] with the remainder consisting of interstitial macromolecules, including proteoglycans. Aortic valve collagen has been studied extensively over the years.^[36-41] The aortic valve contains mainly type I collagen (about 3/4 by content) with some type III collagen (about 1/4). Type V collagen has also been found in the cardiac valves; no doubt, these tissues contain many of the other newly discovered lesser collagens that are found in many different types of connective tissues.

Collagen fiber bundles are the main load-bearing components of the aortic valve. The collagen fibers

Fig. 3 Aortic valve cusp transilluminated with polarized light, demonstrating the pattern of collagen fiber bundles. The arrows denote the lines of force along these bundles.

bear the membrane stresses in the belly of the cusp, collect it, and direct it to the aortic wall by way of branching bundles, as seen in Fig. 3. The tension on these large collagen chords is substantial and actually deforms the aortic root during valve closure.^[42] In the belly of the cusp there exists an almost isotropic mesh of collagen that is held corrugated by its attachment to the ventricularis. The collagenous structures within the belly of the cusp are therefore under axial compression by way of their connection to the elastin structures, most of them in the ventricularis.^[33] These connections between the fibrosa and the ventricularis are substantial and pass through the spongiosa (Fig. 4).

In order to collect and channel the stress from the belly of the cusp, the collagen fibers are highly branched, having a fairly consistent pattern (Fig. 5). In Table 1, we see that most of the fiber bundles are either primary or secondary, with some tertiary. In the second table, however, we see that almost half of the bundles contain no bifurcations and that a roughly equal number of primary bundles that contain both secondary and tertiary branches. Roughly half the cusp, therefore, has bundles that run from attachment

Fig. 4 Detail of elastin fibers joining the fibrosa to the ventricularis.

Fig. 5 Details of collagen fiber bundle morphology. In the belly of the cusp, the fibers are not pronounced (C). As the fibers progress toward the edges, they become larger and raised from the surface (B,D). The free edge of the cusp is very dense (A). Morphologic measurements (E) demonstrate a consistent pattern of equally bifurcating collagen fiber bundles.

to attachment to the aorta without any major branching. These data therefore provide some key design features for a composite, tissue-engineered aortic valve cusp.

Aortic Valve Elastin

The elastin component of the aortic valve is only about 1/2000th as stiff as the collagen component, and

Table 1 Collagen fiber bundle measurements

Type of bundle	Bundles per cusp	S.D.
Primary	11.6	2.9
Secondary	13.1	3.0
Tertiary	8.1	4.5
Primary—no bifurcations	5.1	2.7
Primary with secondary	3.6	1.4
Primary with sec. and tertiary	3.0	1.4

therefore does not participate in load bearing during valve closure.^[43] Elastin structures, however, do affect aortic valve mechanics, as evidenced by the preload of the fibrosa and ventricularis.^[31,33] Aortic valve elastin can be visualized through NaOH digestion and scanning electron microscopy. In the aorta, elastin occurs typically as concentric sheets, often with pronounced fenestrations.^[44] In the aortic valve, elastin structures are considerably more complex. In general, aortic valve cusp elastin occurs as continuous amorphous masses or as networks of discrete fibers. Amorphous elastin is found as a continuous sheet less than 1 μm thick, whose surface detail varies from smooth to slightly textured under high magnification, sometimes with integrated fibers visible on the surface (Fig. 6A). The other type, fibrillar elastin (Fig. 7A), is not formed into large continuous sheets, but is visible as individual fibers organized into structures ranging from loosely connected individual elements to complex, intricate meshes. Individual fibers can be as large as 5 μm in diameter, but most are less than 1 μm across. The sheet elastin often transitions to fibrillar elastin, with

Fig. 6 Morphology of sheet elastin viewed using (A) SEM and (B) TEM. Sheets of elastin clearly run between bundles of collagen.

Fig. 7 (A) Typical morphology of fibrillar elastin; and (B) transitions (shown circled) from sheet to elastin fibers. The configuration of the fibers suggests that elastin bears load.

branching structures that are clearly organized to bear, channel, and distribute load between the fibrillar and sheet elastin (Fig. 7B).

Each of the three morphologically different structures—the fibrosa, spongiosa, and ventricularis—have all of these elastin types in varying amounts and conformations. The ventricularis contains a continuous sheet of dense elastin that stretches over the entire layer, becoming a fibrous mesh toward the edges. On the inside of the leaflet, elastin fibers protrude from the ventricularis, branch and anchor into the sheet like roots, and progress toward the fibrosa through the spongiosa (Fig. 7).

The elastin of the fibrosa is more delicate and complex than in the ventricularis. The fibrosa has a highly organized network of tubes that radiate out from the central region of the cusp toward the line of attachment of the cusp to the aortic wall. These tubes are typically 100 to 500 μm in diameter, and their walls are made of dense or amorphous sheet elastin (Fig. 8A). Smaller tubes up to 80 μm in diameter stretch circumferentially across the middle of the cusp, are packed densely together parallel to each other, and are oriented from commissure to commissure.^[35] Figure 8B is a schematic diagram of the elastin tube structures in the fibrosa.

We now know that elastin is not primarily confined to the ventricularis, as suggested previously,^[45,46] but is widely distributed throughout the aortic valve in what appear to be highly functional elements. In the ventricularis, the substantial amount of sheet elastin generates the preload that holds the fibrosa in its wrinkled configuration (see Fig. 2). Within the fibrosa, the most striking feature is the presence of directional tubes, the largest collection located around the line of attachment of the cusp to the aorta, with the tubes directed toward the center of the cusp. TEM images have shown that these tubes indeed surround the large collagen fiber bundles that emerge from the valve cusp and anchor into the aortic wall. These fiber bundles follow the lines of principal stress and move and respond to stress as the cusp is loaded. As the valve is loaded in systole, the cusps extend radially by over 30% on average,^[47] and considerably more in certain areas. Such radial extension is made possible by an unraveling of the corrugations in the central part of the fibrosa and by the pulling apart of the collagen fiber bundles. The elastin network of the cusp—particularly the struts between the elastin tubes (Fig. 8A)—therefore stores energy during diastolic loading, and returns it to the collagen network in systole when the cusp is

Fig. 8 Typical morphology of elastin tubes from the central area of the fibrosa. (A) These tubes are connected by elastin struts and arranged so that they radiate outward from the leaflet. (B) Each tube envelops a collagen fiber bundle and links the bundles together.

unloaded. The energy stored in the stretched elastin is therefore used to return the collagen structure to its resting configuration.

Cellular Population

Both allografts and xenografts lack a viable cell population. Over time, both allografts and xenografts appear to lose collagen fiber crimp, have a collapsed central spongiosa, and stain negatively for glycosaminoglycans. Thus, the ground substance associated with valve leaflet viscoelasticity and the overall collagen fiber morphology eventually disappear from these acellular tissues. Indeed, we have shown^[48,49] that glycosaminoglycans completely disappear from implanted bioprosthetic heart valves. Because aortic valve interstitial cells have been shown to have considerable biosynthetic activity in some animal models,^[50] it can be argued that the restoration and maintenance of a viable cell population in bioprosthetic heart valves is one way of prolonging their functional lifespan from the mechanical viewpoint. We recognize, however, that very little is known about the biology of aortic valve interstitial cells. Indeed, any new findings are very important to the field of tissue engineering. Currently, it is understood that there may be at least three subtypes of valvular interstitial cells, characterized primarily by the differential expression of marker proteins such as contractile filaments.^[51–53] How these different cells contribute to the synthesis of interstitial GAGs is presently unknown. The rapid loss of GAGs from transplanted xenograft and allograft valves, however, suggests that GAG synthesis is likely one of their prime functions.

AN ARGUMENT FOR PROPER MATRIX MECHANICS

Collagen, elastin, and GAGs are the structural components of essentially all of the body's connective tissues. What is important to the proper function of each of these diverse connective tissues is not the mere presence of their structural components—not even their correct relative amounts—but rather their functional organization and their mutual interactions. The aortic valve has nearly identical amounts of collagen and elastin as does the mitral valve, but they clearly do not function the same. A mitral valve leaflet cannot be transplanted into the aortic position and be expected to function properly in the long term. Indeed, the inability of transplanted connective tissues to function long-term in a foreign environment has been clear for many years, given the experience of the autologous pericardial valves pioneered by Dr. Jack Love.^[54]

Bovine pericardium has been used to make very successful bioprosthetic heart valves for a number of years.^[55] Their primary disadvantage, however, is that they are antigenic and need to be cross-linked with glutaraldehyde. As described above, glutaraldehyde treatment leads to calcification and to eventual valve failure. It was thought that autologous pericardium would be a better alternative to bovine pericardium, because it is not antigenic and hence does not need to be cross-linked with aldehydes. When Dr. Love began experimenting with such valves, he found that autologous pericardium rapidly contracted into dense scar tissue and the valve failed to function. Indeed, the only way that contraction could be prevented was to kill all the cells in the pericardium by a brief immersion in glutaraldehyde. The importance of killing the cells was later confirmed by Duran^[56] with alcohol-treated pericardial patches. The mechanism of this cell-mediated contraction is only now being elucidated.^[57]

The presence of cells in engineered tissues can be both beneficial and detrimental. We know that cells respond to the strains of their underlying matrix.^[58–60] Clearly, when cells populate a matrix that experiences mechanical strains different from what the cells expect, they respond in unpredictable ways. Abnormal strains lead to abnormal cell activity.^[61] When used to fabricate a prosthetic valve, living pericardium is subjected to loads very different from those imposed on it during normal function and it therefore experiences abnormal loads. Accordingly, the pericardial cells in the autologous valve do not respond in the appropriate way and are likely responsible for the rapid contraction and scarlike remodeling of the pericardial valve leaflets. By way of analogy, cells isolated from heart valves, seeded on the tissue-engineered substrates that do not induce the proper strains in the cell cytoskeleton during valve loading, will receive the wrong signals. These cells are therefore unlikely to behave properly in the tissue-engineered valves and should not be expected to remodel the degrading matrix into a functioning heart valve. Although the creation of aortic valvelike tissue has been reported in the literature,^[62–64] closer examination of the histological images by an experienced observer reveals a scarlike matrix that bears little resemblance to the finely structured matrix of the native aortic valve.

Surprisingly, the experience with acellular matrix xenograft valves has also been disappointing. A fully-formed aortic valve is perhaps the best matrix for a tissue-engineered valve. If such a matrix could be obtained from an animal, for example, and its antigenicity reduced by means other than cross-linking, it would function much like a human allograft. Indeed, if the patient's own cells were to repopulate this graft, then a hybrid-autograft/xenograft bioprosthesis could be created.^[65] This approach was first tried in vascular grafts with some success^[66] and later applied to pericardium in

an attempt to fabricate prosthetic leaflets.^[67] The approach involves first extracting the porcine cells and their membrane-associated antigens with various detergents to clean out the valve. Such a valve could then be cultured with cells from the recipient to create a hybrid living human/porcine valve. Although we pursued this approach in the early 1990s,^[65] we had little success. We were not able to fully remove all the cellular debris and still maintain proper matrix mechanics. However, Goldstein, working for CryoLife Inc., persevered and eventually succeeded in developing such a valve, which was eventually implanted into patients.^[68] Indeed, this device received CE Mark approval for use in the pulmonary position of pediatric patients in October 17, 2000. Recently, personal communications from Cryolife have confirmed that 5 patients in Australia have received this valve, and apparently all 5 have had to have the valves removed for complications resulting from uncontrolled scarring or inappropriate remodeling. Because of the proprietary nature of this technology, no published information is available regarding its rumored failure, and these reports are difficult to confirm. However, these anecdotes are consistent with the experience of Love^[54] (inappropriate matrix leads to scarring), and of others who have attempted the hybrid valve approach and were unsuccessful. Besides CryoLife, the other prominent company that attempted this was LifeCell Corp.^[69] Their approach apparently failed in sheep experiments because of highly variable fibrosis and never progressed to clinical trials. Clearly, for some unknown reason, porcine aortic valve scaffolds experience variable fibrosis and do not support a stable population of recipient cells once implanted.

Further discouraging the use of the decellularized scaffolds are findings that human aortic valve allografts do not naturally repopulate. In the aortic valve allograft, there exists perhaps the most perfect matrix for recolonization by host cells. Yet in a matter of months, these valves become totally acellular.^[26,70] The viable host cells quickly die and recipient cells do not repopulate this seemingly ideal matrix. Over time, the allograft valves fail from progressive mechanical damage, possibly mediated by a low-grade foreign-body response.^[71,72]

There is no question that both biodegradable matrices and acellular matrix xenografts are exciting technologies that may eventually be made to work. A third alternative to fabricating a tissue-engineered aortic valve has been pursued in our laboratory.

THE BIOMIMETIC CONSTRUCT

Our concept for a tissue-engineered heart valve is to build up a permanent, nonbiodegradable, composite

Fig. 9 Schematic diagram showing the arrangement of collagen, elastin, and GAGs within the valve cusp.

structure from biological molecules, one that closely mimics the structure and function of the native aortic valve. We believe that for the aortic valve, remodeling of the matrix is not essential. Indeed, the highly cross-linked nature of native aortic valve collagen indicates that it is very mature, very old, and does not remodel. Our new understanding of the role of valvular interstitial cells, as producers of glycosaminoglycans, suggests that the main function of these cells is to replenish the GAG stores that are rapidly depleted during cyclic loading.^[48,49,73] A biomimetic construct modeled along the lines of the schematic shown in Fig. 9 would be fabricated in the laboratory using conventional engineering approaches, would be ready to bear cardiac loads immediately upon implantation, would not need to remodel, would respond mechanically to loads in a manner identical to that of native valves, and would thus stimulate the valvular interstitial cells in a manner that is much more natural than the biodegradable matrices. Such a construct would therefore have a lower risk of succumbing to the nonspecific scarring and fibrosis that have affected current versions of valvular scaffolds. We acknowledge, however, that cellular response to strains in the underlying matrix is very much a function of the cells selected for the construct. At this stage, we are focusing on the structure and function of the matrix only, choosing cells that will be most suitable for the fabrication of the matrix. The choice of which cells to use for constructs that are to be implanted into animal models will be made later, when the engineering parameters of our approach are finalized. Part of the ongoing problem with tissue engineering of heart valves is that cardiovascular tissues are far more complex than initially envisioned and have a capacity for self-repair that is far less effective than tissue-engineering principles demand.

Our approach to developing a tissue-engineered aortic valve is not to rely on remodeling of a degrading scaffold, but rather to fabricate the cusp from its basic

building blocks: 1) branching collagen fiber bundles; 2) elastin sheets and tubes; and 3) a highly hydrated GAG matrix. Following are descriptions in greater detail of these specific technologies.

Collagen Fiber Bundles

Our approach to fabricating collagen fiber bundles is based on the principle of directed collagen gel shrinkage.^[74–77] The principle involves first mixing soluble, fibrillar collagen with cells; neutralizing the mixture to induce gelation; and maintaining the system in culture. When the system gels, cells become entrapped within the collagen gel and begin to interact with the collagen fibrils.^[78–83] These cells reorganize the surrounding collagen matrix, contracting it and excluding water. In many ways, this in-vitro contraction mimics wound healing in vivo.^[84] When the gel is mechanically constrained from shrinking in one direction, the collagen fibrils align in the direction of constraint.^[83,85] Highly-aligned, compacted, collagenous constructs can thus be fabricated.

First, neonatal rat aortic smooth muscle cells (SMC) were harvested by a method outlined by Oakes et al.^[86] to establish primary culture. Once these cells are amplified, they are detached from the culture dishes using trypsinization, counted, centrifuged, and added to the collagen suspension at a cell-seeding concentration of 1.0 million cells/ml. The collagen suspension consists of sterile acid-soluble type I collagen (BD Biosciences, Rat tail; 3.94 mg/ml, 0.02 N acetic acid) at an initial concentration of 2.0 mg/ml. The cell/collagen suspension is then pipetted into the wells and incubated at 37°C. Within several hours, the collagen gel forms and attaches to the microporous holders at the ends of the wells. These anchors prevent longitudinal contraction and allow shrinkage to occur only transverse to the long axis of the wells.^[87]

After 8 weeks of culture, the original transparent gel becomes a dense, cylindrical construct with well-aligned collagen fibrils (Fig. 10). The final constructs have the typical nonlinear stress/strain curve of tendonous materials, an extensibility of 14%, a stiffness of 5 MPa and failure strength of 1.1 MPa. Although the stiffness and strength are still lower than what is required, our constructs are already 10 to 100 times stronger than similar collagen-based materials fabricated previously.^[88,89] Ultrastructural analyses have shown that the main reason for the good strength of our constructs is the very high collagen fibril density. Because the constructs are relatively simple, one-dimensional collagen bundles, they compact from two directions, producing an area shrinkage ratio that is greater than 99% (from an area of 324 mm² to less than 1 mm²). When fully compacted, the collagen-fiber

Fig. 10 Images showing how collagen gels attached to holders and shrank over time to form thin, dense collagen fiber bundles.

density visually approaches that of mitral valve chordae (Fig. 11). The obvious differences are less collagen fiber crimp than is present in most collagenous structures and lower failure strength, possibly because of less cross-linking of collagen fibrils by proteoglycans, or other matrix molecules.

Because collagen fiber bundles in heart valves are branched, we have also attempted to fabricate branched structures, with good results (Fig. 12). The key to these geometries is to ensure that tension is properly controlled during the shrinkage process so that the constructs do not tear away from the holders during the early stages. As the images demonstrate, different branching angles and parent/daughter ratios can be engineered with the use of appropriate molds.

Cross-Linked Hyaluronan

Hyaluronan is a glycosaminoglycan polymer with a repeating disaccharide structure (glucuronic acid- β 1, 3-N-acetylgalactosamine- β 1,4-)_n, where *n* can reach 25,000 or more. In solution, hyaluronan forms large, random coil structures, which occupy large solvent volumes. When constrained within a matrix—for example, within a collagen network—hyaluronan exerts a swelling pressure on the matrix that traps water, gives tissues compressive resistance, and imparts viscoelastic properties. Hyaluronan also plays a role during embryonic cardiac development, as invading cells transform cardiac jelly into specialized cardiac structures, like the myocardium and the cardiac

Fig. 11 Typical morphology of collagen fibers (A) in the constructs and (B) in mitral valve chordae. Note the high density of fibers in the constructs. The inset (C) shows that constructs with crimped collagen can be fabricated.

valves.^[90] Hyaluronan is exceptionally biocompatible.^[91–93] Unlike collagen, which has both tissue- and species-specific markers, hyaluronan exhibits structural homology across species. For example, hyaluronan made by bacteria is the same as synthetic hyaluronan.^[94] Because of its interesting viscoelastic properties and its broad biocompatibility, hyaluronan has been used in a number of clinical applications. Perhaps the greatest contribution to bringing hyaluronan to commercial use has been made by Dr. Endre Balazs, the founder of Biomatrix Inc. (Ridgefield, N.J.), now owned by Genzyme. Dr. Balazs pioneered the cross-linking of hyaluronan with divinyl sulfone^[95] and began using it for viscosurgery of the eye.^[96] Other approaches to cross-linking hyaluronan have been attempted, including reactions involving hydrazides,^[97] carbodiimides,^[98] and esters.^[99] However, some problems encountered with the use of these cross-linkers include the extreme conditions needed for inducing cross-linking, the potential toxicity of the gelled product or of the cross-linker, and the inability of the cross-linking chemistry to accommodate desired characteristics of the gels, such as mechanical characteristics similar to native tissues and the ability to support cell attachment. We found none of these problems with the use of divinyl sulfone, and thus have based our hylan work on it. One important advantage of divinyl sulfone is that it utilizes the OH groups on the glycosaminoglycan chains, thereby leaving the more biologically active groups (carboxylate and N-acetyl groups) unaltered. The new molecules therefore have high biocompatibility and unaltered biological activity. It should also be noted that even though divinyl

Fig. 12 Images showing branched constructs at 1 day and at 8 weeks.

sulfone is extremely toxic in its unreacted state, the reaction products (bis-ethyl-sulfone crosslinks) are nontoxic and nonleachable when incorporated as a cross-linker within hylan gels.^[100] Hylan gels incorporating such cross-linked chemistry are approved in a number of product formulations for long-term clinical use, including injections into the knee for the treatment of osteoarthritis or under the skin to correct facial defects.^[96] In the long term, divinyl sulfone-crosslinked hyaluronan persists in the body unaltered. It does not elicit a foreign-body reaction, and it does not calcify. These are features very desirable for use in cardiac valve prostheses.

We fabricated hylan gels using the method of Balazs,^[95] cast them onto the bottom of 24-well tissue culture plates, and coated them with cell-binding matrix factors such as collagen (type I, from rat tail), extracellular matrix (ECM) gel (from mouse sarcoma), laminin, and fibronectin (from bovine plasma). Relative to uncoated controls, these matrix-coated gels induced much better cell attachment and proliferation.^[101] Because particulate gels induced greater cell attachment, regardless of the amount of adhesion protein bound, we sought to manipulate the texture of the hylan gels to maximize cell attachment and cell penetration.

Previously, several researchers used low-intensity ultraviolet radiation as a cross-linking agent in the preparation of natural and synthetic biomedical polymers. Bryant et al.^[102] showed that PVA scaffolds exposed to low-intensity ultraviolet radiation are cytocompatible. Ultraviolet irradiation was also shown to enhance the attachment and chemotaxis of melanocytes on extracellular matrix proteins.^[103] We therefore subjected DVS-cross-linked hydrogels to UV light and carried out similar cell adhesion studies.

As in the previous study, neonatal rat aortic smooth muscle cells did not attach to unmodified hylan gels. They attached sparsely to oven-dehydrated gels and were rounded and nonproliferative. However, cells attached readily to irradiated gels, appeared healthy

Fig. 13 (A) Light microscopy image of the surface of a UV-irradiated gel showing the cracks; (B) confocal images showing a mid-section; (C) transverse z -section of a reconstructed stack of images; and (D) section showing the penetration of cells into the interior. In this image, hyaluronan fluoresces red.

and highly proliferative, and formed multiple confluent layers on the surface within 10 days of seeding.^[101] Cells also migrated into the interior of the UV-exposed gels. Confocal microscopy indicated that in many cases, the cells populated the entire thickness of the gels (Fig. 13C). Cells within the interior appeared highly extended, often as long as 75 micrometers. Cells appeared to migrate into the interior of gels via cracks in the gel that were visible with light microscopy (Fig. 13A). Nonirradiated gels did not demonstrate this topography. It is also noteworthy that these high levels of adhesion and proliferation were achieved without any precoating with matrix factors. Dehydration and UV irradiation were all that was necessary to change the hylans from an inert, watery gel to an elastic substrate that readily supports cellular adhesion and infiltration.

Elastin Structures

As previously mentioned, above, elastin structures are extremely important in the mechanical function of the aortic valve cusp. They exist as fibers, sheets, and tubes

that link together the major load-bearing collagenous structures. Accordingly, we have explored the means by which such elastin structures could be fabricated in the laboratory. We have been quite successful in growing elastin sheets atop hylan gels and around collagen fiber bundles, and have thus created large elastin sheets and elastin tubes (Figs. 14 and 15). These sheets of elastin were isolated through NaOH digestion and imaged with SEM. In most areas, they were solid and continuous (Fig. 15B), and in others, the sheets had fenestrations, typical of those seen in aorta and in the ventricularis of the aortic valve (Fig. 15C). Although we currently do not know why an elastin sheath would form around our collagen constructs in vitro, we speculate that the greater cell density or

Fig. 14 (A) Histologic section of a collagen fiber bundle construct showing the elastin sheath that has formed on its surface, (B) SEM images of NaOH-digested samples of constructs; and (C) native chordae showing the surface topology of the elastin sheaths.

greater tension induced at the surface of the construct may have some role in the formation of the outer elastin sheath.

SUMMARY

Although we have not yet succeeded at assembling all of these structural components, we have established that such a structure can at least be developed in vitro. Our approach is very different from the traditional tissue-engineering approach, in which cells are seeded onto a biodegradable scaffold and a functional organ

is expected to emerge as the scaffold degrades. The advantage of our proposed technique is that it will rely less on the remodeling capabilities of living tissues and more on conventional engineering methodologies. As such, this approach is likely to be more predictable in fabricating the desired types of tissues.

It is unclear which of the three approaches to tissue engineering of heart valves will have success first. Certainly, the road thus far has been longer than initially anticipated. Maybe the true benefit of the so-called tissue-engineered revolution is that researchers will finally look at native heart valve tissue and native cells and begin to study the system with heart valve disease in mind. Maybe the therapy of the future will be not the replacement of diseased valves with tissue-engineered prostheses, but rather the treatment of valvular disease with cells and molecules to slow down and potentially even reverse the course of the disease itself, thus avoiding a prosthesis altogether.

T

INTRODUCTION

The intestine is a complex organ that integrates the functions of many types of cells and tissues. Current attempts to regenerate the intestine have yielded promising results. Nevertheless, significant challenges remain before intestinal tissue engineering can become clinically useful. A review of the state of the art and a discussion on the challenges ahead will be presented in this article.

BACKGROUND

A variety of human diseases require the extensive removal of the intestine. For the small intestine, this can occur in the setting of necrotizing enterocolitis, intestinal volvulus, mesenteric ischemia, and Crohn's disease.^[1-3] For the large intestine, total proctocolectomy is frequently performed for patients with familial polyposis and ulcerative colitis. Although supportive measures and reconstructive procedures are available for these patients, the current therapies suffer from significant shortcomings.

Short gut syndrome occurs in patients with inadequate lengths of functional small intestine to maintain normal digestion and absorption. Although the prognosis of patients with short gut syndrome depends on several variables, including the presence of the ileocecal valve and colon and the underlying etiology of the disease, the length of the remaining small intestine is arguably the most significant factor. In many series of patients with short gut syndrome, it has been shown that their survival depends on the length of the remaining small intestine.^[3] While the exact length of the remaining intestine may be difficult to determine owing to its elastic and dynamic nature, it is generally accepted that short gut syndrome occurs when more than two-thirds of the small intestine is removed. In adults, as a general rule, 200 cm of the small intestine is needed for adequate bowel function. When the remaining length of the small intestine is less than 100 cm, the mortality of the patients begins to rise.

The therapy for short gut syndrome consists of providing parenteral nutrition, optimizing the health of the remnant intestine, and enhancing bowel adaptation.^[4] Besides the estimated cost of \$200,000 per patient each year, the use of long-term parenteral nutrition is associated with significant complications such as catheter sepsis and liver cirrhosis. Surgical procedures to optimize the intestinal function include creating intestinal valves and recirculating intestinal loops, interposing a colonic segment in an isoperistaltic or antiperistaltic fashion, and tapering and lengthening dilated intestinal segments.^[5-9] Most of these procedures have met with only limited success.^[10,11] The outcome following intestinal transplantation is improving; but it is still limited by complications of immunosuppression and donor availability.^[12]

For patients who need the removal of their entire large intestine, reconstructive surgery utilizing the distal small intestine to create an ileoanal pouch is now the standard of care.^[13] Nevertheless, the ileoanal pouch procedure is associated with dilation, inflammation, stool frequency, and pelvic sepsis. The frequency of complications associated with the ileoanal pouches is over 50% in 10 years, and the removal of the pouch is required so that a permanent ileostomy is necessary in some cases.^[14,15] The colonic metaplasia and the chronic inflammation of the pouches have been postulated to increase long-term neoplasia.^[16]

Tissue engineering offers the potential to regenerate an autologous intestine. For patients with short gut syndrome, this would represent a new, life-saving therapy that will allow them to be weaned from parenteral nutrition and to eat normally. For patients with colonic failure, this would avoid much of the morbidity associated with the current restorative procedures. Although a complex organ, portions of the intestine had been regenerated using cells, scaffolds, and signals.

INTESTINAL ARCHITECTURE

The intestine is derived from the lateral folding of the trilayered embryonic disc to form a tube during

development. The innermost aspect of the intestine is lined with epithelial cells facing the lumen of the gut. These cells originated from the embryonic endodermal cells. Beneath the intestinal epithelium lie the lamina propria, the submucosa, and the smooth muscle layers, all derived from the embryonic mesoderm. The serosa is the outermost layer of the intestine and is penetrated by the mesentery blood vessels and lymphatics. Dispersed throughout the intestine are intrinsic and extrinsic autonomic nerves, both of ectodermal origin. The intestine lengthens during fetal development and postnatal growth. The human fetus in the second trimester has 150 cm of intestines which double to 300 cm in full-term newborns.^[17] Thereafter the intestine continues to elongate, reaching an average length of 600 cm in adulthood, although there is a wide range from 350 to 700 cm, depending on the age, height, weight, and race.^[18]

A review of the normal intestinal histology reveals the layered architecture of the intestinal wall. The epithelium is the first one-cell thick layer followed by several other layers including the lamina propria, the submucosal plexus, the circular smooth muscle, the myenteric plexus, the longitudinal smooth muscle, and the serosa. Each layer consists of its own specialized cells with their unique environment. The intestinal epithelium covers the mucosa with a layer of columnar absorptive cells, goblet cells, endocrine cells, epithelial stem cells, and Paneth cells. The intestinal epithelial stem cells reside near the bottom of crypts and give rise to all of the other cell types in the epithelium. Epithelial cells generated in the crypts migrate toward the villi where they undergo maturation, followed by apoptosis over the course of a few days. The absorptive cells are highly polarized. They possess apical microvilli that form the brush border and basally located nuclei. The brush border contains digestive enzymes and nutrient transporters, and the basolateral surface contains adenosine triphosphate-dependent pumps that maintain the ionic gradient inside the cells to facilitate the directional transport. The goblet cells are variably dispersed among the absorptive cells. They secrete a mucopolysaccharide complex believed to act as a protective layer for the intestinal epithelium. The endocrine cells are located in both the villi and crypts. Their basally located granules contain gastrointestinal hormones such as somatostatin vasoactive intestinal peptide and motilin. The Paneth cells are located in the lowest part of the crypts. They also secrete proteins such as defensins that have a wide range of antibiotic effects.^[19]

The lamina propria lies beneath the intestinal epithelium and is the core of the villi. A rich network of lymphatics and blood vessels is located in the lamina propria to transport the absorbed nutrients into the systemic circulation. There are also numerous intraepithelial lymphocytes and lymphoid nodules in this region, and they provide immunity against the intestinal

flora and secrete immunoglobulin A. The submucosa is rich in elastic fibers. In the duodenum, the submucosa is filled with secretory glands that produce an alkalotic viscous fluid to neutralize the gastric acid.

The peristaltic action of the intestine results from the rhythmic contraction of two smooth muscular layers coordinated by the enteric nervous system and paced by the interstitial cells of Cajal. The smooth muscle cells are oriented along two axes with one arranged circumferentially around the intestine and the other longitudinally along the intestine. They can be identified by immunostaining for α smooth muscle actin and smooth muscle myosin heavy chain. The enteric nervous system is organized as a network with ganglia at the nodal points. It has been estimated that the enteric nervous system contains as many neurons as the central nervous system. The myenteric plexus lies in between the two smooth muscle layers and stimulates the contraction of the smooth muscle cells. The interstitial cells of Cajal are considered to be the pacemaker cells of gastrointestinal tract. They form contacts with the smooth muscle cells and enteric neurons and are responsible for the generation of rhythmic slow waves of the intestine. The serosa is the outermost layer and consists of a squamous epithelium that covers the entire gastrointestinal tract and is continuous with the peritoneum.

FEASIBILITY STUDIES

The intestine is a complex organ composed of many cell types, including epithelial cells, immune cells, endothelial cells, smooth muscle cells, pacemaker cells, and nerve cells. These cells are highly organized into tissues that are intricately integrated with each other to bring about the coordinated function of the intestine. Although the regeneration of such complex organ may seem unlikely at first, there is some evidence in the literature that documented the feasibility of intestinal tissue engineering.

Much of the early work on intestinal regeneration is focused on the epithelium, which is known to possess stem cells with the tremendous ability for growth. The growth of intestinal mucosa in ectopic locations is observed in many clinical settings, such as their aberrant presence in fistulous tracts in Crohn's disease. When an opening created in the small intestine is patched closed using the serosa from another intestinal segment, the epithelial cells migrate onto the new surface and form structures resembling the normal intestinal mucosa.^[20] Such "neomucosa" can be grown on a variety of surfaces, including biological and prosthetic materials.^[21,22] Although the clinical utility of the neomucosa is limited, as the newly generated epithelium contracted over time,^[23] the innate ability of the intestinal epithelial cells

to grow and to organize sets the stage for the initial efforts in intestinal tissue engineering.

By using the neonatal small intestine as the starting source, one can procure rodent intestinal organoids that are made up of heterogeneous cell types.^[24] These organoids were attached to a biodegradable polymeric scaffold following isolation and were implanted into the omentum of syngeneic rats.^[25] After six weeks, a cystic structure formed in the peritoneal cavity. The inner lining of such cysts resembled epithelial cells of the small intestine, and the outer layer was composed of fibrovascular tissues. When the opened cysts were anastomosed to the side of an intestinal segment, the lining cells blossomed into structures resembling intestinal crypts and villi.^[26] When the function of these cysts was tested in an animal model of short gut syndrome, the weight loss observed in rats with surgically created short gut syndrome was lessened in the presence of the cyst.^[27] These results established the feasibility of small intestinal tissue engineering.

Using an analogous technique for the large intestine, colonic tissues can also be regenerated from organoid units procured from both neonatal and adult animals.^[28] After four weeks of implantation into the omentum, a 4-cm cyst formed in the peritoneal cavity. Such cysts could be anastomosed to native intestine and exhibited similar histological architecture as the native colon. Furthermore, such tissue-engineered colons could decrease the output from an ileostomy in rats, suggesting absorptive function *in vivo*. Although these demonstrations are impressive, several major challenges still need to be addressed before intestinal tissue engineering can be applied to patients.

CELLS

Before intestinal tissue engineering can be brought into the clinical arena, it is necessary to find an alternate cell source for tissue regeneration. For the small intestine, the established technique employed organoid units pooled from several neonatal rat donors to procure sufficient cell mass to generate a single cyst. When the adult small intestine was used, the procured organoids were not able to generate similar intestinal cysts after implantation into the omentum. This reflects the tremendous growth potential of cells obtained from neonatal animals. There is, however, no readily available neonatal human small intestine that can be used in a similar fashion. In contrast, for the large intestine, the established technique was successful in employing either neonatal or adult rats as the donor for intestinal organoids. However, patients who might benefit from tissue-engineered colons will have diseases that affect the entire colon, such as familial polyposis. The diffuse nature of the disease will not permit the use of the

autologous colon as the source for cell procurement. Therefore, the search for a substitute cell source is a critical next step in intestinal tissue engineering.

For the intestine to function properly, it must possess adequate peristaltic function to transport the enteric content down the gastrointestinal tract. This is evident from a variety of human diseases where a histologically normal intestine fails to function because of poor intestinal motility. The current tissue-engineered intestine has an adequately regenerated mucosa, but the presence of a functional neuromuscular layer has not been well documented. Although some studies to date have shown the presence of smooth muscle cells and ganglia, no documentation of peristalsis has been demonstrated. Analogous to the intestine in Hirschsprung's disease, such tissue-engineered structures would not be clinically useful without motility.

Embryonic stem cells have the potential to generate every cell type in the body. Using murine embryonic stem cells, Yamada et al. were able to generate an *in vitro* gut-like organ.^[29] These dome-like structures possessed an inner epithelial layer and an outer smooth muscle layer. They also exhibited coordinated peristalsis and showed immunoreactivity for interstitial cells of Cajal and neurons. Despite this tremendous potential, the acceptability of therapeutic cloning remains highly controversial. Neural stem cells derived from the central nervous system were transplanted into the gastrointestinal tract.^[30] Such neural stem cells expressed the receptors for the glial cell derived nerve growth factor and could produce nitric oxide *in vitro*. After transplantation, these cells continued to express the neural nitric oxide synthase and survived for at least eight weeks.

Besides embryonic stem cells, postnatal stem cells have also been utilized for intestinal tissue engineering. Gastrointestinal smooth muscle cells have been isolated and grown in culture.^[31] They are capable of expansion *in vitro*, although the cells tend to lose differentiation during the growth phase. Cells from the enteric nervous system are derived from the neural crest cells during development. It has been shown that neural crest stem cells persist in the intestine of postnatal animals.^[32] These cells can be isolated using an antibody to the surface receptor p75. The p75-positive cells can be expanded *in vitro*, and they can be differentiated into neuronal and glial cells. The enteric neuronal cells do not innervate the smooth muscle cells by the classic neuromuscular junction. Instead, neurotransmitters diffuse from the nerve terminal toward the smooth muscle cells. The interstitial cells of Cajal can be identified by the surface marker c-kit, a receptor tyrosine kinase for stem cell factor. These cells can also be isolated and cultured *in vitro*,^[33] and the cultured cells exhibit rhythmic spontaneous action potentials. For a tissue-engineered intestine to have adequate peristaltic action, it is likely that all of these cellular elements

need to be present and integrated in the regenerated structure.

SCAFFOLDS

The scaffold allows the design of the overall shape, provides a surface for cellular attachment, and can simulate an environment that is conducive for tissue regeneration. Both natural and polymeric materials have been used for intestinal tissue engineering.^[25,34] Microscopic features, such as the intestinal villi, can be replicated using three-dimensional printing techniques.^[35] It is likely that both physical and biological cues can be incorporated into the design of the scaffold to facilitate tissue engineering.^[36]

Although started as a cylindrical scaffold seeded with intestinal organoid units, the cysts generated in the omentum did not retain the tubular shape.^[25] The spherical shape of the cysts does not allow for ready scale-up to clinically useful dimensions. By increasing the diameter of the cyst to increase the surface area, the dilated cysts would cause stasis and bacterial overgrowth within the lumen and would be considered as diverticula of the intestine, which is clinically a pathological condition.

Analogous to its normal state, the ideal geometry for intestinal tissue engineering is a cylindrical structure that scales with length of the scaffold. When a tubularized scaffold is interposed between intestinal segments, intestinal obstruction occurs because of the lack of adequate motility in the scaffold.^[22,37] When an acellular, tubularized scaffold was interposed between intestinal segments isolated from intestinal continuity, a new intestinal epithelium regenerated over the tubular construct over 4–16 weeks.^[22,34] The spontaneous epithelialization is not surprising, given the ability of the normal intestinal epithelium to turnover. Underneath the epithelium, however, there is little smooth muscle regeneration. When the scaffolds were seeded with mesenchymal stem cells, smooth muscle was still not regenerated after epithelialization was complete.^[38] The lack of multiple intestinal layers implies that other environmental cues are needed for the regeneration of the smooth muscle and the enteric nervous system.

SIGNALS

Besides the cells and the scaffolds, the proper signals are needed to guide tissue regeneration. A myriad of factors have been shown to stimulate the growth of the intestinal villi and crypts in animal models,^[39] including epidermal growth factor,^[40,41] hepatocyte growth factor,^[42,43] glucagon-like peptide 2,^[44,45] interleukin 11,^[46] and insulin-like growth factor 1.^[47–50] Although most of

these factors clearly stimulate the growth of intestinal epithelial cells, the optimal dosage and the exact timing for the delivery of these factors remain to be determined. Furthermore, it may be unnecessary to provide any trophic factors for the intestinal epithelial cells, as evidenced by their propensity to grow spontaneously in conditions without added growth factors as stated previously. On the other hand, intestinal smooth muscle cells and enteric neurons have much less potential to grow in the current models of regeneration. The delivery of factors that will direct the regeneration of these cellular elements is likely to have a significant impact on the progress of intestinal tissue engineering.^[51–55]

Because of its central role in providing the source of energy, the intestine is intricately integrated with the other organ systems. In addition to the regeneration of the intestine itself, other crucial elements are needed to reconnect the intestine with the body. Most importantly, the engineered construct needs vascularization to provide the pathway for nutrient exchange. Angiogenesis does occur in the intestinal cysts generated by the current technique; however, there are significant quantitative differences between the normal growing intestine and the tissue-engineered construct.^[56] In particular, the levels of vascular endothelial growth factor and basic fibroblast growth factor are low in the engineered intestine, and these may serve as the targets for growth factor delivery. Another important pathway to establish is the lymphatic system, which transports chylomicrons back into the circulation. Lymphangiogenesis also occurs in the intestinal cysts, but their function has not been assessed.^[57]

The small intestine also grows in response to applied mechanical forces.^[58] The capacity of the bypassed ileum in pigs can be expanded to 12 times the original volume in eight weeks by using a round, intraluminal balloon expander.^[59] Similarly, the expansion of the jejunal capacity in rabbits using an oval, intraluminal tissue expander was described.^[60] When an intussusception valve was created to obstruct the jejunum partially in rats, the proximal jejunum dilated in response to the increased intraluminal pressure.^[61] All of these studies showed that the intestine was not simply stretched thin but rather intestinal hypertrophy and hyperplasia had occurred in response to the applied force. Although successful in increasing the total surface area by increasing the intestinal diameter, these techniques resulted in dilated segments of the small intestine that would not function well because of stasis and bacterial overgrowth.

There were also attempts directed at lengthening the small intestine by mechanical stretching without causing simultaneous dilatation. The elongation of the ileum in rabbits was achieved by the placement of a round, extraluminal tissue expander adjacent to a fixed intestinal segment.^[62] Because of geometric considerations, the maximal gain in length was limited using this

technique. A more recent study used an external distractor sutured to the serosa of the jejunum in rabbits and reported a near doubling of the initial length after three weeks of gradual distraction.^[63] When the distraction device was removed, the intestinal segment remained longer than its initial length. Another study employed intraluminal expanders to lengthen bypassed ileal segments in rabbits and reported 50% lengthening after two weeks.^[64] They also observed persistent lengthening after the intraluminal expanders were removed. Although promising, none of these studies examined the in vivo functions of the mechanically lengthened bowel.

CONCLUSIONS

There is yet much that we do not understand about intestinal regeneration. The signals critical to the process are unknown, the role of scaffolding remains to be determined, and the necessary cell types are not well defined. New knowledge gained from studying the development of the intestine will yield further insights into nature's intestinal tissue engineering so that better therapies can be developed for patients with intestinal failure.

INTRODUCTION

Ligaments perform essential stabilization roles in synovial joints by maintaining bone alignment and guiding motion. Although many ligaments in the body are regularly injured, those found in the knee joint have received particular attention because they are subjected to large tensile loads and surgical repair often results in poor outcomes. Efforts to create tissue-engineered ligaments can be guided by a thorough understanding of the physiological utility and needs of the natural tissue, and, regardless of the physiological location of the specific ligament to be replaced, must meet a number of functional challenges including biocompatibility, appropriate fixation to/within bones, and adequate mechanical strength and nutrient transport. Recent advances strongly suggest that tissue engineering will soon offer functional tissue replacements without many of the adverse side effects associated with current treatment options.

ANTERIOR CRUCIATE LIGAMENT INJURIES AND RECONSTRUCTIONS

Because knee injuries are common and often debilitating, much of the ligament tissue engineering research has focused on the knee. In the knee joint, the anterior cruciate ligament (ACL) prevents excessive anterior translation of the tibia and is crucial for normal joint function. Acute injuries to the ACL often result in instability, decreased joint function, and, over time, degenerative diseases such as osteoarthritis. This is of considerable concern because it has been estimated that as many as 150,000 Americans suffer an ACL injury each year,^[1] and the number of injuries appear to be on the rise.^[2] Furthermore, when fully or even partially disrupted, the ACL demonstrates a very poor capacity to heal, which often necessitates surgical reconstruction to restore function to the knee joint.^[2]

Long-term solutions to nonhealing ligament injury include surgical reconstructions with autografts, allografts, xenografts and synthetic grafts, or physical therapy. Surgical reconstruction is usually recommended for

active patients who suffer an ACL injury because the instability resulting from an ACL-deficient joint often precludes participation in rigorous sports or recreation activities. However, such surgical reconstructions are not an ideal long-term solution, as some studies have shown that patients who undergo ACL reconstructions have no better long-term results than those who opt not to have surgery.^[3] Autografts used in ACL reconstruction, most commonly the central third of the patellar tendon (PT), require prolonged recovery times, result in weakening of other knee structures and patellar pain, and still often lead to long-term degenerative problems such as osteoarthritis.^[4-6] Allografts and xenografts have had some success, but they are difficult and expensive to procure and still carry a risk of disease transmission.^[2,4] Some studies have also cited marked inflammatory and rejection responses to these grafts.^[1,6,7] Furthermore, required sterilization treatments may adversely affect the mechanical properties of allograft and xenograft tissues, and therefore lead to failure of the grafts.^[4] Synthetic materials such as Dacron (polyester) and Gore-Tex (PTFE) have also been used for ACL reconstructions, but long-term success rates have been poor due to inflammation and foreign-body reaction, material degradation, and eventual prosthesis failure.^[2,6]

Other Ligament Injuries

Injuries to ligaments other than the ACL often result in poor clinical outcomes, although not generally as severe as the long-term results associated with ACL injuries. Lateral ankle injuries, which are most frequently to the anterior talofibular ligament, account for approximately 25% of all musculoskeletal injuries with some 23,000 injuries daily in the United States.^[8] Treatments for lateral ankle sprains range from minimal to no treatment to surgery, with better outcomes for some remedies than others. However, regardless of treatment, many patients still complain of the ankle giving way and pain.^[9] Other studies of lateral ankle sprains find similar results. Ankle sprains often lead to persistent disability, including loss of function and pain.^[10]

The shoulder joint is also a common site for ligament injury. Within the joint, four major glenohumeral ligaments guide joint motion, and, most importantly, check excessive translations and rotations of the joint at extreme positions. Not surprisingly, glenohumeral ligaments tears have been implicated in acute shoulder joint dislocations.^[11] In fact, the glenohumeral joint is the most commonly dislocated joint in the body.^[12] Injuries to the glenohumeral ligaments often accompany damage to other soft tissues in the shoulder joint as the result of a dislocation and frequently result in long-term problems, most commonly increased joint laxity. Pathological joint laxity may result in chronic dislocations, which occur in young patients 66–95% of the time after an acute injury,^[13,14] and the necessity for surgery to prevent further dislocations. Although surgery often prevents further dislocations, almost all patients suffer a reduced range of shoulder motion. Other possible complications include osteoarthritis and recurrent pain, which may be severe enough to necessitate a shoulder arthroplasty.^[15]

Tissue Engineering for Ligament Replacement

Tissue engineering offers the possibility of creating functional soft tissue replacements to treat nonhealing ligament injuries without many of the adverse side effects associated with current reconstructive options. The fundamental basis of tissue engineering for ligament applications is the development of a biocompatible, resorbable scaffold that can be seeded with functioning cells of a relevant phenotype. Upon implantation, these viable cell/scaffold constructs should support joint function and, over time, gradually transfer mechanical loads born by the scaffold biomaterial to the newly developing neoligamentous tissue. Ultimately, the cell/scaffold construct should be replaced by biologically and mechanically functioning ligament tissue.

STRUCTURE AND FUNCTION OF NATURAL LIGAMENTS

Composition and Structure

Normal ligament is composed of approximately 64% water and combined with types I and III collagen, elastin, proteoglycans, glycosaminoglycans, fibroblasts, and small amounts of fibronectin. However, when dry weight is considered, collagen comprises some 70 to 80% of the tissue.^[16] Biochemical analyses have also shown that, of the collagen in ligament, 90%

is type I and approximately 10% is type III.^[17] Elastin composes about 5% of most ligaments and proteoglycans make up less than 1% of the tissue.^[17]

The hierarchical organization of collagen is perhaps the most important feature of ligament tissue with regard to creating functional tissue replacements since this multiscale architecture provides the structural support that defines the primary role of the ligament. At the lowest level of the collagen hierarchy is the α chain, a long polypeptide chain wound in a left-handed helix (Fig. 1). Three α chains are arranged in a larger right-handed triple helix to form a tropocollagen molecule, a rodlike structure approximately 1.5 nm in diameter and 300 nm in length. Tropocollagen molecules are packed together in a quarter stagger arrangement to form microfibrils, which are aligned roughly in parallel along the long axis of the ligament. Microfibrils aggregate to form fibers, and fibers form subfascicles. Subfascicles are surrounded by a connective tissue sheath called the endotenon.^[6,18] Fascicles, which are composed of subfascicles, are likewise surrounded by a connective tissue sheath called the epitenon.^[6] At the highest levels of the hierarchy, fascicles form the ligaments, which are, in turn, surrounded by a thicker structure of loose connective tissue called the paratenon that is enclosed by the synovial sheath.^[19]

T

Physiological Source of Mechanical Properties

Much of the characteristic strength of ligaments is attributed to intramolecular and intermolecular cross-linking within and among, respectively, the tropocollagen molecules that compose the ligament. Aldol cross-links, which constitute the intramolecular cross links, occur between aldehydes on the α chains of tropocollagen molecules.^[20] Conversely, intermolecular cross-links between adjacent tropocollagen molecules form as Schiff bases in the reaction of allysine with lysine or hydroxylysine.^[20]

A feature called crimp is generally considered to be responsible for the mechanical behavior observed for ligaments at low loads and extensions. Crimp refers to the roughly sinusoidal undulations or waviness present in many collagenous connective tissues, including ligament, when viewed under polarized light. Researchers have hypothesized that crimp is responsible for the characteristic toe-region or initial nonlinear portion of a ligament's load-elongation curve (Fig. 2) as crimp appears to straighten out when small loads are applied to the tissue. In this way, crimp enables the ligament to stretch a small amount before it develops substantial force. Presumably, this phenomenon allows the joint surfaces and ligaments to passively guide the motion of the joint through common activities, and for ligament stiffness to increase markedly under extreme

Human right knee shown with patella and patellar tendon reflected to allow visualization of the anterior cruciate ligament.

motions to protect the joint. It should be noted that crimp period and amplitude vary among tissues. Measurements of crimp within the rabbit ACL reveal a crimp period of 45–60 μm and an amplitude of 5 μm . Within the medial collateral ligament (MCL) however, the crimp period is 45 μm and the amplitude is 10 μm .^[20] Its importance to tissue engineering is not yet

Fig. 2 Typical load-elongation curve for porcine femur-ACL-tibia complex demonstrating toe-region and ultimate failure. (Courtesy of James B. Raasch III.)

known. That is, it may be possible to use a synthetic scaffold with a nonlinear constitutive response to mimic the toe-region and subsequent stiffening of the ligament. But, it is also possible that crimp serves a physiological purpose related to mechanotransduction, cell-to-cell signaling, or nutrient transport that must be considered in the final design of a successful tissue-engineered ligament replacement.

Although the hierarchical collagen structure of ligaments has been a primary focus in the creation of functional ligament reconstructions,^[21] the ground substance in this tissue also appears to play a vital role in joint mechanics. In collagenous tissues, such as ligament, ground substance refers to the portion of the tissue containing the large polysaccharides, glycosaminoglycans and proteoglycans, and tissue fluid. Although the ground substance comprises just 1% of the dry weight of ligament, the majority of the water contained within the wet tissue is associated with the ground substance. Glycosaminoglycans are highly negatively charged and contain numerous hydroxyl groups that attract water through hydrogen bonding. It has long been hypothesized that the viscoelastic or time-dependent properties, i.e., creep and stress relaxation, of ligaments are due to complex water-ground substance interactions.

CELLS

Ligament fibroblasts are interspersed within fiber bundles along the tissue and possess numerous cellular organelles, which indicates high levels of metabolic activity.^[16] These fibroblasts make numerous contacts with nearby cells through fine processes that allow the cells to communicate via gap junctions.^[22] However, fibroblast morphology and size vary among ligaments, and these differences are often attributed to variations in the ligament's function and in-vivo environment. For example, fibroblasts within the MCL of the knee joint are rod- or spindle-shaped and have lengths of approximately 15 μm .^[20] Conversely, ACL fibroblasts, which resemble fibrocartilage cells, are round to ovoid in shape with diameters of 5–8 μm .^[20] Within ligaments, fibroblasts play a direct role in synthesizing collagen. α -chain helices are manufactured inside the cells and then passed through the cellular membrane and into the extracellular space where they are modified into tropocollagen molecules and then assembled into fibrils, as described previously. Thus, fibroblasts are responsible for creating the collagen that comprises the majority of the ligament tissue and in remodeling it both on a regular basis and after injury.

LIGAMENT-BONE INSERTIONS

Ligaments form junctions with bones at entheses or insertions. At these junctions, the ligament transitions from soft tissue to hard, bone tissue over a distance of less than one millimeter.^[23] Histological analyses have shown four distinct regions of the ligament insertion (Fig. 3). In a typical direct insertion, Zone 1 is ligament tissue and contains fibroblasts. Zone 2 is composed of fibrocartilage and contains fibrocartilage cells. Zone 2 is separated from Zone 3, which also contains fibrocartilage cells, by a distinctive tidemark, which indicates the presence of mineralized fibrocartilage. Zone 4 is composed of bone and contains characteristic osteocytes. The fibrocartilage cells of Zones 2 and 3 are oval in shape^[24] and do not communicate with other cells via gap junctions. This means that there is no communication between the osteocytes of the bone and the fibroblasts of the ligament. In addition to the communication barrier across the ligament insertion, there is also a vascular barrier. The uncalcified fibrocartilage zone of the ligament insertion does not contain blood vessels and therefore completely separates the vasculature of the ligament from that of the bone. It has been hypothesized that this bone-soft tissue interface, combined with the compression-tolerance properties of the fibrocartilage, allows for dissipation of stress in the joint and therefore protects the ligament from injury.^[25]

Fig. 3 Fibular insertion of a porcine lateral collateral ligament (LCL). Numbers denote the four zones of the insertion, as discussed in the text. Bone (at the lower left of the picture) stains red and blue, fibrocartilage stains light and dark blue, and ligament stains red (at the upper right). Scale bar = 150 μm . Phase contrast photograph. Modified Mallory's Stain. (Figure courtesy of Alycia Wanat.)

There are two distinct types of insertions found in the body, direct and indirect. The more common of the two, direct insertions, which are sometimes referred to as fibrocartilage entheses or chondral insertions, are most frequently observed in joints where the ligament attaches to the epiphyses of long bones.^[26] Direct insertions include both the tibial and femoral insertions of the ACL and the femoral insertion of the MCL. Indirect insertions, which are also known as fibrous entheses or periosteal insertions, tend to attach to the shafts of long bones.^[26] The tibial insertion of the MCL is an indirect insertion as it fans and attaches along the shaft of the tibia.

ROLES IN JOINT GUIDANCE

Ligaments traverse joints and connect bone to bone. The principal role of ligaments in the body is to guide joint motion; however, ligaments also play a critical role in stabilizing joints by preventing excessive movement that would result in injury. Some ligaments also provide structural support for internal organs. At low loads, the characteristic crimp structure of ligaments permits them to guide motion without placing undue stress on the soft tissue. Conversely, their toughness and strength allow them to restrain excessive movement and thus prevent joint damage at high loads. In the knee, two collateral and two cruciate ligaments guide joint motion and limit rotation and translation of the femur on the tibia in all possible directions of motion. In the glenohumeral joint,

ligaments play similar, crucial roles for normal function. Given the lack of bony constraint near the glenohumeral joint, the capsuloligamentous structures, i.e., ligaments that are intrinsically attached to the capsule, in concert with other soft tissue structures, play a vital role by guiding the joint through its wide range of motion without allowing excessive motion. Similar roles are attributed to ligaments in joints such as the elbow, ankle, wrist, and spine.

Mechanical Properties and Loading

Although significant efforts have been put forth to definitively establish the mechanical properties of ligaments of interest, particularly the ACL, controversy still remains. Some concerns arise from differences in testing protocols between research groups since specimen orientation, strain rate, hydration, and other factors affect the apparent mechanical properties of ligaments. However, even when testing conditions are consistent, many researchers have observed significant biological variability between specimens. Some of this variability has been conclusively attributed to factors such as donor age,^[27,28] physical immobilization, and exercise regimen.^[29,30] Noyes^[31] reported that the ACL supports about 445 N under normal in-vivo conditions and fails at approximately 1730 N. Woo^[28] found the linear stiffness of the human ACL from younger donors to be 242 ± 28 N/mm with an ultimate load of approximately 2160 N when tested along the anatomical axis of the specimen. However, these values were found to be significantly lower for both older specimens (Table 1) and specimens tested along the tibial axis, which was consistent with the results of other studies.^[34] In one of the few studies reporting mechanical properties, Noyes and Grood^[27] documented the elastic moduli for ACL specimens from younger and older donors to be 111 ± 26 MPa and 65.3 ± 24 MPa, respectively (Table 1).

Proprioception

In addition to their primary roles in joint stability and guidance of joint motion, ligaments also appear to play a proprioceptive role. That is, nerves within ligaments are involved in afferent functions that convey information to the brain regarding position, motion, and acceleration of the joint.^[32,35–38] Researchers who study the glenohumeral joint have indicated that proprioception may help prevent injuries by signaling appropriate muscular responses that actually protect capsuloligamentous structures in the joint.^[33,39] Numerous studies of the knee joint have also shown that patients with both ACL-deficient joints and ACL reconstructions have a poorer sense of joint position than patients with intact ligaments.^[40–42] The lack of a functional proprioceptive response may contribute to the inferior kinematics and function of the joint that are often implicated in degenerative diseases and poor long-term outcomes for patients with both reconstructed and ACL-deficient joints.

DESIGN CONSIDERATIONS FOR TISSUE-ENGINEERED LIGAMENTS

The European Society for Biomaterials defines biocompatibility as “the ability of a material to perform with an appropriate host response in a specific situation.”^[43] Normally, the concepts of biocompatibility and appropriate host response are framed only in terms of the chemistries of biological systems and materials. That is, a biomaterial that does not initiate a damaging inflammatory or coagulation response is generally considered to be biocompatible. However, for many tissues and tissue replacements, such as ligaments and ligament analogues, mechanical function and tissue integration are also essential components of acceptable performance. For example, an ACL replacement graft with incorrect mechanical

Table 1 Structural and mechanical properties of human ligaments

Ligament	Ultimate load (N)	Ultimate stress (MPa)	Linear stiffness (N/mm)	Elastic modulus (MPa)
Human ACL (16–26 years) ^[27]	1725 ± 269	37.8 ± 9.3	182 ± 33	111 ± 26
Human ACL (48–86 years) ^[27]	734 ± 266	13.3 ± 5.0	129 ± 39	65.3 ± 24.0
Human ACL (22–35 years) ^[28]	2160 ± 157	–	242 ± 28	–
Human ACL (60–97 years) ^[28]	658 ± 129	–	180 ± 25	–
Human LCL ^[61]	309 ± 91		58.1 ± 22.8	
Human Patellar Ligament (age 24.9 ± 4.4 years) ^[62]	–	53.4 ± 7.2	–	363.3 ± 93.7
Human MCL ^[63]	–	38.6 ± 4.8	–	332.2 ± 58.3

properties will cause joint dysfunction, which possibly leads to meniscal damage, further knee joint instability, and the initiation of osteoarthritis,^[44] all of which are certainly inappropriate host responses. Likewise, a tissue replacement that is chemically biocompatible but fails to integrate with the natural tissue cannot be functional in the long term. Put simply, a ligament replacement that does not create a strong fixation with the surrounding bone will not be able to support load. Furthermore, any engineered tissue that doesn't permit nutrient transport via revascularization will eventually develop necrotic regions.

Therefore, a more inclusive consideration of biocompatibility for tissue-engineered ligament replacements should include multiple aspects of appropriate biological function *in vivo*—appropriate chemical and ultrastructural composition, clinically-desirable interactions with surrounding cells and tissues yielding appropriate wound healing and tissue integration, and mechanical/structural properties that allow normal joint function.

Integration with Bone Tissue

The ability of the ligament analogue to quickly affix to bone *in vivo* is one of the most important aspects to consider when creating an effective tissue-engineered construct. Bone heals readily when damaged or grafted, which is a potentially advantageous trait when attempting to integrate an engineered tissue with the body's natural tissues. Without strong bone fixation to the implant, even a mechanically competent engineered ligament will fail because the function of this tissue is ultimately to transmit forces across joints. Ligament analogue-bone integration is therefore a fundamental aspect of appropriate biological function. Since bone heals well, a truly biocompatible construct will take advantage of this response and direct the initiation of bone growth in a way that quickly attaches the engineered tissue to the constituent bone. This can be achieved either by specifically incorporating a segment of bone tissue at the end of the implant *in vitro* or allowing the natural bone tissue to simply assimilate the engineered ligament tissue upon implantation.

Goulet et al.^[45] have attempted to create a bone-ligament interface in their tissue-engineered ligament constructs by casting a ligament fibroblast-seeded gel between partially demineralized human bone anchors. While this approach did yield constructs histologically similar to natural ligament, the functional biocompatibility associated with the ligament-bone integration approach was not assessed. That is, true functional biocompatibility would have been demonstrated by a strong and quick incorporation of the cell-seeded collagen gel with the bone anchors. While

mechanical testing results were not reported for this study, the authors reported a “lack of strength” as the main drawback of their work.^[46] Using a similar approach, Altman et al.^[47] placed coral and cancellous bone anchors at the ends of cell-seeded collagen gel constructs, but they also did not report resulting mechanical properties of the construct. As it turns out, physical placement of bone on the ends of tissue-engineered ligament constructs may not be necessary for appropriate bone fixation. In a series of studies in a rabbit model, Dunn et al.^[48] reported some bone growth into drilled femoral tunnels eight weeks after implantation of collagen fiber constructs despite the lack of any bone tissue-engineering on the fiber constructs prior to implantation.

Despite the critical nature of the bone-ligament interface, surprisingly little research has focused on designing insertion replacements. The type of insertion to be replaced, *i.e.*, direct or indirect, should guide the structure of any such replacements. For example, a relatively hard, porous material that is formed of bone, hydroxyapatite, metals or alloys, etc. would likely be the best choice for anchoring direct insertion replacements and mimicking the natural anchoring structure. A shallow bone tunnel filled with collagen fibers may suffice for indirect insertions. Regardless of the type of insertion to be replaced, functional integration with the surrounding bone and maintenance of mechanical functionality over time are critical aspects that must be achieved for ultimate clinical use.

Maintenance of Mechanical Strength Over Time

Much research on ligament tissue engineering to date has focused on creating a functional construct with regard to the initial mechanical properties. That is, research has focused on creating a ligament-like scaffold that has mechanical properties upon implantation that are sufficiently similar to the natural ligament that there need be no reliance on tissue ingrowth or *in-vivo* strengthening prior to the construct being able to bear loads. Without sufficient mechanical properties upon implantation, a tissue-engineered ligament could easily fail before the body has a chance to integrate or remodel the new tissue. However, simply immobilizing the joint after the implantation of a tissue-engineered ligament to allow for strengthening is not advisable since studies of autograft ACL reconstructions have suggested that patients can achieve better outcomes if the joint is mobilized as soon as possible after surgery.^[49] Concomitant with the requirement of sufficient initial mechanical strength is the need for a mechanically sound implant to maintain strength in the *in-vivo* environment while being remodeled and incorporated into the surrounding tissue. As this is

associated with the natural healing process, it is not only of concern for tissue-engineered constructs. Orthopedic surgeons report that patellar tendon autografts weaken at about six weeks postimplantation^[46] as the surrounding tissues remodel.

In a 1993 study, Dunn and colleagues^[50] created collagen fibers for ligament tissue engineering with the goal of finding the optimal fiber diameter and cross-linking technique to maximize fiber mechanical properties and degradation rates. They found that low-diameter (20–50 μm), dehydrothermal-cyanamide cross-linked fibers yielded high tensile strengths (75–110 MPa) but quick degradation rates (typically within four weeks) and a minimal inflammatory response upon implantation in a rabbit model. On the other hand, glutaraldehyde cross-linked scaffolds did not degrade. Instead, they elicited a strong inflammatory response. Altman et al.^[21] took a different approach to creating a ligament analogue with tensile properties similar to natural ligament by forming silk-fiber scaffolds. They reported ultimate tensile loads of these constructs to be 2337 N, which is similar to human ACL,^[27,28] however, the biocompatibility and degradation rates of these scaffolds were not assessed.

A number of studies have examined the use of polymer scaffolds in ligament tissue engineering. However, many researchers have avoided this approach because the degradation of these constructs can result in acidic byproducts, which can potentially injure cells and surrounding tissue. Lin et al.^[5] seeded ligament fibroblasts on treated polyglycolic acid (PGA) fibers (Dexon II) and reported increased cell proliferation after applying a mechanical stimulus, i.e., fluid mixing, and growth factors. Tissue formation was observed within the constructs due to fibroblast extracellular matrix secretion. No data were reported on the mechanical properties of these constructs, their chemical biocompatibility, or degradation rates. In a similar study, Cao et al.^[51] attempted to construct tissue-engineered tendons with fibroblast-seeded PGA scaffolds. When implanted into the subcutaneous space of nude mice, the constructs appeared histologically similar to natural tendon after six weeks and had mechanical properties on the same order as natural tendon.

Researchers have also attempted to create tissue-engineered ligaments from collagen gels. However, the major drawback of this approach is that, because constructs lack the fibrous structure present in natural ligament, it is very difficult to achieve sufficient tensile strength for ligament application. Huang et al.^[52] applied mechanical tensile loads to fibroblast-seeded collagen gels and did achieve success in cell-mediated strengthening of the constructs; however, the mechanical properties of the constructs remained orders of magnitude lower than those of a natural ligament.

Altman et al.^[47] and Goulet et al.^[45,46] have also attempted to create tissue-engineered ligaments by casting a cell-seeded collagen gel between bone anchors and subsequently applying a mechanical tensile stimulus to the construct. The resulting mechanical properties of these tissues were not reported.

Our research group has attempted a combined approach to ligament tissue engineering by merging reconstituted collagen fiber scaffolds with cell-seeded collagen gels to create a composite material that mimics the composition of natural tissue. In this model, the reconstituted collagen fibers act as the collagen fibers in the natural tissue by supporting tensile loads while the cell-seeded collagen gel acts as the ground substance of the ligament by retaining water and the constituent cells. We produced reconstituted collagen fibers in a similar manner to Dunn and colleagues^[44,48,50,53–57] and cross-linked them in a solution of 1% (w/v) 1-Ethyl-3-(3-dimethylaminopropyl) carbodiimide hydrochloride in water. Fibers were then assembled into bundles and placed in a custom-built Teflon mold where they were surrounded with a cell-seeded collagen gel. After 25 days in culture, compared to nonseeded controls, the elastic modulus of the constructs had nearly doubled from 49.6 ± 3.3 MPa to 83.4 ± 10.8 MPa. These constructs have not yet been tested over long periods of time or in vivo (Fig. 4).

It should be noted that characterizing the modulus and strength of the ligament is not sufficient for ultimate clinical use. Because the toe-region (Fig. 2) of

Fig. 4 Fluorescent micrograph of cell-seeded collagen gel/collagen fiber composite after four days in culture. Original seeding density was 5×10^5 cells/mL. Collagen fibers fluoresce a bright red color. Living cells are stained green. Live/Dead Viability/Cytotoxicity Kit, Molecular Probes, Eugene, OR. Scale bar = 200 μm .

ligament load-elongation behavior is thought to be critical to guiding joint motion, a tissue-engineered ligament analogue cannot be considered successful unless it responds appropriately to relatively small stretches. In this context, reproducing the toe-region seems to be a more important consideration than precisely matching the modulus of the linear portion of the stress-strain curve to an individual patient.

Allowing Vascularization and Nutrient Transport

As stated previously, bone is not the main source of nutrients for ligament since the insertion creates a communication and vascular barrier between the bone and ligament tissues. Therefore, an effective engineered ligament tissue would presumably have to rely on vasculature or nutrient transport from the synovium to support constituent cells, just as natural ligaments do. Such nutrient transport can potentially take place via two methods. The engineered tissue either must have a vascular structure that can quickly integrate with the native blood vessels, or must be permeable enough upon implantation that constituent cells can survive via diffusion of nutrients from the synovial fluid while angiogenesis of the engineered tissue takes place. Both of these vascularization methods are biocompatibility issues. An engineered tissue that is well accepted by the body will be incorporated and vascularized whereas a nonbiocompatible tissue will experience degradation and fibrous encapsulation that will inhibit angiogenesis. Very few ligament tissue engineering studies have examined the issues of cell viability in analogues implanted in an animal model or the ingrowth of vasculature upon implantation. Bellincampi et al.^[58] implanted cell-seeded collagen fibers scaffolds in the knee joints of rabbits and observed seeded cells on the surface of collagen fiber scaffolds as late as six weeks after implantation, but very few cells were present between adjacent fibers. This seems to indicate that cells could survive on the surface of the implant because they were in close contact with nutrients from the synovial fluid. Cells within the scaffolds may not have been able to survive to the same extent because the scaffold was neither particularly permeable nor did it contain a microstructure to act as vasculature. Weadock et al.^[59] examined tissue ingrowth on collagen films treated with different cross-linking techniques in a rat model and found that cyanamide and severely dehydrated cross-linking techniques allowed for capillary growth in collagen implants within 14 days.

Avoiding Undue Inflammation

A major challenge of ligament tissue engineering is achieving a balance between creating a construct that

has sufficient mechanical properties to function effectively in a joint while not eliciting an inflammatory response. Much research has focused on using collagen fiber constructs to achieve this goal. Collagen fibers are an obvious choice because they mimic the structure of the natural tissue, they're biodegradable,^[56,59] and they have a low antigenicity. However, collagen fiber constructs require chemical cross-linking to both mimic cross-linking within the collagen of the natural tissue and provide strength.

In a series of papers focused on ligament tissue engineering, Dunn and coworkers^[48,53,54,60] attempted to strengthen their constructs by using glutaraldehyde cross-linking. However, they report that, upon implantation, the collagen fiber constructs "appeared to have caused an acute inflammatory response." Other observations included fibrous encapsulation of the implant^[53,60] and the presence of mononuclear and multinuclear inflammatory cells.^[48,53,54] Wasserman et al.^[57] found similar results for dehydrothermal and cyanamide cross-linked collagen fiber scaffolds implanted in tendon defects of rabbits. Cross-linking collagen fiber scaffolds with ultraviolet light led to scaffolds that did not initiate an inflammatory response, i.e., seeded cells survived on them for at least four weeks when implanted in the knee joints of rabbits, but they were completely resorbed after eight weeks.^[58] Carbodiimide cross-linking of type I collagen has yielded conflicting results with regard to initiation of an inflammatory response. Dunn et al.^[53] report infiltration of their carbodiimide cross-linked fiber prosthesis used to reconstruct a rabbit ACL by inflammatory cells. On the other hand, Kato et al.^[60] performed a similar study, but they implanted the prostheses in defects created in rabbit Achilles tendons without observing an inflammatory response. Weadock et al.^[59] concluded that carbodiimide should be chemically biocompatible because the only byproduct of its degradation is water-soluble urea.

Appearing Immunologically Acceptable

Tissue engineering efforts for ligament applications should develop not only a scaffolding material to provide functional support for the joint but also a means to remodel and incorporate that tissue with constituent cells once in vivo. Therefore, an ideal replacement would neither elicit an immune response because of the scaffolding material nor because of the constituent cells. The body's immune system recognizes any implanted material—whether it be cells, natural proteins, or a synthetic material—as self or nonself. Even among members of the same species, the immune system can distinguish self-cells from

nonselself-cells. Therefore, without some means to repress or deceive the immune system, the only way to incorporate constituent cells into a tissue-engineered ligament is to use the patient's own cells. However, the means to carry out this procedure has received very little attention because so many questions remain to be answered. For example, is it necessary for donor cells to come from the same tissue that they intend to replace? That is, are ACL fibroblasts necessary to tissue engineer an ACL? Bellincampi et al.^[58] used both ACL fibroblasts and skin fibroblasts to seed collagen fiber scaffolds for ligament tissue engineering. These constructs were later implanted in the knee joints of rabbits, and cell viability was assessed at up to eight weeks. In this study, the researchers removed the rabbits' ACLs to obtain the fibroblasts that were later seeded on the collagen fiber constructs. This would not be ideal with a human patient; however, as two surgical procedures—one to collect cells and the other to implant the cell-seeded construct—would be required. Furthermore, a patient with an older ACL injury may have no tissue because of resorption, and thus no ACL fibroblasts remaining in his or her joint. Although Bellincampi's data suggest that fibroblast source has little influence on cell viability once implanted in the joint, since fibroblasts from the rabbit ACL fared no better than skin fibroblasts upon implantation in the rabbit knee joint, more studies are needed to conclusively answer questions about appropriate cell sources for human tissue replacements.

Since harvesting cells from a patient's ligament tissue or even via a skin biopsy for example are not ideal solutions for obtaining cells to make a tissue-engineered construct, one logical step to avoid an immune response is to use cell lines from another species that have been transformed to be nonimmunogenic. Stem cells are another potential source for non-immunogenic cells for ligament tissue engineering. Both embryonic and adult stem cells offer the possibility of creating a tissue-engineered ligament with nonimmunogenic cells that are also morphologically and functionally ligament fibroblasts. Adult stem cells are fairly easily obtained from either the peripheral blood or the bone marrow of an adult's posterior iliac crest without significant discomfort, harvest site morbidity, or surgical invasion. These adult stem cells have the potential to differentiate into fibroblasts that could then be seeded on a construct to be subsequently implanted in a joint to repair a ligament. On the other hand, embryonic stem cells would have to be harvested from another member of the same species. While these cells have greater potential for differentiation, without some sort of intervention, they would still pose the same immunogenic difficulties that are encountered whenever a tissue transplant takes place. Furthermore, ethical issues involved with these cell lines.

CONCLUSION

As many as 150,000 Americans injure their ACL every year.^[1] Unfortunately, due to poor vascularization and the substantial mechanical demands to which this tissue is subjected, the ACL does not heal of its own accord. Moreover, surgical reconstruction with tissue replacements in the form of patellar tendon or hamstring grafts require long recuperation times. Similar problems are associated with the posterior cruciate ligament in the knee as well as ligaments in the ankle, shoulder, and elbow. Tissue engineering offers the possibility of creating functional tissue replacements to treat these types of injuries without many of the adverse side effects associated with current reconstructive options. The fundamental basis of ligament tissue engineering is the development of a biocompatible, resorbable, cell-seeded scaffold that, once implanted, can provide functional support while gradually transferring the mechanical loads born by the scaffold to neoligament tissue. Recent work indicates that cell-seeded collagen or silk fibers organized into a three-dimensional matrix can provide the appropriate initial stiffness. Skin biopsies or adult stem cell-derived fibroblasts yield host-specific cells, which thereby obviates the concern over the body's immune response. However, more research is required to optimize fixation of the ligament analogue to the native bone and find a means of introducing a nutrient supply. Likewise, the physiological role of crimp should be investigated and elucidated. These issues are all critical aspects of biocompatibility and must be solved in order to engineer functional ligament analogues.

T

INTRODUCTION

Liver-tissue engineering has the potential to prevent and treat liver diseases in a large number of patients worldwide. Hepatic failure can be caused by viral infection, drug reactions, toxins, and vascular complications. Currently, the only treatment for liver disease is orthotopic liver transplantation. However, a shortage of donors has led to a growing waiting list for those in need of hepatic transplantation. In the United States alone, from July 2001 to June 2002, only 5261 of 17,379 patients on the waiting list received a liver transplant, while 1861 died while waiting.^[1] Liver failure also generates a cost of \$ 9 billion each year in the United States.^[2]

The clinical options for hepatic transplantation include cadaveric whole-organ transplantation, reduced-size liver transplantation (RSLT), and split-liver transplantation. Recently, living donor transplantation in children and adults has been introduced. Because only 10–20% of the liver is required for life-sustaining function, and because the liver has regenerative properties *in vivo*, one donor liver can be divided to treat two patients. Because livers are not genetically identical, immunosuppressive drugs are required throughout the transplant recipient's lifetime. Despite vast improvements in therapy and antirejection medications, the immunosuppressant drugs often cause toxic damage to the liver and kidneys, requiring another transplant in later years.

OVERVIEW

The low ratio of available organs to needed organs has sparked the investigation of alternate treatments that would tackle not only the problems of entire liver replacement, but also the onset of liver disease and genetic disorders. Scientists have developed bioreactors to study the growth and function of hepatocytes in three-dimensional configurations. The bioreactor is a continuous flow system that allows for nutrients and oxygen to reach the hepatocytes seeded on a polymer scaffold while carbon dioxide and wastes are removed.

Bioreactors increase the survival and function of hepatocytes by acting as a circulation support system similar to that of the liver. Liver-assist devices (LADs) employ bioreactor advances by using hollow-fiber cartridges in which hepatocytes are seeded to treat liver failure patients in the short term.

The ultimate long-term alternative to transplantation may be an engineered whole-liver replacement. Our laboratory has used the bioreactor paradigm to design a microfabricated liver system that functions as an implantable whole liver replacement. This approach utilizes MicroElectroMechanical Systems (MEMS) technology to etch the vascular network necessary to support viability and function of hepatocytes *in vitro*.^[3] Our group has endothelialized this vascular bed, which can support hepatocytes seeded within an adjacent parenchymal chamber.^[4]

The multidisciplinary field of hepatic-tissue engineering involves cellular developmental biology, molecular biochemistry, polymer chemistry, physics, and other engineering sciences like computational biology and MEMS. Synergy has improved within tissue engineering as researchers make and employ advances in these varied areas. Due to the extensive scope of the field, of hepatic tissue engineering, this article is unable to incorporate every investigator's work and subfield, but presents a brief view of the background, accomplishments, and future prospects of the field.

THE HEPATIC ENVIRONMENT

The liver is a complex organ composed of endothelial cells and parenchyma cells such as hepatocytes, bile duct cells, stellate cells, oval cells (Ito cells), fibroblasts, and Kupffer cells.^[5,6] Most tissue-engineering research focuses on the hepatocytes that constitute 60% of the liver.^[3] This functional hepatic mass carries out toxin removal; metabolic function, including P-450 activity, glycogen storage, and gluconeogenesis for blood glucose regulation; synthesis of urea; and release of proteins, carbohydrates, and lipids.^[7,8] Many functional assays have determined that hepatocytes—both mature

and progenitor cells—exhibit certain functions such as albumin production when perfused from the liver or from a cell line, and cultured in both static^[9,10] and continuous flow systems.^[11,12]

The hepatocyte environment has many important factors that influence the cells' growth and functional, divisional, and apoptotic properties. However, a combination of components is required to alter the pathway of the hepatocytes.^[13,14] Hepatocytes will exhibit normal functions in a homogenous culture with added mitogens but will exhibit increased functional activity when cocultured with hepatic associated cells, which mimic their natural environment. This recreated hepatic cellular environment fosters heterotypic and homotypic cell–cell junctions and allows the cells to communicate via intercellular matrix interactions.^[15] Communication also occurs through insoluble molecules found in the extracellular matrix (ECM).^[13] The surrounding cells and matrix play an intricate role in determining through which pathway the cells will proceed.^[16] Hepatocytes are able to turn on growth and differentiation genes depending on with which ECM molecules the cells adhere or are in contact. These include laminin and type IV collagen (basement membrane), fibronectin, and type I collagen (interstitial matrix).^[13] In addition, binding of cell adhesion receptors (e.g., integrins) can lead to mechanical stresses that affect signaling pathways controlling cells' growth, differentiation, motility, and apoptosis.^[17] Pathways of replication and function are also dependent on the size and shape of the colony. At low densities of cells within a colony, the cells have a tendency to proliferate, expanding the colony to higher densities where they will differentiate and carry out normal metabolic functions.^[14]

Hepatic Interactions

Hepatocytes require external factors including environmental markers, growth factors, and cell signaling from the ECM. Researchers integrate these various environmental factors in culture systems and investigate their effects on growth and differentiation and function of cultured hepatocytes. Many of these growth factors and mediators work in a series of or in combination with other factors in initiating cellular pathways. Factors that are known to control the growth and proliferation of the cell include Epidermal Growth Factor (EGF), Fibroblastic Growth Factor (FGF),^[18] Transforming Growth Factor alpha (TGF- α), Interleukin-6 (IL-6),^[19] and Hepatocyte Growth Factor (HGF).^[10,20,21] Differentiation and function are stimulated by dimethyl sulfoxide (DMSO), nicotinic acid,^[22] corticosteroids, and amino acids.^[19] HGF and Vascular Endothelial Growth Factor (VEGF) mediate

angiogenesis. In addition to proliferation and angiogenesis, cell motility is also mediated by HGF.^[23] These signals and growth factors are among the many that contribute to cell signaling.

Hepatic Cell Source

Despite all the known factors that promote cell growth and differentiation, it is important to choose a source of cells with predictable phenotype and robust activity of desired traits. The forerunners for this role in the field of hepatic-tissue engineering are mature hepatocytes, oval/progenitor cells (primary hepatocytes, small hepatocytes)^[10,24] hematopoietic cells,^[24,25] and stem cells.^[25]

Mature hepatocytes currently in use are immortalized carcinoma cell lines such as SV40 Tag^[5,25] and HepG2.^[24,25] There are advantages in using an immortalized cell line: They are of a human cell line, exhibit a high degree of differentiated hepatocyte function, and are easy to culture in large quantities.^[24,25] It is imperative to maintain safety when using cell lines, and to avoid exposing patients to tumor-derived cells.^[5,25] Studies have shown that rat primary hepatocytes outperform human mature hepatocytes (HepG2) in regard to function and differentiation.^[24] However, obtaining a pure culture of primary rat hepatocytes is problematic, and for long-term survival it is difficult to extend the life of the rat primary hepatocyte through several divisions.^[10] Human primary hepatocytes have proven to be even more challenging to maintain in culture.^[25,26] Stem cells are being considered for their ability to differentiate into a normal liver cell exhibiting hepatic functions while maintaining the proliferating and differentiating abilities of a parenchymal cell.^[5,25] Evidence has shown that hepatic stem cells can be derived from other sources, such as the bone marrow,^[26,27] in addition to those found within the liver (oval cells). The sequences and combinations of signals needed to cue these cells into growth and differentiation are currently being studied.

Also debated as a source of cells are those cells used for xenotransplantation. Porcine hepatocytes have been shown to exhibit qualities and functions similar to human hepatocytes, such as urea synthesis, albumin production, and P-450 cytochrome activity, with the same therapeutic effects.^[8,28] Porcine hepatocytes have the clear advantage of being readily available (unlike human hepatocytes, which are scarce due to the lack of donor organs).^[8] There are many risks in using animal cells, however including the difficulty of overcoming immune rejection and the chance that zoonosis from viruses may transfer to the patient.^[25]

Coculture of Hepatocytes

The interactions between hepatocytes and cocultured cells can alter the hepatocytes' phenotype and stimulate or inhibit specific functional pathways. Rat primary hepatocytes cultured with fibroblasts^[19] or endothelial cells^[15] were able to maintain their viability and function. Cocultures with bone marrow stromal cells^[29] or nonparenchymal cells^[20] facilitated proliferation and differentiation. Epithelial cell and mesenchymal cell coculture have promoted the differentiation of hepatocytes.^[19] Studies have consistently shown beneficial results in the presence of specific cocultures that may help to recreate the natural environment of developing or functioning hepatocytes more effectively.

SCAFFOLDS FOR LIVER-TISSUE ENGINEERING

The model for tissue engineering combines a bioactive cellular component with a structural biodegradable scaffold. Once the desired cells have been isolated, the scaffolds play numerous essential roles in the task of creating functioning tissues and organs. Most cells—including hepatocytes—require attachment to a surface to function properly. In addition to providing an attachment surface, scaffolds help control three-dimensional configuration and growth, affect differentiation and function with surface characteristics and growth factors, and provide a carrier for implantation.^[30] To meet requirements for nontoxicity and nonimmunogenicity, early scaffolds borrowed technology from Food and Drug Administration (FDA)-approved sutures, wound dressings, and hemostatic agents.^[31] However, scientists are developing new biomaterials and are able to more precisely create and control the environment to which cells are exposed in tissue-engineered constructs.

Tissue-engineering biomaterials research focuses on the development and testing of new materials with different mechanical and chemical properties, degradation times, and cell-material interactions, and studies processing techniques that control microstructures and macrostructures to best promote the growth and function of specific tissues. There are many classifications of scaffolds—including gel or solid, biologic or synthetic, and biodegradable or nondegradable but biocompatible (see Table 1). Hybrid constructs have also been developed that combine more than one class of scaffold to vary characteristics of different regions of the constructs.

Poly(glycolic acid) (PGA) and poly(lactic acid) (PLA) are derived from resorbable sutures and have been used since the beginnings of the modern field of tissue engineering. They have crystalline and amorphous forms and can be combined in different ratios to control degradation characteristics. Depending on the desired

Table 1 Examples of different types of tissue-engineering scaffolds

Gels	Hydrogel, collagen gel, and alginate gel
Solids	All other non-gels listed below
Biologic	Small intestinal submucosa (SIS), and other decellularized matrices
Synthetic	All polymers
Biodegradable	Polyglycolic acid (PGA), poly-L-lactic acid (PLLA), polylactide-co-glycolic acid (PLGA), polycaprolactone (PCL), and polyhydroxybutyrates (PHB), Biorubber
Nondegradable and biocompatible	Polydimethylsiloxane (silicone or PDMS), polycarbonate (PC), polysulfone (PS), polyethylenes (PE), polyurethanes (PU), and polyesters

(From Refs. [31–33].)

conditions for development and the rate of ECM deposition, scientists can vary the degradation rate to allow for complete degradation of the polymer either entirely in vitro prior to implantation or after 2 weeks to 2 years in vivo. PLA, PGA, and PLGA have been effective and are in use in clinical applications of tissue engineering;^[31] however, these polymers have limitations due to their brittle nature and acidic byproducts. Numerous other polymers have recently been in the forefront of tissue engineering, including PCL, PHB, and pseudopoly amino acids that have different and more desirable mechanical, chemical, and degradation properties for different tissue applications.^[31] Novel polymers like biorubber^[32] have been developed with varying elasticity and strength for applications like heart- and lung-tissue engineering, and may also play a role in the future of hepatic-tissue engineering.

COATINGS AND FACTORS TO MODIFY SCAFFOLD AND HEPATOCYTE ENVIRONMENT

Scientists often turn to nature for guidance; tissue engineers attempt to recreate physiological conditions for cells by mimicking the environment—including the ECM—to which the cells are exposed in vivo. Attempts to recreate the ECM found in the liver have focused largely on surface characteristics to enhance interactions with cells for increased adhesion, proliferation, spreading, and function while reducing levels of dedifferentiation. Several prominent scaffold modifications include pore size, micropatterning, integration of adhesion factors, and surface coating with factors like collagen, fibronectin, and laminin.

Tissue repair normally takes place in the presence of glycosaminoglycans (GAGs)—especially hyaluronan (HA)—and ECM proteins like collagen, fibronectin, and elastin. In addition to utilizing genetic engineering to employ bacteria to produce ECM proteins or oligopeptides to make the scaffold more suitable for cell attachment, scientists can alter the genes of the cells to attach to a specific scaffold surface. Hepatocyte membrane integrins bind to adhesion domains in ECM proteins composed of short peptide sequences. The tripeptide sequence Arg-Gly-Asp (RGD)—an adhesion domain found in collagen, fibronectin, and vitronectin—and the pentapeptide sequence Tyr-Ile-Gly-Ser-Arg (YIGSR)—present in laminin—are two peptide sequences commonly being attached or incorporated on the surfaces of polymer scaffolds. Researchers have used a variety of intermediate molecules to integrate adhesion peptides to polymer scaffolds. RGD and YISGR have been linked to polyethyleneglycol (PEG), which is bound to ally-amine coating on polymers (PCL, PLLA) via pulsed plasma deposition.^[33] Comb polymers can be used to covalently bind adhesion molecules or other ligands to the surface of scaffolds.^[34,35]

Growth factors such as VEGF^[21] can be added as soluble factors or incorporated on the surface for interactions following cell attachment, in the bulk of degradable polymer used as scaffolding, or in microspheres that are slowly released over varying timescales. One area of concern is the acidic microenvironment created by the breakdown products of scaffolds like PLGA and its effect on cells and the bioactivity of growth factors, drugs, and other candidates for slow release. Researchers are currently developing and testing scaffolds that are more compatible with growth factors, drugs, and cells.

Another expanding area in material science research is the development of so-called smart polymers that are able to respond to changes in their environment such as to the pH, temperature, or concentration of a ligand. By employing a temperature-sensitive coating that has varying temperature-dependent cell adherence properties, researchers have been able to release cells grown to confluence from the culture surface in an intact sheet, avoiding damage to the matrix between cells that results from the use of trypsin in traditional cell passaging.^[36]

IMMUNE RESPONSE

For long-term replacement tissue-engineered implants, it is important to minimize immune responses to tissue-engineered constructs that can lead to inflammation, rejection, and cytokine production. Unlike allogenic transplantation or xenotransplantation, tissue engineering can employ autologous cells that do not require

the administration of immunosuppressive therapies that are toxic to both the liver and kidneys. In constructs engineered from the patient's own cells, the cellular component will be recognized as "self" and will not induce rejection. However, current applications with bioartificial liver-assist devices employ either allogenic human or xenogenic porcine hepatocytes. Efforts have been made to immunologically isolate these cells using blood separation and a series of membranes to prevent the release of any foreign hepatocytes into the blood, and to filter out those that may contaminate the blood or plasma within the device.

Whereas the cell source can be derived from the patient, most forms of tissue-engineered scaffolds are artificial. Because any artificial material implanted over an extended period will induce a foreign-body reaction that leads to scar tissue formation and rejection, it is imperative to use biodegradable polymers in tissue engineering for long-term therapeutic treatments. However, even with biodegradable polymers, there are still potential immunogenic problems. Residual monomer is thought to be a major cause of the rejection of biodegradable polymers, so care must be taken to purify polymers implanted either during or following synthesis. When solvent-casting polymers, extra care must be taken to remove all residual solvents, many of which are toxic to cells. Small intestinal submucosa (SIS) is a natural scaffold devoid of cells derived from the intestinal wall ECM that induces lower immunologic reactions. In SIS, immunoglobulin A (IgA) may suppress immune response despite also having the galactose α -1, 3 epitope (α -gal), which is normally attacked by human immune systems by the naturally expressed anti- α -gal antibody. SIS implants in mice induce levels of interleukins IL-4 and IL-10, but not the interferon IFN- γ , and the antibodies mounted are only of the immunoglobulin IgG1 class.^[37]

HEPATIC BIOREACTORS

The purpose behind creating the bioreactor was to develop a larger, functioning, viable, and proliferating three-dimensional aggregate of hepatocytes required for support and eventual replacement of hepatic functions in an implantable liver construct. A basic bioreactor functions as a continuous flow system that circulates media in lieu of blood through tubing, an oxygenator (lung), and enclosed capsule that contains a scaffold with engrafted hepatocytes in a three-dimensional configuration (see Fig. 1). Hepatocytes in bioreactors have been shown to exhibit normal hepatocyte function for longer periods than seen in a static two-dimensional culture. Researchers of hepatic bioreactors are experimenting to develop more efficient and effective configurations to allow for longer survival and specific function for larger masses of hepatocytes. As the aggregate of cells increases

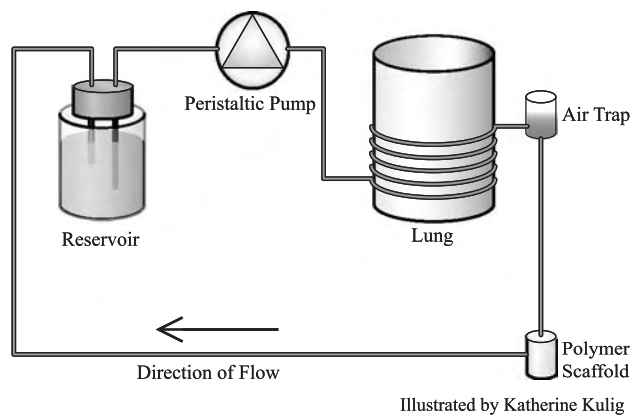

Fig. 1 Bioreactor for in-vitro culture of hepatocyte polymer constructs. (From Refs. [6,11,12].)

in size, fewer cells survive due to limited nutrients, waste removal, and oxygen exchange. Whereas the cells in the peripheral zones thrive with readily available and accessible nutrients and gases, the cells within the core of the construct often have an increased mortality rate due to the impedance to mass transfer. These necessary functions occur in vivo with the assistance of a vascular system. In order to improve the life span and normal hepatic functions of hepatocytes in an aggregate, all cells must be within 100–300 μM of a blood supply.^[38] The bioreactor system supplies the needed surface for attachment via the polymer construct (PGA, PLLA, PLGA) of optimal porosity and through dynamic seeding techniques and even distribution of cells while angiogenesis occurs.^[11] The flow-through design has enabled many investigators to demonstrate long-term viability and increased production of hepatic products such as albumin, cytochrome P-450 activity, and other metabolic processes. The benefits of long-term survival and growth provide insight into the need for tissue replacement, and also act as an in-vitro liver replicate for future drug testing. (See Fig. 1.)

LIVER-ASSIST DEVICES

An expanding area of research that overlaps and has synergy with hepatic bioreactors for tissue engineering is the development of liver-assist devices (LADs). LADs are being tested in both laboratories and clinical trial devices as a gateway treatment for patients with FHF to support them on a timescale of weeks until a liver becomes available for transplant. These systems may also be beneficial in the short term for patients excluded as candidates for transplant.

The primary functional goal of the devices is to detoxify toxins accumulating in the blood stream because of hepatic failure. Laboratories are developing a variety

of LADs that are not yet in clinical trials, using different cell sources and membrane configurations such as a spirally-wound polyester fabric with direct hepatocyte-blood contact^[28] or a multicoaxial set of four porous tubes.^[39] Devices in clinical trials draw from Wolf's idea and combine the hollow fibers used in kidney dialysis cartridges technology with added living hepatocytes to restore some of the biologic function of the liver.^[40] (See Fig. 2.) Many of the configurations incorporate activated charcoal to help remove toxins, in addition to oxygenators and heaters to support the hepatocytes. The hepatocytes are typically seeded on either the fiber surface or in microcarrier beads in the extrafiber space.^[41] The compartment seeded with hepatocytes can also be separately perfused with media to both support hepatocyte function and help remove toxins from the device. High levels of toxins in the blood are thought to be the main reason for the development of encephalopathy from liver failure. In one configuration, hepatocytes are seeded within the hollow-fiber lumen in a collagen gel that contracts 60% to allow flow through the lumen that is independent of the extrafiber flow;^[42] this serves as the basis for Algenix's LiverX200 that will soon begin phase I trials. LADs currently in clinical trials are the HepatAssist[®],^[43–45] ELAD[™] (Extracorporeal Liver-Assist Device),^[46–48] MELS (Modular Extracorporeal Liver Support),^[49–51] and BLSS (Bioartificial Liver Support System).^[52–55] The cells utilized in these clinical trials are human hepatic cell line HepG2/C3A cells (ELAD), human primary hepatocytes harvested from untransplantable livers (MELS), or porcine, hepatocytes (HepatAssist, BLSS). With one exception, the BALs all separate the patient's blood and perfuse only the plasma. The exception is the BLSS, which perfuses with the patient's whole blood through the porous polysulfone (HepatAssist, MELS) or cellulose acetate (ELAD, BLSS) hollow fibers of dialysis cassettes that are seeded with hepatocytes in the extrafiber space. In perfusing only the plasma, precautions are taken to isolate these cells and possible pathogens (including viral particles from the patient's blood) by employing filters with pores 0.2 to 1.5 microns in diameter. Although these devices have been successful for short periods, fully implantable replacement systems are required for long-term therapy.

TISSUE-ENGINEERED LIVER REPLACEMENT

A functional replacement liver has long been the goal of the field of tissue engineering. Greater success has been achieved with other tissues, such as cartilage and skin, due in large part to their relatively low metabolic rates and thin dimensions, respectively. With the major limitation being sufficient circulation for three-dimensional hepatic tissue, approaches such as direct

Fig. 2 A schematic drawn from multiple LADs designed for clinical trial. (From Refs. [42–55].)

hepatocyte injection into existing vascular beds, micro-carrier attachment, and scaffold support and attachment have been investigated as possible means of hepatic functional support and eventual replacement.

One method of vascularizing tissue-engineered liver constructs is to promote angiogenesis into a non-vascularized implant. Angiogenesis research advances have induced an increase up to 260% in matrix neovascularization after one week with the addition to the construct of VEGF and endothelial cells.^[56,57] Adding or integrating angiogenic factors such as VEGF to the environment of hepatocyte constructs has resulted in improved function and viability over constructs without induced angiogenesis. However, successful results in vivo have been limited to thicknesses that would not be feasible for a clinical replacement mass of hepatocytes.

Another approach for gaining sufficient circulation is to inject cells (with or without a gel) into an area of the

body that is already sufficiently vascularized to support the additional hepatocytes. Direct hepatocyte injection has focused on the degree of liver function replaced and the cells' ability to sustain the metabolic functions of the liver. The cells have been injected directly into vascular beds, organs, and body cavities. The spleen and its related peritoneal cavities have been successful in maintaining transplanted hepatocytes.^[5] Cell transplantation has been effective at curing some forms of genetic diseases with specific hepatic function defects; however, the mass of cells that can be injected and supported by the existing vasculature is not sufficient for liver replacement. To improve the attachment and survival of human hepatocytes transplanted into athymic rats, our laboratory provided hepatotrophic stimulation with a portocaval shunt and prevascularized polymer sponges; placing the constructs in subcutaneous tissues and between mesenteric leaves allowed for the concomitant

ingrowth of fibroblasts and vascularization of the construct.^[58]

A prototypical implantable tissue-engineered liver would have three external connections, a blood inlet and outlet, and an outflow for bile, with a preexisting internal network of blood vessels and ducts branching down or almost down to the capillary and ductile level. Whereas complex bioreactors have been designed that can support complex three-dimensional configurations of cells, nonprevascularized hepatocyte constructs do not survive *in vivo* because they do not have access to a sufficient supply of oxygen, nutrients, and waste removal. The mass of hepatocytes required to support a large animal or human would require a rapid blood supply throughout the construct for the cells to survive and function. To solve the problem of mass transport in a thick, metabolically active whole-organ replacement, our laboratory has developed a tissue-engineered vascular bed designed to support metabolic tissues.^[3] Three-dimensional printing is capable of producing complex three-dimensional branching networks, but currently lacks the resolution to fabricate capillaries. Using photolithographic techniques borrowed from the computer chip industry, our group etched patterns of vascular beds with capillary-scale branches on silicon wafers. These patterns can be transferred to biocompatible materials such as polydimethylsiloxane (PDMS) or biodegradable polymers like PLGA. The channels can be sealed and seeded with endothelial cells that have been grown to confluence. Stacks of these vascular beds can then be interposed with layers of parenchymal cells such as hepatocytes and communicate through membranes that allow the transfer of oxygen, nutrients, and waste. (See Fig. 3.) We have recently grown hepatocytes that are supported by a microfabricated vascular bed that communicates

through a porous membrane with the hepatocyte compartment.^[4]

CONCLUSION

Although the modern field of tissue engineering has made great advances in the past thirty years, there is no functional tissue-engineered liver replacement construct to date. However, a number of promising developments and research in diverse fields show clinical improvements in trials and are advancing the field toward a therapeutic alternative to liver transplantation. Progress in understanding cell developmental and molecular biology, polymer scaffold development and testing, development of human liver bioreactors for drug testing, application of gene therapy, and means to store three-dimensional tissue constructs will provide improved methods of treating patients with liver diseases.

As the need for the optimal cell source is considered for research and tissue engineering, ultimate control over the destiny of the cell—be it differentiation or proliferation—is the factor that determines which type of cell line is used. Globally, embryonic, fetal, and adult stem cells are being studied to further characterize their potential and ability to functionally repopulate or replace diseased tissues. As more is understood about stem cells, regulatory and ethical principles must be developed and instituted to prevent therapeutic misuse or premature clinical application. In addition to cell biology research, novel scaffold materials development and testing are essential for the advancing field of tissue engineering. Scaffolds with more ideal physical properties and surface characteristics are only part of the picture; other factors in the hepatocytes' environment must continue to be

Fig. 3 Tissue-engineered liver replacement. (From Refs. [3,4].)

developed to better mimic conditions in vivo. Used in concert with cell transplantation or in cell-polymer constructs, gene therapy may offer powerful means to treat patients with genetic defects that impair liver function. Gene therapy may help prevent immunosuppression if tissue-engineered liver constructs were to house a patient's conditioned cells. Storage of tissue-engineered constructs may become possible as vitrification and desiccation protocols advance with fewer harmful cryoprotectants (such as disaccharides), and as damage to cells and their membranes is minimized.^[59] In addition to future storage facilities, a novel approach to drug testing will also become available.

The Hepatitis C virus (HCV) is the leading cause of liver failure in the United States; in one year those infected with HCV accounted for 8000 to 10,000 deaths.^[25] Unfortunately, there are difficulties in developing drugs to treat the disease; because HCV infects liver tissue only in humans, animal models are ineffective for testing HCV drugs. Researchers can use bioreactors with HCV-infected human hepatocytes to develop effective treatment. The liver also plays a key role in the breakdown of other drugs such that in vitro and implant models with human hepatocytes will help screen drugs that may be either harmful to or inactivated by the liver.

The expanding field of hepatic-tissue engineering has already shown clinical benefit and promises to provide even more robust long-term support for patients with liver disease. In this exciting and multidisciplinary field, it is imperative to collaborate and to integrate a wide array of information in the quest for the holy grail of a tissue-engineered replacement liver. Advances leading to the realization of a replacement liver will serve not only to benefit patients with liver failure, but also to advance the development of therapies for other diseases.

T

INTRODUCTION

The last decade has seen the dramatic development of biomedical technologies for organ replacement. The ability to perform tissue and organ replacement has led to an improvement in quality of life and healthcare. Some of this success can be attributed to the interdisciplinary approaches of tissue engineering. The goal of tissue engineering is to augment, replace, or restore complex human tissue function by combining synthetic and living components in appropriate configurations and environmental conditions.^[1] Scientists with very diverse backgrounds collaborate with engineers to develop tissue analogs. There are generally three key components to consider in any tissue-engineered construct: the cells, the scaffolding or biomaterial construct, and the signaling molecules. Cells are an active living component in the tissue-engineered product. Cellular processes such as adhesion, migration, growth, secretion, and gene expression are triggered or influenced by the three-dimensional organization of the surrounding cells, scaffolds, and signaling molecules. Cells play a central role in building and maintaining specific tissue function, but when they are separated from their natural living environments and cultured *in vitro*, the physiological cellular activities are either diminished or reduced. Thus, it is critically important to develop a fundamental understanding on how the surrounding microenvironments induce and maintain the stability of the cellular functions, and then apply the understanding in designing biomimetic environments to encourage isolated cells to recover their *in-vivo* functions.^[2,3] Scaffolding or biomaterials for tissue engineering are not just inert supports in tissue-engineered constructs as they were used in the early stage of tissue engineering.^[4] The impact of the microstructure, surface chemistry, surface topography, and tissue-integrating ability has been increasingly realized. The precise control of the interactions between cells and scaffolds has received more and more attention. Signaling molecules mediate interactions and may induce cells to generate signals in mechanical, biological, chemical, and electrical forms for communications. The three-dimensional distribution of these molecules should be well controlled. From an engineering standpoint, it is important to choose an appropriate method

for synthesizing or assembling all the components into a biological and medically meaningful structure that will confer desired functions.

HISTORICAL BACKGROUND

Although tissue engineering is a relatively new field, a multitude of strategies has been developed. The design of many tissue-engineered systems, such as the vascular system, bone, and skin, evolved from bioinert prostheses to bioinert surface-coated prostheses, and then to biointeractive and biomimetic prostheses. The approach of bioinert prostheses uses only scaffolding materials, for example, ePTFE and dacron grafts used to replace arteries in cardiovascular surgery.^[5,6] The majority of these grafts not only lack typical components of healthy native tissues, but also lack the ability to restore tissue integrity through quiescent scar formation. A further step in tissue engineering is to reconstruct cell-seeded biomaterials via surface coatings on the biomaterials.^[7,8] In spite of many successes, inflammation and adverse healing responses in these grafts are found to be a serious problem. Therefore, biointeractive or biomimetic prostheses, which have the hope of subduing adverse responses and facilitating the healing process, have been extensively developed in recent years.^[9,10]

A fundamental issue in any design of biointeractive or biomimetic prostheses is the dimensional scale of the interactions. It is known that tissue function is highly related to the tissue structure. The way in which cells interact with other cell types, the surrounding scaffold, and the signaling factors, is dependent on the complex micro- to nano-scale tissue structure. In addition, the effects of physical forces or electrical signals are also dependent on the tissue microstructure. Researchers have attempted to control all these conditions, collectively called microenvironments, precisely *in vitro* using various forms of nano- or microtechnology. When studying cell function and designing tissue replacements, microtechnology can help to replicate the cells' *in-vivo* dimensional, configurational, and compositional environment, thus creating more physiologically relevant models of cell and tissues.^[11-13] Although the promise of tissue engineering is rapidly becoming a

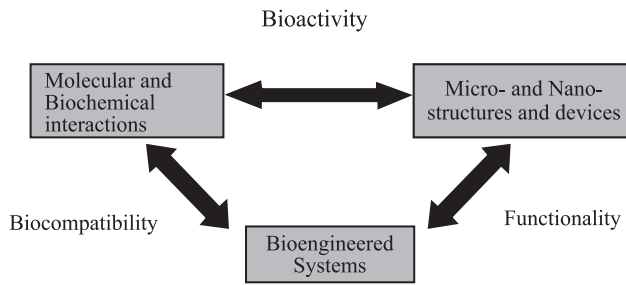

Fig. 1 The influence of the microscale on cellular and subcellular function.

reality, there are several challenges to overcome in the near future. This article will concentrate on one aspect of those challenges, namely the development of tissue-engineering constructs that more closely replicate complex tissue architecture and arrangement. It is through the incorporation of micro- and nanoscale features that we can significantly affect cellular and subcellular function (Fig. 1).

OVERVIEW OF MICROTECHNOLOGY

Traditional microfabrication techniques, such as micromachining using silicon wafer or glass, have been used widely in biological applications, but recently researchers have developed nano- and microtechnology using natural and synthetic polymers specifically for biology and medicine. Here the microtechnology, a collective term for micromachining, surface engineering, and soft lithography, will be briefly reviewed.

Micromachining

The processes of microfabrication and micromachining use photolithography, along with the deposition and selective etching of thin film layers, to create microscale (and even nanoscale) features on a given substrate. Structural materials, as opposed to sacrificial layers, complex features such as microchannels and micropores, as well as other two- and three-dimensional shapes, can be chemically etched in substrates. Using a series of combinations of additive and subtractive microfabrication processing, complex structure with multiple components can be fabricated. Micromachining has conferred many enhancing and enabling qualities to the devices. However, for tissue engineering purposes, sometimes silicon and glass are not ideal choices, so they should be either modified or replaced with biocompatible materials.

Surface Engineering

Surface engineering is the process of modifying the substrate surface with surface modification techniques.

Surface chemical modification of a substrate is one key to long-term interaction with biological systems. Control over biomaterial surface chemistry and atomic microstructure can result in a regulated cell response.^[14] In general, surface modifications fall into two categories: 1) chemically or physically altering the atoms, compounds, or molecules in the existing surface (treatment, etching, chemical modification), or 2) overcoating the existing surface with a material having a different composition (coating, grafting, thin film deposition) (see *Surface Modification*). After surface engineering, the surface can be either biointeractive or bioinert, providing more compatibility for tissue-engineering prosthesis.

Soft Lithography

Soft lithography employs polydimethyl siloxane (PDMS) elastomer to fabricate microstamps, microfluidic channels, and micromolds (Fig. 2).^[13,15] Although the original master is created via conventional photolithography, once the master is created, it can be reused many times outside of a clean room. Thus, the technique is cheaper and more amenable to different substrates^[16] and can be used on nonplanar surfaces as well.^[17]

Novel techniques using soft lithography have been developed and used extensively in biology and medicine. For example, microcontact printing technique employs a microstamp to transfer microscale patterns of chemicals or biomolecules onto a substrate, thus creating patterned surfaces.^[18–20] Microfluidic technique employs one or more paralleled or networked microchannels to pattern proteins or cells onto a substrate.^[21,22] Fluid flow at the microscale exhibits unique phenomena that can be leveraged to create multiple chemical environments.^[23] Laminar flow has been used with PDMS microchannels to adjacently pattern various proteins and cells on the culture substrates.^[24,25] Formation of microscale chemical gradients was created by microfluidics, and the neurons put into the environments with the gradients of chemicals oriented and differentiated according to the gradients.^[26,27] Three-dimensional microfluidics can pattern multiple cell types on the substrate.^[28] Detailed reviews on soft lithography have been given by Whitesides.^[13]

Fig. 2 Examples of surface engineering and soft lithography (a) self-assembled monolayers; (b) microcontact printing. (From Ref. [16].)

ACHIEVING CONTROL BY MICROT TECHNOLOGY

Equally as important as fabrication techniques, the next issue is the application of microtechnology tools in tissue engineering to achieve control over the microstructure and microenvironment, while at the same time developing an understanding of the control mechanism that will impact the tissue-engineering designs. Specifically, techniques that can be used to achieve topographical, spatial, chemical, and immunological controls over tissue-engineered constructs will be addressed. Though not highlighted here, the physical force is also a potential aspect for microcontrolling the environments of cells, for example, micro- and nanoscale mechanical stresses (mechanophysical patterning) generated by cell–biomaterial interactions, since they may have significant effects on phenotypic behavior.^[29]

Topographical Control

Topographic modulation of the tissue response can be one of the most important considerations during the design and manufacture of biomaterials.^[14,30] A tissue-engineered construct that has a well controlled microstructure will better maintain cell morphology, differentiation, and functionality over long periods of time. A key feature of these constructs will be the replication of in-vivo geometry and dimensional size scale that will aid in the maintenance of an in-vivo–like cell phenotype. Silicon micromachining techniques make it

relatively easy to generate the complex geometries on the nano- and microscale that are required to model physiological environments in living tissue. However, recently novel approaches have been developed to create microstructured polymers,^[31–35] which has opened up unique opportunities in substrate development for tissue-engineering applications. The development of microfabricated constructs using natural and polymeric biomaterials may allow us to engineer highly controlled interfaces that are: 1) more physiologically relevant and hierarchically arranged, and 2) biologically, mechanically, and optically compatible.

By combining living cells and two- and three-dimensional substrates with microfabricated topographical features, investigators have begun to address fundamental issues such as cell adhesion, orientation, and migration, as well as tissue integration and vascularization. For example, it has been shown that microtexture has significant effects on cell proliferation and adhesion.^[36] Surfaces with microtopography can augment fibroblast attachment and induce contact guidance of these cells.^[37] Furthermore, DNA profiles were influenced by microtexture and the fact that cells on 10- μm –wide grooves proliferated less than cells on 2- and 5- μm grooves.^[35,38] The arrangement of cells in controlled two- and three-dimensional arrangements has been shown to have beneficial effects on cell differentiation, maintenance, and functional longevity.^[39] In addition, many researchers have demonstrated that topography can influence and direct cell migration. The width and spacing of the lines can be used to control the

speed of cell movement. For example, etched parallel grooves can control cell spreading and migration in the axis of the lines, even when the depth and spacing of the grooved features are as small as 500 nm, about ten times smaller than the typical length of a mammalian cell.^[40] Therefore, the design of microtextured tissue-engineering matrices provides more physiological conditions under which to maintain cells.

Spatial Control

Creating a tissue-engineered product requires specific biological considerations regarding cell type, scaffold materials, bioreactor design, and environmental conditions (signaling proteins, neighboring cells, and physical stimuli). Thus, another important challenge in tissue engineering is to control the spatial organization of cells in their synthetic microenvironments. This is especially vital in the bioengineering of tissues that have multiple cell types and require precisely defined cell–cell and cell–substrate interactions. For example, the functioning of tissue such as retinal, cardiac, and vascular is dependent on the controlled orientation of multiple cell types. A key determination in the engineering of these tissues is how, and to what extent, this microenvironment, be it a two-dimensional surface or a three-dimensional matrix, can be controlled *in vitro* to recreate *in-vivo*-like architecture.

Microtechnology offers the potential to control cell–substrate, cell–cell, and cell–medium interactions on a micrometer scale. Microengineering the interactions between cells and their microenvironments is reviewed by Folch and Toner.^[2] Compared to the traditional cell culture where no or little control is able to be exerted on cells, defined architectures yield more predictable patterns of growth and differentiation. A control over the spatial assignment of cells and their environments effectively mimic the natural ordering of tissues.

Chemical Control

Microtechnology has also been used in the identification and application of defined chemistries in the extracellular microenvironment. The chemical patterning of adhesive and nonadhesive regions onto a substrate at the resolution of single cells has relied on a variety of techniques such as photolithographic patterning of surface chemistries with either covalent linking or chemical adsorption of the protein,^[41] microcontact printing of self-assembled monolayers of different chemistries or proteins,^[18–20] and solution coating of microfabricated surfaces.^[42] Using these approaches, substrates (typically planar) can be designed to promote cell attachment or cell repulsion, provided that the appropriate cell-specific ligands are used. Ultimately, these

approaches may provide clues about chemical cues that direct tissue assembly and regeneration.

Recent advances in cell biology have highlighted the importance of the ligand–receptor interaction for controlling cellular adhesion. Therefore, approaches have been developed to coat surfaces with extracellular matrix protein to create adhesive regions^[43] or to link integrin ligands covalently to the surface. The well known RGD cell adhesion ligand provides a simple mechanism of modifying surfaces on the microscale to mimic the extracellular matrix. Peptides that contain the Arg–Gly–Asp (RGD) attachment site, together with the integrins that serve as receptors for them, constitute a major recognition system for cell adhesion and cell–substrate interaction.^[44] It has been shown that substratum adhesiveness can be micropatterned using peptides to create a model for morphogenetic cues controlling cell behavior.^[45]

Another way to microengineer the interface is by covalently or noncovalently immobilizing bioinert hydrophilic polymer chains or heparin (anticoagulant) molecules onto the material surface. For example, polyethylene glycol (PEG), a water soluble, nontoxic, and nonimmunogenic polymer, has been shown to significantly decrease both protein and cell adsorption on several biomaterials.^[46,47] PEG can be micropatterned with RDG, or other molecular peptides, to create multifunctional surfaces that both repel unwanted proteins and promote cell interaction. By using functional groups such as PEG, surfaces can be tailor made to elicit specific cell and protein response as well as decrease adsorption of nonspecific biologicals. Furthermore, these linkage groups can be further modified by attaching biomolecules, immunomolecules, or recognition factors in order to create more biocompatible and biofunctional interfaces.^[48,49]

Immunological Control

Another key factor influencing the success of tissue-engineered constructs is the interaction with the immune response. The immune response (cell-mediated and humoral) accounts for both short- and long-term biological effects such as hypersensitivity, foreign body reactions/fibrous encapsulation, and ultimately rejection. With regard to acute rejection that occurs due to antibody recognition and complement fixation, investigators have attempted to hinder passage of these effectors by encapsulating cells with size-selective polymer membranes. Such immunoisolation membranes are able to shield transplanted cells via an immunoprotective semipermeable shell. Several diseases are being investigated for treatment by cell immunoisolation, including diabetes, growth hormone deficiency, and Parkinson's disease.^[50–53] Micro- and nanotechnology

may offer a better tool to fabricate membranes of specific pore size, allowing one to optimize the biocapsules specifically for the encapsulation of pancreatic cells.^[54] Such membranes are capable of completely blocking immunomolecules (with sizes of ≥ 15 nm), while allowing the passage of insulin and nutrients (with sizes of ≤ 6 nm).

DEVELOPMENT OF MICROSCALE TISSUE ENGINEERING IN DIFFERENT TISSUES

Most microtechnologies have been directed toward basic cell studies or cellular array for drug screening, as opposed to real tissue-engineered products. Tissue-engineered products are far more complicated than just cell patterns or controlled cell–cell interactions on a flat surface. Tissues and organs are very heterogeneous. They are composed of layers, membranes, cells, and channels. Each function requires the appropriate components: cells, and materials of appropriate sizes (typically micro- or nanoscale). Through these heterogeneous components, sophisticated functions can be achieved. Tissue function is modulated by an intricate architecture of cells and biomolecules on a micrometer scale. With the incorporation of microtechnology into biology, it is now possible to design surfaces that reproduce some of the aspects of that architecture.

The following paragraphs will review the efforts made toward microscale tissue-engineered products in some biological systems: pancreatic, hepatic, cardiovascular, skin, and neural. Although design principles and control mechanisms are shared in all the approaches, due to the difference in structure and functionality between organs, some microtechnology might be more advantageous for particular tissues.

Pancreatic Tissue Engineering

Desai et al.^[55,56] have created microfabricated nanoporous biocapsules for the transplantation of insulin-secreting cells. To turn the microfabricated biocapsules into a tissue-engineered product, several tissue-engineering related issues have been taken into consideration: immunoprotection of encapsulated cells, biocompatibility of the implant, and the effect of microenvironment on cell viability and functions.^[57]

A schematic diagram of the microfabricated biocapsule is shown in Fig. 3. The basic technology that was developed for the pores themselves was the use of a sacrificial oxide sandwiched between silicon layers, thus defining a space that could be opened by a subsequent etching of the oxide in hydrogen-fluoride. To create the final immunoisolation capsule, the silicon substrate is etched up to the membrane, leaving a cavity in the wafer with an encapsulating immunoisolation membrane. Pancreatic islets are placed within the membrane-bound cavities and the two separate microfabricated membranes are bonded together.

The functionality of insulinoma cells, mouse beta cell tumor (betaTC-3) cells, encapsulated in microfabricated biocapsules and unencapsulated cells, has been evaluated in terms of insulin secretion. The amounts were similar in concentration and time release suggesting that glucose was able to pass through the membrane pores sufficiently to stimulate islets for insulin production. Figure 4 shows the typical insulin release profile in response to stimulatory (16.7 mM) glucose. At the same time, the biocapsule excludes the passage of IgG.

The ability to prolong pancreatic islet cells' viability and functionality within the immuno-isolation device can be achieved by providing cells within a three-dimensional matrix that would ideally mimic the biological extracellular matrix^[58] and therefore the in-vivo

architecture of the endocrine pancreas. BetaTC-3 cells were cultured within three-dimensional matrices and compared with cells grown in standard conditions. At day 6, a rearrangement of the cell spatial distribution is observed in the collagen–chitosan matrix and small cell clusters are visible (Fig. 5). Collagen seemed to perform better as a matrix material in the biocapsule, preventing aggregation and maintaining a homogeneous cell distribution. Higher diffusion was associated with collagen and collagen–chitosan, while little diffusion was detected from biocapsules with a simple cell suspension (Fig. 5). The use of matrices, and collagen in particular, proved to augment the functionality of betaTC-3 cells in microfabricated biocapsules.

In order to retain the same performances in vivo as in vitro, the biocapsule must be fully biocompatible and able to integrate into the host body, eliciting a minimal foreign body response. The degree of the foreign body response is known to depend upon several parameters, such as size of the device, the outer morphology of the

capsule, the surgical technique, and the site of implantation. For example, the responses of the biocapsule sutured to the abdominal wall or within the omentum were quite different. And PEG-modification of the membranes significantly improved biocompatibility (Fig. 6).

An immunoprotective capsule has the advantage of being able to use different cell sources other than the cells originated from the host, such as xenogeneic cells and tumor cell lines. Therefore, the cell source for a tissue-engineered product is significantly increased.

Liver Tissue Engineering

The liver is a multicellular complex organ. The adult liver provides a scaffold for many complex cell–cell interactions that allow for effective, coordinated organ function. Coculture is emerging as a necessity in successful designs of the bioartificial liver (see *Liver, Bioartificial; Tissue Engineering of Liver*). Bhatia et al.

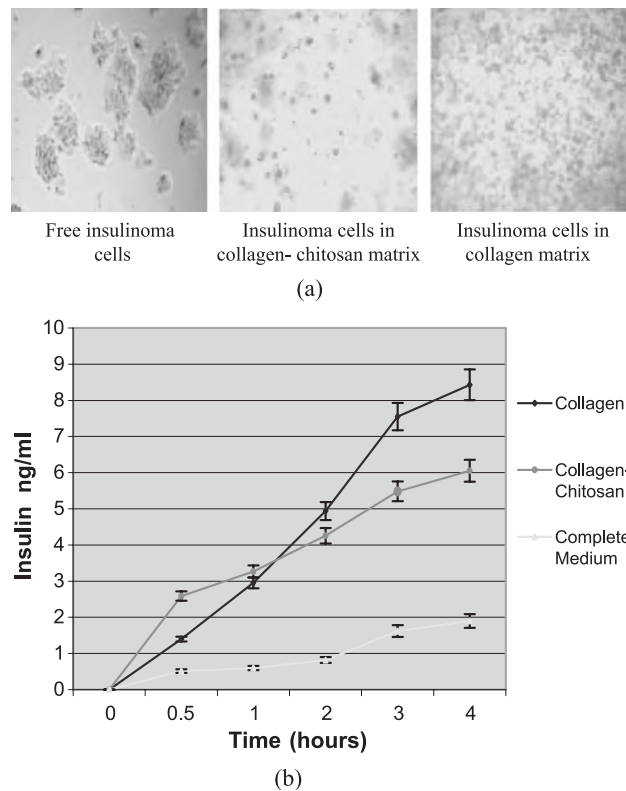

Fig. 5 (a) Cell distribution in different living conditions at day 6. (b) Insulin secretory profile through microfabricated biocapsules.

investigated microscale cell-cell interactions in cocultures for enhancing the liver-specific functions of cells. They developed a technique for micropatterning two different cell types based on strategies for surface modification with aminosilanes linked to biomolecules and the manipulation of serum content of cell culture media. Through this, the spatial organization of hepatocytes and fibroblasts could be precisely controlled. This approach could eliminate variations present in random mixed cocultures. The amount of heterotypic interface and homotypic interface, as well as ratios between two cell types, can be modulated precisely

Fig. 6 Microscopic appearance of tissue surrounding the subcutaneous implants retrieved from Lewis rat after 17 days. Two types of implants were used: unmodified silicon membrane (a) and PEG-modified membrane (b).

(Fig. 7). As a result of the micropatterned coculture, liver-specific function, measured by albumin and urea synthesis, is dependent on the amount of heterotypic interface in the coculture, and albumin production is localized to hepatocytes at the interface. Increase in hepatocyte/fibroblast interaction achieved through micropatterning produced higher long-term function of cultures with similar cell populations but different spatial arrangements.

Another approach, named a vascularized artificial liver, used micromachining technologies on silicon and Pyrex surfaces to generate the branched architecture of vascular network. Hepatocytes and endothelial cells were cultured and subsequently lifted as single-cell monolayers from the two-dimensional molds. Hepatocytes maintained albumin production on the monolayer. The lifted monolayers were then folded into compact three-dimensional tissues with the intent to produce an artificial liver.^[54]

Cardiovascular System Tissue Engineering

The cardiovascular system is a multicomponent, hierarchical system providing for blood circulation. The heart works like a pump to generate forces by beating, and hierarchical vascular systems, including arteries,

Fig. 7 An example of cocultured cells for microscale liver engineering. Compared to micropatterned hepatocytes (alone) on days 1 and 6 (A, C), micropatterned cocultures on days 1 and 6 (B, D) did not display a uniform decline in albumin content.

veins, and capillaries, serve as pipes and tubing for the passage of the blood and exchange of substances between blood and tissues. Tissue engineering of a heart is clearly an ambitious undertaking. But the problem can be broken down into more manageable component tissues and interim milestones.

Forces for the beating of the heart are generated by the contraction of myocytes, the major cell type forming the heart. Therefore, the morphology, orientation, polarization, and mechanobiology of the myocytes in culture are very important. Recapitulating physiological gene expression in cell culture by development of a microfabricated three-dimensional system has been investigated. Both myocytes and nonmyocytes (mainly fibroblasts) from neonatal rat hearts were studied on micropegged and microgrooved substrata. The procedure for generating the microtextured substrate is shown in Fig. 8. Some unique phenotype characteristics were found when cells were cultured on the microtextured surfaces, but not in random culture. It has been observed that three-dimensional surface topography of culture substrates significantly affects in-vitro cardiac myocyte orientation (Fig. 9)^[31] and attachment. Cardiac myocytes prefer to terminate on vertical structures with a subsequent increase in cell height, which is more representative of in-vivo behavior. By creating culture surfaces with topographic features corresponding to cellular dimensions (10–50 μm size range), cells seem to exhibit a more in-vivo-like cellular morphology. The microtopography provides anisotropic or directional growth for cells and thus can recreate tissue architecture at the cellular and subcellular level in a reproducible fashion, facilitating the culture and maintenance of differentiated cell states. The expressions of N-cadherin and connexin-43 for myocytes cultured on a specific microgroove feature were found to be close to those in neonate tissues.^[59]

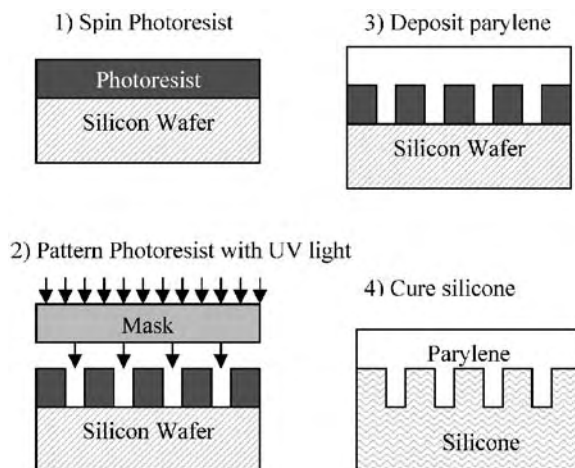

Fig. 8 Example of a process for creating microtextured polymers.

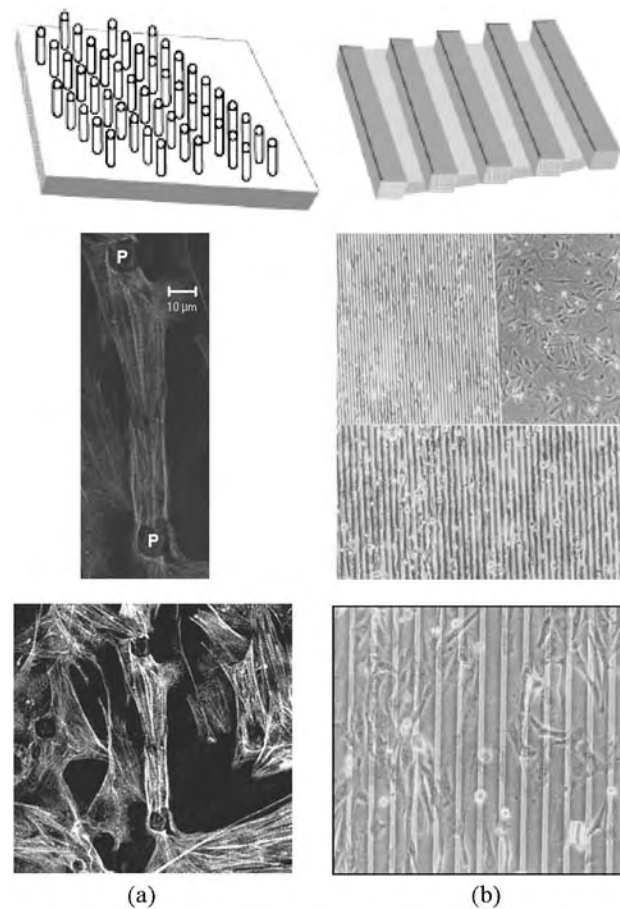

Fig. 9 Micropegs (a) and microgrooves (b) can be used to create microarchitectures that direct cardiac myocyte attachment and morphology.

The normal arteries comprise three lamellar layers: the adventitia, the medial, and the endothelium or intima. The adventitia layer, mainly composed of fibroblasts and collagen, harbors blood and nerve supply; the medial layer, composed of smooth muscle cell and laminin, contributes the bulk of the mechanical strength and controls the vessel size in response to external stimuli; and the endothelium, composed of endothelial cells and basement membrane, prevents spontaneous blood clotting. Mimicry of some or all of the properties of the three layers of a healthy artery has been the strategy of many arterial tissue engineering approaches (see *Tissue Engineering of Blood Vessel*). Current biomimetic approaches of vascular tissue engineering to reproduce the three-tunic structure and mimic some properties are primarily focused on the macroscale; however, microvascular tissue engineering has had less progress. Because of their extremely small size and fragility, it is difficult to assemble very small vessels, such as capillaries, individually in vitro and then later implant them where they are needed. Instead, the approaches considered to date rely on bulk culturing of large

quantities of capillary endothelial cells. Dike et al.^[60] described a microcontact printing technique using SAM for patterning substrates for bovine capillary endothelial cell culture that allowed the control of positions and sizes of attached cells. But this study focused primarily on the demonstration of the underlying technology instead of cell and tissue engineering. Recently, Tan and Desai^[61] developed a layer-by-layer microfluidics technique that provides a tool for bioengineering microscale vascular system with three-layer structure. This method involves a surface modification process and a layer-by-layer microfluidics technique. By taking advantages of matrix contraction by cells, cell-matrix assemblies were delivered and positioned inside the microchannels, thus forming a multilayer configuration inside the channels (Fig. 10). The multilayer having mimetic structure of an artery can be considered a neotissue *in vitro*. The matrix materials that were used for building up the structure were found to influence the 3-D cell migration and the neotissue architecture. It was also shown that the neotissue configurations affect the nature and degree of homotypic and heterotypic cell-cell interactions, which may impact the biological function of the tissue (e.g., ICAM-1 expression in endothelial cells).

Neural Tissue Engineering

Due to its bioelectronic properties, the nervous system is the first biological system in which researchers

extensively employed microtechnology for the construction of artificial implants,^[62] for example, brain stem implants, cochlear implants, retinal prostheses, and cortical prostheses. In the nervous system, specific neurons form complicated and sensitive structures to sense the environments and transmit and process information. To maintain proper signal processing, the intricate network of connections among the neurons is extremely essential. Microtechnology can fabricate structures of a size comparable with the size of the neurons, thus controlling the connections on a one-to-one basis. Furthermore, electrodes with even smaller feature sizes that can interact with nerve fibers can also be fabricated. Microtechnology makes the neuron culture meaningful for signal processing. Microelectrodes for sensing and recording the electrical signals and thus stimulating nerve cells are popular approaches in neural engineering. But recently, the culture of micropatterned neurons using soft lithography has gained more attention.^[63,64] Thus, combining microelectrodes with micropatterned neurons is a new approach in the tissue engineering of the nervous system. An example of this approach is recent work from Lauer et al.,^[65] in which they developed a setup to perform aligned microcontact printing of extracellular matrix proteins on microelectronic devices in order to guide the growth of electrogenic cells specifically to these sensitive spots (Fig. 11). Aligned neuronal growth on patterned devices was demonstrated with dissociated hippocampal neurons.

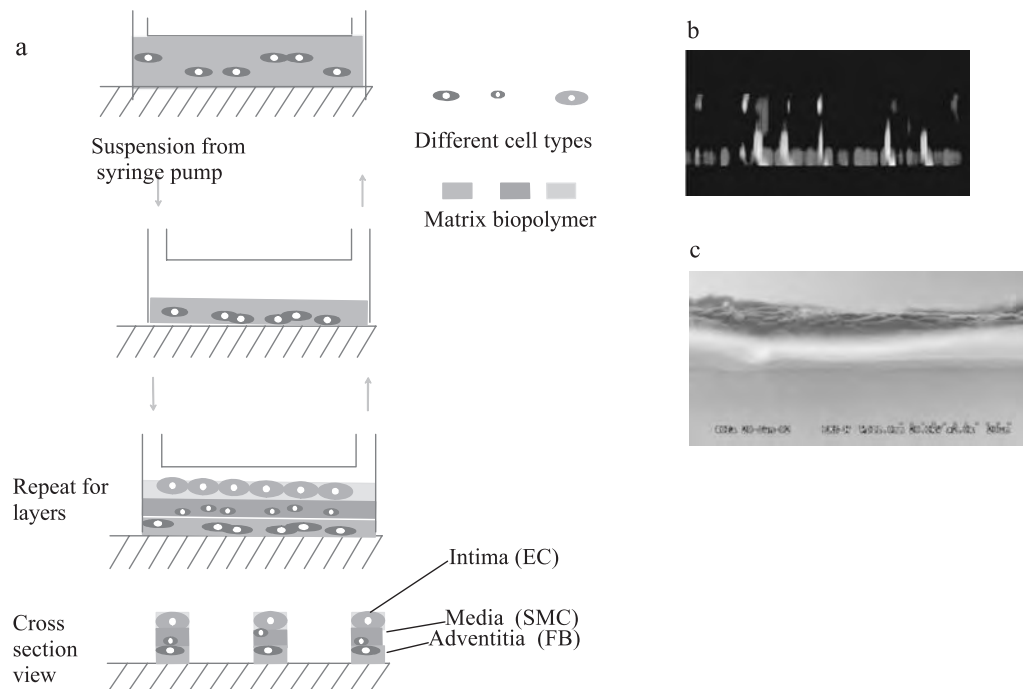

Fig. 10 Multilayer microfluidic approach for the 3-tunic vascular system: (a) setup protocol; (b) reconstituted fluorescence image shows a 3-layer structure; (c) SEM picture shows a 2-layer structure.

Fig. 11 An example of microscale tissue engineering of neural system: (a) a laminin grid pattern aligned to the microelectrodes of a microelectronic recording device; (b) Hippocampal neurons cultured on the pattern for 2 days.

Skin Tissue Engineering

As an effort to microscale tissue engineering of skin, Toner's group produced analogs of the basal lamina with complex topographic features using a microfabrication approach.^[66] Microfabricated pattern, produced by laser machining, was used to mold PDMS elastomer replicates, which were then used as templates for the production of thin membranes of collagen or gelatin. The pattern has features of ridges and channels with a depth scale at 40 to 210 μm and length scales (40 to 210 μm) similar to invaginations found in a native basal lamina. Both the surface of the PDMS and the highly porous collagen-GAG sponge were shown to replicate the features on the master faithfully. Keratinocytes were seeded and cultured onto the collagen or gelatin membrane for composite dermal analogs/equivalents. The equivalents were cultured at the air-liquid interface to induce the differentiation and cornification of the epidermal layer. The keratinocytes formed a translucent, hydrophobic epidermis with gross topographic features that correlated with the microfabricated surface of the membrane. The epidermal layer was found to be composed of differentiated and stratified keratinocytes that conformed to the surface of the skin equivalent, forming ridgelike structures comparable in dimension to those observed in native skin (Fig. 12). And they also found that stratification was enhanced in the deeper

channels, which may be due to the effects of the topographical microenvironment on keratinocyte differentiation/proliferation.

CONCLUSIONS AND FUTURE DIRECTIONS

Although different technologies have been employed in microscale tissue engineering, such as membranes with nanopores, microelectrodes, microfluidic channels, microtextured surfaces, and functional thin-film substrates, they all share the same goal—to fabricate functional biomimetic implantable replacements for tissue. These microscale formats, reminiscent of the precise in-vivo assembly in the tissues, have provided creative tissue equivalents having some enabling functions that macroscale products cannot achieve. Overall, microscale tissue engineering has many advantages over the traditional tissue engineering strategies: 1) It recapitulates complex tissue functions that cannot be easily mimicked with presently employed macromaterials and devices; 2) it provides an implantable biointerface; 3) it provides controlled and predictable interactions and phenomena between cells and materials. Although we are getting closer to the clinical applications of tissue-engineered constructs, many challenges and opportunities remain for the future.

Fig. 12 Skin equivalent with a microfabricated analog of the basal lamina. Keratinocytes were seeded on the surface of a composite dermal analog and grown at the air/liquid interface. Low magnification of a skin equivalent with the shallowest (a) or deepest set of channels (b). High magnification micrographs show differentiated and stratified keratinocytes in individual channels of a microfabricated membrane (c, d).

Multidimensional: 2-D, 3-D, and 4-D

It is now conceivable to achieve biological control by using micro/nanotechnologies that are able to attach, position, and manipulate individual cells and proteins in vitro in two dimensions. However, tissue-engineered products are far more complicated than one or two types of cells attaching and growing on top of a solid surface; they are rather well designed, precisely controlled, heterogeneous and multicomponent 3-D entities. Therefore, although promising, microscale tissue engineering still has a long way to go to achieve clinical and commercial success. Future developments in the design of tissue substitutes will be aided by more understanding of the effects of 3-D scaffolds and tissue architecture on cell function.

The engineering of many tissue structures, such as the branching architecture that is found in many tissues or the intricate network architecture of the nervous system, will probably require methods for introducing and changing molecular signals during the process of neotissue development.^[67] For example, changes in agent concentration with time can influence the differentiated state of cells within tissues. Smart ways to control the microscale features or micropatterned cells or molecules with time may be essential for the next generation of tissue-engineered products. Time adds another dimensional challenge to future research. Therefore, spatio-temporal challenges to microscale tissue engineering are in front of us. A three-dimensional tissue replacement with long lifetime will be a better tissue-engineered product.

Convergence with Other Technique Advancements

Microtechnology alone can not recapitulate adult tissue structure and function. Convergence with other advancements in tissue engineering may open up more opportunities for microscale tissue engineering. For example, the interests of stem cells for cell sourcing are increasing dramatically recently. With the recent advances in stem cell biology, stem cells may be a popular cell source for tissue-engineered products in the future. The primary challenge for stem cell biology is to determine biological and physical cues leading to differentiation of stem cells into functional tissue units (see *Stem Cells*). As reviewed above, microtechnologies offer tools to well controlled microenvironments so that they could be not only useful in developing a detailed understanding of the cues for differentiation of stem cells, but also helpful in guiding the development of cells into the desired tissue product.

Furthermore, many new types of biomaterials are under development. Nanostructured biomaterials

fabricated by self-assembly methods can be used in the tissue engineering fields as well.^[68] With the advance of combinatorial approaches, production of novel materials increases dramatically, allowing the production of more biocompatible polymers suitable for microscale tissue engineering.

In-Vitro Research into In-Vivo Implants

Finally, tissue-engineered products, different from other in-vitro applications such as drug screening, should be aimed at integrating with in-vivo tissues and replacing damaged tissue. The future challenges lies in assembling and applying our collective knowledge, in engineering, biology, chemistry, and physics, to develop functional and clinically relevant tissue substitutes. It is also hoped that we can explore the use of these new tools not only to create more complex substrates for tissue engineering applications, but also to begin to understand fundamental processes in cell biology better.

INTRODUCTION

Insufficient donor tissue and organs available for transplantation represents a crisis of immense proportions, and the problem is steadily worsening. Several potential solutions to this problem are being explored, including mechanical devices, xenotransplants, and tissue engineering. Tissue engineering promises to provide a fully natural solution to the organ shortage, and progress with tissues such as engineered skin, bone, and cartilage has been rapid. However, the field of vital organ tissue engineering presents additional challenges, including the requirement for complex arrangements of multiple cell types in a specific microarchitectural arrangement as well as the requirement for vascularization. Numerous approaches toward this latter goal are being pursued, including the introduction of suitable angiogenic growth factors as well as engineered methodologies that integrate computational fluid dynamics and microfabrication. This article addresses the application of microfabrication technology toward the engineering of vascular networks and vital organ assist and replacement devices. Fluid dynamic models for the vasculature are described, followed by a discussion of applicable microfabrication techniques, and finally examples of cell culture experiments in microfabricated devices are given.

THE REQUIREMENT FOR VASCULARIZATION

The most significant challenge facing vital organ transplant medicine is an ever-increasing shortage of donor organs.^[1] Alternative approaches involving mechanical devices^[2] and xenotransplants^[3] are progressing, as is the emerging field of tissue engineering.^[4,5] While vital

organ tissue engineering faces significant challenges related to cell biology^[6] and vascularization,^[7] engineered skin and cartilage are now in clinical use, and development of engineered blood vessels, bone, tubular structures, and corneas is rapidly advancing.^[8–10] For complex tissues such as vital organs, however, progress has been slowed because of challenging oxygen and nutrient transport requirements which severely limit the thickness of viable engineered tissues. Nature solves this transport problem by developing a vast circulatory network predominated by approximately 10-micron-diameter capillaries in a process known as angiogenesis. One approach for reproducing this microcirculation in engineered tissues and organs utilizes the introduction of angiogenic growth factors, most recently in a stepwise fashion in order to produce blood vessels with long-term viability and appropriate interconnectedness.^[11] A second approach relies on microfabrication technology to produce an engineered organ scaffold which is then populated with endothelial cells.^[12] This second approach—the generation of a microvascular network through the use of fluid dynamic models and microfabrication technology—is the focus of discussion in this article.

ENGINEERING VASCULARIZED TISSUES AND ORGANS

An engineered approach for the generation of vascularized tissues and organs consists of several well-defined steps. The process begins with the generation of a fluid dynamic model which approximates the behavior of blood flow in the target organ, and which accounts for blood's complex nonlinear blood rheology and two-phase composition.^[13] This model forms the basis of the

lithographic masks used to pattern the blood vessel network in the micromachining process. Master molds are then produced using high-aspect-ratio micromachining methods, typically either by silicon etching or by a thick photoresist process. Polymer films are cast in the master molds, and are integrated to form thick three-dimensional (3-D) scaffolds for cell seeding and expansion. Initial work has focused on the fabrication of scaffolds produced using either nondegradable biocompatible templates or biodegradable templates based on copolymers of polylactic and polyglycolic acid or other resorbable polymer systems. Microfluidic networks have been designed, built, and tested, and have produced highly uniform flow patterns that mimic large-scale physiologic properties such as total flow rate and small-scale phenomena such as fluid velocity and hematocrit (blood's fraction of red blood cells) in the capillaries.^[14] Early cell seeding results demonstrate successful attachment and proliferation of endothelial cells in microfluidic channels as small as 30 microns in diameter.^[15,16] The ultimate goal is to scale up the technology to a full 3-D system with the blood volume and cell density required to support a complete organ.

FLUID DYNAMICS OF THE VASCULATURE

Creation of an engineered vasculature begins with the fabrication of a microfluidic network that mimics physiological vasculature. Design of an appropriate network requires understanding of the geometry and flow characteristics of physiological vasculatures and the ability to create a network having the desired properties.

Information on the basic flow behavior in physiological vasculature, such as the total flow rate through an organ is widely available.^[17] Researchers have also used a variety of techniques to determine more specific flow details, such as the flow and pressure distribution in an individual organ and the specific vessel and branching geometries throughout an organ.^[18] Generally an engineered vasculature must match the geometric and flow dynamic distributions of physiological vasculature, including the Murray's hypothesis that the wall shear remain constant throughout the network.^[19]

Modeling Blood Flow Through a Single Vessel

Before modeling a network of blood vessels, we must understand the flow in a single vessel. Blood flow in a vessel is viscous and laminar, so the flow is governed by the viscosity of blood and the geometry of the vessel.

Blood is highly non-Newtonian, meaning its viscosity varies. This is due to the presence of solids, mostly red blood cells. The viscosity of blood varies with the concentration of these cells. The concentration of red

blood cells is known as the hematocrit, and this will vary depending on the size of the blood vessel and the pattern of vessel intersections that the blood flows through. These effects have been examined by analyzing blood flow under well-defined laboratory conditions to determine empirical relations for an effective viscosity for blood in various situations. For blood flowing through vasculature, Casson's equation is commonly used:

$$\mu = \left(k_1 + \frac{k_2}{\sqrt{U/d}} \right)^2 \quad (1)$$

which gives the viscosity μ in terms of the bulk flow velocity U , the vessel diameter d , and two empirical constants k_1 and k_2 .

Once the viscosity is known, the vessel can be represented by a fluid resistance. For a cylindrical vessel, the resistance is

$$R = \frac{8\mu L}{\pi r^4} \quad (2)$$

where L is the length of the vessel and r is the radius of the vessel. Microfabricated vessels are often rectangular, and a similar resistance equation is available for rectangular vessels. Resistance of vessels having other cross-sections can be found by numerical integration of the Poisson equation over the cross section.

The vessel walls may be distensible, in which case the vessel shape will change as the fluid pressure inside varies. Analytical solutions for the geometry shape are available for cylindrical vessels and can be found for other shapes by numerical solution of the plane strain equations.

Modeling Flow Through a Network of Blood Vessels

Flow through a network is modeled by representing each individual vessel with a resistance and solving the entire network, analogous to the modeling of a circuit of electrical resistors. Once the resistance value of a vessel is known, the pressure drop across the vessel is related to the flow rate through the vessel by:

$$P_1 - P_2 = QR \quad (3)$$

where P_1 and P_2 are the pressures at each end of the vessel, R is the resistance of the vessel, and Q is the flow rate of the vessel. Nodal formulation is used to combine all of the individual resistance equations into a matrix equation describing all of the flows in the network. This matrix equation can be solved by Sparse Gaussian Elimination or the Conjugate Residual Method to

determine all of the pressures, which can be substituted back in to find all of the flow rates. All other flow properties—namely, the flow velocity and wall shear—can be found from the flow rates. Thus this solution allows the determination of all flow properties in a network where the geometry is known. If distensibility effects are included, the network must be solved repeatedly as the geometry changes,^[20] and the matrix must be expanded and solved repeatedly to include non-Newtonian effects.^[13]

For designing a network, however, the desired flow properties are generally known and the geometry is unknown. Network design can be achieved two ways. One way is to rearrange the matrix equation to solve for unknown resistances in terms of known pressures and flowrates, then determine the geometry from the resistances. The other approach is to guess an initial geometry and solve for flow behavior, then modify the geometry and solve again, iterating until the desired flow properties are achieved. A sample vascular network design generated using the models described above is shown in Fig. 1.

MICROFABRICATION TECHNOLOGY FOR SCAFFOLD FABRICATION

Micromachining technology—the core fabrication process used to build microelectrical mechanical system (MEMS) structures and devices—has a resolution limit in the range of 0.1 μm , two orders of magnitude smaller than the dimension of the capillaries. Many MEMS devices have structural dimensions as large as one centimeter, yet still maintain critical dimensions and tolerances to ± 0.1 micron.^[21,22] This span of five orders of magnitude demonstrates the applicability of MEMS technology to the formation of vascularized

Fig. 1 Schematic of sample microvascular network based on computational fluid dynamic models designed to replicate organ vascular physiology.

tissues with organized size scales ranging from overall dimensions of tens of centimeters down to cellular dimensions of ~ 5 microns. Photolithographic patterns may be transferred into vascular molds through etching processes, a set of highly developed techniques for producing trenches with a wide range of depths, cross-sections, and geometries in semiconductors, glasses, and polymeric materials. Cellular interactions with vascular networks may be controlled by varying the geometries involved;^[23,24] this behavior has been demonstrated and exploited as part of an important phenomenon known as contact guidance.^[25–27] Micromachining is ideally suited to explore cell-surface interactions as a function of material properties, surface texture, and trench geometry.

Early efforts to produce microvascular networks in vitro utilized silicon micromachined wafers as a platform to demonstrate the basic principle.^[7] These approaches involved the application of photolithographic patterns to silicon wafer surfaces, or the transfer of lithographically patterned features into etched channels in the wafers, to generate a template for the growth of endothelial cells. Results obtained for culturing of endothelial cells in circular channels showed that virtually confluent coatings could be readily achieved in a matter of hours, using a variety of surface coatings such as collagen to promote adhesion and to provide a supporting matrix. Whereas these early studies provided useful preliminary data demonstrating the fundamental utility of microfabrication techniques for producing simulated microvascular networks, the application of polymer replica molding technology represented the most significant advance toward the construction of 3-D vascularized tissue engineered constructs. In this case, silicon micromachined wafers are used as master molds for the production of multiple polymeric films in a layering process designed to produce a large-scale vascularized network for engineering complex tissues and organs. Micromachining process technology is described in numerous references,^[28–30] here the basics of the tools necessary to generate vascularized scaffold structures are reviewed. A schematic of the process sequence is shown in Fig. 2.

Lithographic Techniques

Photolithography technology is the standard method for patterning structures and devices in applications ranging from standard microelectronics to MEMS sensors and actuators and, more recently, bioanalytical devices and systems. For most applications in bioanalysis and tissue engineering, standard contact lithographic processes, in which photomasks are brought into contact with substrates to be patterned, provide sufficient dimensional tolerances. Fundamentally, the

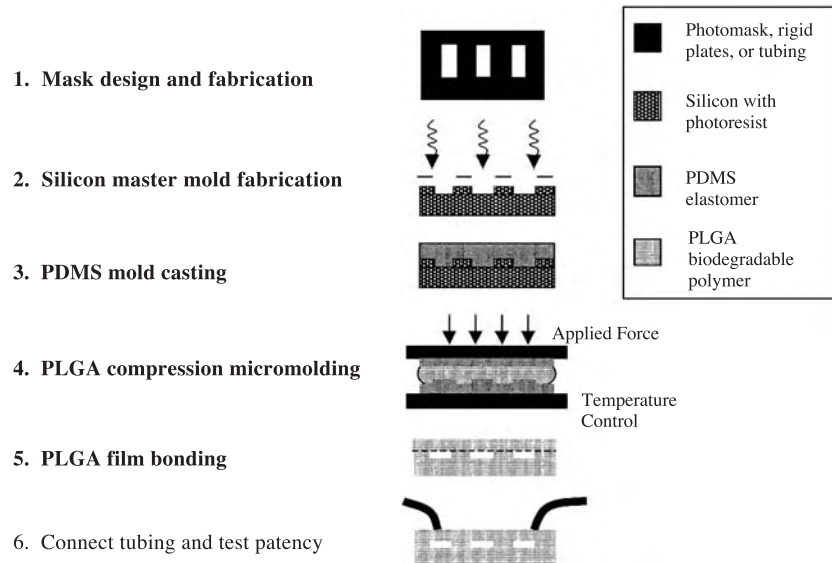

Fig. 2 Process schematic for the microfabrication of polymeric films for vascularized scaffolds. (Courtesy Ref. [15].)

lithographic process proceeds by the generation of a photomask containing a pattern such as the design discussed in the earlier section on fluid dynamics, and the repeated application of this photomask pattern to substrates for device fabrication.

Photomask fabrication techniques vary depending on the requirements of the application, but two general approaches are most often used for biological applications: 1) use of a chrome-metallized glass plate that has been written with an electron beam, typically with resolution between 0.1 and 0.5 microns; and 2) overhead transparency-style masks, written with a high-definition laser printer, typically with resolution no better than 10–20 microns. Although the former technique provides higher resolution, mask turnaround times are days rather than hours, and mask costs are $10\text{--}50 \times$ higher. In either case, masks are generated and then used to produce patterned silicon wafers either for direct cell culture or for the subsequent generation of polymer molded structures for cell culture.

Photolithographic processes involve the use of either positive or negative photoresists which, when applied in thin controlled layers to wafer surfaces by spin-coating, are sensitive to exposure to specified light sources to which they are exposed. Photomasks in contact with wafer surfaces provide light-exposed and light-blocked regions that alternately expose and protect features on the wafers. Once developed and hard-baked, these photoresists serve as protective layers enabling patterns to be transferred into the wafer through subsequent etching processes. Etching processes take one of two forms, either wet chemical etching or dry plasma etching. The former approach is not as useful for tissue engineering applications because of problems with undercutting (dimensional changes during etching) and with etch profiles. In the next section plasma etching techniques will be described.

Plasma Etching

Two types of plasma etching processes are available for generating silicon master molds. The first of these, isotropic reactive ion etching, was developed for applications in the semiconductor industry and is capable of producing trenches with curved sidewalls and depths of up to 100 microns using conventional photoresist technology. Typically, the etch gases used are sulfur hexafluoride or carbon tetrafluoride, and etch rates are usually in the range of 1 micron per minute. The principal advantage of isotropic plasma etching lies in the curved geometry obtained, which produces microchannels in the molded polymer films that are more amenable to continuous lining with endothelium. A significant disadvantage of this approach is the roughly one-to-one increase in feature width with etched depth, a result of the isotropic nature of the process, which causes features to expand beyond their intended lateral dimension during trench formation.

A second class of plasma etching techniques is typically referred to as Deep Reactive Ion Etching (DRIE), a process capability developed in only the last several years for applications in the field of MEMS. Although several variants of this technology exist, the primary embodiment is known as the Bosch process, first developed by Robert Bosch, GmbH, with process tools commercialized by Surface Technology Systems and other companies.^[31,32] This technique produces etched sidewalls that are exactly vertical, and retains the feature width on the photomask very tightly, even as the etched depth increases. Aspect ratios of 25:1 (depth: width) can be obtained using this process, and depths of several hundred microns can be readily achieved. The process consists of repeated cycling between an etching step and a so-called passivation step in which a fluoropolymer is deposited relatively uniformly over the

surface. During the subsequent etching step, the passivating fluoropolymer is removed from the bottom of the trench but persists long enough to protect the sidewalls from being attacked, thereby producing the vertical etch geometry and nearly perfect anisotropy. One important feature to note regarding DRIE etch profiles is the presence of scalloped sidewalls resulting from the cyclic etch-passivation process.

Polymer Replica Molding

Once silicon master molds have been generated using one of the lithographic or etching processes described earlier, polymer films patterned with the reverse image of the mold may be repeatedly generated from the master mold.^[33–35] The only treatment required for replication may be the application of a release agent to the surface of the master mold, depending upon the technique used to generate the master. Typically, lithographically patterned masters do not require release agent application, but etched molds with microscale surface roughness often do require it.

Several techniques are available for polymer film replication, including hot embossing, solvent casting, spin casting, and compression molding, among others.^[36] These are described in detail in the literature; for purposes of brevity, solvent casting of the classic biopolymer poly(dimethylsiloxane) (PDMS) will be presented, and for an example of biodegradable polymer microfabrication, compression molding of poly(lactic) co-glycolic acid (PLGA) will be discussed.

Biocompatible Polymer Replica Molding

The biocompatible polymer PDMS has become a standard for many microfluidic applications. A standard technique for the production of PDMS films using replica molding involves the use of solvent casting, a simple technique capable of producing films as thin as 5 microns with features less than a micron in lateral dimension. The material is flexible, strong, and transparent; is readily amenable to a variety of sterilization methods; and, if cured appropriately, will retain feature dimensions from the master mold to a high degree of accuracy. Typical PDMS molding begins with the mixture of the resin and the curing agent, followed by thorough mixing and vacuum degassing. Once the prepolymer has been prepared, it is poured over the silicon micromachined mold wafer, allowed to settle, and baked at elevated temperature. At this stage the PDMS film is ready to peel directly from the master mold wafer; the thickness of the polymer film is controlled by the volume of the prepolymer solution applied to the wafer. For microvascular network fabrication, PDMS may be used directly as a structural material, or may be

used as a transfer mold for subsequent generation of biodegradable polymer layers, as described in the next section.

Biodegradable Polymer Microfabrication

Ultimately, the utility of microvascular networks lies in their ability to support organ-specific cells and to perform functions as an assist or replacement device. Therefore the preferred platform for a microvascular network is a biodegradable polymer construct, which will provide a scaffolding for cell placement and a mechanical support structure until the growing tissue achieves sufficient strength and viability to sustain itself without the scaffold. Several polymers have been demonstrated as biodegradable scaffolds,^[37] including Poly(Glycolic Acid) (PGA) and Poly(Lactic Acid) (PLA), the copolymer Poly(Lactic-co-Glycolic Acid) (PLGA), polycaprolactone, Poly(Vinyl Alcohol) (PVA), and biorubber. The standard material for biodegradable scaffold fabrication has been PLGA, due to U.S. FDA acceptance, low cost, and availability, and positive results in many early applications. For replica molding, PLGA films must be produced using an intermediate transfer mold, because PLGA adheres strongly to silicon surfaces and because it is not sufficiently flexible to be peeled away from a rigid mold. Solvent casting and spin casting approaches have been utilized with some success; however, compression molding of thin films has resulted in the highest degree of fidelity of feature transfer.^[38]

Compression molding begins with the production of a PDMS transfer mold film, as described earlier. Solid polymer, usually in the form of small beads, is manually deposited on the PDMS transfer layer, which itself is placed on a metal chuck for mechanical support. A second unpatterned PDMS layer is attached to the underside of a second metal chuck and is brought down into contact with the first film through the layer of PLGA beads. Care must be taken to ensure that the two PDMS layers are coplanar in order to achieve a flat PLGA film. The assembly is then heated to a temperature well above the glass transition temperature of the PLGA, sufficient to enable viscous flow of the material so that pattern replication of fine features can take place. Once this viscous flow has occurred, controlled levels of high pressure are applied to the stack, resulting in a thin flat PLGA film with pattern transfer. The assembly is then cooled and the PDMS master is peeled away from the PLGA film. Figure 3 shows an image of a PLGA microvascular network.

Assembly of Microvascular Networks

The foregoing discussion has described some of the necessary components of the process of constructing

Fig. 3 PLGA vascular network layer produced by compression molding from a replica-molded PDMS transfer mold.

engineered microvascular networks; what remains is 3-D assembly into single level or multilayer vascular beds, and seeding of these beds with endothelium to form a functional microengineered vasculature. In this section a simple assembly process is described; more complex approaches resulting in constructs with improved physiological properties have been investigated, but are beyond the scope of this discussion.

A single-layer microvascular network containing a two-dimensional (2-D) array of interconnected channels may be constructed by simply bonding a polymer film patterned with trenches to a flat film and sealing the two films together. For the nondegradable polymer PDMS, this is a very straightforward exercise, as bonding of such layers may be accomplished simply by exposing the two adjacent faces to an oxygen plasma and joining them to form a permanent bond. Inlets and outlets to these 2-D networks are made using direct syringe interfaces, bonding of molded tubing sections, or other means. Such 2-D constructs can then be seeded with endothelium to form the simplest possible microvascular networks.

A 3-D microvascular network can be constructed by stacking multiple layers of vessel networks with fluidic connections for vertical integration. In the simplest embodiment, polymer films containing 2-D channel networks can be stacked with a single vertical connecting tube for the inlet and one corresponding outlet tube.^[16] This configuration is illustrated in Fig. 4; the vertical inlet and outlet tubes are arranged diagonally across a roughly square vessel network array. Although this type of integration scheme greatly simplifies the fabrication process, fluid dynamic models indicate that the resulting 3-D network differs in substantive ways from physiological networks. Principal differences include the density of capillaries relative to larger vessels, a key determinant of oxygen transport properties as most of the oxygen exchange occurs at the capillaries, and the distribution of shear stress in the network, a

Fig. 4 Schematic of integration process for three-dimensional scaffold for organ tissue engineering.

major factor in endothelial cell viability as the main mechanical signal to initiate the biochemical cascade of events through the process known as mechanotransduction.^[39] Therefore, physiological 3-D models require the use of more complex integration techniques in which vertical interconnections are more numerous and occur over a much wider range of vessel diameter scales. One such 3-D integration scheme consists of vertical interconnects arranged in a dense array across each horizontal channel network. Such integration schemes are more challenging from a fabrication standpoint, due to the requirement for high alignment accuracy. However, double-sided alignment tools capable of submicron placement are applicable to construction of these more complex 3-D microfluidic devices.

Porous Microfabricated Devices

The foregoing discussion pertains to the design and construction of microvascular networks for tissue engineering, in which a fluid model is applied to a tissue or organ and a polymeric scaffold is fabricated in accordance with the model. Such structures can be seeded with various cell types in order to produce engineered blood vessel networks, but functional tissues and organs require the integration of organ-specific cell types into the microvascular system. Compartments machined into the engineered scaffolds can be used to house these organ-specific cells; the primary challenges are to arrange these cells so that they retain their function during *in vitro* culturing and following implantation, and to provide for appropriate oxygen and nutrient transport from the engineered microcirculation to the organ-specific cells. Substantial progress in reproducing the microenvironment necessary to maintain hepatocyte function has been reported,^[6,40,41] and recent reports highlight the importance of the 3-D aspect of the local environment.^[42,43] Oxygen transport can be provided by

utilizing polymeric materials with high oxygen diffusion coefficients,^[44] but fully functional cocultured systems will likely require the use of nanoporous structures through which large molecules can pass. With degradable scaffolds, once the polymer has been resorbed, cell-cell junctions in the endothelium will govern the transport of oxygen, nutrients, and waste products.

Porous polymer scaffolds have served as the foundation for an entire class of tissue engineering techniques, in which cell-seeded scaffolds are cultured and implanted for tissue replacement. Methods for providing porous films from PLGA, for instance, have recently been developed.^[45] Microporous and nanoporous films can be processed using the microfabrication techniques described earlier, with some modifications to the fabrication process. For instance, thermal fusion bonding may disturb the nanopore geometries unless additional steps are taken to control the thermal excursions experienced by the device during processing. Ultimately, porous structures will play an extremely important role in engineered scaffolds for vascularized tissue engineering.

ENDOTHELIAL CELL SEEDING OF MICROFABRICATED NETWORKS

Once polymer scaffolds designed to replicate organ microvasculature have been constructed, the next step is to seed them with endothelial cells to generate artificial blood vessel networks. Early efforts involving microfabrication for tissue engineering focused on simple static seeding, in which patterned networks were seeded with endothelial cells with no flow. In more recent work, the use of dynamic cell seeding has been shown to produce confluent cell coverage; this process introduces cells through an inlet port of the scaffold; they are given the opportunity to attach to the walls of the bifurcating channel networks as they proceed towards the outlet end.

Prior to cell culturing, devices are sterilized in an autoclave and perfused with a solution to aid cell adhesion, such as poly-L-lysine, collagen, gelatin, or fibronectin.^[15] The network is then seeded with a cell suspension of approximately 1×10^7 cells/mL using a positive displacement or peristaltic pump at flow rates of roughly $100 \mu\text{L}/\text{min}$. The bioreactor, consisting of a pump, oxygenator, bubble trap, and a reservoir of sterile culture medium, is shown in Fig. 5. The system is then run closed-loop in an incubator at standard culture settings for periods of several weeks. A micrograph shown in Fig. 6 illustrates confluent endothelial cell attachment after two weeks in culture. In the initial stages, single cells and aggregates begin to attach. After several days, channels approach near-confluence, and finally, after four weeks, surfaces in most regions of

Fig. 5 Bioreactor for endothelial cell culturing in microvascular scaffolds. (Courtesy Ref. [12].)

small model networks are fully covered with a single layer of endothelial cells. One salient observation regarding the culture experiments is the fact that autoclave sterilization generates no measurable pattern distortion. Additionally, channels coated with cell adhesion molecules exhibit enhanced cell attachment when compared to phosphate-buffered saline coated control channels. Experiments have successfully concluded after four weeks without the occurrence of occlusion or contamination.

APPROACHES FOR WHOLE ORGAN ENGINEERING

This description represents the first step in the development of a new microfabrication technology for vascularized tissue engineering. Silicon micromachining technology is well-suited toward the generation of templates for endothelial cell growth due to its high precision, design flexibility, and the ability to form specific geometric shapes by varying process recipes. Replica molding of biocompatible polymers on these

Fig. 6 Endothelial cells lining microvascular channels after two weeks of culturing.

high-definition silicon micromachined substrates enable the production of sheets of patterned materials suitable for cell seeding, attachment, and growth. Recent work has resulted in the extension of this replica molding technology to biodegradable materials.

Cell culturing has been shown to produce scaffolds capable of being seeded with endothelial cells to near confluence. Although cells have been introduced into microchannels for sorting or analysis purposes, they are not typically cultured long-term in microfluidic devices. We have successfully seeded and cultured endothelial cells in microfabricated channels for periods as long as four weeks, demonstrating that cells successfully attach, proliferate, and migrate in closed channels with small geometries. This is a critical milestone toward the ultimate goal of fabricating microvasculature and enabling the development of bulk organ tissue engineering. The two-phase composition (red blood cells and plasma) of blood and its nonlinear rheology present several complications at the microcirculation level that must be considered in order to build a full model of the fluid dynamics of the vasculature.^[13] Several phenomena must be considered, including interactions between red blood cells and the walls, leading to axial migration, dynamic reduction of hematocrit (the Fahraeus effect), correlations between red blood cells and velocity, reduction of red blood cell transit time, reduction of hematocrit contained in vessels relative to discharge hematocrit, and reduction of flow resistance below the level expected based on bulk flow (Fahraeus–Lindquist effect). These phenomena are all incorporated into our computational model and will be fully utilized in our design of the model systems in order to build channel networks that replicate physiological behavior more accurately.

Microfluidic devices such as those described in this work may be used to maintain and support large numbers of cells due to the favorable surface-to-volume ratio and short diffusion distances. As a longer-range goal, such devices may be used to engineer blood vessels; however, many challenges remain. Multiple cell types will be required, and the roles of extracellular matrix and cell–cell junctions will need to be determined. Ultimately, the physiology of the vasculature must be reproduced at both the macroscale and the microscale.

Full realization of tissue-engineered organs grown in the lab will require the use of microfabrication techniques that produce complex 3-D templates for cell adhesion and growth. Techniques for integrating multiple layers of microfluidic scaffolds will be required, as will methods for generating interpenetrating arrays of channels for multiple cell types. Efforts are now focused on developing 3-D fabrication techniques based on replica molding to produce scaffolds for vascular networks integrated with parenchymal cells to produce complex organs such as the kidney and liver.

CONCLUSIONS

Progress in the field of tissue engineering has so far been limited by the size and scale of tissues that contain cells with high nutrient and oxygen requirements. Advances in microfabrication technology represent an important opportunity for the field, because these fabrication techniques are capable of producing structures at size scales commensurate with the requirements of physiological systems in a range of biocompatible and biodegradable materials. These fabrication techniques are scalable and cost-effective, and will ultimately play a role in the development of tissue-engineered devices for therapeutic applications in the field of transplant medicine.

ACKNOWLEDGMENTS

The authors would like to thank the members of the MEMS Technology Group at Draper Laboratory—in particular, Edward Barnard, Connie Cardoso, Isaac Costa, Brian Orrick, and Mert Prince—for their efforts in fabricating micromachined silicon devices and polymer replica molds. In addition, we would like to thank Dr. Wing Cheung and Dr. Michael Shin of the Massachusetts General Hospital and their colleagues in the Organ Fabrication Group, Kimberly Morgan of Boston University, and Kevin King of MIT. Tissue Engineering of Pancreas

Hiroo Iwata

Institute for Frontier Medical Sciences, Kyoto University, Kyoto, Sakyo-Ku, Japan

INTRODUCTION

Type I diabetes mellitus, which is caused by autoimmune destruction of pancreatic β -cells, is a devastating condition that affects millions of peoples worldwide. The use of conventional insulin therapy for control of glucose levels cannot inhibit development of serious chronic complications such as nephropathy, retinopathy, and cardiovascular disease in diabetic patients. Tight glycemic control through intensive insulin therapy can deter the chronic complications of diabetes. However, it places an enormous burden on patients, and intensive insulin therapy is associated with a high risk of severe hypoglycemia, which can also be life-threatening. Alternative treatments for type I diabetes are transplantation of a whole pancreas or islets of Langerhans (islets), which is made of endocrine tissue and secretes insulin. Although whole pancreas transplantation offers the possibility of excellent glycemic control in a physiologic manner, it also subjects patients to the risks of major surgery and complications related with pancreatic juice produced by acinar tissue. Islet transplantation has been expected to be able to offer the possibility of internal glycemic control without subjection of the patient to the risks of major surgery. However, low yield of islet isolation and deterioration of islet functions caused by conventional immunosuppressive regimens limited clinical success of islet transplantation.

A major breakthrough in clinical islet transplantation was made in recent years. Islet transplantation led to insulin independence and normal glucose metabolism in patients with type 1 diabetes mellitus, and these patients remained independent of insulin within a follow-up period up to 20 months after islet transplantation. Key innovations are comprised in the immunosuppressive regimen combining anti-IL-2 receptor monoclonal antibody, sirolimus, and tacrolimus without corticosteroid therapy. In addition, cold ischemia time was kept short, islets were grafted freshly without culturing *in vitro*, and mass of transplanted islets exceeded 9000 islet equivalents per kilogram body weight of the recipient. However, it still subjects patients to the peril of immunosuppression. The ability to safely engraft cells into patients is of particular importance to diseases like type I diabetes that can be effectively treated by traditional means.

Therefore, much effort has been focused on the development of the methods to transplant islets without

employment of immunosuppression. A tissue-engineering method, i.e., bioartificial pancreas (BAP), is the most promising approach to realize this requirement.

BIOARTIFICIAL PANCREAS (BAP)

In BAP, islets are enclosed into a semipermeable (SP) membrane prior to transplantation (Fig. 1). Immunoisolation is based on the premise that islets, which were once sequestered within a SP membrane, are protected from the host immune system. It can inhibit occurrence of adverse host immune reactions against the transplanted islets. Islets enclosed can survive under sufficient supply of oxygen and nutrients through the membrane and must be capable of detecting blood glucose levels and producing a sufficient and properly timed level of mature insulin to maintain glycemic control. Various types of BAP devices have been examined. These include spherical microcapsules, diffusion chambers, and devices anastomosed to the vascular system as arteriovenous shunts or capillary units (Fig. 2).

Membranes

A SP membrane is a common important structural unit in BAP. Immunogenicity of islets, i.e., allogeneic (allo-) or xenogeneic (xeno-), is a key factor for governing the selection of a membrane with the appropriate semipermeability. Allo-transplantation is organ and tissue transplantation between genetically different individuals within one species in which the predominant cause of graft rejection is activation of cellular immunity by interactions of host T cells. On the other hand, xeno-transplantation is transplantation between individuals from different species while humoral immunity including antibodies and complement proteins is thought to play a major role in the graft rejection. In the allo-transplantation, for a recipient without preformed antibodies, a membrane that can mechanically inhibit contact of the host immune cells with the graft is expected to effectively protect the graft from rejection. On the other hand, in xeno- and allo-transplantation, for a recipient carrying natural or preformed antibodies against the donor tissue, a SP membrane must be designed not only to inhibit cellular

Fig. 1 Basic idea of a bioartificial pancreas (BAP).

contacts, but it also can inhibit permeation of antibodies and complement proteins.

Distinct different types of SP membranes, hydrogel (HG) membranes and ultrafiltration (UF) membranes have been employed for immunoisolation since the early 1970s. In the HG membrane, the increase in the solute molecular weight results in reduction in the diffusion coefficient due to interaction of the solute molecule with the HG polymer network. UF membranes are microporous in character and mechanically sieve molecules according to their molecular weight. For both types of membranes, contact inhibition between the host immune cells and the graft can be easily attained. However, there is still some ambiguity in immunoisolation efficacy of both types of the membranes against humoral immunity.

BAP Devices

Microcapsule

The microcapsule fabricated from alginate and poly-L-lysine (PLL) was originally described by Lim and Sun in 1980.^[1] Microcapsules made of alginate-PLL polyion complex membranes have extensively been reviewed.^[2] Cut-off molecular weights of the membranes can be easily controlled by changing the molecular weights of the polyelectrolytes and the time for polyion complex formation. They do not induce inflammatory reactions. The viability of enclosed islet cells is high. Many groups have examined immunoisolation efficacy of the microcapsules made of alginate-PLL polyion complex membranes. Results in diabetic models using rodents indicated that these BAP can function for periods of several months to more than one year. However, its immunoisolation efficacy has not been consistency in other diabetic models. Long-term survival of microencapsulated porcine islets transplanted into diabetic Cynomolgus monkeys was reported.^[3] Unfortunately, other groups have not yet reproduced

Fig. 2 Schematic representations of various types of bioartificial pancreas (BAP).

the result. Its clinical experience will be discussed subsequently.

One major drawback of this type of polyion complex microcapsules is low mechanical strength. When implanted into recipients, they are seriously deformed and sometimes are even ruptured in the peritoneal cavity. To overcome this problem, microbeads made of HGs such as agarose^[4] and barium-alginate were introduced.^[5] Functions of microencapsulated islets in agarose HG as BAP were extensively examined in vitro and in vivo in Japan.^[6] The ability of the agarose microcapsule to achieve marked prolongation of alloislet graft is shown in Fig. 3. NOD mice that received a transplantation of 1500 nonencapsulated, i.e., naked, islets from C3H mice into the peritoneal cavity demonstrated normoglycemia, but its blood glucose levels reverted to the preoperative high level after 10 days of the transplantation. On the other hand, C3H islets enclosed agarose microcapsules can reverse hyperglycemia for 190 days. Spherical microcapsules containing allo-islets appear to have high therapeutic potential.

Diffusion chamber

Diffusion chambers include planar chambers, flat sheet devices, and cylindrical hollow fiber macrocapsules. Chambers can be implanted in various sites such as the peritoneal cavity, the subcutaneous site, or the renal capsule. They can be also readily retrieved in a relatively simple way. Microporous millipore membrane^[7] and microporous polycarbonate membrane (nucleopore membranes)^[8] have been used to fabricate planar chambers. Usually, in chambers, islets are immobilized in HGs such as collagen, calcium-alginate, or agarose to prohibit aggregation of encapsulated tissue into large

T

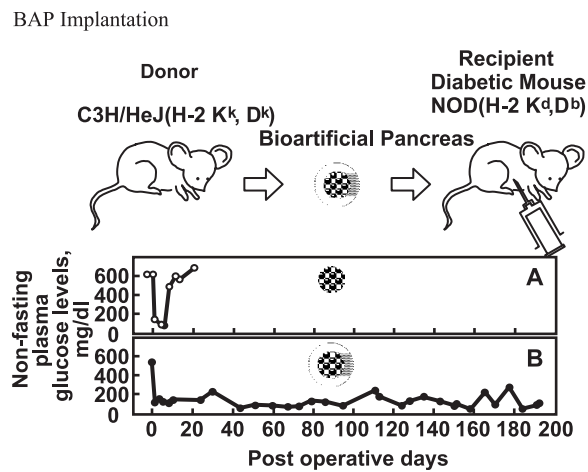

Fig. 3 Plasma glucose levels of diabetic NOD mice receiving 1500 naked islets (A) or microencapsulated islets (B) into the peritoneal cavity. Islets from C3H mice were enclosed in 5% agarose hydrogel microcapsules.

clumps. In the recent 10 years, the hollow fiber geometry has been preferred over the planar chamber due to its smaller foreign body response. In studies, hollow fibers made of poly(acrylonitrile-co-vinylchloride) (Poly(AN-co-VC))^[9] and sodium-methallyl sulphonate, AN69^[10] have been employed. Hollow fiber devices made of Poly(AN-co-VC) demonstrated the feasibility of long-term immunoisolation of islets and the long-term biocompatibility in rodent and canine models. The device with canine islets can provide correction of hyperglycemia in dogs with surgically induced diabetes for a period of more than one year without the use of immunosuppressive drugs. The outer surface showed only scattered foci of macrophages and lymphocytes.^[9] The major drawbacks of this device are that hollow fibers, as a consequence of their shape, tend to break when forced to bend under physiological stress, and that enormous lengths of fibers would be required to enclose a sufficient number of islets to normalize blood glucose levels of human patients.

Intravascular capillary unit

The original device was composed of a number of small-diameter, hollow fibers enclosed in one, large-diameter housing tube.^[11] The hollow fibers were made of Poly(AN-co-VC), that were similar to those used in diffusion chamber devices. Islets were loaded in a space between the hollow fibers and the housing tube. Although the design allows close contact between the islets and the blood flow, the duration of normoglycaemia is usually restricted to several hours due to blood clotting in the lumen of hollow fibers. The intravascular device was modified to be composed of a single, coiled and

tubular membrane with an internal diameter of five to six millimeters.^[12] The tubular membrane has been modified, but it is composed of Poly(AN-co-VC) with a nominal molecular weight cutoff of 50 kDa. The device with allo-islets demonstrated a long-term normoglycemia in a canine model without clotting of blood in the lumen of the tubular membrane. The intravascular devices have shown some degree of success. However, the complications associated with thrombus formation and tissue hyperplasia at the blood vessel anastomosis sites limit its clinical application because the ability to safely engraft cells into patients is of particular importance to diseases like type I diabetes that can be effectively treated by traditional means.

Immunoisolation Efficacy of Membranes Against Humoral Immunity

Prevention of immunocompetent cells entering into the islet compartment is easily attained; thus, immunoisolation of allo-islets is successfully achieved using various artificial membranes. Restoration of normal glucose metabolism by BAP containing allo-islets has already been reported in various animal diabetic models as mentioned in the preceding discussion. However, the supply of donor tissue remains quite inadequate if BAP enclosing allo-islets were to be developed as effective therapy for clinical treatment of human diabetic patients. Xeno-islets from pigs and cows have been considered as potential sources of islets for BAP preparation. One of the major aims for development of BAP devices is to overcome the vigorous humoral and cellular immune responses associated with transplantation of xeno-tissue. Use of porcine and bovine islets is expected to overcome severe shortage of human pancreatic tissue. Various BAP devices, which allow xeno-transplantation in rodent models, have been reported.^[3,4] However, reports on successful immunoisolation of xeno-islets in higher animals, such as dog and monkey, have been limited. Immunoisolation efficacy of membranes, which have been used for preparation of various BAP devices, will be discussed in some detail.

Different types of SP membranes, such as HG membranes and UF membranes, have been employed for BAP preparation. UF membranes with a nominal cut-off molecular weight of approximately 50 kD have been preferentially used to prepare BAP devices with xeno-islets because it has been believed that the membrane allows passage of oxygen and nutrients, but it restricts passage of antibodies of which molecular weights are much higher than 50 kD. The representative membrane employed is Amicon's XM-50 membrane made of (Poly(AN-co-VC)). Researchers working on BAP believe that the solute permeability through a

membrane that is determined by pressure-driven sieving experiments can predict its immunoisolation efficacy. However, it should be carefully borne in mind that the fractionation efficiency of a membrane is known to highly depend on separation processes employed.

In-vitro permeation studies of solutes through the XM-50 membrane were performed under both pressure-driven filtration and concentration-driven permeation processes.^[13] The XM-50 membrane can reject 99.4% of bovine serum albumin (MW = 69 kD) in the filtration solutions under the pressure-driven filtration. It effectively fractionated the solutes according to their molecular weights near 50 kD by UF, as claimed in the supplier's catalog. On the other hand, the XM-50 membrane could not fractionate the solutes on the basis of molecular size under the diffusion-controlled process. When a device made of XM-50 membrane is used in vivo, molecules permeate through the membrane, which is driven by the concentration difference. The UF membrane, such as XM-50 membrane, loses the molecular size cut-off property in the diffusion-driven process and, thus, cannot protect xenografts by fractionating microsolute and immune biomacromolecules according to their molecular weight. The immunoisolation efficiency of the XM-50 membrane has been overemphasized by many researchers. The standard pressure-driven measurements are inadequate to predict the rate or selectivity in diffusion-based devices, and its diffusive transport properties must be determined for a membrane to be used for immunoisolation.

The other type of membrane that has been used for immunoisolation is a HG membrane. It is made of cross-linked, water-soluble polymers. It does not have distinct molecular weight cut-off, and its selectivity is characterized by the diffusion coefficients of solutes. The increase in the molecular weight results in reduction in the diffusion coefficient due to more prominent interaction of the solutes with the polymer network. The time during which a solute diffuses through a membrane with thickness of L and then reaches to the membrane surfaces is roughly expressed by

$$t = \langle L^2 \rangle / aD$$

in which D is the diffusion coefficient of the solute through the HG membrane and a is a number determined by the shape of device, e.g., $a=2$ for a planar chamber or $a=6$ for a sphere. The thickness of the membrane of a planar chamber is assumed to be one millimeter. The diffusion coefficient of antibody through the membrane should be less than 10^{-13} cm²/sec to prolong the time for more than one year. During this time, antibody reaches the surface cells. However, it is quite difficult to render the diffusion coefficient of antibody through the HG membrane that is less than

the 10^{-13} cm²/sec, which simultaneously maintains the rapid insulin release through the same membrane in response to glucose stimulation.

Microencapsulated xeno-islets sustained normoglycemia for long periods in diabetic rodents without immunosuppression.^[6,14,15] Hollow fibers fabricated from an acrylic copolymer, XM-50, were used to encapsulate rat islets for transplantation in diabetic mice.^[16] The fibers effectively inhibit rejection, and xeno-islets in the fibers survived and functioned to maintain normoglycemia. Hyperglycemia returned when the fibers were removed at 60 days. Encapsulation in SP membranes effectively protects xeno-islets from immune destruction in the rodent models. On the other hand, reports on successful immunoisolation of xeno-islets in higher animals have been limited.^[2] Discrepancy observed between rodents and higher animals as recipients might be explained by taking stability of complement proteins into consideration. Antibody binding to antigens on the xeno-cell surface alone cannot give lethal damage to the cells. For destruction of the xeno-cells, antigen-antibody immune complexes should activate the complement system. Some proteins of the rodent complement system, such as C1, C2, and C5, are less stable than those of higher animals. Complement proteins take a certain amount of time to permeate through the membrane and reach the cell surface. It might be expected that labile complement proteins are denatured and thus lose the cytolytic activity during permeation.

At this point, it can be summarized that neither UF membranes or HG membranes can effectively fractionate the solutes on the basis of molecular size and thus cannot immunoisolate xeno-cells from the host immune system for a long period.

Porcine Endogenous Retrovirus Infection

The possible use of porcine islets in preparation of BAP has been actively examined to overcome severe shortage of human islets. However, in 1997, it was reported that porcine endogenous retrovirus (PERV) genomes can be infectious transmitted to human cells in culture.^[17] After this report, many groups have been examining whether PERV genomes can be infectious transmitted to human cells. There are some ambiguities in the possibility of PERV infection from porcine islets to human patients. However, microchimerism and PERV transmission were frequently observed in both mouse and human tissues during grafting of porcine cells into nude mice bearing human tumours and sometimes during porcine islet xenograft in this model.^[18] This strengthens the notion that there is a risk of transmitting PERV during porcine islet xenograft. Even though porcine islet cells, even with PERV

inserts and transcripts, have very little probability of transmitting PERV to human cells during coincubation, it is difficult to rationalize the use of porcine islets for treatment of human diabetic patients. The ability to safely engraft cells into human tissues is of particular importance to insulin-dependent diabetes.

Xeno- β -cells are potential source of cells for BAP. However, tissue from animals carries the risk of transmitting novel infectious agents into humans. As the preceding discussion demonstrated, islets from xeno-animals are more immunogenic than allo-animals; thus, it is difficult to find membranes that can effectively protect xeno-islets reproducibly in higher animals for a long period. In conjunction of these two facts, new sources of insulin-producing human cells must be exploited for treatment of human diabetic patients.

NEW CELL SOURCES

Stem Cell

Two functions are essential to any cells for use in BAP preparation. The cells must be capable of detecting blood glucose levels and releasing a sufficient and properly timed level of mature insulin to maintain glycemic control. Other desirable properties include plentiful and reproducible production of these cells. Stem cells offer a potential solution to these requirements. In theory, stem cells can proliferate in their undifferentiated state and then be converted to take on required functions by the use of genetic and epigenetic manipulations.

Embryonic stem cell

Embryonic stem cells (ES cells) are self-renewing elements that can generate the most cell types in the body. ES cells are an attractive potential source of insulin-releasing tissue for BAP preparation and other cell transplantation therapies. Recent studies, using mouse ES cells as an experimental system, demonstrated the promise of ES cells as a potential source of cells for the treatment of diabetes. Cell selection strategies using insulin promoter to derive the expression of antibiotic resistance genes was employed in derivation of insulin-producing cells from ES cells.^[19] These ES-derived insulin-secreting cells regulated insulin secretion in vitro in the presence of various secretagogues and contained roughly 90% of the insulin content of a normal mouse islet. Clusters obtained from this clone were implanted in the spleen of streptozotocin-induced diabetic animals. Transplanted animals correct hyperglycemia within one week and restore body weight in four weeks.

Another group generates cells with insulin and other pancreatic endocrine markers from mouse ES cells by a multistep cell culture strategy.^[20] The multistep strategy begins with the production of a highly enriched population of nestin-positive cells normally found as neural precursor cell from embryoid bodies. A critical step in this strategy is to plate the embryoid bodies into a serum-free medium (ITSFn) in which many other cell types die, which thus increases the proportion of nestin-positive cell. These cells were then expanded in the presence of a mitogen, a basic fibroblast growth factor (bFGF), in another serum-free medium and followed by mitogen withdrawal to promote cessation of cell division and then differentiation. The culture media, including a B26 supplement and nicotinamide, improved the yield of insulin-producing cell clusters. Insulin secretion occurs in response to physiologically appropriate glucose concentrations. However, insulin-positive cells in these cultures contains 50 times less insulin per cell than normal islet cells.

To increase population of insulin-positive cells in the culture and insulin content in the cells, various modifications have been introduced in the culture condition. In-vitro treatment of human fetal pancreas with nicotinamide and an inhibitor of phosphoinositide 3-kinase (PI3K), LY294002, increased total endocrine cell number and insulin content while reducing DNA synthesis. By referring to this fact, a PI3K inhibitor, in spite of a B26 supplement, was added to the culture medium during development of insulin positive cells from ES cells. The production of insulin at increased levels was greatly improved by this treatment.^[21]

Ectopic transcription factor expression constitutes a powerful genetic approach to stem cell differentiation. Pdx1 and Pax4 are essential for proper β -cell development. Constitutive expression of Pax4 in combination with the multistep cell culture strategy facilitates ES cell differentiation into the pancreatic lineage, which leads to the formation of isletlike spheroid structures that produce increased levels of insulin.^[22]

Insulin-producing cell clusters derived from human ES cells are a more promising alternative for human islets for BAP preparation. Recent data demonstrates that insulin-producing cells can be also derived from human ES cells. Using human ES cells in both adherent and suspension culture conditions, spontaneous in-vitro differentiation of ES cells were observed, and cells with characteristics of insulin-producing β -cells were generated.^[23] Immunohistochemical staining for insulin was observed in a surprisingly high percentage of cells. Secretion of insulin into the medium was observed in a differentiation-dependent manner and was associated with the appearance of other β -cell markers using reverse transcriptase-polymerase chain reaction (RT-PCR). These findings validate the human ES cell

as a possible future source of insulin-releasing tissue for preparation of BAP.

Most of the methods employed for derivation of insulin-releasing cells from ES cells have been developed on the basis of the multistep cell culture method originally reported by McKay et al.^[20] As mentioned above, efficient differentiation of ES cells to insulin-releasing cells have been reported. However, Rajagopal and Melton et al.^[24] supposed that the cells derived from ES cell concentrate the insulin from the culture medium rather than produce hormone from their careful examination of the cells derived from five ES cell lines, both murine and human. They mentioned that it is difficult to exclude the possibility that paucity of β -cell differentiation is due to cell line variability or suboptimal culture condition, but they did conclude that insulin staining alone can overestimate genuine β -cell differentiation when exogenous insulin is present in the culture medium. In spite of the results, Melton remains optimistic and mentioned that no clear data persuades him that it will be impossible to turn ES cells into insulin-producing cells. Much more careful studies should be done to derive insulin-releasing cells from ES cells by employing C-peptide staining, electron microscope, Northern analysis, metabolic labeling, and so forth.

Adult stem cells

Pancreatic stem cells have previously been well reviewed.^[25,26] The pancreas is composed of the exocrine (duct and acinar) and endocrine compartments, but, embryonically, all the cells are differentiated from the duct epithelium. In addition, throughout much of life, there is continued addition of new small islets neogenesis or differentiation from ductal progenitors. Adult, somatic, or nonembryonic stem cells may possess some advantages over ES cells as a cell source for BAP preparation, such as exclusion of the possibility of teratoma formation.

It was demonstrated that cells from pancreatic ductal epithelia of mice proliferate extensively in culture and have the ability to form large numbers of islet like cell cluster in vitro.^[27] The proliferation and differentiation capacity of these cells may warrant their classification as stem cells. These islets produce insulin I and II in addition to glucagon and somatostatin. With the addition of nicotinamide and a glucose load, these structures significantly up-regulate insulin production and can decrease blood glucose levels following transplantation into diabetic NOD mice.

Isletlike clusters of pancreatic endocrine cells were derived from human pancreatic tissue containing ductal fragment and acinar tissue.^[28] Pancreatic tissue from human islet isolations were cultured under conditions that allowed expansion of the ductal cells as a

monolayer in which the cells were overlaid with a thin layer of Matrigel. With this manipulation, 50- to 150- μ m diameter isletlike clusters of pancreatic endocrine cells budded from the monolayer of epithelial cells. Over three to four weeks in culture, the insulin content per flask increased 10- to 15-fold as the DNA content increased up to sevenfold. The human islet buds exposed to stimulatory 20 mM glucose had a 2.3-fold increase in secreted insulin. Thus, duct tissue from human pancreas can be expanded in culture and then be directed to differentiate into glucose-responsive islet tissue in vitro.

The need for transplantable human islets has stimulated efforts to expand existing pancreatic islets and/or grow and differentiate stem cells. These approaches may provide a potential new source of pancreatic islet cells for BAP preparation.

Genetically Engineered Insulin Releasing Cells

For preparation of BAP, plentiful and reproducible production of cells, which can produce a sufficient and properly timed level of mature insulin in response to changes of glucose levels, is required. Genetic engineering of non- β -cells for glucose-responsive insulin secretion offers some promise in developing BAL. But, two major obstacles should be overcome. Most somatic cells simply engineered using proinsulin cDNA cannot process proinsulin into mature insulin and thus release proinsulin. The timing of insulin delivery is crucial for optimal regulation of glucose homeostasis. However, most insulin-releasing cells derived from non- β -cells hardly timely regulate insulin secretion in response to glucose stimulation. Preparation of insulin-releasing cells that is capable of processing and releasing insulin in such a way that normal glucose homeostasis is maintained is crucial for preparation of BAP.

Various attempts have been done to derive non- β -cells that release mature insulin in response to glucose stimulation. In some attempts, insulin gene was driven to express with various glucose-sensitive promoter elements.^[29,30] However, insulin secretion dynamics is not adequate for glycemic regulation. The timing of insulin delivery is crucial for optimal regulation of glucose homeostasis. The slow time course of transcriptional control by glucose makes synchronizing insulin production with the periodic fluctuation in blood glucose levels an extremely difficult task. To overcome this difficulty, some endocrine cell lines were examined. The secretion kinetics of some endocrine cells closely parallels that of insulin, and those endocrine cells can process proinsulin. K cells located primarily in stomach, duodenum, and jejunum secrete the glucose-dependent insulinotropic polypeptide. A tumor-derived K-cell line

was examined to produce human insulin by providing the cells with the human insulin gene linked to the five-foot regulatory region of the gene-encoding GIP.^[31] NCI-H716 intestinal cell line driven from a poorly differentiated caecal adenocarcinoma was also employed.^[32]

All of these works have been done using immortalized cell lines. Those gave good models of gene therapy for diabetes. However, the obtained insulin-releasing cells could not directly apply to the preparation of BAP because cell proliferation in BAP could not be easily controlled.

BAP Made of Insulin-Releasing Cells from Stem Cell

In clinical islet transplantation, approximately 20 milliliters of a packed tissue of islets have been infused to the liver through the main portal vein.^[33] As demonstrated in the preceding discussion, the insulin release ability of the cells derived from ES and somatic stem cells is much less than that of islets. For example, cell clusters derived from ES cells produced insulin at 13% or less of levels found in pancreatic islets.^[21] From simple calculation, we find out that more than 150 milliliters of those packed cells should be transplanted to result in the long-term freedom from the need for exogenous insulin. We will meet a lot of difficulty to implant such a large volume of cell suspension. To minimize trauma, the volume of the final implant should be minimized as possible.

Some BAP devices are mostly dead space and are therefore too large for convenient implantation. For example, when the radius of a microcapsule is three times larger than that of an isletlike cell cluster, a volume of the microcapsule becomes 27 times larger than that of the cluster because the volume of a sphere increases with third powers of the radius. The final volume of the BAP made of insulin-producing cell cluster from the stem cell is:

$$150 \text{ ml} \times 27 = 4050 \text{ ml}$$

It is unrealistic to transplant such a large volume of BAP in the clinical practice. Much effort should be exerted to enhance insulin production of cells derived from stem cells or new concepts for preparation of BAP should be introduced to minimize the BAP volume from now on.

CLINICAL TRIALS

Although serious investigative efforts were devoted to develop BAP during the last quarter of the 20th century, very few clinical trials have been done, and results of only two clinical studies can be available from journals easily accessible. Clinical trials approved by

the U.S. Food and Drug Administration were initiated in 1993 by two investigative groups. The two have used very different approaches. One implanted alginate-PLLA microcapsules containing human islets into the peritoneum of a 38-year-old diabetic male.^[34] The patient, who was immunosuppressed with cyclosporin for a preexisting kidney transplant, received a total dose of 10^6 pooled allo-islets administered. Exogenous insulin administration could be discontinued for one month. However, results are difficult to evaluate because the recipient received tight immunosuppressive therapy. The other groups designed to investigate whether immunoisolation protects islets against the autoimmune challenge of type I diabetes.^[35] This is an important issue because autoimmune rejection of transplanted islets normally destroys unencapsulated islets in a nonimmunosuppressed host. Islets were macroencapsulated in semipermeable hollow fibers made of Poly(AN-co-VC) having a nominal molecular weight cut-off of approximately 65 kDa. Capsules were implanted subcutaneously into type I and type II diabetic patients for two weeks. From histologic analysis and in-vitro glucose challenge tests, the investigators concluded that this trial demonstrated the short-term biocompatibility and acute immunoprotective capacity of the Poly(AN-co-VC) hollow fibers.

TECHNOLOGY OF BAP FOR OTHER DISEASES

Various endocrine diseases, in addition to diabetes, have had experimental and clinical recovery by implantation of bioactive molecules releasing cells enclosed in a SP membrane. The technology of BAP have been expanded to the treatment of chronic pain^[36] and neurodegenerative diseases,^[37] including Parkinson's disease, Alzheimer's, and amyotrophic lateral sclerosis (ALS). Other disorders that have been addressed with this type of therapy include hypocalcemia, dwarfism, anemia, hemophilia, and cancer.^[38]

CONCLUSION

In the past two decades, BAP has progressed from in vitro investigation through small-animal and large-animal studies into clinical investigation. Relevant mechanisms of host recognition and immunoreactivity against allograft appear cellular in nature; therefore, only the exclusion of host effector cells is required for immunoprotection of allo-islets. Membranes of this type are not difficult to prepare. The major obstacle for clinical application of BAP is a severe shortage of insulin-releasing cells. Differentiation and maturation of human insulin-releasing cells from human ES cells or

adult stem cells are not easily achieved. On the other hand, xeno-insulin releasing cells, i.e. porcine islets, are not difficult to obtain. However, tighter membranes, which not only provide protection against cellular attack but also confer protection against immune rejection mediated by antibodies and complement proteins, are required. In addition, the other hard task is to deny the possibility of the risk of transmitting novel infectious agents, such as PERV, from animal tissue into human. In these two approaches, the former seems to be promising. Human ES cells were established, and various approaches to differentiate ES cells to somatic functioning cells have been intensively studied. Human ductal fragment tissue is also another promising source for insulin-releasing cells.

Understanding the immunologic and molecular basis of host response to implanted devices and establishment of methods to differentiate stem cells to insulin-releasing cells, though incomplete, has proved adequate for successful BAP implants containing allo-cells for treatment of type I diabetic patients.

T

INTRODUCTION

Nerve damage debilitates thousands of Americans each year and leads to problems such as paralysis. In addition to the physical and emotional outcome, financial burdens amounting to nearly \$7 billion in the United States of America alone are associated with nerve injury (American Paralysis Association, 1997). In fact, nearly 50,000 peripheral nerve repair procedures were performed in 1995 (National Center for Health Statistics, 1995). Nerve injuries can occur in the spinal cord in the central nervous system or, more commonly, in nerve bundles in the peripheral nervous system. Nerve injury can result from mechanical, thermal, chemical, or pathological mechanisms.^[1]

Current clinical methods to treat peripheral nerve injury rely primarily on either end-to-end anastomosis or grafts (e.g., autologous nerve or vein grafts) to bridge the severed nerve ends. Short gap repair has shown success with end-to-end reconstruction. However, this technique is limited by the tension introduced into the nerve cable when the nerve ends are reconnected, which can inhibit nerve regeneration. The use of autologous nerve grafts addresses the problems associated with end-to-end reconstruction, but there exist some limitations including incomplete regeneration and the possibility of irreversible damage.^[1] In addition, there are other disadvantages associated with the use of autologous grafts, including loss of function at the donor site, the inability to directly match the size of the donor nerve to the injured nerve, and the need for multiple surgeries.

The shortcomings of the current clinical methods have motivated the search for new engineering techniques that stimulate nerve regeneration. One such technique is the development of a synthetic guide that provides an optimal physical and chemical environment to enhance peripheral nerve repair.

This article highlights the recent advancements in the area of peripheral nerve tissue regeneration. Collaborative efforts between disciplines ranging from biology to materials science are facilitating the development of engineering strategies to enhance peripheral nerve regeneration. A selection of the current approaches

researched for peripheral nerve tissue engineering are reviewed in this article including guidance therapies, and physicochemical- and genetic-based approaches.

NERVOUS SYSTEM ANATOMY

The nervous system regulates and controls the sensory and motor functions of the body (Fig. 1A). It is divided into two main subsystems: the central nervous system (CNS) and the peripheral nervous system (PNS). Together the CNS and PNS monitor and control every organ system through positive and negative feedback loops. Communication in the nervous system is modulated by the transmission of electrical signals. The CNS, consisting primarily of the brain and the spinal cord, is linked to the PNS via branched spinal, cranial, and autonomic nerves. The PNS, which is composed of nerves (bundles of neuronal fibers), connects the CNS to other parts of the body.^[2] The CNS is distinguished from the PNS in that it contains both the nerve cell body and their processes, whereas the PNS consists only of the processes. Dorsal root ganglia (DRG), which carry incoming sensory information, are the only exception; DRG cell bodies are contained in the PNS along with their neuronal processes.

The basic functional unit of the nervous system is the neuron, which is composed of the nerve cell body and its neuronal processes. The cell body consists of the usual organelles common to all cells. Usually the cell body is located within the CNS and serves as the focal point for outgrowth of nerve fibers. Neuronal processes (i.e., dendrites and axons) are cytoplasmic extensions from the cell body that expand in various directions. Their primary function is to communicate between the nerve cell body and other cells. Dendrites function to receive signals in the form of graded potentials that travel over short distances. Axons serve to transmit signals in the form of action potentials. Action potentials propagate through the axon and end at the terminal branches near its target, which can be another neuron, muscle fiber, or end sensory organ such as pacinian corpuscles in subcutaneous tissue.^[3,4]

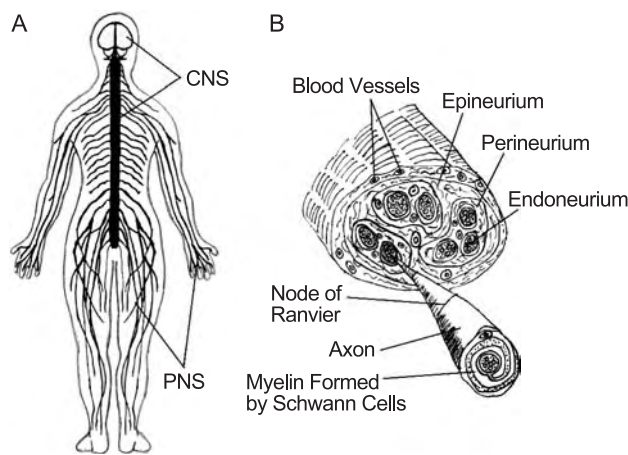

Fig. 1 The nervous system: A) The central nervous system (CNS) includes the brain and spinal cord. The peripheral nervous system (PNS) contains two main pathways (afferent and efferent) and connects the CNS to other parts of the body. B) Schematic diagram showing enlarged segment of neurons that are arranged to present the relationship of the axons to the myelin sheath formed by Schwann cells and connective tissue organization.

Glial cells, which are more abundant than neurons, play a critical role in nerve function. They provide physical and biochemical support for neurons. Specifically, Schwann cell cytoplasm insulates axons found in the PNS by creating myelin, multiple concentric layers of phospholipid membrane.^[3] In addition to being wrapped with myelin, axons are organized by a connective tissue that wraps around concentric layers, resulting in a bundle or fascicle (Fig. 1B).

NERVE TISSUE DEGENERATION

Injury and the subsequent response by nerve tissue is a well documented process in the PNS. Moments after injury, a process known as Wallerian or anterograde degeneration occurs in the distal end of the nerve stump (the end farthest from the cell body). First, the neuronal cytoskeleton begins to break down, followed shortly thereafter by the partial dissolution of the cell membrane. Fragmentation of the myelin sheath occurs and leads to the formation of axon and myelin fragments (ovoids), as illustrated in Fig. 2. The proximal end of the nerve stump (the end closest to the cell body) swells but often only undergoes minimal degradation. It is through the proximal stump that the neuron retains the potential to regenerate and reestablish nerve function.^[5]

Myelin protein is collected in ovoids, which flatten as the axon they enclose deteriorates. The loss of myelin due to neuronal injury suggests that signals from the axon are necessary to maintain both myelin

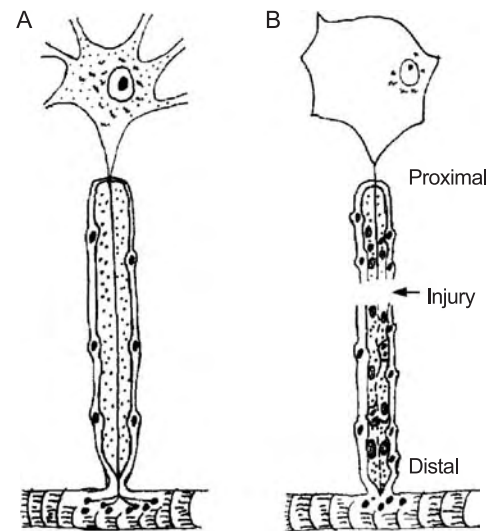

Fig. 2 Wallerian degeneration: A) Illustrated is a normal nerve fiber in its intact form innervating skeletal muscle. Represented in this image are the positions of the nucleus within the cell body and organized Schwann cells. B) When severing injury occurs, the nucleus moves to the cell periphery, and the distal end of the nerve fiber and its myelin sheath disintegrate. This is followed by phagocytosis of myelin debris by macrophages. Adapted from Ref. [5].

protein production and Schwann cell insulation. Eventually, phagocytic cells, such as macrophages, clean myelin debris; this process can take up to seven months in humans.^[6]

MODE OF AXONAL REGENERATION

Axonal regeneration requires motility of the growth cone (a specialized region on the tip of a growing neurite) and extension into damaged and degenerating nervous tissue. The mammalian PNS has a well recognized ability to support axonal regeneration, but PNS regeneration is limited by a slow rate of axonal growth that diminishes the ability of the damaged nerve to reestablish appropriate cell-to-cell signaling. Regeneration is dependent on the type of injury (e.g., crush, partial cut, complete transection) and can be limited by the size and location of the injury.

Crush injuries generally do not require surgical intervention. However, in the case of transection injury, surgical intervention is often necessary to repair and guide regenerating axons into the growth environment of the distal stump. Although distal segments of the axons degenerate, connective tissue elements (e.g., extracellular matrix proteins) of the distal stump generally remain intact. Despite the surgical efforts to utilize the remaining distal stump, repair often fails to achieve complete functional recovery. This problem is

further complicated if the injury requires regeneration over great distances. The regeneration period can be much longer than predicted from reported regeneration rates of 3–5 mm/day in humans.^[7] Therefore, it can take months and even years to achieve functional recovery.^[8]

Axonal outgrowth mediated by growth cone motility is accompanied by proliferating Schwann cells that eventually bridge the fibrin matrix that is formed post injury (Fig. 3A). Axonal sprouts emerge from the first node of Ranvier (unmyelinated region of a myelinated axon) proximal to the injury site.^[9] Axons with multiple sprouts could initially grow slowly until enough sprouts assemble to allow routing of structural material (basal lamina tubes generated by Schwann cells) to the dominant sprout, resulting in nerve fiber regeneration (Fig. 3B). If growing neurites do not enter these tubes and reestablish contact with Schwann cells, then growth is disorganized and regeneration remains incomplete even after several months (Fig. 3C). Growing neurites can form a painful neuroma if they are unable to find a path to direct their growth.^[5]

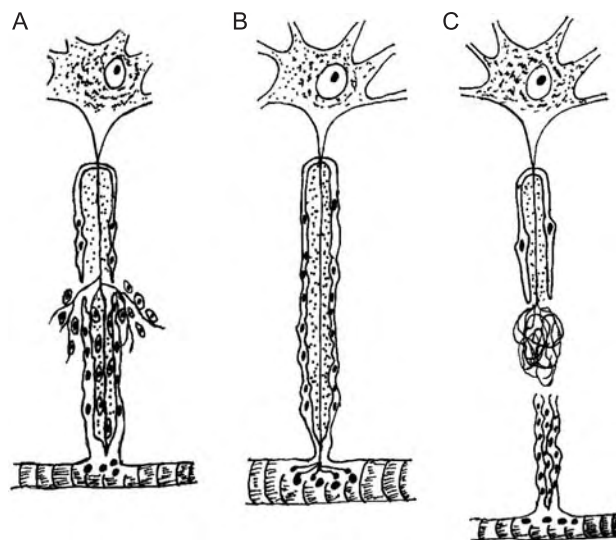

Fig. 3 Axonal regeneration: A) Following injury, Schwann cells lead neuronal outgrowth by forming a bridge between the proximal and the distal stump. This is succeeded by the formation of neurites that sprout from the proximal end. Schwann cells play multiple roles in neurite formation by serving as guides for reinnervation of the regenerating axon and by providing a chemical environment conducive to neuron survival and growth. B) Many of the neurites do not survive, but with the help of Schwann cell tubes, most of the neurites proceed to their destination successfully. C) If the neurites do not reestablish contact with the distal stump, then they become disorganized, leading to poor alignment of nerve ends, formation of a neuroma, and failed reinnervation. Adapted from Ref. [5].

ASSESSMENT OF FUNCTIONAL RECOVERY

Recovery of function in injured peripheral nerves is dependent on axonal outgrowth, reinnervation of target organs, and the subsequent establishment of functional characteristics of regenerated nerve fibers.^[10] One of the most common experimental models used is the rat sciatic nerve for evaluating motor and sensory function. Despite research efforts to develop a model system to study peripheral nerve regeneration, the rat sciatic nerve remains the choice for many neuroscientists. The rat sciatic nerve is comparable to subhuman primates because it has equivalent capacity for regeneration and for functional recovery evaluation.^[11] Several parameters are used to assess nerve regeneration including histology (axon count and diameter), electrophysiology (compound nerve action potentials and compound muscle action potentials), axoplasmic and horseradish peroxidase transport across the nerve reconstruction site, and sciatic function index (SFI) of walking tracks.^[12,13]

Histology is the most common method of monitoring nerve regeneration.^[1] Histology uses light or electron microscopy to determine the overall diameter of the regenerated nerve cable, size and number of axons, axon morphologies, presence of Schwann cells, and degree of myelination at the midpoint of the regenerated nerve cable. Histological sample analysis is subjective and does not necessarily indicate reinnervation and the subsequent functional recovery. Many studies report only histological findings, because these can be performed rapidly. Another method called retrograde labeling permits direct evaluation of reinnervation and axonal branching. In this method, a target muscle is injected with dye that is conducted along the axonal processes, using retrograde transport, back to the cell bodies. Both histological and retrograde labeling require that the animal be sacrificed, eliminating the possibility of any further measurement of regeneration in the same animal. Many studies combine structural and functional methods to give a more accurate assessment of true regeneration.^[1]

Another method of assessing nerve regeneration measures electrophysiological response by placing electrodes proximal and distal to the transection site.^[10] Electrophysiological response measures compound nerve action potential and conduction velocity of regenerated fibers. Electromyography (EMG) provides an alternative where information on reinnervation is obtained by measuring compound action potentials in the muscle after stimulation of the nerve. The main advantage of EMG over morphological studies is that it is a functional rather than structural measure of regeneration that can be monitored over the duration of the regeneration process.^[1,10]

Walking track analysis, which is used to develop sciatic function index (SFI), is an additional method for

assessing functional recovery. In 1982, De Medinaceli first reported the use of SFI to evaluate total lower-limb function.^[14] Walking track analysis is a noninvasive method that provides a quantitative means to evaluate sciatic nerve function based on several measurements of the footprints made on X-ray film. Since then investigators have modified SFI analysis by using finger paint and white paper, which eliminated radial diffusion problems commonly associated with X-ray films.^[15,16] The factors that are involved in SFI analysis include print-length factor (PLF), toe-spread factor (TSF), and intermediary toe-spread factor (ITF). These factors are then applied to the Bain-Mackinnon-Hunter (BMH) sciatic function index-formula: $SFI = -38.3 \times PLF + 109.5 \times TSF + 13.3 \times ITF - 8.8$. An SFI of 0 is normal and SFI of -100 indicates total impairment, which would result from complete transection of the sciatic nerve.^[12] Measurements are based on the footprints that are the direct outcome of coordinated function involving sensory input, motor response, and cortical integration. Therefore, many researchers believe that SFI provides a better method for evaluating functional recovery when compared to basic electrophysiology and morphometric analysis of axon growth and muscle reinnervation.^[11]

ENGINEERING STRATEGIES FOR NERVE REGENERATION

Researchers have combined knowledge from various disciplines to address the limitations of current approaches for improving nerve regeneration. Some engineering strategies currently being investigated include nerve guidance channels, acellular nerve grafts, support cells, neurotrophic factors, biomimetic strategies, stem cells, and gene therapy.

Nerve Guidance Channels

The nerve guidance channel, also called the nerve conduit, is one method used to bridge the gap between the proximal and distal ends of the nerve when nerve damage spans a distance that is too great for anastomosis. The channel allows the natural wound healing process to occur in a protected environment. In addition to providing a physical pathway, the conduit decreases the infiltration of scar tissue and increases concentrations of locally produced growth factors.

Several physical properties of the guidance channel appear to affect the extent and quality of regeneration dramatically. Some of these properties, depicted in Fig. 4, include conduit dimensions, wall porosity, surface texture of the inner luminal compartment, and inherent electrical properties.^[17] Conduits may swell *in vivo*; thus, the conduit dimensions need to be large

Fig. 4 Properties of a nerve conduit that are under active research include (clockwise from top-left): 1) biodegradability or a porous channel wall, or both; 2) the inclusion of support cells; 3) electrical activity; 4) the release of growth-promoting molecules; and 5) the inclusion of internally oriented matrices.

enough to allow for swelling without inhibiting axonal growth. The walls of the conduit should be sufficiently porous to allow nutrients to flow freely, but the pores should be small enough to exclude inflammatory cells. The ideal guidance channel would be composed of a material that maintains its physical integrity long enough for the nerve to fully regenerate, but eventually degrades leaving only natural tissue. It is believed that regeneration distance can be increased by the optimum combination of guidance channel materials and growth factors and/or support cells in the conduit lumen.^[17]

Many natural and synthetic materials have been explored for use as guidance channels. Some of the natural materials tested in nerve applications include veins, laminin, fibronectin, collagen, fibrin, hyaluronic acid, alginate, and agarose.^[18] Natural materials tend to have good biocompatibility and low toxicity and augment the migration of support cells. Some difficulties associated with the use of natural materials include a possible host immune response (necessitating the use of immunosuppressive drugs) and challenging manufacturing constraints (e.g., batch-to-batch variations and small sources of natural components).^[17]

As an alternative to natural materials, synthetic materials are attractive for use in guidance channels because of the control that can be obtained over the chemical and mechanical properties. Properties of synthetic polymers can be tailored to possess a wide range of physical characteristics (e.g., biocompatibility, porosity, degradation, and mechanical strength).^[19] Synthetic materials can be formed into a variety of macroscopic structures such as meshes, sponges, and bundled tubes in an attempt to mimic the natural nerve tissue structure more closely.^[18]

Initial studies of synthetic guidance channels used silicone tubes because of their flexibility and

biocompatibility. The silicone tube is a useful model for studying nerve regeneration in vivo because it is transparent and thus allows spatial and temporal examination of the regeneration process.^[20] A variety of studies have explored the effect of growth-promoting matrices (e.g., laminin and collagen) placed within the lumen of the silicon guidance channel.^[18,19] The downside of this model is that the silicone tube is not biodegradable. Fibrosis and chronic nerve compression are associated with long term use of nondegradable conduits.

To overcome limitations of nondegradable materials, Langer and coworkers have worked with a bioresorbable polymer system of poly(lactic acid) (PLA), poly(glycolic acid) (PGA), and their copolymers, poly(lactic-co-glycolic acid) (PLGA).^[21] These polymers have been FDA approved for a variety of applications and have many attractive features for tissue engineering. One can control degradation by varying molecular weight, copolymer ratios, and crystallinity. These polymers are easily processed into a variety of structures including microparticles, films, and nerve guidance conduits.^[19,22]

In addition to PLGA, a variety of other synthetic materials have been explored. Nonresorbable polymers that have durability such as poly(tetrafluoroethylene) and resorbable polymers such as poly(organo)phosphazine and poly(caprolactone) have been explored to improve the rate and quality of regeneration.^[23–25] Another material, poly(vinylidene fluoride) (PVDF), has also been explored for nerve guidance channels. PVDF is a piezoelectric material that has the ability to generate transient surface charges by mechanical deformation. This unique property of PVDF has been exploited for nerve guidance channel development and has been shown to enhance nerve regeneration.^[26] A complete listing of all the materials used to create guidance channels is beyond the scope of this article. Table 1 highlights some of the polymers that have been researched. For an excellent review of the natural and synthetic materials used in this area, see Seal et al.^[18]

Recent advancements have led to the development of a few nerve conduits that have received FDA approval. Some of these include collagen-based nerve conduits by Collagen Matrix, Inc.^[33] and Integra NeuroSciences, which markets the NeuraGen™ conduit.^[34] Another nerve conduit, available from SaluMedica, is an elastomer/hydrogel-based system that is marketed as SaluBridge.^[35] However, these conduits can be used only for small defects (<5 mm). Thus, strategies to repair larger defects are still under active research.

Acellular Grafts

An alternative to nerve guidance channels and autologous nerve grafts is the use of an acellular nerve

graft. Acellular nerve grafts are nonautologous tissues that have been treated to eliminate all living components, while maintaining extracellular matrix (ECM) structure. Possible sources of nerve graft tissue include: 1) allografts or nerve tissue from the same species and 2) xenografts or nerve tissue from a different species. Currently, autologous grafts are the only type of graft used clinically, because cellularly intact allografts and xenografts generate a vigorous immune response in the host. However, acellular nerve grafts could provide an alternative to autologous grafts because they do not provoke an immune response.

A review by Lundborg discusses a variety of studies using acellular nerve and muscle allografts for peripheral nerve regeneration.^[35] Specifically, acellular muscle tissue grafts have been explored because of the similar structure of the basal lamina tubes found in nerve and muscle tissue. Small amounts of muscle tissue can be removed without significant loss of function.^[36] Acellular grafts composed primarily of insoluble ECM components can be used to provide a scaffold for nerve regeneration. Some methods used to develop acellular grafts are: 1) detergents; 2) alternate cycles of freezing and thawing; and 3) irradiation. These methods aim to remove the living cellular components while preserving the ECM structure.^[17,35] Biomolecules and support cells can be subsequently introduced into the acellular graft to improve graft performance.

Support Cells and Neurotropic Factors

Glial cells (e.g., Schwann cells) are necessary for optimal axon migration. These cells release bioactive factors that further enhance nerve migration,

T

although the underlying mechanism for this system is not well understood. One study showed that a nerve can regenerate across a distance of 15–20 mm in a rat model using a guidance channel seeded with Schwann cells, compared to 10 mm in a control channel without Schwann cells.^[37] Schwann cells secrete an assortment of neurotropic/neurotrophic factors such as nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), and ciliary neurotrophic factor (CNTF). Schwann cells are also a common target for gene therapy, which attempts to boost in-vivo production of regeneration-promoting factors. Gene therapy will be discussed in greater detail later in this chapter.

Soluble neurotropic factors, which influence direction of neuron outgrowth, and neurotrophic factors, which promote neuron survival, have been incorporated directly into nerve guidance channels. Some of these factors include NGF, BDNF, insulin-like growth factor (IGF-1, IGF-2), platelet-derived growth factor (PDGF), fibroblast growth factor (FGF), and CNTF.^[19] Both neurotropic and neurotrophic factors have been delivered by osmotic pumps,^[38] gels,^[39] and fibronectin mats^[40] to provide temporal release and spatial organization to guide neuronal regeneration.

Biomimetic Strategies

In spite of the recent use of various natural and synthetic materials to bridge severed nerves, no material has surpassed the current clinical choice of the autologous nerve graft. In order to develop nerve guidance channel materials that enhance nerve regeneration, researchers are focusing on modifying existing materials to change their interfacial and biological properties. Current research efforts are focused on developing biomimetic systems that are composed of and organized with biomolecules that play a significant role in the development of neural tissue.

The overall goal of biomimetic strategies is to create a microenvironment that mimics the natural growth environment. Guidance cues in the microenvironment play a critical role in directing axonal growth during embryonic development. These guidance cues can be either instructive or permissive. Instructive cues lead to growth-cone motility based on the combination of inhibitory and attractive growth factors. Permissive guidance cues (e.g., laminin, fibronectin, and type IV collagen), which are found in the basal lamina, aid in supporting neurite outgrowth.^[42] By structurally patterning these permissive guidance cues, researchers have shown the ability to enhance nerve fiber extension both in vitro and in vivo.^[43–45]

A biomimetic surface is created in a selective manner to control cell receptor-mediated interactions with

ligands (guidance cues). By spatially controlling the distribution of ligands, patterned substrates can be used to guide neurite extension. One of the first attempts in substrate patterning demonstrated that linear paths of laminin promoted the initiation and growth of neurites from dorsal root ganglia.^[46] More recent studies using microlithography and microcontact printing have shown potential in using collagen, laminin, and other extracellular matrix (ECM) proteins for enhancing nerve regeneration.^[47,48] Biomolecules that mimic laminin and fibronectin activity were immobilized on PLA surfaces with micron-scale precision.^[49] Results of this study showed spatial control of cells and directed neurite extension.

There are many lithographic techniques used to control surface chemistry for developing micropatterned substrates. A thorough review by Wheeler et al.^[50] provides an explanation of these techniques including photoresist, laser ablation, and microcontact printing. The overall goal of these techniques is to develop a micropatterned substrate that contains two different chemical components: one component with a nonadhesive property and the other with an adhesive property. By using the adhesive component, cell attachment and the subsequent activity can be studied. These types of advancements in surface patterning have provided enormous opportunities for developing micropatterned substrates for axonal guidance and ultimately for designing nerve regeneration systems.

Stem Cell-Based Approaches

The versatility of stem cells to differentiate into specialized cells has drawn tremendous attention to their potential in the treatment of neurodegenerative diseases such as Parkinson's disease, multiple sclerosis, and Huntington's disease. Recent work using adult bone-marrow stromal cells (MSCs) that were transplanted into the distal stump of rat sciatic nerve showed significant improvement as measured using walking track analysis.^[51] Because MSCs injected into a lesioned peripheral nerve can survive, migrate, differentiate into Schwann cells, and promote functional recovery, they may be an important source for cellular therapy in several neurological diseases. Such studies show great potential for the use of stem cell transplantation in neuronal regeneration, but ultimately the understanding of optimal differentiation conditions and disease pathology will be necessary for developing stem cell-based therapy. As the basic biology and the capacity of stem cell-based therapy is further elucidated, the potential for using stem cells in nerve regeneration applications will improve.

Gene Therapy–Based Approaches

Advancements in gene transfer techniques have provided new opportunities to induce expression of specific proteins in selected cells. The ideal gene delivery system should be able to transduce nondividing cells, target specific cells, be nontoxic and nonimmunogenic, have high transfection efficiency, be able to bypass or overcome intracellular endosomal mechanisms, and be able to translocate into the nucleus effectively or integrate into the cellular genome without disturbing innate gene expression.^[52]

The natural tendency of viruses to infect host cells has been utilized for its advantage in gene therapy. By deleting the virulence genes with recombinant DNA tools, viruses can be used as effective carriers for a gene of interest (Navarro). Modified adeno-associated virus (AAV) and herpes simplex virus (HSV) vectors can deliver and express foreign genes in neurons. Several studies using AAV as a method for delivering genes for neurotrophic factors such as BDNF, CNTF, glial cell line–derived neurotrophic factor (GDNF), and neurotrophin (NT-3), have been shown to prevent loss of motoneurons after axotomy in neonatal rats.^[53–55] The overall goal of these studies was to induce overexpression of neurotrophic factors within a peripheral nerve graft to promote axonal growth. While preliminary results show potential for using viral vectors for gene therapy, further characterization and optimization are necessary to develop an effective treatment.

Although viral vectors exhibit high transfection efficiency, their use in vivo has resulted in several drawbacks such as nonspecific targeting, low capacity for carrying large therapeutic genes, risk of replication, and a possible host immune reaction.^[56–58] The safety issue in using viruses as gene carriers was brought into focus by the recent death of an 18-year-old gene therapy patient.^[59] This has compelled advancements in gene therapy with nonviral vectors to achieve safe and efficient transfection (e.g., polymer microspheres and liposomes). However, to date, nonviral vectors have not been applied for peripheral nerve tissue regeneration.

Genetic engineering techniques have been used to enhance nerve regeneration by promoting the local expression of neurotrophins (e.g., NGF), cell-adhesion molecules (e.g., NgCAM and axonin-1/TAG-1), and cytoplasmic surface phosphoproteins (e.g., B-50/GAP-43).^[60] One particular study utilized genetically engineered human dermal fibroblasts (hDFBs) to release human NGF. Results from this study, both in vitro and in vivo, showed significant enhancement of NGF levels that mimic the natural environment for regenerating nerve.^[61]

Although experiments with gene therapy–based techniques to stimulate regeneration have shown some success, a greater understanding of factors that

regulate neurogenesis is necessary. Once a greater understanding of the underlying pathologies of neurodegenerative diseases is achieved, gene therapy approaches will provide the most promising and natural approach to nerve tissue regeneration.

CONCLUSION

Despite the growing sophistication of medical technology, nerve tissue regeneration remains a frequent, costly, and serious problem in health care. Limited regeneration has been accomplished by using the autologous graft, but a more effective and convenient system to overcome peripheral nerve injury is still under investigation. The strategies highlighted in this chapter have shown preliminary success. A combination of these promising approaches will provide a better treatment option for damaged nervous tissue.

INTRODUCTION

Tears in the rotator cuff tendons are common and increase in frequency with age. These injuries are a significant cause of debilitation and economic hardship. While some injuries respond to conservative treatment, those that do not improve may require surgical intervention. Recovery from surgery takes considerable time and is complicated by adhesion formation, decreased tendon strength, and compromised function. For these reasons, the rotator cuff could benefit from healing augmentation, improved remodeling, or de novo synthesis of graft material. Tissue engineering seeks to repair or replace a variety of tissues through the delivery of implanted cells, scaffolds, genetic material, or proteins at the time of surgery. Its study combines aspects of both medicine and engineering and focuses upon advancements in cell biology and the development of new biological tissues. The integration of these components leads to the creation of new systems to augment the healing process.

Because tendons serve an important biomechanical role in the musculoskeletal system, the restoration of their mechanical properties is an important consideration in the development of an appropriate tissue engineering model. The concept of “functional tissue engineering” addresses this issue by giving increased attention to the functional properties of a given tissue and the restoration of healing tissue to an acceptable functional level. This concept demands understanding of normal tissue function, limitations of damaged tissue, definitions of a successful repair, and recognition of the appropriate determinants in reaching this goal.

This article focuses on basic principles of functional tissue engineering as it applies to the rotator cuff. We will discuss the requirements for a viable model of functional tissue engineering. As noted, these needs include an understanding of the biomechanical properties of healthy tendon, definitions of a successful repair, and recognition of physical and biological

factors that affect the utility of a potential model. We will review the pathological bases for rotator cuff disorders and how these lead to tendon injury. Several current models of functional tissue engineering will be examined including rehabilitation, cell therapy, scaffolds, and gene therapy. The mechanisms of action of these models will be described in addition to their potential uses. While these studies investigate the components important to a successful functional tissue engineering program, they also demonstrate our limited depth of knowledge regarding the true regulatory mechanisms of the healing process and foreshadow the continued advancements additional study will achieve.

BASIC PRINCIPLES OF TISSUE ENGINEERING DESIGN

The Key to Success

A successful tissue engineering program has several requirements.^[1,2] Before the healing tendon is considered, the biomechanical properties of tissue in vivo and the mechanical parameters that result in failure must be identified. Biomechanical analyses have identified multiple tensile regions in each tendonous unit of the rotator cuff. Principal units have been identified in each component of the rotator cuff. The anterior third of the supraspinatus, midsuperior, and inferior portions of the infraspinatus, and superior and midsuperior portions of the subscapularis tendons have been identified as these primary units (Table 1).^[3-5] Generally, there needs to be an understanding of the basic events in the normal healing of a rotator cuff focusing on identification of therapeutic targets. This includes defining the temporal, spatial, cellular, and molecular events involved with tendon healing as well as the origin of the responding cells. The intra- and extracellular signaling pathways used by these cells need to be elucidated in addition to the regulation of

Table 1 Tensile properties measured in human rotator cuff tendons

Tendon	Cross-sectional area (mm ²)	Ultimate load (N)	Stiffness (N/m)	Ultimate stress (MPa)	Elastic modulus (MPa)
SS anterior third	25.5	411	N.R.	17	N.R.
SS middle third	24.7	153	N.R.	6	N.R.
SS posterior third	21.9	88	N.R.	4	N.R.
IS superior portion	29.0	463	134	16	120
IS midsuperior portion	26.3	677	171	27	156
IS midinferior portion	20.8	315	97	16	111
IS inferior portion	26.2	550	149	22	140
TM	49.0	67	23	1	14
Sub. superior portion	40.3	623 (0°) 478 (60°)	147 (0°) 209 (60°)	N.R.	N.R.
Sub. midsuperior portion	N.R.	706 (0°) 598 (60°)	175 (0°) 182 (60°)	N.R.	N.R.
Sub. midinferior portion	N.R.	454 (0°) 400 (60°)	128 (0°) 130 (60°)	N.R.	N.R.
Sub. inferior portion	27.3	75 (0°) 30 (60°)	27 (0°) 10 (60°)	N.R.	N.R.

Note: Values for the infraspinatus and teres minor tendons are combined measurements for both 0° and 60° of abduction. Values are listed for the subscapularis tendon in both 0° and 60° of abduction. SS = supraspinatus. IS = infraspinatus. TM = teres minor. Sub. = subscapularis. N.R. = not recorded.

(From Refs. [3–5].)

pathway inhibitors. The investigator needs to be able to create the engineered tissue by altering the responding cells, augmenting the healing signals, blocking the inhibitor pathways, or creating de novo tissue in a bioreactor. In the case of true functional tissue engineering, stem cells placed on a scaffold need to be manipulated with the proper signaling molecules in the correct biomechanical environment to form a tendon. Additionally, there needs to be the ability to evaluate the properties of the engineered tissue quantitatively. This assessment demands established standards of successful biomechanical restoration. Prior to application, a potential model must be shown to be effective with the essential characteristics of the human clinical condition.^[2,6]

Defining the Standards of a Rotator Cuff Tendon

Before a tissue engineering model can be created, defining standards for the engineered tissue is an initial step and guides the remaining developmental process. In rotator cuff healing, this need translates to understanding the basic events involved with tendon healing at the muscle–tendon junction, along the tendon, and at the tendon–bone interface, along with the

responding cells, cytokines, chemokines and matrix proteins involved in these activities.

In addition to evaluating microscopic and molecular indicators of healing, standards must be established to characterize a successful repair. The ability of an engineered tissue to withstand forces approximating those experienced during a healthy state helps to define this goal. Biomechanical properties for a given tissue must be understood and prioritized. Stress and strain parameters should be measured in both normal and repaired tissue, and these factors must be studied to elucidate their impact on the healing process. The underlying organizational composition of the tissue principally determines the biomechanical properties in engineered tissue. Load has several effects on the normal biochemical and biomechanical qualities of tendon that vary according to the magnitude and type of force applied and are mediated by several growth factors including platelet-derived growth factor (PDGF) and insulin-like growth factor-1 (IGF-1).^[7]

Understanding the Pathological Basis of Rotator Cuff Disorders

Pathological responses to a loaded environment may be a result of lower metabolic activity in tendon associated with an inability to react to changes in load.

An increase in the proportion of collagen III, increased fibril diameter, reduced collagen turnover, increased mature cross-linking, decreased proteoglycan and water content, and reduced cellularity have been found to occur with aging. These changes produce a less compliant tissue that is more susceptible to injury and inadequately prepared to heal efficiently following pathological events. All of these changes can be addressed with tissue engineering.^[7-9]

Injury may be precipitated by direct events or may be purely a result of chronic degeneration. Initially following insult, the tissue surrounding the tendinous injury undergoes a hemorrhagic response that triggers the inflammatory pathway. Secretion of growth factors, including PDGF, transforming growth factor- α and β (TGF- α , TGF- β), basic fibroblast growth factor (bFGF), and epidermal growth factor (EGF), accompanies this response to direct the attraction and proliferation of fibroblasts and to stimulate collagen and protein synthesis. Fibroblasts play the central role in healing and remodeling tendon at the site of injury. This process takes considerable time, and even at maturation, the biomechanical properties of healed tissue are inferior to those of uninjured tendon due to a complicated system including a proportional decrease in the amount of collagen I and an increase in the amount of collagen III (Fig. 1). Again, these cytokines can be targets for tissue engineering.^[10]

Difficulty in elucidating the cellular pathways of the healing process in tendon has provided an obstacle to developing an ideal system of repair augmentation. While attempts have been made to identify the origin of cells that respond to growth factors secreted in the

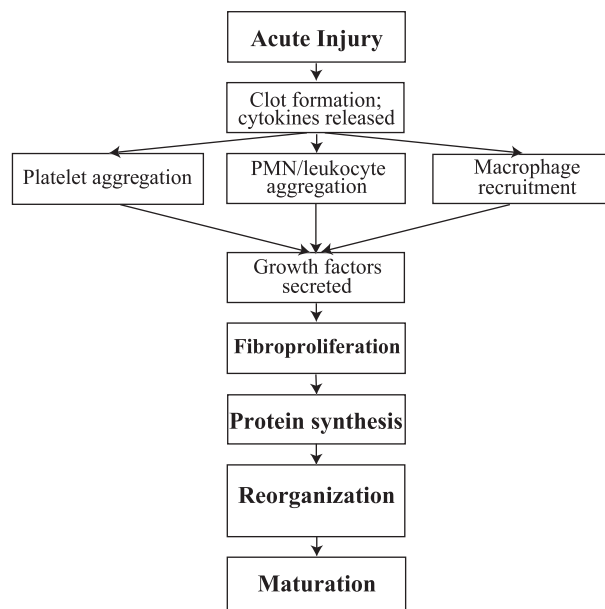

Fig. 1 Sequence of biological and mechanical events in the healing process in tendon following acute injury.

area of repair, both extrinsic and intrinsic sources have been described and no certain answer has been elucidated.^[11,12] We have recently investigated the heritage of cells involved in the healing tendon. The objective of this study was to examine the specific ancestry of cells that participate in tendon healing including myoblasts, activated satellite cells, differentiated skeletal muscle cells, vascular and nonvascular smooth muscle cells, pericytes, endothelial cells of developing and mature blood vessels, and bone marrow-derived cells. This study suggested that smooth muscle cells from mature or immature vessels or from pericytes are a major source of responding cells in the fibroproliferative stage of tendon healing and that cells of endothelial origin respond to a tendon injury by participating in neo-vascularization but do not contribute to fibroproliferation. Despite the hypothesized role satellite cells play in healing, activated satellite cells do not have a major role in healing tendon injuries. Cells of bone marrow origin contributed to the inflammatory process. However, despite recent studies suggesting bone-marrow stem cell recruitment to various sites, in this study bone marrow-derived cells did not contribute to the fibroproliferative response or develop into tendon cells. This study helped to elucidate the origins of cells involved in the various steps of the healing process.^[13,14]

CURRENT DIRECTIONS OF TISSUE ENGINEERING IN THE ROTATOR CUFF

Given the biomechanical demands placed upon tendon and the potential inability of aged or damaged tendons to meet these requirements, an ideal healing system is one that is both capable of restoring damaged tendon to its full functional ability and of promoting healing tissue to a biomechanical stability comparable to its healthy state. The time course of healing in tendon and the inferior tensile properties in healed tendon make the unaided repair process less than ideal. A successful model of tissue engineering for tendon repair in the rotator cuff is one that is capable of augmenting this process through improved remodeling and characterized by a faster return to near-normal biomechanical stability.

In addition to facilitating repair within the tendon substance, a successful model of tissue engineering must be able to achieve functional recovery along the tendon-bone interface. As the tissue properties change from soft, compressible material to hard, incompressible material, the tendon-bone interface is expected to be the most common site of failure due to stress concentrations.^[15] This interface has been categorized into four histological zones. The continuous change in composition across these zones helps to maximize the efficiency of load transfer across the tendon-bone

interface.^[16] We recently studied the genetic expression of extracellular matrix components and histological changes in the insertion site of a rat supraspinatus tendon that was acutely detached and repaired. Results indicated that a dramatic healing response occurred at the site of injury but that the healing tissue was poorly organized and was ineffective in recreating the original insertion site.^[15] A successful model of functional tissue engineering must be able to maximize the efficiency of healing along the transition from tendon to bone and promote an organized healing response. For this process to occur, a model of tissue engineering must be successfully integrated into the healing region and must help to guide healing progress. The continuous transition in tissue zones found in the healthy tendon–bone interface must be recreated to optimize mechanical function. Biomechanical properties must be restored to near normal levels to ensure interface stability. The healing process must occur in a timely, organized process to optimize early stability and tissue recovery time. These issues within both the tendon substance and the tendon–bone interface must be addressed in the development of a model of functional tissue engineering.

To achieve these goals, attempts at tissue engineering in rotator cuff tendons have taken several directions. Several of these studies have demonstrated promise as potential means of augmenting the healing response in damaged tendon. Unfortunately, no studies have combined all of these techniques into one system. In this section, we will describe several models of tissue engineering that have demonstrated improvements in tendon healing. Rehabilitation is a mechanical therapy that aims to improve tendon healing through the application of regulated mechanical stresses on the healing tendon. Cell therapy focuses upon the implantation of stem cells, or other pluripotent cells, into a site of tendon healing. These cells may serve a role in regenerating tissue and producing growth factors important in the healing process. Small intestine submucosa is an acellular biological scaffold that has come under recent examination as an organized matrix for the direction of connective tissue healing. Gene therapy is a broad field of study that is based upon the incorporation of genetic material into host tissue to augment the healing process from a genetic biochemical level. The proposed mechanisms by which each of these models serves to augment tendon healing will be discussed in addition to their appropriate roles in the repair of the rotator cuff.

Rehabilitation

Mechanical techniques focus upon the physical manipulation of repaired tendon to meet its original

needs. Because the primary functions of the rotator cuff and other tendons are as load-bearing constructs, physical rehabilitation of tendons focuses on placing healing tendon in a similar mechanically loaded environment under controlled conditions. While adequate rest following rotator cuff repair is necessary for healing to occur and recent studies have suggested that rest can lead to improved organization within tendon, extended rest may lead to shoulder stiffness, muscle atrophy, and disorganized healing.^[7] Controlled rehabilitation accentuates tendon healing in an organized manner.

Several studies have demonstrated that postrepair continuous passive motion and physical therapy increase tendon mobility and stiffness and help to prevent postoperative adhesion formation.^[17–20] In addition, several in-vivo studies have shown that increased stress in the region of repair following surgery, such as that seen in physical therapy, is associated with a greater organization of collagen fibrils and a higher rate of matrix synthesis compared to controls for both tendon and ligament.^[21,22] While this activity demonstrated a significant improvement in healing compared to control specimens with rotator cuff injuries, healing tissue was still found to be biomechanically inferior to uninjured tendon to at least 16 weeks following injury.^[21] These studies demonstrate the potential of mechanical rehabilitation to improve healing in damaged and repaired tendon and define the inferiority of healing tissue compared to healthy tendon during periods of rehabilitation.

Cell Therapy

Mesenchymal stem cells (MSCs) and other stem cells are pluripotent cells isolated from various sources that have not yet differentiated into a specific cell line. These cells have the potential to develop into a wide variety of tissues including bone, cartilage, tendon, fat, marrow stromal cells, and muscle. Studies examining the transplantation of allogeneic and xenogeneic stem cells into human tissue both in vitro and in vivo have shown that these cells maintain their pluripotency following transplantation and undergo site-specific differentiation.^[23–25] In this manner stem cells transplanted into a region of damaged tendon may differentiate into endothelial cells, osteoblasts, and fibroblasts to act as a biological patch and to augment the healing process further through the increased production of collagen and proteoglycan.^[10]

While the potential for improved healing is substantial in this model of tissue engineering, many challenges exist that must be met in order to develop a functional application of cell therapy to tendon repair. An adequate source of stem cells must exist for a

substantial transplantation of stem cells to be a reality. Autogenous donation is ideal in terms of delivering an immunologically low-risk population of cells, but the collection process may incur other morbidities. Allogenic and xenogenic sources may be easier to develop but carry the risk of potential rejection or disease transmission.^[26] Once a reliable population of stem cells is isolated, a delivery vehicle must be selected that will protect the cells but will also allow them to function normally following transplantation. Once both of these needs are met, a technique must be developed to combine the stem cells with the carrier *in vitro* and deliver them *in vivo*. This composite must be provided in such a way that makes its use feasible, safe, and efficacious.^[26]

Early studies in animal models and in humans have demonstrated successful implementation, survival, and differentiation of MSCs in tendon, but more work is required to elucidate fully the recipient response to donor cells and to determine optimal conditions for successful implementation of the technique.^[27–29] Standardization of a safe, effective delivery system will facilitate the potential use of cell therapy as an adjunct to tendon repair.

Small Intestinal Submucosa

Various methods of soft tissue grafting, including tendon and fascial autografts, allografts, xenografts, and synthetic constructs, have been examined in the repair of large tendon and ligament defects. Results from these studies have been inconsistent and complicated by adhesion formation, infection, functional failure, and immune rejection.^[30,31] Porcine small intestinal submucosa (SIS) is highly collagenous biological scaffold that has been found to promote a site-specific reconstructive response in connective tissue. This healing process is characterized by active angiogenesis and host cell migration and differentiation. The resulting new soft tissue is more representative of the surrounding host tissue than typical fibrous scar tissue.^[30]

Several studies have demonstrated the utility of SIS for tissue engineering in the repair of tendinous, ligamentous, and fascial defects in animal models.^[30–34] Examination of the use of SIS in grafts of rotator cuff defects has shown promise for the use of SIS grafting as a successful means of repairing large tendon defects.^[30] The assessment of healing at 6 months after the surgical repair of infraspinatus tendon defects using SIS grafts indicated a similar tendon size compared to sham-operated specimens and exhibited extensive signs of remodeling without adhesion formation. Histologically, the tendon–bone insertion site of SIS-regenerated tendons was similar to healthy

controls. While mechanical testing indicated that SIS-regenerated tendons were able to withstand lower failure loads than healthy tendon, these loads were similar to those in sham-operated tendons. This study supports the use of SIS in rotator cuff repair because it shows some improvements over conventional repair techniques. Of particular interest is the potential use of SIS in large gap defects precluding normal repair because it may provide the necessary scaffold to support tendon healing across extended distances.^[30]

The effectiveness of SIS appears to be determined by multiple microenvironmental factors, including vascular supply, oxygen availability, pH, and mechanical factors. While the development of new tissue along the SIS scaffold appears to depend, in part, on the quality of surrounding connective tissue in the site of a graft, stress along the grafted SIS is also important to the induction of regenerative processes. Progression of cellular infiltration and organized remodeling has been found to be greater in tendons that are mobilized postoperatively compared to those that are immobilized.^[34] This behavior is particularly advantageous for use in load-bearing tissues such as tendon. SIS is a promising model for augmented tendon healing because of its ability to serve as a scaffold for organized remodeling in damaged tissue with minimal scar formation.

Gene Transfer

While MSC transplantation and SIS grafting are models of tissue engineering that act by supplying adjunct cells or a scaffold to augment the healing progress, gene transfer therapy is a model that seeks to directly induce greater healing ability in the cells already in existence around a site of injury. Several growth factors have been implicated in the healing response of tendon including TGF β , TGF- α , bFGF, PDGF, IGF-I, and EGF.^[7,35–38] The goals of gene transfer, in regard to tendon healing, are to up-regulate the synthesis of these growth factors and to suppress production of endogenous proteins that may inhibit efficient, organized remodeling of damaged tendon.

In order for transfer to occur to host cells, an appropriate vector must be developed that will successfully deliver genetic material to the desired target and allow implementation into the host's genome. Viruses, liposomes, and gene guns are all methods of delivery that have demonstrated potential use for this purpose.^[10] Successful delivery and implementation of genetic material into the host's genome will lead to synthesis of the proteins encoded by the delivered gene or to down-regulation in the production of an

unwanted protein from a separate path. The advantages of this model of tissue engineering are that it induces a significant, local production of a substance that augments healing and that it is not complicated by morbidities associated with the insertion of donor tissue. The disadvantages are those most commonly associated with the vectors used for gene delivery. The production of certain viral vectors is a difficult process with a frequently low yield. Several viral strains carry a risk of mutagenesis that may interfere with the intended genetic result. Some strains of virus, adenovirus being the most notable, are capable of stimulating an inflammatory response and secondarily immunogenic rejection in the host. Gene guns, which involve particle bombardment of genetic material into host tissue, require specialized equipment that significantly increases the costs of production and utilization. Liposomes and naked DNA, while less immunogenic than other vectors, are not as successful as other methods in transfecting host cells. Because of these limitations, vector development remains an extremely active component of gene transfer research.^[39]

While the use of gene transfer is in its early stages, some studies have demonstrated successful incorporation of marker genes into tendon and ligament.^[40,41] Promising studies have explored the transfer of antagonists to FAK, a protein kinase linked to adhesion formation, and of genes encoding PDGF.^[10,39] In our lab, we have used both plasmid DNA and adenovirus-mediated gene transfer to demonstrate successfully reporter gene expression at the site of rotator cuff injury (Fig. 2). The success of these studies shows the potential for the use of gene transfer in the tendon. Future studies will continue to examine the insertion

Fig. 2 Rat rotator cuff tendon at six days after transfer of a Luciferase reporter gene. A collagen carrier mixed with plasmid DNA was placed in a 2 mm defect in the rat supraspinatus tendon. Luciferase expression is demonstrated by brown staining on histological examination (200 ×).

of genes to augment the production of growth factors involved in the healing processes of tendon or of antagonists to inhibit the production of proteins found to interfere with organized remodeling.

CONCLUSIONS

As described above, the goals of tissue engineering are to increase the healing response of the body to insults in order to regenerate tissues efficiently and to produce new tissues that are comparable to healthy tissue in strength and function. In the case of tendon, this goal translates to a restoration of load-bearing function with a decreased risk of recurrent failure. The rotator cuff is a musculotendonous complex that is likely to benefit from the development of tissue engineering models for tendon repair.

Several techniques have been utilized as parts of tissue engineering strategies ranging from mechanical techniques to stem cell-based gene therapy. Mechanical techniques, such as immobilization and physical rehabilitation, seek to augment tendon healing by exposing healing tendon to low-level mechanical forces in a controlled environment. The use of MSCs is a cellular model that uses the incorporation of pluripotent cells into the healing tendon. These cells are capable of differentiating into cells resembling their surrounding environment. They help regenerate repaired tendon in a more organized manner closely resembling the original type of tissue. SIS grafts are biological scaffolds that augment repair organization and mechanical stability. Gene transfer techniques involve transfecting cells in the region of repair to increase the production of certain prohealing growth factors and decrease the production of antagonistic proteins. These methods augment the healing process in existing cells without incorporating new tissue into the repair site. While each of these techniques has limitations, they demonstrate promise for the development of repair methods and therapies to reduce the complications and morbidities of rotator cuff repair significantly. Such a development would improve the quality of life in postsurgical patients and lessen the limitations of postoperative function and economic hardship. Continued support for the study of tendon tissue engineering is vital to the achievement of these goals.

INTRODUCTION

Tissue engineering is an interdisciplinary field that blends classical engineering and the life sciences. The field, by name, is still in its infancy, yet the principles are as old as interventional surgery. The desire to restore, maintain, or improve tissue function remains the end goal, but a new set of tools and techniques are emerging. The study of structure–function relationships in both normal and pathological tissues has been coupled with the development of biologically active substitutes or engineered materials. These advances have led to a variety of approaches for the development of engineered tissue analogues. The common trait to most of these strategies begins with the creation of a porous scaffold. The focus of this article will be the processes used to create tissue engineering scaffolds that are capable of mimicking native tissue.

OVERVIEW

The synthetic scaffold is used by the tissue engineer as an analogue of the extra-cellular matrix (ECM). Ideally, the synthetic scaffold should mimic both the structural and functional profile of the native ECM. One such approach is to create a scaffold with large pores to allow cell penetration and remodelling. Additionally, scientists attempt to reproduce either the overall appearance of the ECM or mimic the materials found in the ECM. Some fabrication techniques allow for the combination of multiple approaches. Regardless of approach, a biomimicking ECM analogue is critical to successfully mimic cell–matrix interactions and induce the expression of normal cellular phenotypes.

In order to meet this criterion, tissue engineering scaffolds must be designed to conform to a specific set of requirements. The first requirement is that the material must be biocompatible and function without interrupting other physiological processes. This functionality includes the ability to promote normal cell

growth and differentiation while maintaining three-dimensional orientation/space for the cells. Secondly, the scaffold should not promote or initiate any adverse tissue reactions.^[2] In addition, for clinical and commercial success, scaffold production should be simple yet versatile enough to produce a wide array of configurations to accommodate the size, shape, strength, and other intricacies of the target tissue.^[1–7] Once implemented, *in vitro* or *in vivo*, the material should either be removed from the site through degradation and absorption or incorporated through native remodeling mechanisms that leave only native tissue.

Beyond these generalized requirements, the interactions of single native cells within the immediate surroundings of those cells must also be analyzed. Cells are not autonomous entities kept in proximity to each other by the ECM nor do cells “communicate” only with other cells. Cells and the ECM have a dynamic three-dimensional interrelationship that is kept in balance and influenced by both internal and external stimuli. Evidence indicates that part of this bidirectional communication is a result of direct mechanical connections between fibrous proteins in the ECM and the cells’ cytoskeleton via integrins.^[8] This model requires that any scaffold material must be able to interact with cells in three dimensions and facilitate communication. The goal is to create a scaffold that will duplicate all the essential intercellular reactions and promote native intracellular responses. The incorporation of tissue-inductive factors into these scaffolds may also be useful to facilitate this communication.

After materials, size is the most critical factor when designing a tissue engineering scaffold. These scaffolds must allow cell penetration and neovascularization in order to be viable. The most commonly held paradigm requires pores larger than 10 microns, and in some cases larger than 100 microns, to allow cellular ingrowth and vessel formation.^[5] Observations of native tissues reveal that the structural ECM protein fibers are one to two orders of magnitude smaller than the cell itself, thus, allowing the cell to be in direct contact

with many of the fibers defining its three-dimensional orientation.^[9] Resolution of pore size, total porosity, and ECM fiber size may be a crucial factor in determining the success or failure of a tissue engineering scaffold.

SCAFFOLD FABRICATION TECHNIQUES

With the task of producing a scaffold that meets the above conditions, scientists have employed numerous fabrication techniques that include traditional engineering methods such as casting, molding, and extrusion; textile technologies such as spinning and weaving; decellularization of donor tissue; and engineering rapid prototyping technologies. All these methods have the common goal of producing highly porous scaffolds with large surface areas. Each technique has its own strengths and weaknesses. The aim of this article is to serve as a compilation and review of these methods in a concise format.

Fiber Bonding

Developed in the early 1990s, fiber bonding is a technique that develops tissue scaffolds from a mesh of polymer fibers. This process leads to the formation of highly porous scaffolds with a large ratio of surface area to volume. Two methods to accomplish this have been described. In the first method, a poly(L-lactic acid) (PLLA)/methylene chloride solution is cast into a glass Petri dish that contains a nonwoven poly(glycolic acid) (PGA) fiber mesh. The methylene chloride is then removed through evaporation followed by 24 hours of vacuum drying. This process leaves the PGA fiber mesh intact, but coats the PGA fibers with the solvent cast PLLA. At this point, the nonbonded PGA/PLLA composite is heated beyond the melting points of these polymers. PGA fibers bond at their cross-points, and it is thought that the PLLA matrix preserves the PGA fiber structure and three-dimensional shape during heating. Scaffolds are then quenched and any remaining water vapors are removed through vacuum drying. The final step in the process is the removal of PLLA by dissolving the composite structure in methylene chloride, again leaving the PGA intact, followed by vacuum drying. Scaffolds prepared in this manner were found to have a porosity of 81%, with pore diameters up to 500 μm .^[10]

In a second processing method, described as spray casting, PLLA or poly(lactide-co-galactide) (50/50 PLGA) is dissolved in chloroform and sprayed over the surface of a tube-shaped PGA fiber mesh using a dental atomizer. Chloroform is a poor solvent for PGA and, therefore, has minimal effect on its fiber structure.

A lyophilizer is used to remove the solvent, leaving PGA fibers that are bonded at their cross-points by PLLA or PLGA. Areas of bonding occur only on the external surface of the scaffold, with fibers deep in the scaffold remaining unchanged. The PLLA or PLGA film that develops on the surface of the scaffold appears to be dependent on the concentration of the polymer solution. The surface properties of this scaffold are dictated by PLLA or PLGA, while the mechanical properties are dictated by the PGA mesh. These scaffolds show an interconnected pore structure, with pore diameters as large as 500 μm . Scaffolds demonstrate a greater resistance to compressive forces when bonded with PLLA compared to PLGA.^[11]

Fiber bonding techniques are particularly useful for creating scaffolds with interconnected pore networks and high porosities. The fiber structures also provide a large surface area-to-volume ratio. Some limitations are that pore sizes cannot be controlled easily and both methods require the use of potentially toxic solvents. Polymer selection is limited to a few polymers whose physical properties meet the requirements necessary for fiber bonding conditions. These strategies have produced flat and tubular scaffolds, but do not permit the creation of complex three-dimensional structures. Furthermore, high temperatures and organic solvents preclude the incorporation of bioactive molecules into the scaffold.

Solvent Casting and Particulate Leaching

Solvent casting and particulate leaching are based on the principle that porogens (most commonly salt particles) can be dispersed into a polymer solution and later dissolved, creating a highly porous scaffold, also known as a foam. Several different processing techniques have evolved. In one method, PLLA or PLGA is dissolved in methylene chloride or chloroform. Salt particles are added to the solution, and the solution is cast into a glass dish. The solvent is allowed to evaporate, and the scaffold is subsequently vacuum dried. Salt particles are then leached from the scaffold by immersion in water. Scaffolds are then dried, and the result is a highly porous, highly crystalline structure. The scaffold surface in contact with the glass dish typically has a different morphology than the surface that is open to air.^[12] Alternatively, before salt particles are leached, scaffolds can be subjected to a heating and compression molding process, followed by cooling in water and vacuum drying.^[13] These methods have produced scaffolds with 500 μm diameter pores and porosities of over 90% (see Fig. 1). Waxy hydrocarbons have also been utilized as porogens, and highly porous scaffolds as thick as 2.5 cm were constructed.^[14] Pentanes or hexanes, which could leave

Fig. 1 Poly (L-lactide) tissue engineering scaffold formed through a combined gelation and sugar-leaching technique. The typical pore diameter is approximately 500 microns. (Reprinted with permission of Elsevier Science [Ref. [45] p. 723].)

toxic residues, are needed to remove waxy hydrocarbons from a scaffold. Poly(ethylene glycol) (PEG) can be blended with PLLA or PLGA, resulting in a more pliable scaffold, while maintaining high porosity and pore diameters over 100 μm .^[15] With all of these techniques, the pore diameter is dependent on the size of the porogen, and porosity is dependent on the porogen concentration.

Solvent casting and particulate leaching overcome one of the difficulties of fiber bonding in that they allow more precise control over pore size, total porosity, and surface-to-volume ratio. Highly porous structures with large pore diameters can be readily manufactured. In addition, processing parameters control the crystallinity of the scaffold. Like fiber bonding, this method requires potentially toxic solvents. Also, there are some concerns regarding irregularly shaped pores that may not be completely interconnected or uniformly distributed throughout the scaffold, due in part to evidence suggesting incomplete leaching of the porogens. Finally, as in fiber bonding, rigorous processing conditions generally prevent the inclusion of bioactive molecules.

Membrane Lamination

One of the limitations of the aforementioned scaffold processing methods is the inability to create complex three-dimensional structures. Membrane lamination was developed in an effort to overcome this obstacle while maintaining high porosity.^[16] First, a conceptual contour plot is created by dividing a three-dimensional shape of interest into cross sections of equal thickness. Each layer (or slice) has a specific contour according to

its location within the structure. Multiple scaffolds (membranes) are produced from PLLA or PLGA using a solvent casting and particulate leaching process. Membranes are then cut into unique shapes corresponding to each contour template. The membranes are sequentially bonded together at their adjoining surfaces using a small amount of chloroform, eventually forming a three-dimensional scaffold. Subsequent analysis demonstrates that pore morphology and average pore diameter are unchanged by the lamination process. In addition, the boundaries between individual layers cannot be distinguished with scanning electron microscopy. Membrane lamination is capable of producing scaffolds with pore diameters over 150 μm and porosities up to 90%.^[16]

An obvious advantage of this technique is the ability to create a complex three-dimensional scaffold. Layered membranes retain important physical properties of individual membranes, such as porosity and pore diameter. Drawbacks of membrane lamination are similar to those of solvent casting and particulate leaching, notably the use of toxic solvents. Also, there is no mechanism to align pores between layers; consequently, most channels are not connected through the bulk of the scaffold.

Melt Molding

Melt molding is another method that uses the principles of solvent casting and particulate leaching to manufacture complex three-dimensional scaffolds. A polymer powder is mixed with gelatin microspheres, placed into a Teflon mold, and heated beyond the polymer glass transition temperature. PLGA is generally preferred over PLLA or PGA because it can be processed at lower temperatures. Elevated temperatures can preclude the incorporation of bioactive molecules and may decrease the gelatin solubility. After heating, the composite structure is placed in water, which leaches out the water-soluble microspheres.^[17] This technique is similar to solvent casting and particulate leaching in that pore size and porosity are determined by porogen diameter and concentration, respectively. Also, like other leaching methods, pores do not have uniform diameters and incomplete porogen removal is probable. In contrast, melt molding does avoid the use of toxic solvents.^[17]

One of the highlights of melt molding is that the scaffold shape is limited only by the degree to which the Teflon mold may be shaped. Another improvement over previously discussed processing methods is the lower temperature requirement. This fact, along with the absence of toxic solvents, creates more favorable conditions for the incorporation of bioactive molecules

into scaffolds. One restriction is that this technique is typically limited to PLGA.

Extrusion

Extrusion is a technique for producing tubular scaffolds and was originally utilized in tissue engineering to facilitate guided regeneration of nervous tissue.^[18] The process begins by making PLLA or PLGA wafers by solvent casting and particulate leaching with salt particles. Dried polymer/salt wafers are placed in a piston-extrusion tool, which is mounted on a hydraulic press. The tool is heated, pressure is applied between the nozzle and the piston, and a composite structure is extruded in a tubular conformation. Tubes are then cooled, immersed in water to leach the salt, and, lastly, vacuum dried. The pressure required for extrusion is dependent on the extrusion temperature. Pores up to 300 μm in diameter and porosities of 83% are possible. Both the pore size and porosity increases as the salt weight fraction increases. Using larger salt particles also increases pore diameter. Pore size is unaffected by the extrusion process for temperatures less than 275°C.^[18]

Scaffolds created by extrusion have large pore diameters and high porosity, and the process allows for good control over these parameters. It is thought that these scaffolds may provide an opportunity for the incorporation of microspheres carrying tissue-inductive factors if they can be shielded from the high processing temperatures or the organic solvents. The use of toxic solvents may be a limiting factor for both the bulk material and any embedded microspheres. Other drawbacks associated with solvent casting and particulate leaching are mentioned in previous sections.

Gas Foaming

Gas foaming is another method for producing porous scaffolds without the use of organic solvents. This technique is based on the ability of carbon dioxide (CO_2) molecules to cluster and form nuclei (gas nucleation). There are a number of different approaches to manufacturing gas foams. With the first method, PLGA pellets are put through heating and compression molding, which yields solid polymer disks.^[19] These disks are saturated with CO_2 over a 72-hour period in a high pressure chamber. The pressure is then rapidly returned to ambient levels. This processing method has produced scaffolds with porosities of 97% and pore diameters of 100–500 μm . Porosity and pore structure are dependent on the amount of gas dissolved in the polymer, the rate and type (homogeneous or heterogeneous) of gas nucleation, and the diffusion rate of gas molecules through the polymer to the pore nuclei.^[19]

A similar process was described that combines the principles of gas foaming and particulate leaching.^[20] The primary distinction is that salt particles are incorporated into the polymer at the initial stage and later leached from the scaffold by water immersion. Another difference is that all steps are carried out at ambient temperature. The use of salt particles has allowed pores to be more interconnected, with pore diameters of 100–500 μm and porosities up to 97%. It should be noted that two types of pores form: large, open pores from the salt particles; and small, closed pores from gas nucleation.^[20]

A third method of gas foaming begins by mixing ammonium bicarbonate into a PLLA solution (in methylene chloride or chloroform).^[21] This combination forms a paste-like material, which can be readily molded into various shapes. The mold is allowed to air-dry at atmospheric pressure. At this step in the process, there are two options for creating pores. One technique involves vacuum drying the composite for two weeks, followed by immersion in warm water. The other option is to immerse the composite in hot water, followed by a cold water bath. In both cases, the scaffold is subsequently freeze dried. Scaffolds subjected to a prolonged vacuum-drying step show a dense surface skin layer and partially collapse during the process, making this method generally unacceptable. With hot water immersion, however, interconnected pores with diameters of 200–500 μm and porosities over 90% are possible.^[21]

Gas foaming was originally developed to overcome the need for toxic solvents; the first and second methods discussed maintain this quality, but the third technique does involve organic solvents. After the initial disk is formed in method one, all the aforementioned approaches avoid high temperatures in processing, a factor important for the potential use of bioactive molecules. In comparison to solvent casting and particulate leaching, gas foaming is reported to produce scaffolds with more uniform pore structure and stronger mechanical properties. Some drawbacks of the first method are that a polymer skin forms over the surface of the scaffold and gas nucleation leads to a closed pore morphology. Another drawback is that it is difficult to form a complex three-dimensional scaffold using gas foaming techniques other than the third method without sophisticated molding techniques.

Freeze Drying

Freeze drying is a method of removing solvents via sublimation. This process is commonly performed in a lyophilizer by subjecting frozen specimens to a deep vacuum, thus reducing the solvents' vapor pressure. One freeze-drying method that has been described is

emulsion freeze drying.^[22] Water is added to a PLGA/methylene chloride solution, forming two immiscible layers. The layers are homogenized, and the result is an emulsion consisting of a continuous polymer/solvent phase and a dispersed water phase. This emulsion is poured into a copper mold and quenched in liquid nitrogen. Lastly, scaffolds are freeze dried to remove the water and solvent. Scaffold structure is determined by a number of thermodynamic principles, a discussion of which is beyond the scope of this article. This technique is capable of producing scaffolds with 15–35 μm diameter pores and porosities as high as 95%.^[22]

Freeze-drying techniques have been applied to a number of different polymers, including PLLA, PGA, PLGA, and a PLGA/PPF blend.^[23] The polymers are dissolved in glacial acetic acid or benzene and frozen at -10°C , followed by lyophilization for one week. Scaffold morphology (capillary versus leaflet) depends on the type of polymer and solvent used. Furthermore, the investigators demonstrated the incorporation of the drug isoniazid into these scaffolds and concluded that the polymer type influences the drug's rate of release.^[23] No data on porosity or pore sizes was collected in this study.

Some advantages of the freeze-drying technique are that it does not require either a separate leaching step or the use of high temperatures. Scaffolds fabricated with the first method have an interconnected pore network and high porosity. One drawback is that the pores are relatively small, however. Both of the described techniques require the use of toxic solvents. Another drawback is that long processing times are necessary. While no measurements were reported in either paper, the latter method of freeze drying has shown the potential for the incorporation and release of bioactive molecules.

Phase Separation

Phase separation is another means of scaffold processing designed with the intent of incorporating bioactive molecules. A liquid–liquid phase separation technique has been illustrated to produce foams with the potential for drug delivery.^[24] PLLA and solid naphthalene are mixed in a flask, heated, and stirred to obtain a homogenous solution. The solution is then poured or sprayed (using an atomizer) into a cooled mold. Naphthalene is removed by vacuum drying for 12 hours. This process creates polymer-rich and polymer-poor phases within the solution. The specific foam morphology and pore distribution depend on the thermodynamic mechanism of phase separation (spinodal decomposition versus metastable nucleation). This technique creates a relatively uniform pore distribution with diameters of 50–100 μm . Porosities up to

87% can be achieved, depending on the polymer concentration in the solution.^[24] The investigators were able to incorporate different dyes into the scaffolds, and results showed that the distribution and rate of release were influenced by the hydrophobicity of the polymer molecules.

An alternative method, solid–liquid phase separation, has been developed to enhance the mechanical properties of scaffolds.^[25] PLLA or PLGA is dissolved in dioxane or a dioxane/water mixture, and hydroxyapatite (the mineral component of normal bone) powder is added to the solution. The mixture is cooled to solidify the solvent and create a solid–liquid phase separation, and then quenched in liquid nitrogen. Several days of freeze drying are needed to remove any remaining solvent. Scaffolds with porosities of 95% and interconnected pore diameters as large as 600 μm are possible. The porosity, pore size, and pore morphology are dependent on the polymer concentration, polymer structure, hydroxyapatite content, phase-separation temperature, and solvent.^[25]

The foremost advantage of the first method is the potential use of the scaffold as a delivery vehicle for bioactive molecules. Enhanced mechanical strength resulting from the second technique is particularly relevant for the engineering of osseous tissue. Both methods use organic solvents that may have detrimental effects on cells.

Acellular Matrix and Submucosa

All of the processing methods discussed thus far have utilized synthetic polymers to construct scaffolds. However, a number of studies have also investigated the use of natural biomaterials for tissue engineering. Virtually all body tissues are built upon an ECM that consists of structural and functional proteins, proteoglycans, and glycoproteins. Collagen (primarily type I) is the most abundant ECM protein. Cytokines and growth factors are also present in the ECM. The composition of the ECM varies according to tissue function and location. In short, decellularization involves the removal of cells from the ECM through a series of chemical and/or enzymatic steps, resulting in an acellular matrix that can serve as a tissue engineering scaffold. One such scaffold has been successfully prepared using the following technique.^[26] Whole bladders are excised and run through a series of chemical washes to lyse cells and remove cytoplasmic and nuclear material. In the final step, bladders are placed in 70% ethanol for 24 hours, washed with Sorenson's phosphate buffer, and refrigerated in Dulbecco's PBS until ready for use. In addition to the bladder, ECM can be harvested from the dermis, small intestine, pericardium, stomach, basement membrane,

and stroma of the decellularized liver, and decellularized Achilles tendon.^[27] In general, cell extraction from these sources leaves behind primarily collagen and elastin.

The submucosa (natural biomaterial) is defined as the layer of tissue beneath a mucous membrane or the layer of connective tissue beneath the tunica mucosa. Submucosa was used as early as 1989, when a small intestine submucosa was utilized as a vascular graft in a dog model.^[28] ECM and submucosa are touted as good biomaterials for tissue engineering because of the array of proteins, growth factors, and cytokines located in these tissues. These factors are believed to contribute significantly to neovascularization and nerve regeneration, as observed during *in vivo* studies.^[29] Natural biomaterials are also thought to be less immunogenic than synthetic scaffolds. This, however, varies greatly by source and processing even though collagen is highly conserved across species. A drawback of ECM and submucosa is that they are rapidly degraded *in vivo*. This is especially true of submucosa, which is relatively thin (approximately 0.1 mm thick). Scaffold shrinkage *in vivo* is also problematic with ECM. Calcification is commonly reported for both ECM and submucosa. Though the discussed methods do not require toxic chemicals, some methods have utilized chemical cross-linking agents to improve mechanical properties. It should be noted that doing so may often cause a fibrous tissue response.^[29]

Connective Tissue Capsule

When a foreign object is placed inside the body, the immune system reacts by surrounding the material with a layer of connective tissue. Investigators have taken advantage of this phenomenon to create natural cell delivery vehicles.^[30,31] A sterile silicone sheet, tube, or block of desired shape is placed in the subcutaneous tissue, and, after several weeks, a capsule forms around the block during wound healing due to the foreign body. If the foreign body is placed close to a large blood vessel, it has the potential to form a single vascular pedicle, which can be mobilized as a flap. The capsule, which is several millimeters thick, generally contains a highly vascularized layer of fibroblasts, a dense collagen network, laminin, and fibronectin. The capsular surface may act as a basal lamina upon which cells can organize and develop. Similar methods have been developed to grow vascular prosthetics in a patient's peritoneal cavity.^[32]

This technique has the advantage of eliciting a strong angiogenic response, which is often a critical factor in determining the extent of tissue development. Furthermore, a variety of shapes are possible, depending on the shape of the implanted foreign body. A

limitation of this method is that at least two procedures are required: one to insert the silicone object and one to seed cells and/or perform the surgical procedure of interest. The time required for capsule formation can be up to several weeks. Mechanical strength of this tissue is questionable.

Rapid Prototyping Techniques

The utilization of rapid prototyping techniques to build tissue engineering scaffolds is becoming more prevalent. In general, this method allows for the design and construction of thick constructs that are highly porous and possess an intricate network of interconnected pores. These techniques include stereolithography (SLA), laminated object manufacturing (LOM), selective laser sintering (SLS), fused deposition modeling (FDM), solid ground curing (SGC), and three-dimensional printing (3-DP).^[33] Target tissue data from magnetic resonance imaging (MRI) or computed tomography (CT) scans can be fed into a computer to generate a model with the same gross architecture. These models can then be used in conjunction with one of the previously mentioned rapid prototyping systems to duplicate the design as a three-dimensional structure.^[34]

One such method describes the use of FDM to fabricate scaffolds from polycaprolactone (PCL),^[35,36] as shown in Fig. 2. Once a three-dimensional object is digitally created on a CAD workstation, the file is transferred to the FDM software, which mathematically slices the model into horizontal layers of known thicknesses. These layer thicknesses are a function of the equipment and polymers used, but are typically a few hundred microns. A tool path is also generated and the parsed file is downloaded to the FDM hardware. The FDM consists of an extrusion head above a precision X- and Y-axis positioning platform that traces out each layer fed into the machine. The Z-axis is controlled by automatically lowering the platform after each slice is reproduced.^[37]

A thermoplastic polymer, in this example PCL, is fed into the temperature controlled extrusion head and heated to a semi-fluid state. The polymer is then extruded and deposited onto the base, where it quickly cools and solidifies. This rapid cooling allows for unsupported structures to be built and is one advantage FDM has over many other rapid prototyping methods.^[33] For the purpose of testing, a honeycomb-like structure was produced with pore sizes that ranged from 160 to 700 microns.^[36] Fibers between 260 and 370 microns were produced for the structure. The slice thickness was set at 254 microns. The combination of these parameters resulted in scaffolds with porosities ranging from 48% to 77%. Mechanical testing showed

T

Fig. 2 Top (a) and side (b) view of a polycaprolactone tissue engineering scaffold produced via a CAD/CAM-fused deposition modeling approach. Size bar insert is 500 microns. (Reprinted with permission of Elsevier Science [Ref. [36] p. 1176].)

that the constructs possessed high compressive strength and that strength could be tailored by varying the honeycomb pattern. Scanning electron and light microscopy confirmed the highly ordered patterns and the repeatability of the structure. Tissue culturing on the scaffold demonstrated that cells penetrated the scaffold and proliferated within its three-dimensional space.^[35,36]

Another rapid prototyping technique utilized for development of tissue engineering scaffolds is 3-D printing (3-DP). Briefly, this technique uses ink jet printing heads filled with special polymers attached to a frame over a precision X-axis and Y-axis positioning table. Molten droplets of low melting point polymers are formed by the piezoelectric transducer and these droplets solidify upon contact with the positioning table or previously completed layer to form beads. Adjacent beads overlap to form lines and adjacent lines overlap to form layers. Multiple print heads allow different polymers to be used in a single layer or model. After the layer is complete, the top surface of the layer is flattened to control thickness and provide a flat surface for the next layer to be built. The platform is lowered, and the process is repeated to build the next layer, which adheres to the previous layer, until the entire model is complete.^[37]

This 3-DP technique was utilized in a two-step fabrication process to create a novel collagen scaffold.^[38] CAD software was used to design a mold possessing the negative shape of the scaffold. The CAD file is then downloaded to the 3-DP equipment and a model was printed by controlled droplet deposition of mold and support materials to form each layer. The completed mold containing support material structures was immersed into a selective solvent to remove the mold material. A collagen dispersion was then cast into the mold cavity and frozen. The support material was then dissolved in ethanol, and the collagen scaffold was subjected to critical point drying. The result was a dry collagen scaffold with controlled pore channels and porous channel walls. This technique is capable of details as fine as 181 microns, but only details of 200 microns and larger could be precisely controlled by the software in this example.^[37]

Both of these rapid prototyping techniques are capable of producing structural scaffolds with specifically designed geometries and networks of inter-connecting pores. Material choices range from bioabsorbable thermoplastics like PCL and poly(lactide-co-glycolide) to collagen. The CAD software can be coupled with MRI and CT data to create scaffolds that very closely match the target organs. One of the major drawbacks may be resolution limitations; these techniques typically have X, Y, and Z resolutions of a few hundred microns to one millimeter. These scaffolds have been shown in the lab to facilitate cellular ingrowth but the pore/layer size mismatch with cells (10 to 100 times larger than a cell) may prevent completely natural interactions. In addition, the more sophisticated methods, such as the 3-DP collagen scaffold, could leave residual toxic solvents in the scaffold.

Electrospinning

One textile manufacturing process that is gaining popularity for creation of tissue engineered scaffolds is electrospinning. Electrospinning traces its roots to electrostatic spraying, which was first described more than 100 years ago. In electrostatic spraying, charge is injection into a liquid, typically 5–30 kV, from an electrode. The charged liquid is separated some distance from a second electrode of opposite polarity to establish a static electric field. A so-called Taylor Cone forms, due to the competing forces of the static electric field and the liquid's surface tension. For liquids with a finite conductivity, charged droplets are dispersed from the tip of the Taylor Cone and are delivered to a grounded target. If the liquid consists of a polymer melt or a polymer in solution and the concentration of

that polymer is sufficiently high to cause molecular chain entanglement, a fiber, rather than a droplet, is drawn from the tip of the Taylor Cone.^[38]

A basic electrospinning system consists of a charged polymer solution (or melt) that is fed through a small opening or nozzle (usually a needle or pipette tip). Because of its charge, the solution is drawn toward a grounded collecting plate (usually a metal screen, plate, or rotating mandrel), typically 5–30 cm away, as a jet. During the jet's travel, the solvent gradually evaporates, and a charged polymer fiber is left to accumulate on the grounded target. The charge on the fibers eventually dissipates into the surrounding environment. The resulting product is a nonwoven fiber mat that is composed of tiny fibers with diameters between 50 nanometers and 10 microns.^[39] This nonwoven mat forms the foundation of the scaffold. By varying the orientation of the fibers in the scaffold, from parallel alignment to a random arrangement, the mechanical properties of the scaffold can be varied.^[39]

As Fig. 3 shows, the electrospinning process has been used to create tissue engineering scaffolds composed of PLLA, PGA, and PCL (including blends and copolymers), as well as natural polymers such as collagen, elastin, and fibrinogen.^[38–43] All the scaffolds were reported to have strengths and stiffnesses that are equivalent to native soft tissues. Uniaxial material characterization demonstrated the anisotropic nature of the aligned scaffolds, mimicking the anisotropic characteristics of most soft tissues. Both in-vivo (rat intramuscular implant) and in-vitro cell culture studies were performed to confirm biocompatibility and cellular infiltration. These scaffolds had porosities greater than 80% and pore diameters that ranged from a few hundred nanometers to approximately 10 microns. Since

Fig. 3 Random fibrous mat of PGA produced through the process of electrospinning. The fiber diameters average 0.63 microns with pore dimensions of approximately 0.20 microns.

cells were able to penetrate all these scaffolds,^[38–44] the previously mentioned paradigm for cellular infiltration must be reevaluated. It is possible that cells respond differently to fibers that more closely mimic the size of natural ECM fibers.

A lack of mechanical strength is often touted as the principal disadvantage of most textile-based scaffold fabrication techniques. In addition, the fluorinated solvents necessary for many of the polymers to be electrospun are toxic. These solvents could adversely affect cellular response if not fully extracted from the scaffolds. The initial compatibility tests did not indicate any solvent-related problems in rat models; however, tests for residual solvents were not conducted (unpublished data). Also, cross-linking agents were used when preparing the natural polymer scaffolds. These effects must also be elucidated. Even with these possible limitations, electrospinning shows great promise in the development of biomimicking tissue engineering scaffolds.

CONCLUSION

Current research in tissue engineering is at the threshold of providing significant benefits to patients and physicians in the treatment of injury and disease. Many methods have emerged, from the simple concept of placing cells in a degradable scaffold to building native tissues either in vivo or in vitro. These advances come on the back of breakthroughs in the life sciences that provide critical information about the nature and development of tissues and diseases. Ultimately, engineers must match applications, materials, and fabrication processes to best meet the needs of the tissue they wish to build.

INTRODUCTION

The congenital defects and traumatic injuries that compromise the structure and function of skeletal muscle range from the functionally benign to the profoundly debilitating. In either circumstance, dysfunctional muscle can impact a patient on a number of levels. A defect to the musculature of the face may not have a significant impact on patient mortality; however, even a relatively minor cosmetic defect can have profound psychological effects and greatly degrade the quality of life. In many cases, for example, the reconstruction of cleft palate in young children, a relatively minor increase in the amount of tissue available for reconstructive surgery can greatly improve the therapeutic outcome. From a clinical prospective, we believe that congenital defects of the face might represent one of the initial applications where bioengineered muscle can have an impact on patient health care. Other potential applications include bioengineered muscle for the reconstruction of facial muscles damaged by traumatic injury and implants designed for protein or gene-mediated therapies.

STRUCTURE OF MUSCLE

To truly restore function to a damaged muscle, the architectural features of the native tissue must be substantially reconstituted in the bioengineering paradigm. The structure and mechanical properties of skeletal muscle are defined by a dynamic interaction between the active, contractile cellular elements of this tissue and the passive, structural constituents of the surrounding extracellular matrix. The active cellular elements of the prototypic skeletal muscle are distributed into dense, parallel arrays. This structural feature allows the tissue to effectively apply force along a defined axis. The multinucleated skeletal muscle cell, or myotube, exhibits a highly organized internal cytoarchitecture. The myofibrils, the contractile filaments of muscle, are tightly packed within the sarcoplasm of these cells. Each myofibril is subdivided into a series of tandem repeating structures called sarcomeres. The molecular motors of contraction, the actin thin filaments and myosin thick filaments, are organized into nearly crystalline arrays within the sarcomeres. Accessory cytoskeletal proteins stabilize the structural arrangement of the sarcomeres and link adjacent

myofibrils to one another and the surrounding extracellular environment. The myofibrils are interspersed with columns of mitochondria and are surrounded by projections of the membranous sarcoplasmic reticulum. T-tubules, which are invaginations of the plasma membrane (sarcolemma), penetrate the myotubes and interact with the sarcoplasmic reticulum to distribute the wave of depolarization initiated by the central nervous system that regulates voluntary muscle contraction.

The active cellular elements of muscle are surrounded in the extracellular space by a connective tissue scaffolding. This connective tissue scaffolding, or extracellular matrix, supports and defines the overall structural organization of the tissue. It can be arbitrarily subdivided into four interconnected compartments: the basal lamina, the endomysium, the perimysium, and the epimysium.^[1,2] The basal lamina is synthesized by the myotubes and is enriched in laminin, type IV collagen, and a variety of proteoglycans. It is intimately applied over the external surface of each individual myotube and is believed to lend structural support to the outer leaflet of the plasma membrane. The endomysium is continuous with and overlays the basal lamina and is enriched in the extracellular proteins type III collagen, laminin, tenascin, and the multifunctional protein, fibronectin. The molecular composition of the perimysium is similar to that of the endomysium; type I collagen, type III collagen, and fibronectin are present in this compartment. The relative position and structural organization of perimysium are unique and distinguish this connective tissue compartment from the investing endomysium. The perimysium surrounds several individual myotubes and functions to group several myotubes into a discrete structural unit. The largest subdivision of the connective tissue compartment is the epimysium. It is visible at gross dissection and completely encases the entire muscle. The structural integrity of this connective tissue compartment varies across different muscle groups. It is composed predominantly of type I collagen. In addition to lending mechanical integrity, the connective tissue scaffolding of muscle also provides a pathway for the distribution of nerves, blood vessels, and lymphatics. The larger arteries and veins of skeletal muscle run through the perimysium; capillaries and motor nerves are distributed throughout muscle by passing along the endomysium.

EXTERNAL CONSTRAINTS ON THE BIOENGINEERING PARADIGM

To date, the ability to fabricate muscle and other multicellular tissues *in vitro* for use in reconstructive therapy *in vivo* has been limited by a series of nearly circular biological and technical limitations. *In vivo*,

normal developmental processes take place over an extended period of time. During embryonic development, the mass and density of skeletal muscle, and other tissues, increases in parallel with the volume of capillaries present and the capacity of the cardiovascular system to deliver oxygen and provide nutrient exchange. Tissue fabricated *in vitro* lacks cardiovascular support and must be sustained by passive diffusion. This consideration limits the mass and density of tissue that can be fabricated and supported *in vitro*. Small scale constructs of muscle have long been, and routinely, prepared in conventional tissue culture.^[3-5] However, the structure of muscle prepared under conventional culture conditions restricts the degree to which the engineered tissue can tolerate manual manipulation, and, more importantly, the small size of these constructs greatly limits the contractile performance of the resulting muscle tissue. Theoretically, these mechanical and functional limitations can be overcome simply by increasing the density of the cellular elements and the overall mass of the engineered tissue. However, as cell density increases, the ability to provide adequate rates of oxygen, nutrient, and waste exchange to a bioengineered organ become limiting factors. Preparing bioengineered tissue in a bioreactor (a generic designation for a device designed to increase nutrient exchange) can, to some extent, increase the mass of tissue that can be supported *in vitro*. However, when first implanted, any tissue fabricated *in vitro* must still be supported by the passive diffusion of nutrients from the surrounding interstitium until a functional capillary network and nascent interconnections with the cardiovascular system of the host develop. These biological and technical limitations represent daunting barriers to the bioengineering paradigm for muscle and many other types of tissue.

HISTORICAL PROSPECTIVE OF SKELETAL MUSCLE ENGINEERING

Several different procedures have been used in attempts to reconstruct damaged or missing domains of skeletal muscle. For example, in perhaps the most direct approach, intact muscle can be harvested and transplanted directly into a recipient site.^[6-8] The advent and development of microsurgical techniques that make it possible to anastomose small vessels of the donor muscle and the recipient tissue has made this approach feasible, and muscle transplants are used in the laboratory setting with great success.^[9] However, tissue may be routinely, and arbitrarily, harvested from a donor animal and used for experimental transplant therapy. In the clinical setting, this does not represent a common treatment option. Donor material for organ

transplants is critically limited in supply, has a very limited window of viability, and must be matched to the recipient, or the recipient's immune system must be suppressed to manage tissue rejection. A more realistic approach is to use allograft donor material to reconstruct damaged muscle. This strategy, commonly referred to as a Free Tissue Transfer (Free Flap), has been used in cosmetic, and to some extent, in the functional reconstruction of damaged tissues. Donor tissues include the rectus abdominus, latissimus dorsi, serratus anterior, gracilis, and the extensor digitorum brevis muscles. These muscles are used in free tissue transfer procedures because they have a well-defined blood supply that makes it possible to anastomose vessels of the donor tissue to the vessels of the donor site. This procedure is often used to provide protection to the terminal ends of an amputated limb and provide cushioning between the transected bone and a mechanical prosthesis. The use of an allograft for muscle reconstruction has several obvious advantages. This type of donor tissue has the histological features, vascular circulation, and structural integrity of differentiated muscle. As an allograft, an implant prepared as a Free Flap should not invoke any immune response. The limitations to this approach include the functional deficits and the disfigurement that may occur in the donor site. Also, depending on the nature of the surgical site, the implanted tissue will, in all likelihood, not be subject to voluntary control from the central nervous system. An alternative reconstructive strategy, and the one that our laboratories have chosen to pursue, is to address the limitations that are intrinsic to the bioengineering paradigm and fabricate a tissue engineered muscle.

FABRICATION OF SKELETAL PROSTHETICS

The identification of suitable donor material represents one of the barriers that must normally be overcome in the bioengineering paradigm. Unlike many tissue types, this consideration is not necessarily a limiting factor in the fabrication of engineered skeletal muscle. Satellite muscle cells, a population of partially differentiated stem cells, reside within skeletal muscle and are scattered throughout the interstitial space.^[10] Following injury these cells are induced to divide, differentiate, and repopulate the muscle bed.^[11] The characteristic distribution and biological properties of the satellite cell make it possible to isolate this population from discrete and unobtrusive sites by conventional biopsy techniques and use it as donor material in muscle reconstruction.

Satellite muscle cells can be grown and expanded in tissue culture and, under the appropriate conditions, will undergo differentiation to form striated myotubes.

Differentiation is initiated by the formation of cell-to-cell contacts between adjacent satellite cells. The specific phenotypic properties of the resulting myotubes are determined by an interaction between the intrinsic genetic potential of the cells and the extrinsic environmental signals that shape muscle architecture. For example, the differentiation and the expression of contractile filaments, other muscle-specific cytoarchitectural features, and the basal lamina are regulated by the intrinsic potential of the cells. Extrinsic signals, such as neuronal inputs, soluble growth factors, mechanical forces, and the composition and tertiary structure of the extracellular matrix can interact to regulate striated muscle cell mass, cell shape, and cell polarity.^[12,13] Incorporating these extrinsic phenotypic signals into the bioengineering paradigm to direct the expression of the desired structural characteristics is an essential element of the fabrication process.

In the course of characterizing satellite muscle cells, a subpopulation of multipotent stem cells has been detected. This subpopulation, termed muscle-derived stem cells (MDSC), exhibits a reasonably robust capacity to differentiate into a variety of tissue types.^[14] The MDSC may represent a readily obtainable donor source of material that can be used in the reconstruction of other tissues or to augment satellite muscle cells in the reconstruction of skeletal muscle. For example, there is evidence that some MDSC cells can undergo differentiation into microvascular endothelial cells. This type of cell population could make it possible to fabricate a muscle construct that is preseeded with cells that can form a capillary network.

IN VIVO TISSUE ENGINEERING

The satellite muscle cell is a nearly ideal donor source and theoretically can be used to fabricate a skeletal muscle prosthesis as an autologous graft, limiting the risk of host vs. graft rejection. The efficacy of using satellite muscle cells as a donor source of material was demonstrated in classic experiments, even before this cell type was fully characterized. In these experiments, the epimysium of a donor muscle was incised, the muscle removed en bloc, and minced into small segments or dissociated into a single cell suspension.^[15,16] The donor material was then reimplanted into the original muscle bed and within the intact epimysium. In effect, the epimysium functioned as a natural, albeit primitive, tissue-engineering scaffolding. Over time, the differentiated muscle remaining in the donor tissue died and the surviving satellite muscle cells underwent division, repopulated the muscle bed, and subsequently differentiated into striated muscle. Skeletal muscle reconstructed with this strategy exhibits a rather hazardous cell polarity, but can achieve a very acceptable

degree of mechanical performance. In the rat, muscle reconstructed in this manner can undergo reinnervation and generate contractile forces that approximate normal, intact tissue.^[15]

The chaotic muscle structure observed in the early reconstruction experiments probably results from the complete disruption of the basal lamina, and the other compartments of the extracellular matrix, that occurs when the intact tissue is isolated en bloc to prepare the donor material. Following injury *in vivo*, and in the course of normal muscle regeneration, the basal lamina of a damaged myotube can remain substantially intact, even as the underlying cell undergoes necrosis. This extracellular ghost of the dying cell can act in concert with other components of the extracellular matrix in directing the differentiating satellite muscle cell to adopt a defined polarity.^[17] In the absence of extracellular elements, satellite muscle cells are not constrained to spread along a defined axis and adopt the polarized phenotype that characterizes intact muscle.

There are obvious limitations in the use of muscle fragments or single cell suspension therapies in the reconstruction of damaged tissue *in situ*. Signals that are intrinsic to the satellite cell allow this donor source to differentiate. However, the extrinsic signals necessary to shape muscle polarity are not fully provided in this type of natural bioengineering strategy. It represents a relatively passive approach that does not allow the surgeon to sculpt the implant to any great extent and requires a preexisting muscle bed to act as an implantation site. This is a structural feature that may be completely absent in a patient with a congenital defect or a devastating traumatic injury. In addition, the haphazard distribution of myotubes in muscle that has been reconstructed from tissue fragments or dissociated cell preparations makes this therapeutic approach unsuitable for many applications due to functional and cosmetic considerations. However, these experiments provide several essential insights. Foremost, these experiments demonstrate clear proof of concept and indicate that muscle reconstruction therapy using a satellite cell population is a feasible strategy. This approach anticipated how a local microenvironment might be used to regulate and control the expression of the differentiated skeletal muscle phenotype.

TISSUE ENGINEERING SCAFFOLDS

An amalgam of the transplant and dissociated cell strategies is to tissue-engineer a muscle implant *in vitro* for reconstructive surgery *in vivo* using satellite muscle cells or another suitable donor source of material. This engineered tissue must be sufficiently robust to

withstand manual manipulation, the physical rigors of the *in vivo* environment, and yet large enough to generate a meaningful amount of work. Conversely, the tissue cannot be so massive or dense that it cannot be supported by the passive diffusion of nutrients from the surrounding environment while cardiovascular support is established from the host. Passive oxygen influx usually is sufficient to support the metabolism of a 1-mm diameter cylinder of working muscle, a rather small prosthesis. In our design philosophy, the tissue-engineering scaffold plays a central role in overcoming the diffusion constraints that limit construct mass. We believe that a tissue-engineering scaffold must have sufficient mechanical integrity to support and define the initial structural properties of a bioengineered organ. Simultaneously, the scaffold must support rapid microvascular endothelial cell migration and the formation of nascent blood vessels. Over time, the fabrication scaffolding should be degraded and replaced by constituents of the native ECM as the bioengineered construct begins to assume the structural features of mature tissue. This latter characteristic greatly reduces the risk of host vs. graft rejection.

Considerable effort has been directed at developing proteins of the collagen family into tissue-engineering scaffolds. The collagens are highly conserved, represent the principal structural elements of the native interstitium, and are the most abundant protein species of the mammalian system. Collagen is typically isolated by acid extraction of a starting material. A hydrated gel forms when the acid soluble fraction of the extract is returned to physiological ionic concentration and neutral pH. Unfortunately, the delicate nature of these gels has limited the usefulness of this type of collagen isolate in tissue-engineering applications.

In muscle bioengineering experiments, myoblasts and satellite muscle cells have been seeded onto the exterior of preexisting collagen gels^[18] or mixed with collagen and literally enveloped within the material as it undergoes polymerization.^[19] Subsequently, the cells have been allowed to differentiate within the three-dimensional environment of the gel. The value of tissue fabricated by seeding cells onto a collagen gel is limited by the preferential distribution of differentiated myotubes on the external surfaces of the scaffold and the low overall cell density that is achieved with this approach. Experiments in which cells are directly incorporated into a collagen gel as it undergoes polymerization have yielded more densely and uniformly populated constructs.^[19] However, these constructs still remain far less dense than intact tissue and, as a result, the mechanical properties of the tissue are largely defined by the delicate fibrils of the collagen gel. Several different techniques have been used to address the underlying structural limitations of the collagen gel.

“ENGINEERING” THE TISSUE ENGINEERING SCAFFOLD

Cell-mediated bioengineering has been used in attempts to improve the mechanical properties of the conventional collagen gel.^[20] In this strategy, interstitial cells are seeded onto a collagen gel and cultured for several days prior to the addition of the donor material. The objective of this preincubation interval is to allow the interstitial cells to deposit nascent collagen, remodel and condense the scaffold, and cross-link the collagen fibrils of the existing collagen gel. Unfortunately, this technique is time consuming and appears to provide marginal benefits. Collagen gels also have been augmented with synthetic, biocompatible materials. For example, incorporating sheets of polyester mesh into a collagen gel lends considerable strength to the scaffolding while allowing the construct to retain a substantial portion of its elastic properties.^[21] However, tissue fabricated with this type of strategy is still composed of sparsely distributed cells, and nearly any nonbiodegradable material can function as a nexus for an inflammatory response, fibrotic encapsulation, and tissue rejection.^[22]

An alternative approach is to increase the structural stability of the muscle prosthesis by subjecting the tissue to mechanical stimulation to induce hypertrophic growth *in vitro*. This type of training can greatly increase the mass of individual cells and promote the deposition of ECM constituents, thereby improving the structural characteristics of the construct.^[23] Elegant experiments have been conducted with a variety of different devices designed to impart static and cyclic strains on tissue-engineered muscle.^[24,25] Very specific patterns of *in vitro* training have been demonstrated to be necessary to promote maximal growth in these experimental systems.^[26,27] However, even trained skeletal muscle remains less dense than native tissue and diffusion constraints still place severe limits on the mass (and density) of tissue that can be fabricated. In effect, tissue-engineered muscle is subject to a physiological failure mode; the muscle is too small or far too sparsely populated by striated muscle myotubes to produce a meaningful amount of contractile activity.

Mechanical loading of muscle tissue *in vitro* also can induce the expression and activation of matrix metalloproteinases (MMPs). These enzymes, which are nearly ubiquitous across all tissue types,^[28] mediate the degradation of a variety of matrix constituents. In bioengineered muscle, the premature destruction of the tissue engineering scaffolding that supports the construct by these enzymes may lead to the catastrophic failure of the prosthesis; we refer to this as an adaptive failure mode. In adaptive failure, elements of the tissue engineering scaffolding may be degraded long before

the mechanical stimulation induces cell hypertrophy or the deposition of sufficient matrix constituents to stabilize the structure of the muscle.

GROWTH AND MUSCLE ADAPTATION

From these data, it is clear that it is possible to fabricate a muscle-like construct *in vitro*. However, we conclude that diffusion constraints and other biological limitations will restrict the mass and overall contractile performance that can be achieved with this type of tissue. To fabricate a clinically relevant muscle prosthesis, the diffusion constraints that limit construct design must be addressed. Embryonic development, neonatal growth, and maturation are events that occur gradually over an extended period of time. During development, the differentiation of striated tissue is subject to regulation by neurohormonal elements, soluble peptide growth factors, and mechanical activity. These events promote myotube differentiation and hypertrophy, capillary growth, and the elaboration of the extracellular matrix. The tissue is conditioned and, over time, undergoes hypertrophy and increases in density. As a result, it is able to sustain and survive progressively more intense mechanical activity. This mechanical activity is a critical element in the regulatory events that control the growth and overall mass of skeletal muscle. Recapitulating the morphogenetic events that direct the formation of the striated muscle phenotype in an artificial environment will be difficult, at best. From a biological perspective, the structural integrity and viability of muscle tissue subjected to mechanical conditioning *in vitro* can begin to exhibit evidence of deterioration within days. This is particularly evident in tissue fabricated with traditional collagen gels. *In vitro* training regimes promote muscle hypertrophy and the expression and deposition of matrix constituents. Unfortunately, these same mechanical loads also induce the expression, deposition, and activation of MMPs. Collagen gels, by nature, are already quite delicate and are subject to rapid attack and degradation by these proteases, leading to the loss of construct integrity. Mechanical stimulation is essential for muscle growth; however, the catabolic aspects of the hypertrophic response induced by mechanical stimulation outpace and literally “outrun” the anabolic events that should lead to a more structurally stable construct.

A similar maladaptive response can be observed when tissue that is engineered *in vitro* is placed *in vivo*. With respect to an intact muscle, tissue fabricated *in vivo* is not subject to a very challenging mechanical environment. This is true even for tissue that has undergone a preconditioning training regime. At implantation, bioengineered tissue is instantaneously bombarded by a host of biochemical and mechanical

signals; these signals initiate an adaptive hypertrophic response. We should note that one reason to precondition tissue is to blunt the impact of the hypertrophic signals that are encountered when engineered muscle is implanted. Components of the adaptive hypertrophic response are highly desirable, and necessary, to promote the formation of muscle structure and the seamless integration of the engineered tissue into the host site. The expression, deposition, and activation of matrix metalloprotease enzymes are an integral element of this response. These enzymes exhibit a broad spectrum of proteolytic activity against matrix constituents and, like *in vitro*, the loss of scaffold integrity *in vivo* can lead to catastrophic failure of the implant before the muscle has fully adapted to the host site. Any inflammatory response within the implant site can be expected to further exacerbate the enzymatic attack of a bioengineered scaffold composed of native proteins; enzymes of the MMP family are expressed by a variety of circulating inflammatory cells. Clinically, it is not feasible to completely suppress MMP activity, even within the local domain of the bioengineered tissue. Enzymatic activity associated with the MMPs is necessary and essential for the migration of microvascular endothelial cells and the subsequent formation of capillary networks.^[29] Blocking MMP activity will suppress the angiogenic response that is so necessary for implant survival. Finally, the diffusion characteristics of tissue fabricated *in vitro* limit the mass of the construct, even with the advent of devices that can support progressively larger-scale constructs. When implanted, tissue engineered *in vitro* must still be supported by the passive diffusion of oxygen and nutrients from the surrounding tissue of the host. This characteristic places upper limits on the mass of tissue that can be fabricated *in vitro* and used for reconstructive surgery *in vivo*.

INTEGRATING SCAFFOLD DESIGN WITH TISSUE FABRICATION STRATEGIES: ELECTROSPINNING

In our design philosophy, we believe that a bioengineered organ should be fabricated *in vivo* at the recipient site from a stem cell population, or in the case of a striated muscle prosthesis, from a population of satellite muscle cells. These cells are then allowed to undergo differentiation *in vivo*. By using undifferentiated cells as a donor source, it may be possible to mimic aspects of the developmental process and circumvent, within limits, the diffusion constraints that ultimately restrict the bioengineering paradigm. With respect to fully differentiated muscle, undifferentiated and noncontractile satellite muscle cells (or stem cells) exhibit nominal oxygen demand. This is a desirable

characteristic for any tissue that must initially be supported by the passive diffusion of nutrients from the surrounding environment. In reality, our bioengineering strategy is a combination of events borrowed from development and the wound repair process.

Our fabrication scheme places strict constraints on the tissue-engineering scaffolds used to construct the tissue. The scaffold must define the initial structural properties of the tissue; a loose aggregate of undifferentiated cells may have nominal oxygen demand, but it lacks any structural cohesiveness. The scaffold must confine the donor cells to the implant site and provide the cues necessary to promote the expression of the proper phenotype, a densely populated muscle composed of parallel arrays of myotubes. Microvascular endothelial cells from the surrounding interstitium must freely penetrate the scaffold and form functional capillary beds as the differentiation process proceeds. Next, the scaffold must be biocompatible and, ideally, replaced by a native matrix that is expressed and deposited by the donor cell population as the implant begins to assume the structural features of differentiated muscle. In this specification, the rate or interval over which the tissue-engineering scaffold is remodeled and lost must be controlled. Finally, to reach commercial and clinical success, the scaffolding material must pass FDA scrutiny.

We have concluded that conventional scaffolds cannot meet these design constraints and require the development of a new class of tissue-engineering scaffolds. Collagen gels, synthetic materials, and conventional hybrid materials lack the biological properties necessary to meet the stated design considerations. Our laboratories believe that electrospinning technology may represent a strategy that provides the nucleus necessary to develop more physiologically relevant tissue-engineering scaffolds.^[30] A detailed description of electrospinning is beyond the scope of this discussion, but it is described in detail elsewhere in this volume. In brief, in electrospinning, a polymer solution, or melt, is prepared and injected with current to create a charge imbalance.^[31] The charged polymer solution is then placed in proximity to a grounded target, creating an electric field. At a critical voltage, the charge imbalance overcomes the surface tension of the polymer source, forming an electrically-charged jet. Within the electric field, the jet is directed toward the grounded target and solvent evaporates as it traverses the air gap (Fig. 1). Depending on reaction conditions, and the polymers used in the process, electrospinning can be utilized to produce a fine aerosol of material or a continuous nonwoven mat of fibrillar material. We have adapted electrospinning and use it to process collagen and other native proteins into sub-micron diameter fibers, a scale that approaches the diameter of the native collagen fibril. An ultrastructural examination of electrospun collagen reveals a 67 nm

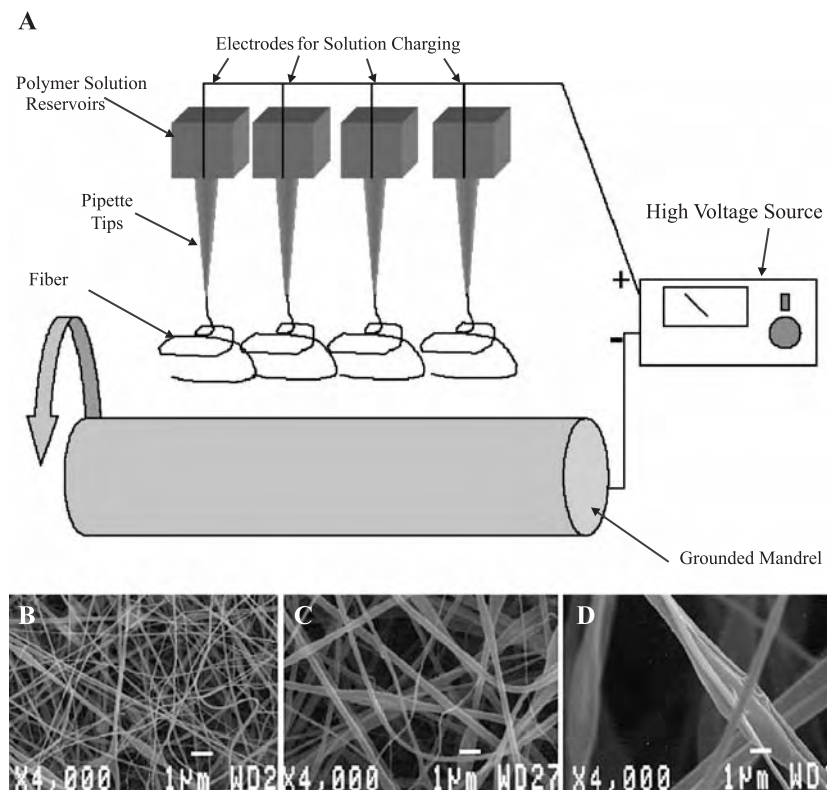

Fig. 1 (A) Schematic of electrospinning apparatus used in the fabrication of scaffoldings for tissue engineering. The key elements of the electrospinning system include a high-voltage power supply, a source reservoir for the polymer, and a grounded mandrel. Our system utilizes a cylindrical target mandrel; however, the electrospinning process can be adapted to produce much more complex shapes. Single and/or multiple polymers can be independently or simultaneously delivered to the electric field from one or more source reservoirs. Electrospinning distinct and unique polymers from separate sources in a temporal sequence can be used to produce a laminated structure. Fiber orientation can be regulated by controlling the motion of the target mandrel with respect to the source solution reservoir. The polarity of the system depicted in this image is arbitrary and, depending on the material to be processed, can be reversed. (B–D) Demonstration that fiber diameter varies as a function of the starting concentration of polymer. These images depict the average fiber diameter obtained by electrospinning collagen at 60 mg (B), 80 mg (C), or 100 mg/ml (D). Note all images were captured at the same magnification (4000 \times).

repeating banded pattern.^[30] In the native collagen fibril, this banding pattern is associated with the formation of specific binding sites that appear to facilitate cell migration. In our biocompatibility studies, electrospun collagen is nonimmunogenic. When implanted within the interstitial space of the rat, vastus lateralis muscle tissue-engineering scaffolds of electrospun collagen are infiltrated by functional capillary beds within seven days.^[32] Similar results were observed in a guinea pig model. In comparison, scaffolds of electrospun poly(glycolic acid) (PGA) initiated a pronounced immune response in these tests, despite the observation that this material exhibited similar fiber diameters and porosity values. We have concluded from these experiments that fibrils of electrospun collagen recapitulate many of the structural and functional properties of the native collagen fibril. An added advantage to electrospun collagen is the observation that collagen has FDA

approval in many fields of use, potentially reducing the obstacles that must be addressed in order to bring this type of scaffolding material to the clinical setting.

IN VIVO MUSCLE ENGINEERING: A FEASIBILITY STUDY

To test our design principles, we have fabricated a muscle prosthesis using electrospun scaffolds of collagen. In preliminary experiments, we have used electrospinning to produce a collagen-based tissue-engineering scaffold. Conditions were optimized to produce individual fibrils that ranged in diameter from 500 to 800 nm. This scaffold was deposited onto a cylindrical target mandrel, producing a cylindrically-shaped construct (4-mm I.D. \times 40 mm in length, with a wall thickness 250–300 microns). The construct was

removed from the target mandrel and hydrated. One end of the construct was sutured shut; the lumen of the cylinder was filled with a suspension of satellite muscle cells isolated from the neonatal rat.^[32] The remaining end of the cylinder was then sutured shut. This technique results in a seamless tube with satellite muscle cells within the central lumen of the cylindrical construct. The outer electrospun scaffolding functioned as a fascial sheath; the terminal ends were slightly extended beyond the enclosed cell population and then flattened to serve as a tendon. The entire bioengineered muscle was then implanted into the adult rat (150 g) in the plane subjacent to the vastus lateralis. The distal ends of the bioengineered construct were sutured to the tendons of origin and insertion for the overlaying vastus muscle. The objective of these experiments was to supplement the quadriceps muscle and produce a quadriceps muscle group with the bioengineered tissue. Within seven days, the implanted tissue exhibited evidence of differentiation and the formation of functional capillaries. After eight weeks, the bioengineered tissue displayed the histological features of differentiated muscle. Parallel arrays of myotubes that were densely packed with myofibrils were evident. The electrospun matrix was substantially remodeled and appeared to be replaced by native materials.

FUTURE DIRECTIONS

As the bioengineering paradigm matures in the fabrication of striated muscle constructs and other tissues, additional hurdles must be addressed. For a skeletal muscle prosthesis, it will be essential to identify rational strategies that can be used to promote the reinnervation, or the formation of nascent and functional nerve–muscle contacts, between the host and the implanted bioengineered muscle. Striated tissue must be placed under voluntary control to truly restore function to a domain of damaged or missing muscle. Without conscious control, the tissue represents little more than filler material. Another issue that requires attention is the development of techniques to increase the overall mass of tissue that can be fabricated on site.

Once again, developmental events and the process of wound repair may provide the insights necessary to achieve these objectives. For example, the terminal ends of a damaged peripheral nerve can resprout, grow in a directed fashion, and reinnervate muscle. This is a common occurrence following injury. The very earliest muscle fabrication experiments demonstrated that muscle bioengineered and fabricated within the fascial sheath of a preexisting muscle bed will undergo innervation.^[15,16] The formation of nascent capillary beds within an injured domain of muscle represents another essential milestone in the regeneration process.

Microvascular endothelial cells are specifically recruited from the surrounding tissue to a damaged domain to restore normal circulation. The processes of neurite outgrowth and angiogenesis are both directed by a variety of soluble factors that can be released in response to an insult that causes structural damage. Our laboratories have begun to examine the efficacy of incorporating selected peptide growth factors directly into tissue-engineering scaffolds during the electrospinning process to modulate the composition of the local microenvironment. Our objective is to use the tissue-engineering scaffold as a solid phase delivery device and establish a gradient of these peptides to direct neurite outgrowth and accelerate capillary formation.

TAILORING THE COMPOSITION OF THE TISSUE ENGINEERING SCAFFOLD

Because electrospinning is carried out at high voltages with very little current, sample heating and the attendant risk of damaging the tertiary structure of peptides is limited. For many growth factors, the solvents used in electrospinning are more likely to induce unfavorable changes in peptide structure than the electric fields used to produce the tissue-engineering scaffold. We have used nerve growth factor (NGF), a peptide that may have efficacy in promoting the directed outgrowth of peripheral neurons, to model how the electro-supplementation of tissue-engineering scaffolds might be used to direct reinnervation. NGF is a soluble member of the neurotrophin family.^[33,34] This growth factor is necessary for normal neural development in the mammalian system and may induce neurite outgrowth in the central and peripheral nervous systems of vertebrates. Receptors for NGF have been detected on motor neurons following injury and during the reinnervation of injured tissue.^[35] Analogous to NGF, vascular endothelial growth factor (VEGF) is a small peptide that plays a role in regulating the proliferation and migration of microvascular endothelial cells.^[36,37] Gradients of VEGF can be used to direct—and accelerate—the formation of capillaries in defined domains.

To characterize the basic release profiles of NGF and VEGF from electrospun collagen, we directly supplemented our electrospinning solutions with 0, 500, or 1000 ng of 7S NGF per 80 mg of collagen per 1 ml of electrospinning solvent (trifluoroethanol, TFE). The 7S NGF isolate was selected for use because this subunit contains the biologically active elements of the peptide. We utilized an intact isolate of a recombinant VEGF peptide in our experiments. Electrospun scaffolds of collagen supplemented with or without NGF were prepared, vapor cross-linked in glutaraldehyde (2%) for 15 minutes, and placed into 1 ml centrifuge

tubes containing 1 ml of sterile phosphate-buffered saline. This type of cross-linking interval stabilizes the collagen fibrils and partially immobilizes the incorporated peptides within the matrix. Aliquots of 100 μ l were taken from each experimental condition at varying intervals (0, 1, 2, 4, 24, 36, and 92 hours). Collected samples were frozen until analyzed. Finally, the amount of NGF present in the different samples was evaluated by ELISA.

In proof-of-concept experiments, the release and recovery of NGF varied as a function of the starting concentration of growth factor present within the electrospun scaffold. The release of NGF from the samples supplemented with 500 and 1000 ng NGF was linear over the initial interval of the assay and appeared to peak at 24 hours (Fig. 2A). To determine if NGF released under these conditions retains bioactivity, we next cultured PC-12 cells in the presence of the electrosupplemented scaffold. In tissue culture, cells of the PC-12 line will flatten and extend neurites in response to a critical concentration of NGF. This characteristic behavior makes this cell line a nearly ideal model to evaluate our novel peptide delivery system.

Assays with PC-12 cells indicate that NGF released from electrospun materials retains sufficient biological activity to induce neurite outgrowth (Fig. 2B–C). To examine how the structure of electrospun collagen might contribute to the sequestration of NGF, we have used electrospun gelatin as a substrate to deliver NGF. Gelatin is identical in chemical composition to acid soluble collagen (both are isolated from calf-skin). However, gelatin is heat denatured during the processes used to prepare this protein for commercial distribution (heated prior to electrospinning and partially degraded). Gelatin and collagen will both electrospin from TFE into submicron diameter fibrils; however, only electrospun collagen exhibits the 67 nm repeat typical of the native collagen fibril. Electrospun gelatin lacks this feature and individual fibers exhibit a nondescript amorphous structure in longitudinal thin sections. In controlled release experiments with electrosupplemented gelatin, very little incorporated NGF was released from this type of matrix. The underlying mechanisms that are responsible for this result remain to be determined. However, it seems clear that NGF associates with the fibrils of electrospun collagen and

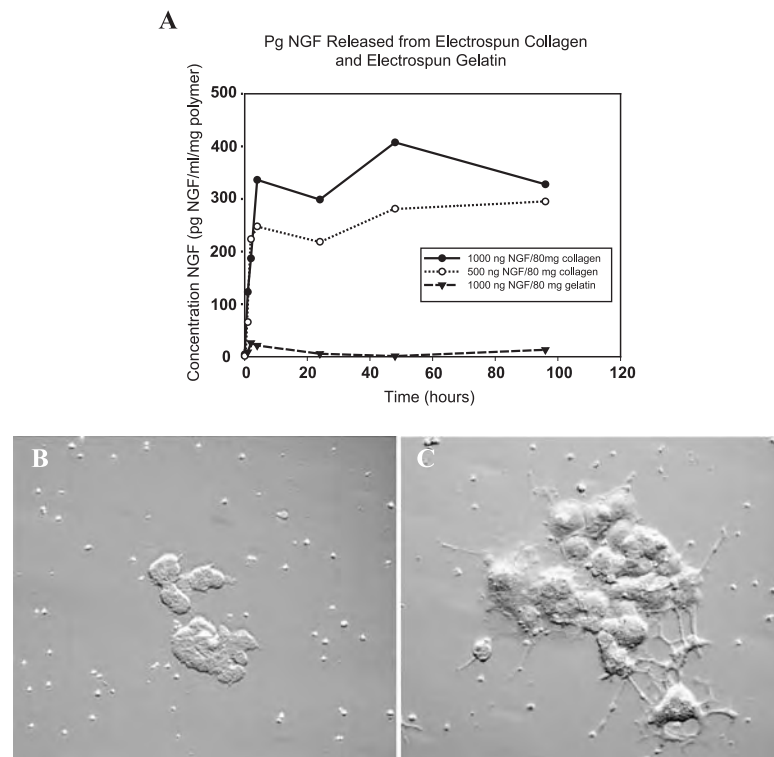

Fig. 2 (A) Representative release profile of NGF from electrospun collagen. Release kinetics are similar regardless of the starting NGF concentration; however, not surprisingly, a higher initial starting concentration results in the release of more total peptide. Panels (B) and (C) illustrate the response of PC-12 cells to NGF released from electrospun collagen. In the absence of NGF, these cells expressed a rounded cell shape in tissue culture. In contrast, after 96 hours of culture in the presence of NGF released from electrospun collagen, extensive neurite outgrowth was evident (C). These data indicate that NGF retains biological activity when delivered from electrospun collagen to the cultured PC-12 cells.

electrospun gelatin in fundamentally different ways. NGF or other neural active peptides may at some time be exploited to bring bioengineered tissues under voluntary control of the central nervous system.

One variable that is difficult to evaluate from our *in vitro* experiments concerns how the release profile might be affected by cellular activity and protease-induced remodeling of an electrospun matrix. This will clearly alter the release kinetics and the actual concentration of growth factor incorporated into the matrix necessary to modulate the microenvironment may be far less (or more) than our *in vitro* experiments might indicate. For example, our preliminary work with materials implanted *in vivo* suggests that 50 ng of VEGF incorporated per 80 mg of collagen (prepared in 1 ml of electrospinning solution) can have a dramatic impact on capillary ingrowth (Fig. 3). As noted, we lightly cross-link electrospun collagen to stabilize the

fibrils. This treatment also links incorporated peptides to the electrospun fibrils. There are risks to this processing strategy. If cross-linking is too extensive, the peptide may be damaged or never released in a biologically relevant pattern to induce microvascular endothelial cell migration. In controlled-release studies conducted *in vitro* with VEGF, a 15-minute interval of vapor fixation substantially reduced the rate of VEGF release from an electrospun matrix of collagen (Fig. 3). These data suggest that fixation intervals could be tailored to modulate the release profile.

To test the biological activity of electrospun VEGF, we have implanted samples of electrosupplemented collagen into the belly of the rat vastus lateralis muscle. Cylinders of electrospun collagen supplemented with or without 50 ng/80 mg collagen were prepared (2 mm I.D. \times 20 mm in length) and placed into a blunt dissected channel within the muscle. In controls

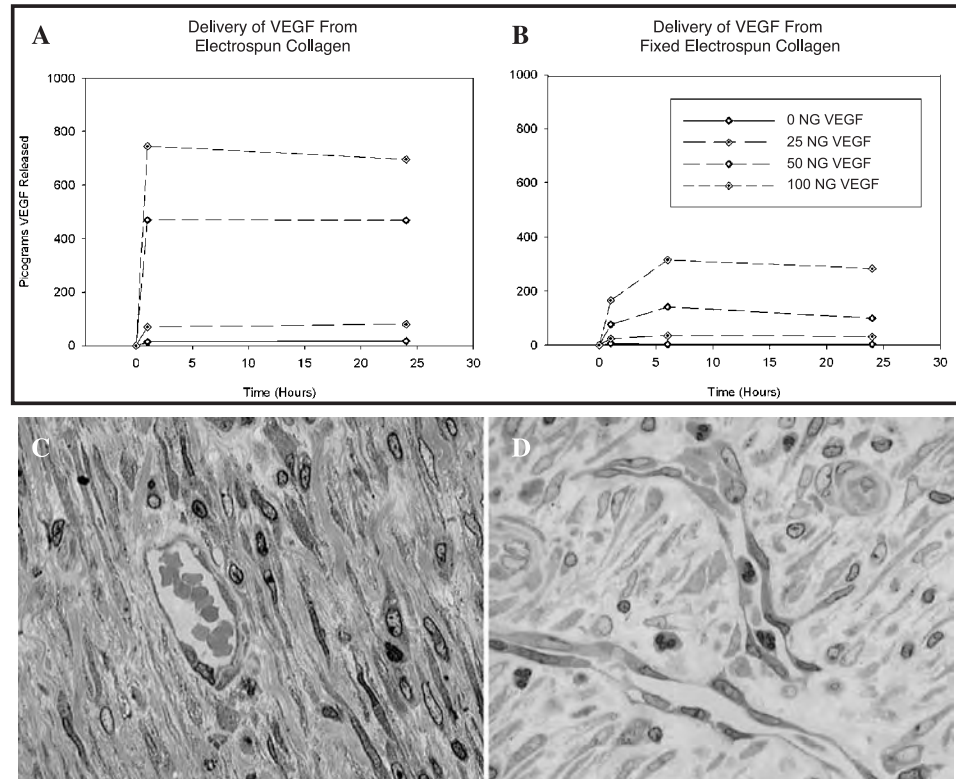

Fig. 3 Representative release profile of VEGF from unfixed (A) and fixed electrospun collagen (B). VEGF was coelectrospun at a rate of 0, 25, 50, or 100 ng/80 mg of collagen. The material was then immersed in PBS and samples were isolated and subjected to ELISA at varying intervals. A second sample of this same material was subjected to a 15-minute interval of glutaraldehyde vapor fixation prior to experimentation. Results indicate that fixation reduces the rate of release; compare relative concentration of VEGF released in panel A versus panel B per unit of time. Panels C and D illustrate the performance of electrospun collagen *in vivo*. Samples were implanted for seven days within the rat vastus lateralis and recovered for microscopic analysis. Panel C depicts electrospun collagen minus VEGF, Panel B electrospun collagen plus VEGF. Note that even unsupplemented collagen supports rapid cellular infiltration and the formation of functional capillaries (C). Panel D depicts the increased frequency of blood vessels in a longitudinal orientation. At recovery, this tissue was visibly more vascular (D).

(un-supplemented with VEGF), interstitial cells from the surrounding tissue freely migrated into the implanted scaffolding. Within seven days, the material was densely populated. Functional capillaries were evident throughout the tissue. During processing for microscopic evaluation, we remove the implanted material and cross-section the samples perpendicular to the long axis of the cylinder and through the wall of the electrospun scaffold. In this orientation, the bulk of the vessels present in control samples exhibit a round or ovoid cross-sectional shape. In contrast to these results, samples recovered from electrospun cylinders of collagen supplemented with VEGF exhibited a higher capillary density. There was also an increased frequency of vessels observed running in a longitudinal orientation with respect to the local axis of the electrospun matrix. These data indicate that supplementing electrospun collagen with VEGF has efficacy in promoting the increased growth of capillaries within a local microenvironment. Delivering effective doses of angiogenic peptides to the local microenvironment may allow larger tissue masses to be fabricated on site in vivo by accelerating the ingrowth of nascent capillaries.

We note that the delivery of VEGF to local domains by gene transfer has been explored to some extent. In these experiments, the local microenvironment of cells genetically engineered to express increased levels of VEGF exhibits increased capillary density.^[38,39] One limitation to this approach, however, concerns how the persistent elevated expression of VEGF might affect the local environment. Many growth factors must be present at a critical concentration over some interval of time to exert biological effects; however, it may not be desirable to have those same peptides permanently present at increased levels. Certainly this issue could be addressed by using inducible promoters; however, supplementing a tissue-engineering scaffold with a defined amount of VEGF protein, or other peptide, may represent a viable alternative to gene transfer.

CONCLUSIONS

The bioengineering process is complex and subject to biological and technical limitations. However, there is considerable evidence to suggest that it is feasible to bioengineer skeletal muscle. From a clinical perspective, it remains an open question where and under what circumstances this type of treatment regime might be undertaken. Until effective methods can be developed to overcome the diffusion constraints that limit the overall mass of tissue that can be fabricated in the bioengineering paradigm, we will be limited to the production of relatively small pieces of muscle. In the near term, this would appear to restrict the use of

engineered skeletal muscle to the treatment of congenital defects and/or injuries affecting the facial musculature. However, as noted, even a traumatic injury to the face is rarely life threatening. This places constraints on the number of patients that might be eligible for this type of reconstructive therapy and thereby limits the incentive to make capital investments in the bioengineering of muscle. A similar argument can be made for a variety of other tissue types. Muscle tissue also might be fabricated and designed solely for use as a platform to deliver specific gene sequences or protein products systemically or to the local microenvironment.^[40,41]

From a basic science perspective, research in the bioengineering of skeletal muscle has, and will continue, to provide valuable insights into the bioengineering process. Using a tissue to model the bioengineering process that is not absolutely essential for life has distinct advantages in this respect. We believe that many of the lessons that can be derived from the bioengineering of skeletal muscle can be applied to other organs. For example, the fabrication of skeletal muscle represents an excellent intermediate step in the construction of more clinically sensitive tissue such as the myocardium. Gene therapy applications using muscle-derived stem cells have also shown promise. These engineered cells may be used to develop treatments for such intractable injuries as lacerated tendons^[42] and nonhealing bone fractures.^[43] The biotechnology industry is poised to expand substantially over the next several decades. Before tissue-engineered organs can become an integral part of clinical practice, issues concerning the distribution of tissue to patients will become the limiting factors rather than the actual construction of the tissue.

T

INTRODUCTION

Skin loss can lead to death or to an unacceptable quality of life, and efforts of tissue engineers to synthesize skin have focused on that vital clinical need. The approaches used have varied from those in which an organoid that mimics skin is synthesized in vitro (cultured epidermal autograft, living skin equivalent, living dermal replacement) to those in which a biologically active scaffold, optionally seeded with keratinocytes, is implanted (dermis regeneration template) at the desired anatomical site to achieve in-vivo synthesis (regeneration). Protocols for these apparently contrasting technologies are summarized and compared. Theoretical approaches include the hypothesis that organ regeneration is induced when wound contraction at an injured anatomical site is appropriately blocked by an active scaffold. Further developments in both in-vitro and in-vivo experimental approaches are expected to derive from the additional hypothesis, based on data from two organs (skin and peripheral nerves), that the necessary and sufficient reactants for organ synthesis comprise simply a biologically active scaffold seeded with epithelial cells of the desired organ.

SKIN WOUND HEALING

The integration of the engineering disciplines with the biological sciences has led to many medical advances and new fields of study. One such field, tissue engineering, was recognized by the National Science Foundation in 1987^[1] and defined as the application of the methods of engineering and the life sciences toward the development of substitutes to restore, maintain, or improve biological function. Tissue engineering is a rapidly evolving field. Attempts to substitute organs such as skin, peripheral nerves, kidney, conjunctiva, liver, and others have led to exciting and often satisfactory, but not ideal, results. In this article we describe and compare the various methodologies developed to synthesize skin.

Structure and Function of Skin

The skin is the body's largest organ. Like many other organs in the body, it comprises three structures: epidermis, basement membrane, and dermis. Together, these structures allow skin to perform four known critical physiological roles.^[2] First, it prevents dehydration and invasion from microorganisms and protects from mechanical, chemical, thermal, and ultraviolet insults. Second, it behaves as a signal transducer as it contains receptors for touch, pressure, pain, and temperature. Third, it thermoregulates the body by sweating and vasoconstriction. Fourth, it possesses certain metabolic functions as it synthesizes vitamin D and liberates triglycerides from the subcutaneous adipose stores.^[3] Fig. 1 presents a schematic of some of the structural features of the skin.

The epidermis is the external layer, in direct contact with the environment. It has a thickness of approximately 100 μm and is mainly composed of stratified layers of keratinocyte cells (keratinocytes). In the epidermis, layers of keratinocytes are organized in a maturity gradient in which the innermost (basal) layer comprises relatively immature cells containing negligible amounts of keratin. Cells from the inner layers continuously migrate outward, becoming increasingly mature as well as increasingly filled with keratin until they reach the outer layer (stratum corneum) and are eventually sloughed off. Pigment-containing cells (melanocytes), as well as Langerhans cells that participate in the immune defense of the body, reside in the epidermis as well.

The basement membrane is located between the dermis (stroma) and epidermis (epithelia), providing an anchoring layer for the two tissues. It has a thickness of approximately 100 nm and is primarily composed of collagen types IV and VII. It also contains fibronectin, the proteoglycans heparin sulfate and chondroitin sulfate, as well as entactin, α 1-microglobulin, thrombospondin, and tenascin.^[4] The basement membrane is often characterized by electron microscopy using immunohistochemical markers to detect one or more of several specific proteins, such as laminin or type IV collagen.^[3]

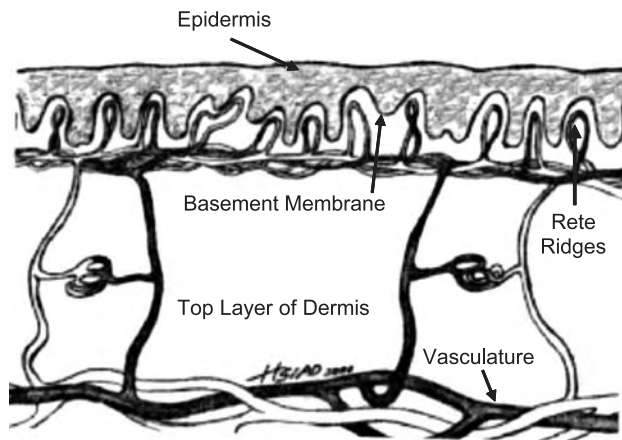

Fig. 1 Schematic diagram of the anatomy of skin. Skin is composed of three layers: epidermis, basement membrane, and dermis. The top portion of the dermis is well vascularized and provides nutrients to the epidermis and basement membrane via capillary loops in rete ridges. (Image adapted from Ref. [2].)

The dermis is the thick, innermost layer of skin, mainly comprising type I collagen and elastin. The combined contributions of these two different types of macromolecules provide robust mechanical support for the epidermis. The dermis contains a rich vascular system that feeds the avascular epidermis and basement membrane and comprises sensory nerves that terminate in the epidermis. Finally, the dermis contains several skin appendages such as hair follicles and sweat and oil-secreting glands.^[3]

Mammalian Response to Skin Injury

Adult mammals respond to injury with contraction and scar synthesis; in the fetal stage, they respond by regeneration. During wound contraction in the adult, specialized contractile cells known as myofibroblasts orchestrate closure of the open wound by exerting forces on the edges of the wound that bring the edges together toward the interior of the injury. Contraction differs from scar formation and regeneration in that there is mechanical deformation of the injured site and there is no extensive synthesis of new tissue. Scar formation is the process by which collagen fibers are synthesized by fibroblasts in the presence of the mechanical field generated by contraction, and leads to filling up of the fraction of the anatomical defect that did not close by contraction. Scar formation and contraction account for wound closure in the adult. However, the resulting tissue structure is the product of an irreversible healing process; it lacks most of the physiological function and normal appearance of normal skin. In contrast, the process of regeneration,

spontaneously available to the fetus during the early stages of gestation, restores all physiological function and appearance; it erases all, or almost all, evidence of an inflicted severe wound and results in reversible wound healing. In the general wound-healing process, closure occurs by contributions from one or more of these three processes; the simple relationship among them is known as the defect closure rule.^[2]

It is very unlikely that the three wound closure processes act independently from each other. However, the extent of their participation is dictated by the severity and timing of the injury along the path of organism development. For example, deep fetal skin wounds that have been inflicted before the third trimester of gestation heal almost flawlessly by regeneration,^[5,6] without contributions from contraction and scar synthesis, while those inflicted after that period generally close by contraction and scar formation with no contribution from regeneration. It has been suggested that fetal healing reflects lack of or suppression of an inflammatory response following injury during the early stages of development.^[7] In contrast, a strong inflammatory response characterizes the response to severe injury of the mammalian adult, where wounds heal irreversibly. The severity of injury is a critical factor as well. In the adult, injury strictly limited to the epidermis and basement membrane heals reversibly, while the dermis (stroma) heals irreversibly.^[2,8]

Need for Skin Substitutes and Current Treatments

The practice of skin replacement dates back to before 1000 B.C. Such practice was aimed at the survival of the injured and is commonly recounted in the popular stories of American Indians who replaced lost skin with that of animals. Today in the United States, more than 80,000 patients a year suffer from severe skin burns that require clinical treatment.^[9] This figure does not include individuals that suffer from venous or diabetic ulcers or those that are subjected to plastic or reconstructive surgery that typically requires the use of skin grafts. When serious enough, these injuries represent a threat to the survival of the organism because they may allow massive bacterial invasion that may lead to sepsis and may induce severe water, protein, and electrolyte loss that can lead to shock. Autografting has provided the standard method when treating full-thickness (completely excised dermis) wounds, corresponding to the severity of injury in a third-degree burn. It has the capability of restoring all functions and structures, but it is limited to fairly small wound areas and has the often significant disadvantage of leaving behind a morbid donor site. Issues of biocompatibility have prevented allogeneic grafts from becoming the

definitive treatment. Furthermore, current treatments for serious skin injuries have a focus beyond survival; they are concerned with restoring organ function as well. In addition to the need for clinical skin replacement with burn patients and those undergoing reconstructive surgery, there is a current need for in-vitro skin models useful in drug testing. In response to such a complexity of requirements, the field of tissue engineering has developed methodologies aimed at synthesis of physiological skin either in vitro or in vivo. A review of such methodologies and results obtained by their use, as well as their advantages and disadvantages, will be presented in the following section.

SKIN EQUIVALENTS AND SKIN REGENERATION TEMPLATES

Recent advances in the methodologies of scaffold synthesis and cell culture have allowed for the development of skin regeneration templates and a number of dermal and epidermal equivalents. Here we review those methodologies that have been at least minimally successful in providing cover for various types of skin wounds and that have led to the development of commercial products for the treatments of patients with severe skin wounds. We refer to these technologies by their commonly used names and acronyms: cultured epidermal autograft (CEA), living dermal replacement (LDR), living skin equivalent (LSE), and dermal regeneration template (DRT). The results of the use of such technologies have been mixed and there is need for further research and experimentation, as the goal of a complete substitution of skin remains elusive. Still, these results are promising and suggest that the ultimate goal of perfect organ replacement is not far ahead. Many of the protocols and results described hereafter have been extensively reviewed.^[2]

Cultured Epidermal Autograft

One of the first approaches used to treat massive skin injuries was that of covering wounds with epidermal grafts synthesized in vitro. These are commonly known as cultured epidermal autografts (CEAs) and have preceded the era of contemporary skin tissue engineering. CEAs were developed as a result of pioneering cell culture work in which the problems of contamination,^[10] viability,^[11] and low cell expansion numbers^[12] were addressed. Later, Rheinwald and Green^[13,14] modified these early techniques for cultivation of enzymatically isolated keratinocytes from biopsies, developing a new methodology that resulted in cultures of stratified, keratinizing keratinocytes with expansion factors of over 10,000 within approximately

three weeks. When treated with CEAs, dermis-free defects have been observed to form a highly differentiated epidermis and basement membrane.^[15]

CEAs have been moderately successful in preventing water and protein loss and protecting the body from infectious agents. The “take” of grafts based on CEAs has been reported to be very good on partial skin wounds, but questionable on full-thickness skin wounds. Two of the disadvantages of CEAs are that they require fairly lengthy cultivation periods after injury and that they are quite fragile during handling. Cultured epidermal allografts have been developed as well,^[16] but they are prone to face biocompatibility issues. In addition, there is no evidence that a normal dermis is synthesized when dermis-free defects are grafted with CEAs, and the lack of mechanical strength of the resulting integument resulting from the use of CEAs on dermis-free defects has been attributed primarily to a lack of anchoring fibrils (reviewed in Ref. [2]). Despite these shortcomings, CEAs are often used as temporary biologically active dressings for chronic open wounds.^[17]

Living Skin Equivalent

An early trend in tissue engineering was an attempt to synthesize the desired tissue structure in vitro followed by transplantation of the missing tissue. The potential of such technology is significant, especially in the preparation of skin substitutes for drug screening applications.

An early approach at synthesizing as much of the structure of skin as possible prior to grafting became known as the living skin equivalent (LSE). LSE consists of two layers that mimic the dermis and the epidermis and are synthesized sequentially in vitro.^[18–21] First, human skin fibroblasts are incorporated into a collagen solution in tissue culture medium. Second, the resulting suspension is gelled at neutral pH and allowed to incubate until the gel is contracted by the fibroblasts. Third, the top surface of the resulting collagen lattice is seeded with keratinocytes and, after several days of expansion, exposed to air to promote the synthesis of a partly keratinized epidermis. Formation of a stratum corneum was promoted in the presence of increased calcium concentrations and in the absence of epidermal growth factor. The resulting epidermis has been characterized by the presence of desmosomes, tonofilaments, and keratohyalin granules;^[22] however, it has been noted that the permeability of this layer is several times higher than that of intact skin.^[23] The cells in the LSE seem to display skinlike behavior, having been shown capable of secreting soluble growth factors such as the interleukins 1, 3, 6, and 8, transforming growth factors α and β , and basic fibroblast growth factors.^[24] However, the LSE lacks a continuous basement membrane in vitro.^[25]

Initial testing of the LSE began on full-thickness skin wounds in the rat.^[22] Both the dermal and epidermal layers underwent considerable remodeling during the early stages of integration. The LSE epidermis appeared to be fully differentiated and functional by the first week after grafting, while its dermal component was observed to be vascularized at two weeks after grafting. No dermal appendages were found, and there were no rete ridges in the dermo-epidermal junction. Grafting onto athymic mice revealed that the presence of LSE initiated synthesis of a basement membrane with occasional anchoring fibrils.^[26] Other studies failed to detect elastic fibers,^[25] although nerve fibers were observed,^[27] in the remodeled neodermis. Clear evidence of synthesis of a physiological dermis has been lacking. Parenteau and coworkers^[23] were able to observe the formation of rete ridges after grafting by lengthening the exposure period to air of the keratinocyte layer during the manufacturing of the graft.

Treatment of human skin injuries with the LSE has provided mixed results. When full-thickness skin wounds arising from burns were treated with the LSE, lysis of at least 20% of the grafted area was observed within two days.^[28] In another study, the tissue from patients who had skin tumors removed and treated with the LSE contained evidence of contraction and scar formation.^[29] However, skin ulcers treated with the LSE closed significantly faster than those treated with traditional methods.^[30]

Living Dermal Replacement

Other attempts at synthesizing skin substitutes *in vitro* have focused on using meshlike polymers as scaffolds for cells. In one such study, the cells were seeded in a synthetic biodegradable polymeric mesh comprising a copolymer of lactic acid (10% wt.) and glycolic acid (90% wt.), referred to as polyglactin-910 surgical mesh (PGL).^[31,32] The mesh was first cultured with neonatal skin fibroblasts until confluence was achieved and several components of the extracellular matrix (ECM), such as collagen, fibronectin, glycosaminoglycans, and growth factors, were secreted. The next step in the manufacturing process involved seeding the mesh with keratinocytes until confluence was achieved in this step as well. The resulting graft became known as living dermal replacement (LDR), and its properties were initially studied by grafting full-thickness skin wounds on athymic mice.

LDR has been reported to be capable of preventing wound contraction in dermis-free defects provided that keratinocytes have been seeded in the polymeric mesh. The inflammatory response to the polymeric mesh was observed to be minimal. It was further reported that,

by 20 days after grafting, the seeded scaffold had been completely degraded and the resulting epithelium had become cornified. No rete ridges had formed. The tissue that has formed underneath the epithelium was reported to contain a large number of fibroblasts and was vascularized.^[31,32] This technology has been used as a temporary wound cover for burn patients who had been previously treated by excision of necrotic tissue.^[33] The LDR has also been placed underneath a meshed autograft to treat human full-thickness skin wounds.^[34] In both experimental and control groups, basement membranes were formed and wounds were observed to close at similar speeds. However, formation of elastic fibers was not observed in the neodermal tissue one year after grafting. In addition, it was noted that the take of the graft was reduced when the polymeric mesh was utilized underneath the autograft.

Dermis Regeneration Template

The final technology that will be reviewed is that pertaining to synthesis and use of the dermis regeneration template (DRT). The DRT has been successful at regenerating most, but not all, of the structures of skin, including a highly functional dermis and epidermis, as well as rete ridges that have not been synthesized using other techniques. It is currently used clinically to treat patients with severe skin wounds as well as in reconstructive surgery applications.

The DRT is an analogue of the extracellular matrix (ECM) comprising a graft copolymer of type I collagen and a sulfated glycosaminoglycan (GAG). Although a large number of ECM analogues have been synthesized over the years, the specific collagen-GAG copolymer referred to as DRT has shown unprecedented biological activity, consisting of blocking of wound contraction and induction of partial skin regeneration. ECM analogues of this type are prepared by mechanically dispersing bovine tendon collagen and chondroitin 6-sulfate in aqueous acetic acid, a good solvent for collagen fibers. The resulting suspension is frozen to a desired temperature in the range -5 to -60°C , and the resulting polymer-containing ice is sublimated under vacuum, leaving behind a porous polymeric network with a characteristic pore volume fraction and average pore diameter. The pore structure of the resulting solid is essentially a negative replica of the ice dendritic structure formed during the freezing step, and therefore the average pore diameter depends critically on the freezing temperature selected during the preceding step. The degradation rate of the ECM analogue can be manipulated by subjecting it to processes for physical or chemical cross-linking. Detailed

methodologies for synthesizing ECM analogues have been published.^[35]

The biological activity of the ECM analogues can be controlled by varying the collagen/GAG ratio, density of covalent cross-links, pore volume fraction, average pore diameter, and pore channel orientation. Appropriate variations in matrix characteristics have been capable of successfully inducing the regeneration of skin,^[36–40] peripheral nerves,^[41,42] and the conjunctiva^[43] in adults. In particular, it has been shown that the biological activity of the DRT is lost when the chemical composition, cross-linking density, and average pore diameter deviate from their optimal levels.^[40] The DRT has been used as a bilayer device, with a thin film of poly(dimethyl siloxane) (silicone elastomer) bonded to its top surface to prevent flow of exudates out of the wound, protect the defect against bacteria, and maintain moisture permeability to nearly physiological levels.^[44] The silicone layer is either spontaneously ejected or is peeled off using negligible force several days after grafting.

A prominent characteristic of DRT is its ability to delay significantly the onset of wound contraction. The area of a standardized full-thickness skin wound in the guinea pig model contracted with a half life of eight days in the absence of the DRT graft but in 25 or more days in the presence of the biodegradable DRT.^[36,38,45] Delay of contraction of a standardized wound has since become a critical assay for biological activity of analogues of ECM.^[40] The kinetics of contraction of full-thickness skin wounds in the guinea pig are illustrated in Fig. 2. Underneath the newly synthesized epidermis in the strongly contracting guinea pig model, histological studies revealed the presence of nonvascular scar tissue in the untreated wounds and a small mass of well-vascularized neodermis in wounds treated with DRT.^[36,38,39,45] The available data from several independent sources have been reviewed, and it has been hypothesized that contraction and regeneration are antagonistically related in the adult mammal.^[2]

Seeding the DRT with keratinocytes, separated from a small skin biopsy, prior to grafting has led to a significantly different product.^[36–39,46] The keratinocyte-seeded DRT was capable of arresting, rather than simply delaying, the onset of contraction about 35 days after grafting and eventually induced synthesis of a skin that was physiological in all respects except for the absence of appendages (sweat glands, hair, etc.).^[36,38] This imperfectly regenerated skin possessed a normal epidermis, basement membrane, dermo-epidermal junction with rete ridges, well-vascularized dermis, elastin fibers, and nonmyelinated nerves.^[36–39,46]

Further studies with the DRT seeded with uncultured keratinocytes were conducted in the swine model, in which full-thickness wounds contract somewhat less than in the rodent models.^[47–50] The newly

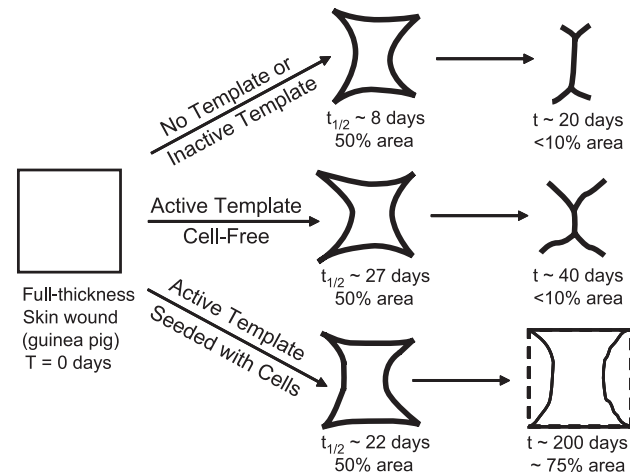

Fig. 2 The kinetics of contraction of full-thickness skin wounds in the guinea pig are significantly affected by the type of template used. A cell-free template delays contraction, while a keratinocyte-seeded one arrests it. The wound half life, $t_{1/2}$, refers to the number of days necessary to reduce the original wound area to 50%. (Image adapted from Ref. [64].)

formed epidermis exhibited fully differentiated cells and rete ridges, and the dermis was well vascularized with collagen bundles resembling those of physiological dermis. Histological staining revealed the presence of many structural components of the dermo-epidermal junction (Fig. 3). Hair follicles and sweat and oil glands were not observed.^[47–50]

Clinical trials of the cell-free DRT have been conducted with patients suffering from massive skin wounds.^[51–53] No evidence of scar was observed post-grafting in both the gross and histological levels. Full-thickness wounds proceeded to heal resembling physiological skin, although skin appendages were missing. The take of the DRT was reported to be good, and only a minimal immune response to it was detected.^[54] Long-term follow-up studies have failed to report complications with the regenerated tissue when used to treat patients with severe burns.^[55]

The DRT has also been used in an attempt to synthesize skin *in vitro* by seeding it with fibroblasts and keratinocytes, leading to a so-called “composite graft.”^[56–59] The epidermis and some of its structures, such as its stratified organization and desmosomal connections, have been successfully recreated. Histological studies of dermis-free defects in the athymic mouse treated with this composite graft provided evidence for the presence of laminin, type IV collagen, anchoring fibrils, and rete ridges in the dermo-epidermal junction. The synthesized dermis in burn patients resembled physiological dermis, although no skin appendages were observed.^[60,61]

Fig. 3 Histological images of full-thickness swine skin wounds regenerated with the cell-seeded DRT containing evidence of synthesis of the dermo-epidermal junction. (a) Immunohistochemical staining for type VII collagen 12 days after grafting, a marker for anchoring fibrils in the basement membrane. Scale bar, 150 μm . (b) Vascular loops in rete ridges are identified by immunostaining for factor VIII at 35 days after grafting. Scale bar, 75 μm . (c) Hemidesmosomal staining pattern of the regenerated epidermis resembles that of normal skin. Immunostaining for the $\alpha_6\beta_4$ integrin at 35 days after grafting. Scale bar, 100 μm . (All images adapted from Ref. [49].)

THEORETICAL DIRECTIONS OF FUTURE RESEARCH

Skin was the first organ to be partially regenerated and has provided impetus for further studies along the direction of regeneration of other organs. A review of

the available data has led to the hypothesis that organ regeneration in the adult becomes possible provided that the adult processes of wound closure, i.e., contraction and scar synthesis, have been appropriately blocked.^[2] This line of reasoning is supported by several lines of independent evidence, including the observations that the biological activity of the DRT scaffold requires the presence of appropriate ligands for cell-matrix binding, as well as a minimal density of ligands and an optimal duration of the scaffold in a nondegraded form.^[62] These structural features are required for optimal blocking of contraction in standardized animal models. Tests of this hypothesis require studies with organs other than skin, peripheral nerve, and the conjunctiva. Efforts to accelerate the regeneration process and improve the quality of the final product may also involve seeding of stem cells into the scaffold.^[63]

A major question that continuously reappears in the thinking of tissue engineers refers to the choice of an in-vitro versus an in-vivo protocol. In this debate, the relative merits of synthetic protocols that make maximal use of in-vitro conditions to achieve synthesis of an organoid prior to eventual implantation at the correct anatomical site are contrasted to the advantages of using protocols that make minimal use of in-vitro processes and rely instead on in-vivo synthesis via induced regeneration. The advantages and disadvantages have been discussed, with particular emphasis on the lack of a physiological cytokine field (the spatial concentration history of several cytokines during the multiday healing process) in protocols currently conducted in vitro.^[2] In-vitro synthetic approaches make use of simpler reaction conditions but suffer from lack of a theoretical paradigm to guide the selection of reaction conditions. On the other hand, although protocols for regeneration derive systematically from a theoretical paradigm (see preceding discussion), they suffer from the relative experimental complexity encountered when a reaction is conducted in vivo. The two approaches share a required nontrivial final step, consisting of implantation and successful incorporation into the desired anatomical site of the host either of the organoid prepared in vitro or of the scaffold (with or without seeded cells) used with in-vivo protocols. This critical similarity of in-vitro and in-vivo protocols suggests strongly that in future research efforts these two approaches will coalesce, leading to a unified approach that varies in the particulars of the organ being synthesized.

Progress toward a unified synthetic approach in tissue engineering has recently become possible following systematic representation of experimental protocols for tissue and organ regeneration as examples of complex chemical synthetic processes. In this symbolic scheme, each experimental protocol used to

study regeneration is represented as a reaction diagram. Not to be confused with a chemical equation (which includes information on the stoichiometry, i.e., the relative masses of reactants and products), a reaction diagram is a much simpler symbolic representation of the synthetic process. It identifies simply the reactants added by the investigator, the reactor conditions, and the product obtained in each case.^[2] Such a representation simplifies greatly the task of comparing a large variety of experimental strategies used by different investigators and leads easily to identification of the pathway that requires the minimal number of reactants. Systematic use of this approach has led to rules that can be used to synthesize *in vivo* (regenerate) a hypothetical organ consisting of epithelia, basement membrane, and stroma; the reactants required for such a synthesis are simply a scaffold seeded with epithelial cells dissociated from the desired organ that is implanted in an anatomically well-defined site. This protocol has been successfully used to partially synthesize skin, the conjunctiva, and peripheral nerves *in vivo* (regeneration).^[2] The simple protocol suggests the elements of a systematic approach for investigators of *in-vitro* synthetic protocols as well.

Tissue Engineering of the Small Intestine

Simon M. Gabe

Biomaterials & Tissue Engineering Group, St. Mark's Hospital, London, United Kingdom

Aldo Boccaccini

Imperial College London, London, United Kingdom

INTRODUCTION

Recent developments in material science and cellular biology have enabled bioengineered tissues to be developed with applications relevant to clinical medicine. Less than a decade ago, many scientists believed that human tissue could only be replaced by a transplant from a compatible donor or with fully artificial parts made of plastic or metal, e.g., joint prosthesis or cardiac pump. Tissue engineering is an interdisciplinary field that applies the principles of engineering and the life sciences toward the development of biological substitutes that restore, maintain, or improve tissue function. The primary goal of all approaches in tissue engineering is the restoration of function through the delivery of living elements that become integrated into the patient. Although some techniques of guided tissue regeneration rely on matrices alone, and other approaches rely on cells alone, most investigators in tissue engineering use cells combined with matrices to achieve new tissue formation. The development of a tissue-engineered intestine requires overcoming obstacles in developing epithelial growth and differentiation on top of a vascularized subepithelial matrix as well as developing an innervated muscular layer.

In tissue engineering, there are two fundamentally different approaches, or philosophies, that can be taken. The first is to replicate the organ anatomically, with the expectation that the function of the engineered organ will therefore be the same. The second approach is simply to replicate its function. In general, researchers who aim to engineer intestine have adopted the anatomical approach and while this has been successful to a large degree, key problems including the development of a muscular layer and neuronal innervation are major challenges to its success. If, on the other hand, the aim is to develop an absorptive surface with neointestinal epithelium, it is possible to be more imaginative about how this can be achieved.

This article will cover the early work that led to the realization that it is possible to develop intestinal neoe epithelium. Scaffold developments are then addressed, followed by the different approaches employed

by investigators. Finally, important new developments in scaffold technology and stem cell biology are covered as well as how this may benefit patients in the future.

Why Engineer Small Intestine?

The most important drive to develop a small intestinal construct is to help patients who have short bowel syndrome (SBS) and are dependent on intravenous nutrition (IVN) in order to survive. SBS is a form of intestinal failure characterized by diarrhea, dehydration, malabsorption, and progressive malnutrition. If the fluids, electrolytes, and nutrients are not replaced, there is deterioration from dehydration and malnutrition to death. SBS occurs after extensive small bowel resection and disturbs the normal absorptive processes for nutrients and fluids. This clinical condition afflicts both adults and children in whom less than one-third of the normal jejunal-ileal length remains. IVN has improved survival, but is associated with serious complications including cholestasis, fibrotic liver disease, and venous thrombosis with progressive loss of venous access as well as catheter-related sepsis.^[1] Patient survival on home parenteral nutrition (HPN) is quoted at 86% at two years and 75% at 5 years.^[1]

In adult patients with short bowel syndrome, a small bowel length of <100 cm is highly predictive of permanent intestinal failure, and the presence of terminal ileum and/or colon in continuity enhances weaning off IVN and improves survival.

Surgical procedures are described to lengthen the small bowel and increase the absorptive surface area in children.^[2] However, these can rarely be performed in adults, as complications such as fistula formation and sepsis are much more frequent in Crohn's disease, which is the most common underlying pathology in this patient group. Possible surgery can be performed to restore continuity in cases where some intestine has been disconnected, but again this applies only to a small number of patients. Small intestinal transplantation is a promising method of treatment and survival rates have improved considerably over the past five

years. Currently, one- and three-year graft survival is 53 and 31%, respectively, and one- and three-year patient survival is 77 and 55%, respectively.^[3] These are still not as good as the survival rates on HPN and patients can suffer serious complications associated with transplantation and immunosuppression including rejection, sepsis, and lymphoproliferative disease. Currently transplantation therefore is reserved for patients who have had severe complications of IVN.^[3,4] Furthermore, in the field of transplantation, the scarcity of donor organs has become a major limitation, especially in the pediatric population. Thus, for patients suffering with intestinal failure and requiring HPN, it would be of considerable benefit to engineer an intestinal construct that could increase absorptive area for nutrient absorption without the need for potent immunosuppression. In addition, other advantages of developing an intestinal construct are that it will improve our understanding about epithelial regeneration, epithelial-mesenchyme interactions, cell-matrix interactions, and the actions of different growth factors in the intestine.

The Development of Primary Cultures of Intestinal Epithelium

In the early 1990s, the maintenance of proliferation of isolated intestinal epithelial cells *ex vivo* was a major limitation. While epithelial cell lines had been developed from colonic adenocarcinoma and from transformed cell lines, these cells had undergone changes and selection to facilitate long-term, *in vitro* growth. These cell lines were not adequate to use to develop an intact or normal epithelium. In order to develop a primary culture of intestinal epithelium, it is necessary to culture cells from the crypt bases. At each crypt base resides epithelial stem cells that divide to produce daughter cells that migrate up toward the crypt mouth and differentiate along their journey.^[5]

In 1992, Evans et al. developed a method for the preparation of intestinal epithelial cell primary cultures in the rodent.^[6] This important article describes a reproducible method for growing small intestinal epithelium derived from the suckling rat intestine in short-term, primary cultures. In this method, organoid units are obtained from neonatal rats, representing the intestinal epithelial crypts (Fig. 1). This group found that the optimal method of isolating small intestinal epithelium was by using a mixture of crude collagenase and dispase to digest the supporting connective tissue. This enzymic solution has a low level of tryptic activity and does not result in complete separation of the epithelial cells, allowing clusters of crypts and villi to be released after gentle pipetting. When cultured, the organoids can be seen to contain heterogeneous

Fig. 1 Organoid units. Intestinal epithelial organoid units are defined as villus structures with overlying epithelium and a core of mesenchymal stromal cells. The average size of an organoid unit is 0.1 mm \times 0.25 mm and, on average, 40,000 organoid units can be isolated from a neonatal rat small intestine.

populations of cells, with fibroblasts and smooth musclelike cells.

In the gastrointestinal tract, multipotential stem cells are found within gastric glands and intestinal crypts. These cells are capable of producing all four main types of epithelial lineages found in the gut: columnar cells, mucin-secreting cells, endocrine cells, and Paneth cells. The isolation and use of organoid units to provide a source of epithelium for tissue-engineered small intestine neotissue has been favored to date because it guarantees the capture of the multipotential stem cells. In addition to the epithelial stem cells, the seeded organoid unit also contains the other cell lineages present within the crypt. A layer of intestinal subepithelial myofibroblasts surrounds each intestinal crypt, which is thought to play a role in epithelial-mesenchymal interactions by secreting growth factors, such as hepatocyte growth factor, and transforming growth factor- β and keratinocyte growth factor. These growth factors can bind to receptors located on the adjacent epithelial cells, allowing paracrine regulation of cell differentiation. Subepithelial myofibroblasts probably play a vital role in supporting adhesion and growth of the isolated epithelial organoid units that are seeded onto scaffolds during the creation of artificial intestinal constructs.^[7,8] The presence of mesenchymal cells is important for epithelial cell proliferation^[9,10] and differentiation.^[11]

The technique described by Evans et al. to isolate primary cultures of intestinal epithelium continues to be used with only minor modifications. However, the key development has been to implant these organoid units *in vivo* in order to develop them into a neoe-pithelium. This has been performed subcutaneously,^[12-16] on mucossectomized colon,^[17] and after

placing the units on a three-dimensional scaffold and connecting them to the native intestine.^[7,8,18–20] In addition, this method has been successfully used to isolate colonic epithelial cells from resected mucosa and biopsy specimens.^[21]

The Scaffolds

Scaffolds requirements and materials

The scientific challenge of tissue engineering encompasses understanding the cells themselves, their mass transport requirements, and biological environment as well as the development of suitable scaffold materials, usually porous, that act as templates for cell adhesion, growth, and proliferation. Several physicochemical and biological requirements have to be fulfilled by the scaffold, depending on the particular tissue under consideration, which are closely dependent upon the scaffold porosity and porous structure. Thus, the scaffold properties should be specifically tailored to enable cell penetration and tissue formation in three dimensions. Ideally, tissue engineering scaffolds should have the following characteristics:^[22] 1) three-dimensional and highly porous with an interconnected pore network for cell growth and flow transport of nutrients and metabolic waste; 2) biocompatible and bioresorbable with a controllable degradation and resorption rate to match cell/tissue growth *in vitro* and/or *in vivo*; 3) suitable surface chemistry for cell attachment, proliferation, and differentiation; and 4) mechanical properties to match those of the tissues at the site of implantation. Moreover, a suitable scaffold should be made from versatile processing techniques that can produce irregular, usually complex, shapes to match that of the defect in the tissue of the patient.

Materials used to fabricate scaffolds for soft tissue engineering are therefore selected to provide temporary structures that exhibit adequate mechanical and biological properties. The use of biodegradable scaffolds avoids the need for a permanent implant made of an engineered material remaining in the tissue. In general, materials chosen for the fabrication of tissue engineering scaffolds belong to the group known as third generation biomaterials, *i.e.*, materials that are both resorbable and bioactive.^[23] These materials are designed to stimulate specific cellular responses at the molecular level. For example, molecular modifications of degradable polymers elicit specific interactions with cell integrins and thereby direct cell proliferation, differentiation, and extracellular matrix production and organization.

Numerous bioresorbable matrices are being investigated as scaffolds for soft tissue engineering and tissue repair, including naturally occurring or

biologically derived matrices,^[24–26] synthetic polymers,^[27–30] and polymer composites.^[31]

Significant examples of natural scaffolds are decellularized biological matrices, which are either allogeneic or xenogeneic tissues that are decellularized by enzymatic or detergent methods. Examples of biologically derived scaffolds are collagen-based matrices and small intestinal submucosa. Other natural polymers considered are hydrogels like gelatin, agar, or fibrin. However, the materials most commonly used as scaffolds for mammalian cells are of synthetic origin.^[25] Advantages of using synthetic scaffolds include the ability to precisely engineer the material's composition and micro- and macrostructure. This allows tailoring of scaffold properties, thus enabling the incorporation of optimal conditions for cell survival, proliferation, and subsequent tissue formation.

Synthetic bioresorbable polymers have been increasingly used as tissue engineering scaffolds during the past 10 years, particularly polylactide (PLA), polyglycolide (PGA), and their copolymers, but also hydrogels, polyhydroxybutyrate, and polyhydroxyoctanoate. PLA- and PGA-based polymers in particular have already demonstrated success in clinical use, for example, as resorbable surgical sutures and meshes or in drug delivery systems, and they have the Food and Drug Administration (FDA) approval for clinical use. The use of bioresorbable synthetic polymers in tissue engineering applications has been reviewed in a number of publications.^[22,27–30]

Porosity and pore structure are key parameters determining the properties and the applicability of scaffolds. Figure 2 shows a summary of the different functions related to the pore structure of a tissue engineering scaffold. In general, scaffold porosity, pore morphology, and pore orientation must be tailored to the particular tissue under consideration. Porous polymeric tissue engineering scaffolds of three-dimensional (3-D) structure have been prepared by numerous techniques, including solid-liquid and liquid-liquid phase separation, solution casting, gel casting, gas saturation, gas foaming, fiber bonding, fabric forming, and related textile-based processes. Porous scaffolds have also been produced by sintering of polymeric microspheres, combined solvent casting and extrusion, emulsion freeze drying, several rapid prototyping techniques, *e.g.*, 3-D printing and fused deposition modeling, as well as by various solvent casting/particulate leaching methods using different porogen additives. Overviews regarding fabrication methods for 3-D porous polymeric scaffolds for tissue engineering are given by several authors.^[22,30,32,33] Regardless of tissue type under consideration, one of the major challenges faced by tissue-engineered devices is promoting healing in three dimensions, which is particularly relevant when complex organ shapes are required,

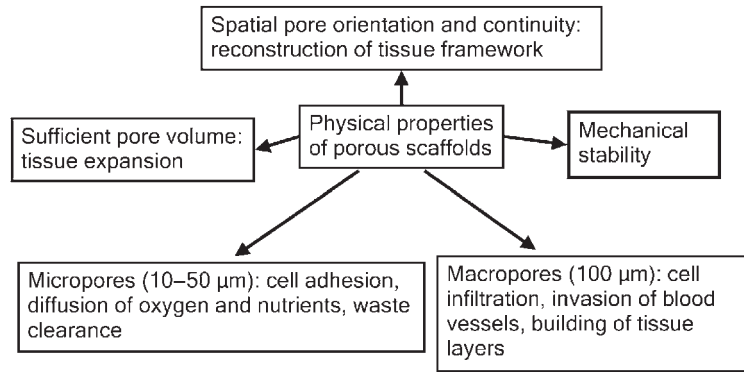

Fig. 2 Schematic diagram showing the different functions of a tissue engineering scaffold, depending on its porosity and pore structure.

T

e.g., multilayered tubular structures such as intestine. Allowing blood vessel formation (neovascularization) through the scaffold is also critical to the success of the approach.

Scaffolds for tissue-engineered intestine

Limited options are available for tissue engineering scaffolds suitable for engineering tissues containing a luminal structure. In fact, there has been relatively limited previous research on developing macrotubular, synthetic biodegradable constructs for tissue engineering applications in comparison with other simple-shaped scaffold architectures. These previous studies have focused mainly on developing scaffolds for vascular tissue engineering, but applications in other areas requiring tubular scaffolds such as peripheral nerve, long bone, and intestine^[34,35] have been considered.

There are a number of challenges related to the development of tubular scaffolds with the desired pore structure, which are related to attaining the optimum flexibility and pliability of the materials used and the maintenance of the tubular shape and structural integrity *in vivo* for the required period after implantation. Intestinal tissue is composed of a layer of smooth muscle sandwiched between a layer of collagenous vascularized support matrix and an epithelial lining. Such a structure can be built by seeding the different cell types for each layer sequentially on suitable porous, degradable scaffolds.

Successful scaffold architectures developed specifically for intestine tissue engineering are those created by Vacanti's group,^[35] which are based on biodegradable polymer tubes, 10 mm in length, with an internal diameter of 2 mm, created from sheets of nonwoven mesh of polyglycolic acid (PGA) fibers (fiber diameter, 5 μm, porosity >0.95, mean pore size, 250 μm) and sprayed on the outer surface with 5% poly-L-lactic (PLLA) acid. These tubes were coated with 200 ml of 0.1% collagen solution and seeded with intestinal epithelial organoid units (6.0104 units/polymer).

Pliable biodegradable polymer foams with potential use as scaffolds for intestinal tissue have been developed by Conley Wake et al.^[34] The materials used were poly(lactic-co-glycolic acid) (PLGA) and poly(ethylene glycol) (PEG) blends and the fabrication technique was based on solvent casting and particulate leaching. A wide range of shear moduli (0.59 to 9.55 MPa), porosities (0.79 to 0.94), and pore diameter (71 to 154 μm) was achieved by varying the processing conditions.

Another recent scaffold structure for tissue-engineered intestine has been developed by Shimizu's group in Japan,^[36,37] which is based on a collagen sponge substrate. The collagen was extracted from porcine skin by enzymatic treatment. The collagen consists of type I and type III atelocollagen. The collagen sponge scaffold was reinforced by polyglycolic acid felt applied to the base. Figure 8 represents schematically the operative procedure followed, which was mainly intended for lengthening small intestine.^[37]

Recent developments

A recent development by the authors has focused on highly porous tubular foam scaffolds fabricated from poly(D,L-lactide-co-glycolide) (PLGA) copolymers. The foams were fabricated following a thermally induced phase separation process, also termed freeze drying.^[30] Different polymer concentrations and casting volumes of solutions were assessed for their suitability to produce porous membranes for the fabrication of tubular constructs. The membrane selected for use in an *in vivo* study contained the largest pores, while retaining its structure. Tubular foam constructs were fabricated by rolling the polymer membranes into a tube. The opposing edges were joined by slowly dissolving in chloroform and pressing the edges together. This resulted in a tube with a lumen approximately 3 mm in diameter and walls approximately 1.5–2 mm thick. Figure 3 shows a scanning electron microscopy (SEM) micrograph of the typical

Fig. 3 Scanning electron microscopy (SEM) micrograph of a tubular porous structure formed by rolling the PLGA membranes and dissolving the opposing edges with chloroform.

microstructure of the tubular constructs used. These scaffolds demonstrate good biocompatibility when tested *in vivo* and become rapidly cellularized.

Models

The small intestinal mucosa is an intricate, precisely organized structure composed of both epithelial and mesenchymal tissues, which interact to produce a functional and regulated organ. Different groups have had diverse approaches in developing an artificial layer of small intestinal mucosa. Campbell's group has concentrated on growing organoid units in a subcutaneous plane in mice, while the Vacanti group has grown these organoid units on a three-dimensional scaffold and obtained a cystic structure lined by a neomucosa anastomosed onto the intestine. A different approach has been to lengthen the intestine using a subepithelial matrix, and other groups have focused on developing a suitable matrix that enhances neoeptithelial growth. These different approaches are described subsequently in more detail.

Organoid units implanted subcutaneously

A novel model successfully developed by Campbell's group, primarily as a way of examining small intestinal mucosal regeneration, has been to implant neonatal mouse organoid units subcutaneously. Tait et al. used this method and demonstrated that small intestinal-like structures had developed after 14 days in 39% of cellular transplants to nude mice, and 84% of cellular transplants to inbred rats.^[15] The structures that developed were composed of a circumferential layer of epithelium surrounding a central, mucin-filled lumen and formed crypts and villi. Furthermore, the epithelial

cells had differentiated to form absorptive enterocytes, goblet cells, Paneth's cells, and entero-endocrine cells. Brush border enzyme expression increased as the structures matured and by day 25, the enzyme concentrations were comparable to the control small intestine.^[16] Continuing work from the same unit confirms that subcutaneously implanted organoid units show a temporal sequence of neomucosal morphogenesis and differentiation^[12,14] (Fig. 4). Characterization of the neomucosa revealed that it maintains all the key features of the normal intact intestinal mucosa. In addition, using a mixture of transgene marked and unmarked cells, Slorach et al. demonstrated that neomucosa forms initially from single organoids, which then fuse as they increase in size to generate a chimeric mucosa.^[14]

The next extension of this model has given us a better understanding of some of the factors controlling intestinal epithelial regeneration as well as extending the cells used to human cells. Sattar and colleagues isolated organoid units (disaggregated human fetal intestinal epithelium) from human fetal small intestine and transplanted these units subcutaneously in SCID mice.^[13] The implanted organoid units induced a coordinated regeneration response with separation of cell populations at different stages of histogenesis and cytodifferentiation (Fig. 5), in keeping with the murine model previously described. In addition, growth regulatory genes were assayed and, during early regeneration, Bcl-2, Ki67, and p53 were expressed throughout the epithelial compartment. This indicates suppression of apoptosis (Bcl-2), enhanced proliferation (Ki67), and differentiation (p53). On completion of neomucosal regeneration, these genes were expressed only in crypt epithelium and were absent from the villi.^[13]

The success of this method in generating ectopic intestinal neomucosa can be put down to the cell mix within the organoid units. Patel et al. compared the growth of organoid units with cell suspensions derived from organoid units and demonstrated clearly that the implanted cell suspensions did not develop into small intestinal neomucosa.^[12] This illustrates that the preservation of cell interactions in the organoids is beneficial to the regeneration of mucosa from the crypt stem cells. Earlier work using enterocytes derived from organoid units from 20-day fetal rat intestine developed to form an intestinal-like mucosa when cocultured with fetal mesenchyme prior to implantation into the renal subcapsular space of adult nude mice.^[38] The importance of the mesenchyme in regulating and maintaining endodermal differentiation suggests that mesenchyme has a role in regulating epithelial stem cell function.

These experiments demonstrate that after extensive mucosal disaggregation, postnatal organoid units, which contain small intestinal epithelial progenitor

Fig. 4 Model of neomucosal development from grafted organoids. Type I, II, and III cysts are derived from single organoids containing only TA cells, only stem cells, and both TA and stem cells, respectively. (1A) Type I cysts (have a limited ability to proliferate). (1B) Type I cysts increase in size and produce an undifferentiated flattened epithelial lining. (1C) These cells take on a columnar phenotype as they differentiate into absorptive enterocytes, goblet, and entero-endocrine cells. (2A) Type II and III cysts. (2B) Undifferentiated epithelial cells proliferate to produce polarized columnar epithelial cells. (2C) At distinct sites, proliferating epithelium begins to migrate down toward the underlying mesenchyme. The mesenchyme migrates through the layers of smooth muscle cells toward the epithelium. (2D) Cell migration continues, leading to the generation of crypts with Paneth cells at their base. (2E) Regions of epithelium between the crypts protrude toward the central lumen, leading to the generation of intestinal villi and full intestinal mucosal architecture. (3A) Neighboring cysts may fuse together. (Adapted and reproduced from Ref. [14].)

cells, retain the capacity for organotypic regeneration of neomucosa when transplanted to ectopic sites in adult recipients. Importantly, these small aggregates of epithelium and stroma are capable of generating the topographical signals necessary for the three-dimensional regeneration of this tissue. Furthermore, the

multipotent generative potential of the stem cells within these cellular aggregates is maintained with production of all progeny.

Organoid units transplanted onto mucosectomized colon

In an attempt to develop a functional intestinal neomucosa, Campbell's group has seeded organoid units onto the ascending colon after surgical mucosectomy in rats.^[17] They demonstrated that a neomucosa with typical small bowel morphology developed in 76% of grafts. The neomucosa that developed had normal morphology with crypts and villi developing as well cellular differentiation with the formation of enterocytes, goblet cells, entero-endocrine cells, and Paneth cells. Control loops underwent a mucosectomy without organoid implantation and showed no epithelial regrowth.^[17]

This study demonstrates that with appropriate stromal support, transplanted small intestinal stem cells have the capacity to re-epithelialize denuded colonic muscle with small bowel neomucosa.

Organoid units on an artificial matrix

Using the principles of tissue engineering, Vacanti's group studied the transplantation of intestinal cells using synthetic biodegradable polymer scaffolds to generate new intestinal tissue. Initial efforts to tissue engineer small intestine began with a study by Vacanti and colleagues in 1988, in which cell preparations were attached to biodegradable artificial polymers and implanted into animals.^[20] This technique involved harvesting single cells and clusters of fetal and adult small intestinal cells. The cells were seeded onto biodegradable polymers of polyglactin 910, polyanhydrides, and polyorthoester. The fetal intestinal cells proliferated on the polymer scaffolds and after four days in culture, the cell-polymer scaffolds were implanted into host animals (omentum, interscapular fat pad, or mesentery). In three cases, there was successful engraftment of fetal intestinal cells when implanted into the omentum and coupled with a partial hepatectomy. This was encouraging and raised many issues to be addressed including the development of primary cultures of intestinal epithelium, three-dimensional scaffolds, and the role of growth factors.

Subsequently, pure populations of crypt stem cells isolated from adult intestine were transplanted on biodegradable scaffolds to generate stratified epithelium, reminiscent of embryonic gut development.^[18,19] More recently, the same group has shown that transplantation of fetal organoid units on biodegradable scaffolds survive, proliferate, and regenerate small cystic structures

T

lined with intestinal mucosa.^[8] The scaffolds used were tubes created of nonwoven polyglycolic acid fibers (PGA). These allowed nutrient-waste exchange between implanted cells and the surrounding tissue, while allowing neovascularization of the developing tissue. However, PGA fiber meshes are incapable of resisting significant compressional forces. To stabilize the PGA meshes, atomized solutions of poly(L-lactic acid) (PLLA) and a 50/50 copolymer of poly(D,L-lactic-co-glycolic acid) (PLGA) were sprayed over meshes formed into hollow tubes. The PLLA and PLGA coated the PGA fibers and physically bonded adjacent fibers. This increased the compression resistance, and bonding with PLLA allowed the tubes to degrade more slowly.^[39]

Organoid units seeded onto polymer scaffolds can survive, vascularize, proliferate, and form cysticlike structures after implantation. The inner lumen of the cyst becomes lined with a well-developed neomucosal layer characterized by crypt-villous structures and surrounded by smooth muscle.^[7,8] In these studies, the neomucosa that develops within the cysts is histologically normal with cell differentiation, brush border enzymes are present, and electrophysiological testing exhibited similar transepithelial resistance to adult ileal mucosa. In further studies, cysts were anastomosed onto the native intestine after three weeks^[40–43] (Fig. 6). Histological examination demonstrated that 10 weeks after anastomosis, cysts are lined by a neomucosa in continuity to native small bowel across the anastomotic site. The effect of anastomosis increases the villus number, height, and surface length when compared to neomucosa formed in cysts that were not anastomosed onto the native intestine (Fig. 7). Other factors that will stimulate neomucosal growth include small bowel resection^[40] and, to a lesser extent,

portacaval shunting.^[44] In addition, tissue-engineered intestine can develop a mucosal immune system with an immunocyte population similar to that of native small intestine.^[35] This technique has also been applied to the colon to create an artificial pouch lined with colonic mucosa.^[45]

Intestinal extension using a subepithelial matrix

In Japan, Shimizu's group has developed a different technique that exploits the body's wound healing ability to enable tissue to be regenerated at the site of a tissue defect in vivo. They have grafted an acellular collagen sponge, which acts as a scaffold for migration of host cells and tissue,^[37] and have successfully repaired defects created in the trachea,^[46–48] esophagus,^[49–52] and stomach.^[37]

To regenerate a segment of stomach, a 4 × 4 cm square portion of the anterior stomach wall was resected and a silicon sheet used to repair the defect on the luminal side. On the serosal side, a blood-soaked collagen sponge scaffold was sutured and then wrapped with omentum.^[37] Four weeks later, the silicon sheet was removed endoscopically and at this stage, there was an inflammatory infiltrate into the sponge scaffold. After another 12 weeks, gastric mucosa had grown over the scaffold.^[37]

The same technique has been applied to lengthening the small intestine.^[36,37] After forming a jejunal bypass, a 5 cm segment of disconnected jejunum was resected and a silicone tube stent inserted from the luminal aspect. Collagen sponge scaffold was then sutured to the serosal side (Fig. 8) and wrapped with omentum. Four weeks later, the silicon tube was removed

Fig. 6 a) Tissue-engineered neointestine after anastomosis to native small intestine at the time of harvest (arrow indicates tissue-engineered neointestine). b) Patent anastomosis between the tissue-engineered construct and native small intestine (bar = 5 mm). (Reproduced from Ref. [42].)

endoscopically and at this stage, regeneration was observed at the site of the scaffold graft. Twelve weeks after removal of the silicon stent, the mucosal layer covered the luminal surface of the regenerated intestine.^[36] Both of these techniques succeeded in allowing intestinal mucosa to grow over an artificial cellularized scaffold. However, the regenerated segment lacked a muscular layer and this was addressed by seeding mesenchymal stem cells into the developing graft.^[36] Unfortunately, a muscle layer was not generated in this way, as it is likely that pluripotent cells will need specific stimuli to encourage them to develop in a particular direction.

Recent Developments

Stem cells

Following intestinal mucosal irradiation, the majority of crypt cells are lost and there is evidence using microcolony assays to suggest that only a single stem cell is required to regenerate the crypt with all of the intestinal epithelial cell types.^[30,53,54] Investigations of human gastrointestinal stem cells have proved difficult because of a lack of distinct intestinal stem cell

markers. Without these markers, pure populations of stem cells cannot be harvested and used for tissue engineering purposes. It has been hypothesized that colonic stem cells might be isolated and cultured on the basis of specific $\beta 1$ integrin expression patterns.^[55] Cells located in the lower third of crypts expressed higher levels of $\beta 1$ integrin than the remainder of the crypt, a finding similar to the distribution of $\alpha 2\beta 1$ integrin in the small intestine.^[56] Cell sorting based on the increased expression of $\beta 1$ integrin in colonic crypts produced a population of cells with increased ability to form colonies, indicating $\beta 1$ integrin may be a surface marker on the clonogenic cells of the colonic crypt.^[55] Other candidate markers for intestinal stem cells include Musashi-1, a neural binding protein, and Hes1, a transcriptional factor regulated by Musashi-1.^[57,58] These molecules are coexpressed at the putative position of stem cells, in the crypt base, and cells just above the Paneth cells, suggesting they may be markers for epithelial stem and early progenitor cells.

The discovery that stem cells in some tissues are not lineage restricted suggests it may be possible to generate epithelium for tissue-engineered small intestinal constructs from nongastrointestinal tissue. Historically, hematopoietic bone marrow stem cells have been considered to give rise to a single lineage of formed

Fig. 7 Neomucosa at 10 weeks after implantation. a) Construct not anastomosed, and b) anastomosed onto the native intestine. P = polymer, L = cyst lumen, O = omentum, F = fibrovascular tissue. (Reproduced from Ref. [42].)

elements found in peripheral blood. Recently, the plasticity of adult bone marrow stem cells has been demonstrated in irradiated humans who received bone marrow transplantation. In addition to the formation of new erythroid, granulocyte/macrophage, megakaryocyte, and lymphoid lineages,^[59] hematopoietic stem cells can also differentiate into many different cell types including hepatocytes,^[60] endothelial cells,^[61] renal tubular epithelial cells,^[62] and neuronal cells.^[63] More relevant to small intestinal tissue engineering is the finding that bone marrow-derived cells from male donors were identified in regenerating damaged epithelium in every part of the gastrointestinal tract of female bone marrow transplant recipients.^[64] Importantly, the number of bone marrow-derived gastrointestinal epithelial cells was markedly increased during mucosal repair and epithelial regeneration after graft versus host disease (GVHD) or ulcer formation.^[64] This phenomenon has also been observed with bone marrow-derived pericryptal myofibroblasts in the intestines of human patients suffering from GVHD following bone marrow transplantation.^[65] Stem cell plasticity therefore raises the possibility of seeding tissue-engineered constructs with an individual's own bone marrow stem cells, thus avoiding problems associated with either allograft reactions or autologous donor cell shortages that may arise from a diseased organ. It remains to be seen whether transdifferentiated bone marrow stem cells used for this purpose possess the same functional and sustained regenerative capacity as the endogenous cell types of the target tissue.^[66]

CONCLUSION

The past 15 years have brought many advances in tissue engineering of the small intestine, and different animal models have now been developed in the subcutaneous plane or onto artificial matrices, either using mucosal regeneration or by transplanting organoid units onto the matrix. These models aim to replicate both the anatomy and function of the small intestine and, while it is currently possible to develop an intestinal epithelium on a biodegradable scaffold, there is

more work to be done to increase the developed surface area to be significant in short bowel syndrome. Further developments will also be necessary to develop an innovated muscular layer. Advances in stem cell and scaffold technology and an increasing understanding of growth factors in the intestine will help bring tissue engineering of the small intestine into the clinical arena, where there is a clear clinical need.

T

INTRODUCTION

Rupture of tendons due to either high load or laceration is a common injury, especially for the hand. Tendon disorders are traditionally treated by reducing inflammation, restoring flexibility, and, if necessary, performing surgical repair.^[1] It has been estimated that hand surgeons repair nearly one-third of a million digital flexor tendon injuries per year in the United States.^[2] Despite the fact that surgery of tendons is a common procedure, its outcome is often unsatisfactory. Recovery after tendon surgery can take months. At best, the restored tendon is about half of its initial mechanical properties, so surgeons often face patients' dissatisfaction. On the other hand, if left untreated, healing tendon is not as good as original structure from a mechanical point of view. Moreover, the related pain is difficult to treat.

Several factors may explain these unsatisfactory results such as the difficulty to anchor the tendon in muscle, the high mechanical constraint on the repair structure, or the unavailability of ideal tendon grafts (currently, tendon grafts are either auto, allo, or synthetic). It has been shown that early mobilization following tendon surgery gives superior results.^[3] The repaired tendon should then be able to support immediate loading. However, suturing techniques to joint split ends of tendons, while providing sufficient mechanical strength to limit gapping, are inadequate to carry normal loads.

Based on the shortcomings of the actual tendon surgery, tendon tissue engineering may offer an alternative approach. The objective in developing an engineered tendon will then be the reconstruction of the injured structure with structural and functional properties as good as the original. Moreover, an engineered tendon could reduce the rate of secondary problems by making the surgical procedure less extensive.

This article gives first some general details on anatomy and physiological properties of tendons, followed by a list of requirements for an ideal engineered

tendon. A review of the actual state of the art in tendon replacement is then performed, and finally, some remarks on the future of tissue engineering of tendons are proposed.

ANATOMICAL AND PHYSIOLOGICAL PROPERTIES OF TENDONS

Tendons are dense, regularly organized, and by their arranged collagen fibers, allow connection between muscles and bones. The structure is composed of long arranged collagen fibers, and the function and behavior of tendons depend on of their mechanical properties.

They are capable of resisting important strength in order to transmit the muscular power to the bones and articulations. They protect the muscle (fascia) and fix the length of the muscle belly. They also play a role of damper and shock absorber.

A tendon is composed of multiple fascicles surrounded by a fascicular membrane and septa. Inside the fascicle, we find a mix of fibroblasts in relative central position and fibrils. The fibrils are composed of microfibrils, which themselves are made of tropocollagen.

The fascicular membrane is the endotenon, which is draped over by a sliding structure, the peritendon. Between the peritendon and the endotenon run vessels, nerve, and lymphatics. Depending on the localization, the organization of the surrounding layers is more complex.

A hand flexor tendon is encircled by a well-defined sheath covered by synovial cells. In this situation, the external layer (paratenon) is called tenosynovium, but if there is no synovial lining, the paratenon is called tenovagium.

At the musculo-tendinous junction, the perimysium is continuous with the endotenon. At the other extremity on the tendon–bone interface, the collagen fibers and the endotenon become continuous with the periosteum.

The tendon insertion into bone is of two types. The first one described by Cooper and Misol,^[4] shows a transition from the tendon to a layer of fibrocartilage with digitations in the periosteum. The fibrocartilage is progressively ossified and merges with bone. The second one is more complex and is characterized by having the periosteum as an intermediate layer. Superficial fibrils are fixed into the periosteum and deeper, directly into bone.

Tendon is largely vascularized, the blood flow coming from the perymysium, periosteum attachment, and surrounding tissues. In particular, the perfusion through the surrounding tissue reaches the tendon penetrating the paratenon, the mesotenon, or vincula. We can separate vascularized from avascular tendons: vascularized tendons concern those with a rich surrounding vascularization, which penetrate directly inside the endotenon. The avascular tendons are contained in a sheath, and the vessels are penetrating through thin structure (mesotendon or vincula), which reticulate and bind the tendon.

The innervation plays a sensory role through mechanoreceptors located near the musculo-tendinous junction.

REQUIREMENTS FOR TISSUE ENGINEERING OF TENDON

Several requirements need to be fulfilled in the tissue engineering of tendons. Some are common to most engineered tissues used for applications in musculo-skeletal applications, but some are specific for the tissue engineering of tendons.

Common Requirements in Tissue Engineering

1. It is usually stated that an engineered tissue is composed of three elements: scaffold, cells, and growth factors. Tissue engineering is then, by definition, multi-disciplinary. In order to bring useful and adequate solutions, it is especially important that physicians, who will be the users of the developed engineered tissue, are involved at every step of the project development. For example, surgical procedures should be anticipated since the beginning of the project to insure that the developed tissue will be manageable in the constraint environment of a surgical room.
2. As a basic rule, the engineered tissue should be easy to use and its manipulation should be as close as possible to the actual standard surgical procedures.
3. The engineered tissue will need to be approved by governmental agencies (e.g., FDA) before being available on the market. Especially if cells and/or

growth factors are used, it is important to be aware of the tests required by these governmental agencies to obtain an approval for clinical use. This would avoid the repetition of experiments not following established standards.

Specific Requirements for Tendon Tissue Engineering

1. Tendon auto-grafts are freely available during surgery. Due to economical constraints on the health care system, it would be difficult to propose an expensive engineered tendon. The only economical factors, which may favor the use of an engineered tendon from the health insurance point of view, would be the reduction of the operative time and a faster patient recovery. Based on these economical considerations, the production and stock management of the engineered tendons should be considered from the beginning of the project.
2. Tendon biomechanics is complex due to its non-linear stress-strain relationship and viscoelasticity (Fig. 1).^[5,6] In-vivo forces quantification of tendons is also a useful approach for the determination of mechanical design parameters.^[7] An engineered tendon should be able to reproduce these mechanical behaviors. It should be noted that different tendons might present different mechanical properties as has been shown for fatigue damage.^[8]

Fig. 1 Experimental and theoretical stress-strain curves obtained at four different rates of elongation for one human patellar tendon specimen. Good correlation between experimental and theoretical curves are found. The proposed constitutive law with only three parameters is then able to fit nonlinear stress-strain curves obtained at different strain rates. (Reproduced with permission from Ref. [6].)

3. Fixation on bone and muscle may be the weakness mechanical part of the engineered tendon. It is then important to incorporate this point in the design of the tendon. For example, it has to be decided early in the project if the scaffold will be sutured or glued to the muscle. In case of high mechanical constraints (early loading), it would be more advisable to suture than to glue the tendon. However, the drawback of tendon suturing is the possibility of inducing a devascularization of the tendon and a corresponding necrosis of the tissue. It should be noted that if left untreated, some tendons might spontaneously heal, suggesting that the gluing process of tendon to muscle is a normal way of healing.
4. Tendon cells must communicate to sustain growth and matrix expression.^[9] It has been shown that cells in the epitenon and internal compartment of whole tendon are connected physically to each other and express gap junctions.^[10] Successful engineered tendon replacements must include designs that allow for cell-to-cell connectivity to allow intercellular communication. Scaffolds should then be easily seeded by cells and encourage cell division and matrix expression.^[9]
5. If tendon fibroblasts are used, it has to be noted that these cells are site-dependent and may induce different results regarding proliferation and/or gene expression.^[11,12] Autologous cells' transplantation has the advantage of not inducing immune reaction and is more easily implemented from a regulatory point of view. However, an initial biopsy followed by a cellular expansion period is necessary, rendering this approach time consuming. Disadvantages of autologous cells' transplantation disappear with allogous cells' transplantation, but the benefit of no immune reaction and easier regulatory implementation are, on the other hand, lost. A careful selection of the cells used, depending on the application, should then be performed.

ACTUAL APPROACHES FOR TISSUE ENGINEERING OF TENDON

In the term tissue engineering, we consider all the engineering and biological approaches used in the development of an artificial tendon. Different solutions proposed for treating tendon rupture are presented from the scaffold, cells, and growth factor/gene therapy points of view.

Scaffold

In order to bridge tendon lesions, synthetic scaffolds have been used with relatively modest success.^[13]

Synthetic tendon made of Dacron™, nylon, or even carbon fibers has been used. One of the only synthetic scaffolds remaining on the market is the Leeds-Keio ligament made of polyethylene terephthalate (PET). Recently, it has been shown that treatment with radiofrequency (RF)-generated glow discharge increased cell attachment and proliferation on this PET implant.^[14]

Organic polymers' matrix, such as acellular collagen, have also been employed as tendon graft.^[15] These scaffolds are supposed to provide early mechanical support and promote cellular infiltration. However, achilles tendon repairs using collagen scaffold achieved only 36% of normal maximum force.^[16] Naturally occurring extracellular matrices were also proposed for tendon repair. There are limited locations within the body that can be used as the source of these extracellular matrices. One is derived from porcine small intestinal submucosa.^[17] With this tissue used as tendon scaffold, a transient and significant weakening of mechanical properties was found compared to patellar tendon in the first months after implantation in an animal study. After 12 months, no difference was found. In order to increase the mechanical properties of the scaffold, collagen scaffold with poly-L-lactic acid was developed.^[18] Mechanical properties were increased with this method. Probably one of the most promising scaffold developments from biomechanical and biocompatible points of view would be based on biomimetic strategy. In this approach, the scaffold should include polymeric collagen as the fundamental fibrous phase and being cross-linked to give the mechanical strength of the engineered tendon. To this end, derived from skate egg capsule, a collagen-based scaffold was developed.^[11] Fibers produced from pepsin-solubilized, bovine tendon type I collagen were polymerized with di-catechol nordihydroguaiaretic acid (NDGA). These NDGA cross-linked fibers showed high mechanical properties comparable to native tendon and demonstrated excellent biocompatibility properties.^[19]

Cells

As for other engineered tissues (e.g., bone, cartilage), incorporation of cells is supposed to increase the healing potential of the tissues. A combination of scaffold and cells is then developed, the scaffold playing either the role of cell delivery system alone or cell delivery system and mechanical support.

Use of autologous mesenchymal stem cells seeded in collagen gel *in vitro* and then implanted in the body has been proposed.^[20] The results indicated that delivering mesenchymal stem cell-contracted, organized collagen implants to large tendon defects could

significantly improve the biomechanics, structure, and probably the function of the tendon after injury.^[21] Mesenchymal stem cells, which have the potential to differentiate in (tendon) fibroblasts, hold the promise to be used for allogous cells' transplantation. However, if the cells are not oriented in the gel, only modest improved biomechanical properties are observed compared to natural repair of unfilled defect.^[22] The orientation of the cells in the gel, in particular due to the gel contraction mediated by cells, improved the biomechanical properties.^[23] Besides mesenchymal stem cells, it may be useful to use differentiated fibroblasts in order to speed up the healing process. Moreover, fibroblasts seeded on a scaffold and in vitro mechanically stimulated the mechanical properties of the graft.^[24] So, it has then been proposed that the delay between rupture and surgery may be used to engineer the tendon in vitro by applying mechanical stimulus. This approach may, however, be difficult to apply from an economical point of view. In order to amplify the potential of cells in the healing process, autologous mesenchymal stem cells might be genetically modified to produce growth factors useful in the healing process of tendon.^[25]

Growth Factor/Gene Therapy

Use of growth factors is related to a good understanding of the tendon healing process. This healing process could be viewed as four overlapping phases: hemorrhagic, inflammatory, proliferation, and remodeling/maturation. The second phase, inflammatory, is probably a key phase as many different growth factors and cytokines are produced and will drive the outcome process of healing. A detailed description of these phases may be found in Ref. [26]. It has been shown that treatment with growth factors such as PDGF and IGF-1 stimulate DNA synthesis of tendon fibroblasts.^[27] However, as for other tissues, issues such as the difficulty to deliver the growth factors or the supraphysiologic concentrations needed to induce an effect^[28] need to be solved. A potential solution might be the use of gene therapy. Genetically modified cells^[25,27] or gene-activated matrix^[29] might be used to target specific location (ruptured zone of the tendon) and specific biological process (healing of the tendon). This approach is still in its infancy, but promising results have already been obtained.

FUTURE DEVELOPMENT FOR TISSUE ENGINEERING OF TENDONS

As mentioned by Hildebrand,^[25] the regeneration of normal tendon has not been achieved and further refinements are necessary for these treatments. Indeed,

none of the actual solutions followed all the requirements noted earlier for tissue engineering of tendons. Especially, problems like fixations of tendons, incorporation of biomechanical properties, choice of scaffold with adequate degradation properties, or packaging of the engineered tendon^[20] still need to be solved. Nature used millions of evolution years to optimize the functionality of the tendons. It might then be worthy to use this knowledge in order to engineer tendons. The combination of biomimetism, as proposed by Koob^[11] to engineer tendon scaffold, and gene therapy, either with cells, e.g., Ref. [25], or with gene activated matrix^[29] to target specific healing tendon process, held probably the most promising development in tissue engineering of tendon.

CONCLUSION

Important progresses have been achieved recently in tissue engineering. Although no ideal solution exists for tissue engineering of tendons, it is reasonable to believe that good solutions will emerge from laboratories. In particular, the combination of biomimetism and gene therapy with mesenchymal stem cells opens new fields of possibilities from a scientific and clinical point of view. However, the development of tissue engineering of tendons can only be successful if the challenging economical constraints are satisfied. Based on the past industrial experiences in tissue engineering for bone or cartilage, it would be an illusion to believe that engineered tendon with cells may be entirely supported by private industries. It seems more reasonable to develop collaborations between industries and hospitals. The industries would be responsible for developing and managing the scaffolds, and the hospitals would be responsible for managing the cells' bank and seeding process of the scaffolds with the selected cells. With this kind of strategy, it is hoped that, in the future, surgeons will no more face the paradox of treating a ruptured tendon by collecting another tendon in the patient.

INTRODUCTION

Biomedical and dental applications of titanium and its alloys are constantly increasing because of their excellent biocompatibility, corrosion resistance, and balance of mechanical properties, being lightweight compared with the other metallic materials. Nowadays, functionalities like low rigidity, shape memory effect, super elasticity, bioactive modifications, etc. are getting much more attentions. Recent topics on representative titanium and its alloys for biomedical applications, low-rigidity biomedical titanium alloys, shape memory or superelastic biomedical titanium alloys, mechanical properties of biomedical titanium alloys, bioactive surface modification of biomedical titanium alloys, titanium alloys for dental applications, etc. are discussed in this entry.

BACKGROUND

Since the population percentage of aged people is rapidly growing, the number of aged persons demanding replacement of failed tissue with artificial instruments made of biomaterials is increasing. In particular, the use of instruments for replacing failed hard tissues such as artificial hip joints, dental implants, etc. is increasing among the aged people. Till recently, metallic biomaterials have been the most suitable for replacing failed hard tissue. The chief metallic biomaterials are stainless steels, cobalt (Co) based alloys, titanium (Ti) and its alloys. Recently, titanium alloys are getting much attention as biomaterials because they have excellent specific strength and corrosion resistance, no allergic problems, and the best biocompatibility among metallic biomaterials. Pure titanium and titanium–6 mass% aluminum (Al)–4 mass% vanadium

(V) (Ti–6Al–4V) (the numbers in the alloy name indicate mass% of the element) are still the most widely used for biomedical applications among the titanium alloys. They occupy almost all of the market for titanium biomaterials. However, these are basically developed as structural materials mainly for aerospace structures. Therefore, the development of titanium alloys targeted for biomedical applications is required. Therefore, research and development of titanium alloys composed of nontoxic elements has started, and is continuing to increase.^[1–3] The titanium (Ta) alloys composed of nontoxic elements that were developed in the early stage are mainly $\alpha + \beta$ types, whose constituents are a α phase with hexagonal close-packed (hcp) structure and β phase with body-centered cubic (bcc) structure. Nowadays, the mechanical biocompatibility of biomaterials is regarded as an important factor, and therefore the research and development of β -type titanium alloys whose constituent is metastable β phase with bcc structure at room temperature is increasing because they are advantageous in that respect.^[1,4,5]

Very recently, the possibility of the development of new titanium alloys for biomedical applications, which show superelasticity, is growing, and the research and development of shape memory titanium alloys composed of nontoxic elements for biomedical applications is also attracting attention.^[6–11] The superelastic or shape memory characteristics are expected to facilitate new applications of metallic materials not only in the medical field but also for general purposes. The superelastic characteristic of some titanium alloys appears to be difficult to understand through conventional mechanisms, and therefore they are also very interesting from the point of view of material science.^[12,13]

The research and development of bioactive surface modifications for improving the biocompatibility of titanium alloys is also increasingly being done because

the titanium alloys are grouped into bioinert materials from the point of view of patterns of osteogenesis.^[14-16]

Furthermore, the direct or indirect evaluation of biocompatibility using animals or cells, and evaluations of mechanical performance such as fatigue, fretting fatigue, fracture toughness, etc. are also frequently being done.^[17-22]

Both newly developed alloys and mold materials are used in the dental applications of titanium alloys for making dental prostheses.

REPRESENTATIVE TITANIUM AND ITS ALLOYS FOR BIOMEDICAL APPLICATIONS

Biocompatible titanium alloys that have so far been introduced are listed in Table 1.^[23,24] This table includes both those alloys that are already licensed and implemented for use in living bodies and those at the

research and development stage, which are neither licensed nor implemented.

Pure titanium and $\alpha + \beta$ -type titanium alloys, including the Ti-6Al-4V extra-low interstitials (ELI) and

Fig. 1 Tensile loaded-unloaded stress-strain curve of Ti-30Nb-10Ta-5Zr.

Ti-6Al-4V, were originally designed for use as general structural materials, especially for aerospace structures, and were only later adopted for biomedical applications. Then, the toxicity of the β -stabilizing element of V was reported.^[25,26] Therefore, V in Ti-6Al-4V was replaced by another β -stabilizing element, iron (Fe) or niobium (Nb), which are considered to be safer for the living body as compared to V. Ti-5Al-2.5Fe and Ti-6Al-7Nb, which are also $\alpha + \beta$ -type titanium alloys, were introduced.^[27,28] Ti-5Al-2.5Fe has been registered only in ISO standardization, while Ti-6Al-7Nb has been registered in ASTM, ISO, and JIS standardizations.^[29-32] Therefore, it can be said that the development of titanium alloys especially intended for use in living bodies began with the introduction of these alloys. Based on the same concept, other $\alpha + \beta$ -type biomedical titanium alloys like Ti-6Al-6Nb-1Ta and Ti-6Al-2Nb-1Ta have been developed.^[33] The latter is supposed to have been developed mainly as a structural titanium alloy for military use. Subsequently, $\alpha + \beta$ -type titanium alloys that do not contain V or Al, such as the Ti-15zirconium (Zr) based alloys, were introduced.^[34]

The elastic moduli of biomaterials are required to be equal to that of cortical bone because if the elastic moduli of biomaterials are much greater than that of cortical bone, bone resorption occurs. The elastic modulus of the $\alpha + \beta$ -type titanium alloy Ti-6Al-4V, which is around 110 Gpa, is much lower than those of stainless steel and Co based alloys, which are around 1800 and 2100 GPa, respectively.^[35] The elastic modulus of Ti-6Al-4V is still much greater than that of cortical bone, which is around 20 GPa. The elastic

moduli of β -type titanium alloys are known to be smaller than those of α - or $\alpha + \beta$ -type titanium alloys. Therefore, thereafter, mainly β -type titanium alloys were introduced, and most of them aimed at a low modulus of elasticity.^[1,31-40] Of the β -type titanium alloys for biomedical application, Ti-13Nb-13Zr, Ti-12molibdenum (Mo)-6Zr-2Fe, and Ti-15Mo have been registered, and Ti-35Nb-7Zr-5Ta is expected to be registered in the ASTM standardization.^[36-38,40] Previously, β -type titanium alloys with low modulus were mainly developed in the United States, but in recent years they have also been developed in Japan.^[41] The Ti-Nb-Ta-Zr system alloys can be judged as the safest for biomedical applications because Nb, Ta, and Zr are nontoxic and nonallergic alloying elements. Ti-29Nb-13Ta-4.6Zr (TNTZ) has been designed using the d-electron design method based on the DV- X_α cluster theory and was developed at almost the same time when Ti-35Nb-7Zr-5Ta was developed.^[1]

Recently introduced biocompatible titanium alloys contain a large amount of Ta and Nb. These have a melting point and a specific gravity much higher than that of titanium, and have substantially different specific gravities, so the development of melting and casting process technology to obtain high-integrity ingots involved no casting segregation.^[42,43] Levitation melting or cold crucible levitation melting is advantageous to fabricate homogenous ingots that contain a large amount of Nb and Ta.

As low-modulus β -type titanium alloys for biomedical applications, the Ti-Fe-Ta, Ti-Zr-Nb-Ta, Ti-Ta, and Ti-hafnium (Hf) system alloys are also being developed in Japan.^[44-48]

Fig. 2 Contact microradiographs of boundaries of (A) TNTZ, (B) Ti-6Al-4V ELI, and (C) SUS 316 L stainless steel and bones at 8 weeks after implantation.

NICKEL-FREE FUNCTIONAL TITANIUM ALLOYS

Nickel (Ni)-free β -type titanium alloys having not only low modulus but also functions like shape memory effect and/or superelasticity are also being developed or investigated because Ni has been reported to be a strong allergic element, although Ti-Ni shape memory alloys for biomedical and dental applications are still being actively investigated, in particular for stent, catheter, or orthodontic wire applications, and Ti-Ni is the only shape memory alloy that has practical application.^[49-52] The Ti-Nb-tin (Sn), Ti-Mo-gallium (Ga), Ti-Nb-Al, Ti-Mo-Al, Ti-Ta, Ti-Nb, Ti-scandium (Sc)-Mo, Ti-Mo-silver (Ag), Ti-Mo-Sn, and Ti-Nb-Ta-Zr system alloys are being developed as Ni-free shape memory alloys.^[53-61] Among these alloys, around 6% elastic strain has been reported to be obtained in one of the Ti-Nb-Al system alloys by controlling the texture.^[62]

Ti-29Nb-13Ta-4.6Zr also shows superelastic behavior, although shape memory effect is not observed in this alloy.^[63] Fig. 1 shows the tensile loading-unloading curve of Ti-30Nb-10Ta-5Zr powdered metal alloy, which has the simplified chemical composition of TNTZ.^[61] In the elastic region, the tensile loading-unloading stress-strain curve does not follow Hook's

law, showing nonlinear behavior. The features of stress or strain induced martensite transformation are not reflected in the stress-strain curve as shown in Fig. 1, and also in the deformed microstructure. The behavior of this alloy cannot be explained by the increase in the deformation induced martensite transformation and its reversion. In this case, maximum elastic strain is around 3%.

BIOCOMPATIBILITY OF LOW-RIGIDITY TITANIUM ALLOYS COMPOSED OF NONTOXIC AND NONALLERGIC ELEMENTS

Cytotoxicity

The cytotoxicity of low-rigidity Ti-29Nb-12Ta-4.6Zr, pure Ti, and Ti-6Al-4V has been evaluated by neutral red (NR) and 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyl tetrazolium bromide (MTT) methods.^[64] Regardless of the evaluation method used, the cell viability of TNTZ is nearly the same as that of pure Ti and greater than that of conventional biomedical Ti-6Al-4V in both as-extracted and filtrated extracted solutions. Therefore, the biocompatibility of TNTZ is judged to be excellent.

Fig. 3 Healing process of bone fracture from 0 to 22 weeks after surgery using (A) TNTZ, (B) Ti-6Al-4V ELI, and (C) SUS 316 L stainless steel.

Fig. 4 Remodeling at 24 weeks after implantation for (A) TNTZ, (B) Ti-6Al-4V ELI, and (C) SUS 316 L stainless steel.

The trend of cell viability among TNTZ, pure Ti, and Ti-6Al-4V is nearly the same regardless of extracted period, although the cell viability of both as-extracted and filtrated extracted solutions decreases with increase in the extracted period. However, since the cell viability of filtrated extracted solution is greater than that of as-extracted solution in both NR and MTT methods, not only dissolved metallic ion but also fine wear debris affects the cytotoxicity. This suggests that it is necessary to suppress the process of wear as much as possible when metallic materials are used as biomaterials.

Compatibility with Bone and Remodeling

The contact microradiographs (CMR) of the boundaries of bone and low-rigidity TNTZ (in this case, as-solutionized conditions), Ti-6Al-4V ELI, or SUS (steel use stainless steel) 316 L stainless steel (Fe-18Cr-12Ni-2.5Mo-low C) implanted into the lateral femoral condyles of a rabbit is shown in Fig. 2.^[41,65] Each specimen is surrounded by newly formed bone, and the bone tissue shows direct contact partially with the specimen. However, the extent of the direct contact is greater in TNTZ as compared with Ti-6Al-4V and SUS 316 L stainless steel. Therefore, the biocompatibility of TNTZ with bone is excellent.

To confirm the advantage of low rigidity for bone healing and remodeling, using rabbits, tibial fracture

was induced experimentally in tibia by an oscillating saw just below the tibial tuberosity. An intramedullary rod made of low-rigidity TNTZ, Ti-6Al-4V ELI, or SUS 316 L stainless steel was inserted into the intramedullary canal to fix the fracture. Bone healing, remodeling, and atrophy were observed by x-ray transmission image every 2 weeks for up to 22 weeks. The results are shown in Fig. 3.^[41,65]

The outline of fracture callus was very smooth with bone remodeling in TNTZ. A similar phenomenon was observed at 8 weeks in Ti-6Al-4V ELI and SUS 316 L. In TNTZ, the fracture callus was relatively small, and gradually decreased in size from 6 weeks, and there were no traces of fracture at 10 weeks after the fixation. After 10 weeks, no changes could be observed up to 18 weeks. However, a little atrophic change was observed at the posterior tibial bone after 20 weeks. In Ti-6Al-4V ELI, the callus formation and the bone remodeling were almost similar to that in TNTZ, but slower. A slight atrophic change was observed at 18 weeks. In SUS 316 L stainless steel, a large amount of the fracture callus was observed, and remained up to the end of the succeeding period. Bone atrophy seemed to be occurring at the posterior proximal tibial bone at 10 weeks, and became apparent every 2 weeks. The posterior tibial bone became very thin at 24 weeks, as shown in Fig. 4.^[41,66] Therefore, the low-rigidity titanium alloy, TNTZ, was found to resolve the load transmission problem of the current metal implants with the high rigidity.

Fig. 5 *S-N* curves of TNTZ conducted with aging at 598 K for 259.2 ksec after ST (A_{598K}), aging at 673 K for 259.2 ksec after ST (A_{673K}), aging at 673 K for 259.2 ksec after CR (B_{673K}), and aging at 723 K for 259.2 ksec after CR (B_{723K}), and fatigue limit ranges of hot rolled and cast Ti-6Al-4V ELI and Ti-6Al-7Nb. CR indicates cold rolling.

MECHANICAL PROPERTIES: FATIGUE, FRETTING FATIGUE, AND WEAR CHARACTERISTICS

Fatigue and Fretting Fatigue Characteristics

The evaluation and improvement of mechanical performance, in particular plain and fretting fatigue, and wear characteristics, including surface treatment for increasing wear resistance of titanium alloys, are done in air and simulated body liquid.^[67-73] Heat treatment and thermomechanical treatment are applied to improve the mechanical properties and fatigue strength, which is important for the safe use of the implants for a long period.^[74]

In the case of β -type titanium alloys for biomedical applications, since the fatigue strength in as-solutionized conditions is low, heat treatment or thermomechanical treatment is effective to improve the fatigue strength drastically. Fig. 5 shows *S-N* (stress-number of cycles to failure) curves of TNTZ used with various thermomechanical treatments with fatigue limit ranges

Fig. 6 *S-N* curves of Ti-6Al-4V alloy in air and PBS (-) (F, fatigue; FF, fretting fatigue).

Fig. 7 S - N curves of TNTZ and Ti-15Mo-5Zr-3Al (Ti-15-3-3) conducted with each heat treatment obtained from plain fatigue and fretting fatigue tests in air. ST and STA indicate solution treatment and solution treatment followed by aging, respectively.

of hot rolled and cast Ti-6Al-4V ELI and Ti-6Al-7Nb.^[74] For example, the fatigue strength of TNTZ conducted with aging at 723 K for 259.2 ksec after cold rolling (CR), indicated by B_{723K} , is very high in the highest range of the fatigue limit of Ti-6Al-4V ELI, although the elastic modulus is a little higher, around 80 GPa, than that of as-solutionized TNTZ, which is around 60 GPa.^[74]

The fatigue strength of titanium alloys for biomedical applications is, in general, not degraded in both simulated body environment and living body environment, as in rabbit.^[75] However, the fatigue strength of Ti-6Al-4V ELI under the rotating bending condition was reported to be degraded in Ringer's solution, which is degassed by nitrogen (N_2) bubbling

to reduce the oxygen content because the oxygen content in living body liquid is very low.^[73]

When fatigue stress and fretting occur simultaneously, fatigue strength is greatly reduced, by approximately one-third to one-half. This is called fretting fatigue, which may occur, for example, between bone plate and screw. The fatigue lives of pure titanium grades 2 (N (max): 0.03, carbon (C) (max): 0.08, H (max): 0.015, Fe (max): 0.25, Ti: balance, mass%) and 3 (N (max): 0.05, C (max): 0.08, H (max): 0.015, Fe (max): 0.30, O (max): 0.35, Ti: balance, mass%) have been reported to be smaller in simulated body fluid [SBF (-)] than in air, while the fretting fatigue lives have been reported to be smaller than the fatigue lives by 20–30 %, and smaller in Ca^{2+} - and

Fig. 8 S - N curves of TNTZ conducted with solution treatment obtained from plain fatigue and fretting fatigue tests in air and Ringer's solution.

Fig. 9 Weight loss of (A) TNTZ and (B) Ti-6Al-4V ELI oxidized at 773 and 1073 K for various times after solutionizing in friction wear tests in Ringer's solution.

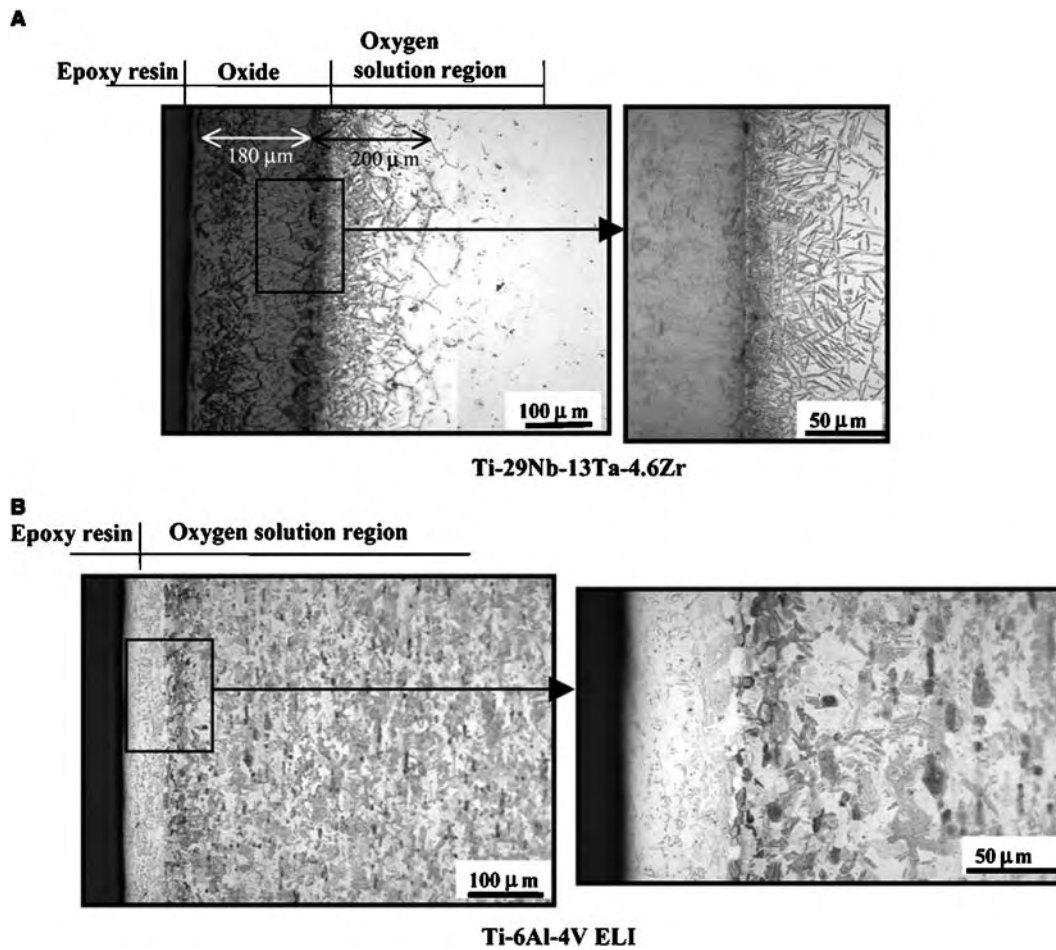

Fig. 10 Optical micrographs showing cross sections of as-solutionized (A) TNTZ and (B) Ti-6Al-4V ELI oxidized at 1073 K for 86.4 ksec.

T

Mg^{2+} -free phosphate buffered solution [PBS(-)] than in air. The fretting fatigue strength of $\alpha + \beta$ -type Ti-6Al-4V in SBF(-) is smaller in both lower- and higher-cycle fretting fatigue life regions, but greater in the intermediate-cycle fatigue life region, while fatigue strength of Ti-6Al-4V is not degraded in SBF(-), as shown in Fig. 6.^[77] $S-N$ curves obtained from fatigue and fretting fatigue tests on β -type TNTZ in as-solutionized and aged conditions, and on $\alpha + \beta$ -type Ti-15Mo-5Zr-3Al in annealed conditions in air are shown in Fig. 7.^[78] Their fretting fatigue limits are around one-third of the fatigue limits. The fatigue limit of Ti-15Mo-5Zr-3Al (TI-15-5-3) is 780 MPa and is the greatest. The second greatest fatigue limit is obtained for aged TNTZ. The as-solutionized TNTZ shows the lowest fatigue limit. Fretting fatigue limit of each material is much lower than the fatigue limit of each material. The fretting fatigue limit of as-solutionized TNTZ is about 190 MPa, which is lower than its fatigue limit by 42%, that is, 140 MPa. The difference in fretting fatigue strength between as-solutionized TNTZ and Ti-15Mo-5Zr-3Al at around 2×10^4 is about 200 MPa, but it is only 20 MPa around the fretting fatigue limit. The fretting fatigue limit of Ti-15Mo-5Zr-3Al is lower than that of aged TNTZ by around 75 MPa. Therefore, the correlation between fatigue strength and fretting fatigue strength is low when comparing fretting fatigue among different kinds

of materials. $S-N$ curves obtained from fretting fatigue tests of as-solutionized TNTZ in air and Ringer's solution are shown in Fig. 8.^[78] The fatigue strength of as-solutionized TNTZ in Ringer's solution is equal to that in air. Therefore, the fatigue strength of as-solutionized TNTZ is not degraded in Ringer's solution. On the other hand, the fretting fatigue strength of as-solutionized TNTZ is slightly greater than that in air in the low-cycle fretting fatigue life region, but a little lower than that in air in the high-cycle fretting fatigue life region. The frictional force in Ringer's solution has been reported to be lower than that in air over the entire maximum cyclic stress and is reported to be about one-third of the frictional force in air at relatively greater maximum cyclic stress.^[78] Therefore, Ringer's solution acts as a lubricant at the fretting area and lowers the frictional force. It is reported that corrosion pits are observed on the whole contact area.^[78] The fretting fatigue crack does not initiate from the pits, but from the edge of the pad. In the high-cycle fretting fatigue life region, pits were not observed on the stick area, but they were observed on the slip area. The fretting fatigue crack initiated from the pit. Therefore, the effect of Ringer's solution as a lubricant is relatively greater in the low-cycle fretting fatigue region, which leads to increase in the fretting fatigue life of as-solutionized TNTZ. However, in the high-cycle fretting fatigue life region, the effect of Ringer's solution as a corrosive agent is relatively greater, which leads to decrease in the fretting fatigue life of as-solutionized TNTZ.

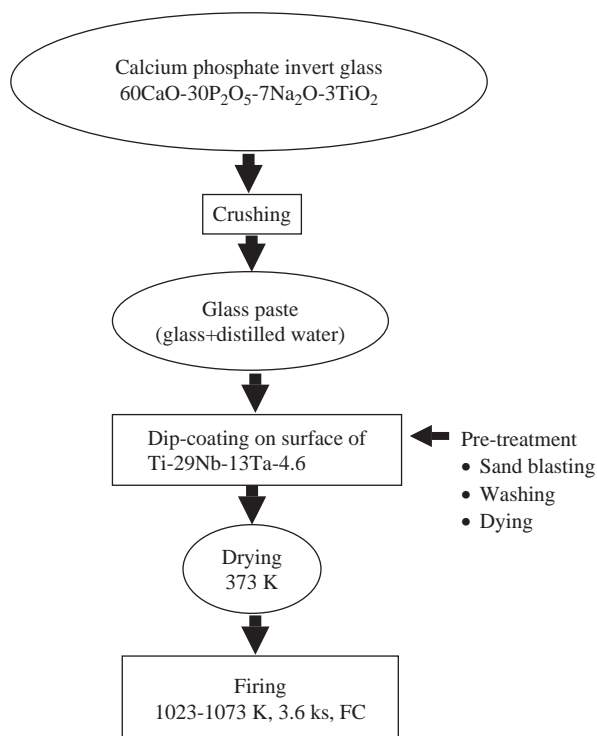

Fig. 11 Schematic drawing of coating process of CaP glass ceramic on surface of TNTZ.

Wear Characteristics

Since the wear resistance of titanium alloys is inferior to that of other metallic biomaterials such as stainless steel or Co-chromium (Cr) alloy, surface modification by oxidation, nitriding, diamond-like carbon coating,

Fig. 12 X-ray diffraction profile of surface of Ti-29Nb-13Ta-4.6Zr coated with calcium phosphate invert glass followed by firing at 1073 K for 1 h; ○: TCP, ●: CPP, ▲: β -Ti; ★: unknown phase.

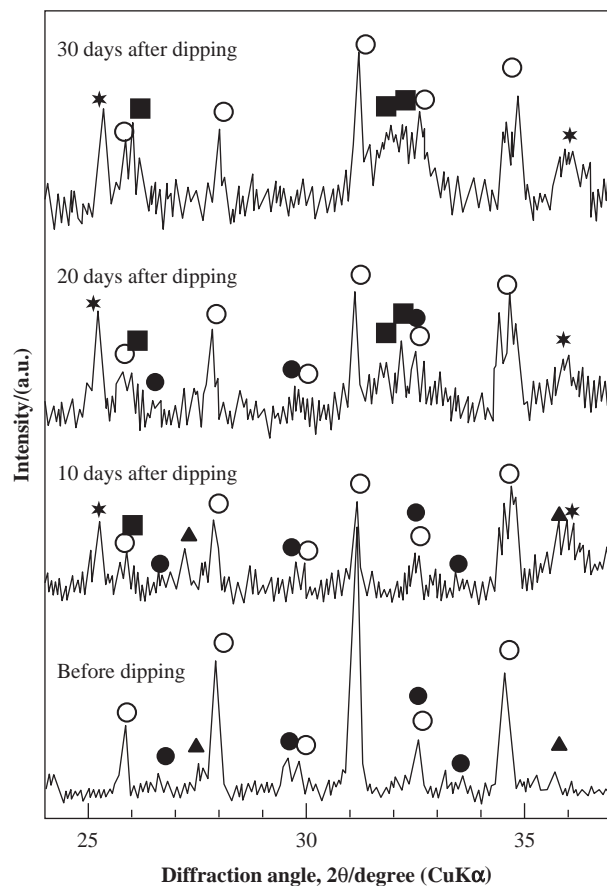

Fig. 13 X-ray diffraction profiles of surfaces of calcium phosphate glass-ceramic-coated Ti-29Nb-13Ta-4.6Zr before and after dipping into simulated body fluid, SBF, for 29Nb-13Ta-4.6Zr for 10, 20, and 30 days; ■:HAP; ○:TCP; ●:CPP; ▲:TiO₂, ★:unknown phase.

and use of a laser beam has been investigated to improve the wear resistance of titanium.^[73,79–81]

The oxidation process in air is the one of the easiest processes for improving the wear resistance of titanium

alloys for biomedical applications. Weight losses of TNTZ and Ti-6Al-4V ELI oxidized at 773 and 1073 K for various times after solutionizing in friction wear tests in Ringer's solution are shown in Fig. 9.^[79] For an oxidation treatment temperature of 773 K, weight loss of TNTZ decreases with increasing treatment time. However, weight loss of Ti-6Al-4V ELI increases in this case. For an oxidation treatment temperature of 1073 K, weight loss decreases in both TNTZ and Ti-6Al-4V ELI with increasing treatment time. It has been reported that in oxidized TNTZ, the phase precipitated below the oxide layer on the specimen surface is the main factor for improving the wear resistance of TNTZ, as shown in Fig. 10.

BIOACTIVE SURFACE MODIFICATION

Titanium alloys show the greatest biocompatibility among metallic materials for biomedical applications. However, they are grouped into bioinert materials as well as ceramics like alumina, zirconia, etc., on the basis of the pattern of osteogenesis, as already stated before, and their biocompatibility is inferior to that of calcium phosphate (CaP) or hydroxyapatite [HAP: Ca(PO₄)₃OH], which is grouped into bioactive materials. Therefore, bioactive surface treatment (bioactive surface modification) is in general applied to titanium alloys for biomedical applications to improve their biocompatibility further. In that case, CaP-type ceramics such as CaP, TCP [β-Ca₃(PO₄)₂], CCP (β-Ca₂P₂O₇), etc. and HAP are mainly coated on the surface of the titanium alloy. In general, the formation of HAP is finally targeted.

The bioactive surface treatment processes are in general divided into dry processes and wet processes. There are various dry and wet processes.^[14]

Dry processes are divided into direct HAP forming methods and indirect HAP forming methods. The

Fig. 14 Scanning electron micrographs of the (A) untreated and (B) autoclaved glass-ceramic-coated TNTZ surfaces after 10 days of soaking in SBF.

Fig. 15 Contact microradiographs of (A, C) TNTZ and (B, D) glass-ceramic-coated Ti-29Nb-13Ta-4.6Zr after implantation in the femurs of Japanese rabbits: (A, B) 4 weeks of implantation and (C, D) 1 year of implantation. Diameter of the samples is 5 mm.

former include plasma spray method, ion plating, RF magnetron sputtering, pulse laser deposition method, ion beam dynamic mixing method, superplastic joining method, etc., where HAP is formed directly on the titanium alloy surface.^[82-87] The latter include calcium ion implantation, where calcium ions are implanted into biomedical titanium alloys, calcium ion mixing method, where Ca is sputtered on the surface of biomedical titanium alloys followed by Ar ion implantation, etc.^[14,88] Calcium phosphate precipitation is enhanced on the surface of biomedical titanium alloys with these treatments when they are implanted into the living body.

Wet processes are also divided into direct HAP forming methods and indirect HAP forming methods. An example of the former is electrochemical treatment.^[89] An example of the latter is alkali treatment,

where the biomedical titanium alloy is immersed into NaOH solution and heated followed by immersing the alloy into living body liquid.^[90]

There is another interesting method where the powder of CaP invert glass mixed with distilled water is coated on the surface of the titanium alloy followed by heating at around 1073 K, and then CaP-type ceramics are precipitated (Fig. 11).^[15,91] Fig. 12 shows the x ray profiles of the surface of TNTZ obtained by this method. Bioactive β -TCP and β -CCP are formed by heating glass-coated TNTZ at 1073 K for 3.6 ksec. Furthermore, HAP is formed by immersing it in SBF, as shown in Fig. 13.^[91] This process is more advantageous for the oxidation resistant titanium alloys containing a large amount of Nb and Ta, such as TNTZ. The apatite formation by soaking in SBF is

Fig. 16 Cross-sectional scanning electron micrographs of (A) TNTZ and (B) the glass-ceramic-coated TNTZ after 1 year of implantation.

Fig. 17 Schematic drawing of cross section of duplex-coated calcia mold.

enhanced by autoclaving at between 393 and 413 K for 1 hr after heating. Fig. 14 shows scanning electron micrographs of the autoclaved and untreated glass-ceramic-coated TNTZ after 10 days of soaking in SBF.^[92] The micrographs show that apatite formation in SBF occurs on the coating surfaces. The autoclaved glass-ceramic-coated TNTZ is completely covered with apatite, while the untreated one is not completely covered and the original glass-ceramic surface is also seen in some areas.

Fig. 15 shows CMR of TNTZ and the autoclaved glass-ceramic-coated TNTZ after implantation into the femurs of Japanese rabbits. The photographs show new bone formation around TNTZ and the autoclaved glass-ceramic-coated TNTZ after 4 weeks of implantation; the bone tissue shows direct contact partially with implants. After 1 year of implantation, the direct contact of bone tissue with TNTZ and the autoclaved glass-ceramic-coated TNTZ can be seen in many areas.

Fig. 16 shows cross-sectional scanning electron micrographs after 1 year of implantation.^[92] Crack propagation occurs between TNTZ and bone, while no crack occurs between the glass-ceramic coating and bone. The glass-ceramic coating bonds directly with bone.

Fig. 18 Photograph of specimen of TNTZ cast using wax pattern formed with duplex coating of fine pure calcia and crushed silica fiber reinforced fine calcia.

DENTAL APPLICATIONS

$\alpha + \beta$ -type titanium alloys like Ti-15Zr-4Nb-4Ta are also still being actively investigated.^[93] Dental casting of Ti-15Zr-4Nb-4Ta is also being investigated, as well as the β -type titanium alloys as stated above.^[94] Recently, the use of Ti-6Al-7Nb instead of Ti-6Al-4V has been increasing in dental applications.^[95]

The precision casting process is predominant for making dental prostheses like crowns, dentures, inlays, etc. In cast titanium alloys, especially the elongation is very low although the strength is kept high. Therefore, methods for increasing elongation without reducing strength are being investigated. Hydrogenation and dehydrogenation processing, that is, thermochemical processing followed by post-heat treatment treatments like α - β solution treatment, β solution treatment, broken-up structure, etc. are effective for improving elongation without reducing strength in cast titanium alloys.^[96,97]

Titanium alloys are very reactive and have a relatively higher melting point compared with other dental alloys like gold (Au) based alloys and silver (Ag) based alloys. Especially, the recently proposed β -type titanium alloys have a very high melting point because they contain high melting point elements like Ta and Nb. Therefore, low melting point titanium alloys and low reactive mold materials are desired for dental precision castings.

In dental precision casting, alumina based and magnesia based mold materials are mainly used.^[98] Magnesia based mold material is more suitable for dental precision casting of titanium alloys than alumina based mold materials.^[99] Calcia based mold material is also reported to be suitable for dental precision casting.^[100,101] However, calcia based mold material is said to be difficult to treat. To solve this problem, the duplex coating method has been developed. In this method, the first coating of wax pattern is done using pure fine calcia slurry, and the second coating of wax pattern is done using crushed silica fiber reinforced pure fine

Fig. 19 Vickers hardness of specimen of TNTZ cast using calcia mold (duplex calcia coating method) and general magnesia based mold as a function of distance from surface of specimen.

Fig. 20 Photograph of dental product, crown, made by duplex calcia coating method.

calcia slurry. The second coating is reinforced by crushed silica fiber to avoid penetration of the molten metal into the backup mold. The duplex coating mold is schematically explained in Fig. 17.^[102] The photograph of the specimen of TNTZ cast using wax pattern produced with a duplex coating of fine pure calica and crushed silica fiber reinforced fine calcia slurry is shown in Fig. 18.^[103] In this case, sandblasting treatment is not carried out. Even without sandblasting treatment, the surface condition of the specimen is very smooth without penetration. The hardness near the surface of TNTZ cast using calcia based mold is very low compared with that of TNTZ cast using magnesia based mold, as shown in Fig. 19.^[103] The photograph of the crown made of TNTZ cast using the calcia duplex coating method is shown in Fig. 20.^[103]

On the other hand, low melting point β -type titanium alloys for dental applications like Ti-29Nb-13Zr-2Cr, Ti-29Nb-15Zr-1.5Fe, Ti-29Nb-10Zr-0.5 silicon (Si), Ti-29Nb-10Zr-0.5Cr-0.5Fe, Ti-29Nb-18Zr-2Cr-0.5Si have been developed to lower the melting point of TNTZ using the DV- X_2 cluster method.^[1,104] Melting points of designed alloys fall by about 50–370 K as compared with that of TNTZ as shown in Fig. 21.^[104] Releasing of the specimen of each designed alloy from the mold that is made of commercial magnesia based investment materials is easier compared with the case of TNTZ as represented in Fig. 22, showing almost no adhesion of mold materials on the surface of the as-cast specimen surface of Ti-29Nb-13Zr-2Cr.^[104] The cytotoxicity of these newly developed alloys has been reported to be excellent.

Fig. 21 Cooling curves of various designed Ti alloys and TNTZ.

Fig. 22 Reproductions of as-cast tensile specimens of (A) Ti-29Nb-13Zr-2Cr and (B) TNTZ.

CONCLUSIONS

Titanium and titanium alloys are the most attractive metallic biomaterials. However, they are not bioactive. Therefore, bioactive ceramic, mainly HAP, surface modification is needed for achieving bonding with bone. Furthermore, to offer scaffolds for growing artificial organs, biomolecular modification of titanium and titanium alloys will be required. For solving this problem, integration of metallic, ceramic, and polymer materials is needed.

T

INTRODUCTION

Transdermal drug delivery is based on the absorption of drug into the skin after topical application. This route of drug administration has a long history dating back to the use of plasters and poultices and was most often used for drug delivery to local skin sites or directly underlying tissue. More recently, the potential of the transdermal route for systemic drug delivery has been recognized and exploited. Transdermal delivery offers many advantages over other modes of drug administration. In contrast to orally delivered drugs, compounds entering the body through the skin escape first-pass metabolism in the liver, often resulting in higher bioavailability. In addition, transdermal delivery can be used in nauseous patients, is little affected by intake of food, and can be easily interrupted. In contrast to intravenous drug delivery, transdermal administration is noninvasive and poses little risk of infection. It is also relatively easy for patients to apply and remove a transdermal system. Because transdermal drug delivery allows continuous delivery of drugs, frequent bolus dosing of drugs with short half lives is avoided. As a result, the side effects, or variability in therapeutic effect due to peaks and troughs in plasma concentration, that are seen with bolus administration are minimized.

Transdermal drug delivery, however, involves the inherent challenge of overcoming the skin barrier. Skin protects the body from the environment very effectively and generally is only permeable to small, lipophilic drugs. Transdermal delivery systems, therefore, not only have to provide drug to the skin under stable conditions and in a format convenient to the patient, but also serve to locally increase the permeability of skin to larger, charged, or hydrophilic drug molecules while minimizing irritation.

Several different strategies have been explored to increase permeability of the skin. Permeability can be modified by chemical additives, use of an electric

field to drive charged molecule across the skin, or mechanical creation of microscopic transport channels through the skin. In this article, we will briefly describe the theory underlying each of these transdermal delivery strategies, the specific demands placed on system components and materials, and some of the applications for each type of system. In addition, we will summarize current knowledge on how to prevent or mitigate irritant skin response to transdermal drug delivery. This review focuses on systems that are either already marketed or in late stages of development. Electroporation and sonophoresis, which rely on the application of a pulsed electric field or pretreatment with ultrasound, respectively, to create transient transport pathways through the skin, are still in early developmental stages and will not be covered here.

BASICS OF SKIN STRUCTURE AND FUNCTION

The primary function of the skin is to protect the body from the environment. The highly specialized outermost layer of the skin, the stratum corneum, forms a physical barrier that prevents loss of water and other vital substances from the body and entry of foreign substances or microorganisms into the body. In addition, antigen-presenting Langerhans cells in the epidermis and dendritic cells in the dermis serve to alert the immune system to any invading microorganisms, creating a second line of defense.

Skin is composed of two fundamentally different layers, the inner dermis and the outer epidermis, which are connected through the basal lamina (Fig. 1). The dermis, which gives the skin its mechanical strength, is a largely acellular structure consisting of interwoven collagen fibers and glycoprotein filaments embedded in amorphous connective tissue. Capillaries in the dermis provide a vascular surface of approximately 1 to 2 cm²

Fig. 1 Cross section of human skin (Masson trichrome staining).

per cm^2 of skin surface for exchange of substances between blood and skin.

In contrast to the dermis, the epidermis is completely avascular and entirely composed of cells. Eighty percent of the cells in the epidermis are derived from keratinocytes, which owe their name to an intracellular abundance of keratin. This filamentous protein forms a cytoskeleton that extends into a supracellular network between keratinocytes through specialized points of cell-cell adhesion (desmosomes). Keratinocytes are continuously generated by the innermost layer of the epidermis, the basal layer or stratum germinativum. As they move to the outside, they differentiate in stages that define the various strata of the epidermis. The entire epidermis renews itself, on average, every 14 days.

From the basal layer, the keratinocytes move into the stratum spinosum, where cellular organelles (lamellar granules) filled with lipids appear in the flattening cells. These granules extrude their lipid contents into the intercellular space in the next layer, the stratum granulosum. Keratinocytes reach their terminally differentiated state as corneocytes in the stratum corneum, the outermost epidermal layer. Corneocytes are devoid of all organelles and filled instead with keratin filaments enmeshed in a protein matrix. A thick band of protein is deposited on the inner surface of the plasma membrane to create the cornified cell envelope, a highly insoluble and chemically resistant barrier, and the plasma membrane is subsequently replaced by a monolayer of ω -hydroxyceramides. The flattened corneocytes are arranged into 15 to 25 cell layers in a regular, interdigitated pattern. Surrounding the cells is a lipid matrix of unusual composition; phospholipids

are virtually absent, and primarily neutral lipids form multiple stacked bilayers reminiscent of membranes. The ω -hydroxyceramide coating of the corneocytes is believed to anchor the cell bricks in this lipid mortar. Together, the corneocytes and the lipid matrix of the stratum corneum create a formidable barrier, which is only disrupted by skin appendages such as hair follicles and sebaceous and sweat glands. These appendages, however, typically cover less than 1% of the surface area and are believed to serve as a route of entry only under special circumstances, e.g., during iontophoresis.

PASSIVE TRANSDERMAL TRANSPORT WITH OR WITHOUT CHEMICAL MODIFICATION

Fundamentals of Passive Transport

Transport of a permeant through the skin is a diffusive process driven by a chemical potential gradient. It can be described by Fick's law, which states that flux of a permeant occurs down its concentration gradient and is proportional to the change of concentration over the transport distance. Flux through a given medium depends on the specific properties of both the medium and the permeant, as measured by the diffusion coefficient. Under steady-state conditions, the relationships described by Fick's laws of diffusion can be used to determine the flux of a drug through the skin, the effective transport distance, or the apparent diffusion coefficient, which expresses the combined contributions of various microscopic diffusion processes.^[1]

The skin's stratum corneum (SC) forms the main obstacle for transdermal permeation. Passive transport

is believed to occur primarily through the SC's intercellular lipid matrix, and the ability of a molecular species to cross the SC depends on both solubility and diffusivity of the permeant in the SC. One principal determinant of diffusivity is molecular volume, which can be estimated from molecular weight;^[2] molecular shape and conformational flexibility also play a role. Solubility of a permeant in the SC depends on its heat of fusion (ΔH_f) and its melting point (T_f), which are measures of the crystal lattice energy of a permeant in its solid state, and the heat of mixing, which can be calculated from the solubility parameters of the permeant and the SC lipids. This relationship is shown in Eq. 1, where x_2 is the mole fraction solubility of the permeant in the solvent (SC lipid), V_2 is the molar volume of the permeant, Φ_1 is the volume fraction of the solvent in the saturated solution, and δ_1 and δ_2 are the solubility parameters of the solvent and solute, respectively:^[3]

$$\ln x_2 = \frac{\Delta H_f}{RT} \left(\frac{T_f - T}{T_f} \right) - \frac{V_2 \phi_1^2}{RT} (\delta_1 - \delta_2)^2 \quad (1)$$

The solubility parameters are the square root of the cohesive energy densities and can be estimated by group contribution methods.^[4] Permeants such as nicotine that combine miscibility with lipid and water, low heat of fusion, and small molecular size are expected to penetrate the SC efficiently.

Permeability of the SC also depends on a number of environmental factors. Increases in the hydration state of the SC due to skin site occlusion or increases in temperature lead to greater fluidity of the SC, resulting in enhanced permeability for some compounds. Chemicals such as anionic surfactants or sulfoxide compounds can also increase the fluidity of the SC by disrupting inter- or intracellular structures. In-vitro and in-vivo methods for measuring skin permeability have been reviewed in detail by Shaw and colleagues.^[5]

System Structure and Function

The basic function of a transdermal drug delivery system is to place drug in contact with the skin under occlusive conditions. A chemical enhancer may be added to the system to raise solubility of the drug in the SC or to increase the SC's fluidity and, consequently, the drug's diffusivity. Most transdermal drug systems are multilayered assemblies minimally composed of a backing layer, a drug-in-adhesive matrix, and a peelable liner (Fig. 2A). More complex transdermal designs include additional layers such as a separate drug reservoir or a rate-controlling membrane (Fig. 2B). The amount of drug released is proportional to the area of drug-containing parts in

Fig. 2 Schematic diagram of two transdermal drug delivery system designs: (A) matrix and (B) membrane-controlled.

contact with the skin. In matrix systems, the rate of transdermal drug absorption depends directly on the skin/adhesive partition coefficient and the diffusion coefficient for drug in the skin and is therefore affected by inter- or intraindividual differences in skin permeability. In membrane-controlled systems, drug must pass through a rate-controlling membrane inserted between the drug reservoir and the adhesive before it contacts the skin. Diffusion of drug through the membrane restricts the rate of transdermal drug absorption in individuals or at body sites with higher skin permeability, thus limiting inter- and intraindividual variability in absorption.

System Components

Development of transdermal systems is a multidisciplinary effort requiring pharmaceutical, dermatological, physical, chemical, and materials science expertise. All system components of transdermal systems must be compatible with the skin, causing little or no irritation and sensitization, and are routinely tested for their topical irritation potential in animal models. In addition, the design of transdermal systems requires careful consideration of the solubility limits, partition and diffusion coefficients, and chemical stability of all system components to achieve desired drug delivery rates and ensure system stability.

T

Backing Materials

Backing materials must be flexible while possessing good tensile strength. Commonly used materials are polyolefins, polyesters, and elastomers in clear, pigmented, or metallized form. Elastomeric materials such as low-density polyethylene conform more readily to skin movement and provide better adhesion than less compliant materials such as polyester. Backing materials should also have low water vapor transmission rates to promote increased skin hydration and, thus, greater skin permeability. In systems containing drug within a liquid or gel, the backing material must be heat-sealable to allow fluid-tight packaging of the drug reservoir using a process known as form-fill-seal.

Drug Reservoirs

Drug reservoirs can be composed of liquids such as ethanol or silicone fluid, polymers such as ethylene–vinyl acetate copolymer, polyisobutylene, or silicone elastomer, or polymer blends such as a polyvinyl alcohol/polyvinyl pyrrolidone blend. Drug release from a polymeric reservoir can be regulated by adjusting the chemical structure of the polymer, using appropriate polymer blends, or adding plasticizers. In matrix systems, the polymeric drug reservoir doubles as the skin adhesive.

Rate-Controlling Membranes

Rate-controlling membranes can be used to regulate the diffusion of both drug and chemical penetration enhancers. Materials for rate-controlling membranes include microporous polypropylene and ethylene–vinyl acetate copolymers. Membrane permeability for drug or enhancer is adjusted through appropriate choice of vinyl acetate content or membrane thickness.

Drugs

Drugs are preferred candidates for transdermal delivery if they exhibit a short half life or are subject to extensive first-pass metabolism and require a parenteral dose of less than about 20 mg/day. Preferred drugs are further characterized by low skin toxicity, a molecular weight of less than about 500 D, a high octanol/water partition coefficient ($1 \leq \log P \leq 2.5$), and/or solubility in mineral oil and water of greater than about 1 mg/ml. Insufficient solubility of the permeant in the skin can be improved by inclusion of a biocompatible chemical enhancer, resulting in increased skin permeation.

Permeation Enhancers

Certain chemical agents enhance the permeation of drug through the stratum corneum. These agents are typically included in the drug reservoir and, like the drug, partition into and diffuse through the skin. It is therefore critical that they have a low potential for irritation or sensitization. Permeation enhancers function by increasing diffusivity or solubility of a drug in the SC, but may have similar effects in the polymeric materials of transdermal devices. Ethanol, a commonly used enhancer with excellent biocompatibility, increases the solubility of drugs in the SC. Ionic and nonionic surfactants, such as oleic acid, glyceryl laurate, and lauryl pyroglutamate, enhance drug permeation by perturbing the ordered structure of the lipid matrix within the SC, leading to higher diffusivity of the drug. Their presence in SC lipid lamellae may also increase drug solubility. Other aliphatic alcohols, fatty acids and their esters, and essential oils have also been studied for use as permeation enhancers.^[6]

Pressure-Sensitive Adhesive

The pressure-sensitive adhesive (PSA) affixes the transdermal drug delivery system firmly to the skin. Adhesive formulations must provide rapid conformation to rough skin, while limiting cold flow during storage or wear. For multiday wear systems, aggressive PSAs with low storage moduli are selected, which permit adhesion to rough skin. Adhesives must be skin-compatible, causing minimal irritation or sensitization, and removable without inflicting physical trauma or leaving residue. In addition, they must be able to dissolve drug and excipients in quantities sufficient for the desired pharmacological effect without losing their adhesive properties and skin tolerability.

PSAs used in commercially available transdermal systems include polyacrylate, polyisobutylene, and polysiloxane. Polyacrylate, the most commonly used adhesive, is a copolymer of up to three different monomers. By varying the composition of the polymer, its properties can be adjusted to a range of drug delivery requirements. In general, all acrylic adhesives are polar in character, allowing them to absorb moisture readily and to maintain adhesion to wet skin. They also dissolve most drugs well, enabling high drug loading of polyacrylate matrices. Polyisobutylenes (PIBs), in contrast, are characterized by a low solvent capacity for drugs. PIBs are often used in membrane-controlled systems where the initial burst of drug released from the adhesive layer should be limited. PIB-based adhesives are mixtures of high and low molecular weight polymers, which provide cohesion and tackiness, respectively. By adjusting the

composition of the PIB formulation, cold flow and adhesiveness can be customized for each system. Silicone adhesives are characterized by low allergenicity. Similar to PIBs, silicones dissolve most drugs poorly and regulate tackiness and cohesion through polymer size. Molecular weight of silicones, however, can be hard to control during storage of drug-adhesive formulations, since drugs containing amine groups can catalyze further polymerization in silicone adhesives retaining residual silanol groups. To address this problem, special silicones have been developed that are rendered resistant to amine-catalyzed condensation through end-capping of silanol functional groups.

Peelable Liners

Peelable liners protect the adhesive from contamination and loss of tackiness. They are usually composed of polyethylene or polyester coated with a release layer of silicone or fluorocarbon agents.

System Applications

The following examples highlight the advantages of transdermal drug delivery systems over other routes of drug administration and illustrate the respective strengths of different system designs.

Duragesic[®] (developed by ALZA Corporation, Mountain View, CA, for Janssen Pharmaceutica, Inc., Titusville, NJ) provides controlled transdermal delivery of fentanyl for patients in chronic pain who require continuous opioid analgesia and whose pain cannot be managed by lesser means. Patches are applied to the upper body for a duration of three days. Since the amount of drug released from the transdermal system is proportional to the skin contact area of the drug-containing silicone adhesive, dosage strengths can be adjusted by varying the patch size. Patches are available in four sizes ranging from 10 to 40 cm², corresponding to dosage strengths from 25 to 100 µg/hour. Ethanol gelled with hydroxypropyl cellulose is incorporated into the drug reservoir as a solubilizing agent, but also partitions into the skin and increases the flux of fentanyl through the skin. Upon application of the system to the skin, a small loading dose of fentanyl is released from the adhesive layer; subsequently, drug release is limited by the system's rate-controlling membrane, which is made of ethylene-vinyl acetate copolymer. Control of drug release from the transdermal system reduces variations in blood concentrations of fentanyl over the delivery period. Breakthrough pain, a common phenomenon with dosing via the oral or intravenous route, is thereby avoided.

Climara[®] (developed by 3M, St. Paul, MN, for Schering, Berlin, Germany) is a drug-in-adhesive matrix system for the delivery of 17β-estradiol in hormone replacement therapy. The polyacrylic adhesive layer, which is laminated to an elastomeric backing membrane, contains both the drug and a mixture of fatty acid esters serving as permeation enhancers. Patches ranging in size from 6.5 to 25 cm² are applied to the abdomen for a duration of seven days, delivering 17β-estradiol at rates from 25 to 100 µg/day. Transdermal delivery of estradiol eliminates the effects of first-pass metabolism in the liver and minimizes fluctuations in plasma levels seen after oral administration. In addition, Climara[®], which is comfortable and inconspicuous to wear, provides a convenient once-per-week dosing schedule.

Ortho EVRA[®] (Ortho-McNeil Pharmaceutical, Raritan, NJ) is a transdermal system for contraception that was introduced in 2002. The 20 cm² patch delivers norelgestromin (150 µg/day) and ethinyl estradiol (20 µg/day) over seven days. This delivery system uses a novel PIB-based adhesive with a hydrophilic polyvinyl pyrrolidone filler, which improves adhesion under moist conditions and increases solubility of drugs in the adhesive. Ortho EVRA[®] combines key advantages of implantable or injectable contraceptives with those of oral contraceptives. Similar to implantable or injectable systems, a transdermal delivery system eliminates the daily fluctuations in plasma levels of contraceptive hormones seen with oral contraceptives and offers a convenient dosing schedule leading to a high degree of user compliance. Like oral contraceptives, Ortho EVRA[®] is fully user controlled, allowing contraception to be terminated at any time.

Additional commercialized transdermal products and their compositions are summarized in Table 1.

ELECTRICALLY ASSISTED TRANSDERMAL TRANSPORT

Fundamentals of Electrotransport

Passive transdermal delivery is generally limited to lipophilic and highly potent compounds of low molecular weight. Electrically assisted transdermal delivery is used to enhance the delivery of polar, hydrophilic, and charged compounds across the skin by means of two fundamentally different approaches: electroporation and iontophoresis. Electroporation employs brief high-voltage pulses to create transient pathways for transport across the skin. Iontophoresis is the application of low-level electrical fields over long periods to drive small, charged agents across the skin.

The Nernst-Planck equation^[7] describes the transport of chemical agents across a membrane under the

Table 1 Transdermal therapeutic systems (TTS) approved in the United States

Active ingredient	Product name	System type	Drug reservoir	Enhancer	Adhesive ^a	Dosage ^b
Scopolamine	Transderm Scop [®]	Membrane controlled	Multilaminar	None	PIB/mineral oil	1.0 mg in 3 d

^bd, days.

influence of an electrical field as the sum of three contributions: passive diffusion, electromigration, and electro-osmosis. For charged species, the contribution of passive diffusion is small due to the lipophilic nature of the intercellular matrix of the stratum corneum. Ionizable components of the skin, such as fatty acids, make the occurrence of electro-osmotic transport, the convective flow of solvent and species dissolved in it, possible. While electro-osmosis plays only a minor role in the transport of small ionic agents, it may be important for the transport of both neutral and charged large molecules including proteins, peptides, and oligonucleotides.^[8] For example, electro-osmosis has been used to extract glucose from the epidermis for the purpose of monitoring blood glucose levels.^[9]

For transport of small ionic agents, electromigration is the dominant process. The amount of ionic agent transported per second (N) has been shown to be linearly proportional to the applied current (I) over a wide range of currents^[10] and depends on the molecular weight (M) and the charge (z) of the agent according to Eq. 2, which is derived from Faraday's law of electrolysis:

$$N = \frac{t_d \cdot I \cdot M}{z_d \cdot F} \quad (2)$$

F denotes Faraday's constant and t_d the transport number, which expresses the charge carried by the ionic agent d as a fraction of the total transported charge. The transport number t_d is unique for each ionic agent and is a function of its mobility, charge, and concentration in the skin as compared with those of other migrating species.

System Structure and Function

Drug delivery from an electrotransport system can be tightly controlled by circuitry that continuously adjusts the magnitude of the applied voltage in order to maintain a specific current. Patient-controlled electrotransport systems are under development, and future combination with biosensors may ultimately provide systems operating with closed-loop feedback. A typical transdermal electrotransport system (Fig. 3) is composed of a source of electrical energy and two electrodes in contact with ionically conductive reservoirs, which are placed on the patient's skin and contain either the drug (donor electrode assembly) or a pharmacologically inactive electrolyte (counter electrode assembly).

Electrotransport systems can be designed as completely integrated or as modular products. In integrated systems, the drug and delivery mechanism are packaged together, making those systems simple to use

Fig. 3 Schematic diagram of an electrotransport device showing the flow of ions in response to an applied voltage.

and convenient to wear. Modular systems, in contrast, use disposable drug patches attached to a reusable power source and electronic circuitry.

System Components

Power source

Skin resistance is greatest at the start of current application and, thus, determines the system voltage required to achieve the desired current into the skin. A voltage of 10 to 20 V, easily provided by a single lithium button cell and voltage boost circuitry, is usually sufficient to achieve the desired current in a few seconds to minutes.

Control circuitry

While a simple field-effect transistor with a feedback resistor is sufficient to control the current delivered from a power source over a wide range of skin resistances, microcontrollers or customized application-specific integrated circuits (ASICs) allow precise modulation of the applied voltage to maintain the required current and also provide safety monitoring features and dosing and system maintenance information for the user.

Electrodes

The electrodes apply an electric field across the skin by converting electric current from the battery into ionic current through the reservoirs, skin, and body. The electrochemical reactions occurring at the electrodes lead to constant change in the chemical environment of the reservoirs. Long-lived nonconsumable electrodes, which are made from electrochemically inert materials such as stainless steel or platinum, lead to the accumulation of hydrolytic products and, thus, a change in pH in the reservoirs. Consumable electrodes, in

contrast, contain electroactive species such as silver or silver chloride, which are oxidized at the anode or reduced at the cathode during the passage of current,^[11] substantially reducing hydrolysis.

Formulation

The formulation includes the ingredients in the drug and counter reservoirs, which typically consist of a solvent, a matrix-forming material, and a drug salt or a biocompatible salt, respectively. Buffers, antimicrobial agents, antioxidants, and additional electrolyte salts or permeation enhancers may be added to affect the rate of delivery, biocompatibility, or product shelf life. The counter ion of the drug salt is often selected to preferentially react with electrochemically-generated species from the electrode; a chloride, for example, will react with oxidized silver ions from a silver anode.

System Applications

A number of iontophoretic systems are currently available or under development (Phoresor[®], IOMED, Salt Lake City, UT; Dupel[®] System, Empi, St. Paul, MN; lidocaine patch, Vyteris, Inc., Fair Lawn, NJ; IontoPatch[™], Birch Point Medical, St. Paul, MN; E-TRANS[®] fentanyl, ALZA Corporation, Mountain View, CA). Three of these systems are described in more detail to illustrate differences in system design (modular versus integrated) and applications (local versus systemic delivery).

The IOMED Phoresor[®] is a modular iontophoretic system, composed of a reusable controller/power source unit connected by a cable to disposable silver/silver chloride electrodes attached to hydrogel reservoirs (GelSponge[®]). The hydrogels must be hydrated with the drug solution of choice immediately before use, and a current of up to 4 mA resulting in current densities of up to 700 $\mu\text{A}/\text{cm}^2$ can be applied. While the Phoresor[®] is a highly versatile system, it is relatively costly and requires the patient to remain stationary during treatment. One of the primary uses of the Phoresor[®] is in the delivery of lidocaine for local anesthesia.

A partially integrated system for the iontophoretic delivery of lidocaine is being developed by Vyteris Inc. The Vyteris system, designed to produce topical anesthesia within 10 minutes, consists of a disposable patch prefilled with lidocaine solution and a small, reusable dose controller.

E-TRANS[®] fentanyl (ALZA Corporation, in Phase III clinical development, Fig. 4) is a fully integrated, nonreusable system for the patient-controlled transdermal delivery of fentanyl for management of acute pain. The self-adhesive system uses silver and silver

Fig. 4 Exploded view of an E-TRANS[®] system showing major components: top housing, printed circuit board assembly, a bottom housing containing reservoirs for placement of electrodes and hydrogels, and an adhesive laminate (diagram from International Patent Publication Number WO 96/39222).

chloride electrodes with polyvinyl alcohol-based hydrogels and a PIB adhesive. In clinical studies, patients experiencing pain could activate the system to have a current of 170 μA applied for 10 minutes, resulting in the systemic delivery of 40 μg of fentanyl. Systems can be worn for up to 24 hours, during which time up to 80 doses can be administered.

MECHANICALLY ASSISTED TRANSPORT

Fundamentals of Mechanically Assisted Transport

Increased skin permeability can be achieved by mechanical disruption of the stratum corneum, the skin's main permeation barrier, through abrasion by scraping or tape stripping. However, the rate of drug absorption through abraded skin is hard to control or predict. In contrast to surface abrasion methods, mechanical disruption of the stratum corneum through the formation of microchannels can be achieved in a controlled and reproducible manner. The artificially formed, superficial microchannels can serve as pathways for even very large or highly charged drug molecules, such as

proteins or nucleic acids. Since the microchannels are confined to the epidermis, which does not contain nerve endings, their formation causes little or no pain or bleeding. Microchannels through the skin typically remain open for about one to 24 h, depending on their size and whether the site is under occlusion. In contrast to surface abrasion, microchannels cause little or no irritation to the skin.

System Structure and Function

Different methods are being developed for the controlled formation of microchannels through the stratum corneum. In needleless injection systems, drug molecules in liquid (e.g., Medi-Jector™, Antares Pharma, Exton, PA, or Biojector™, Bioject, Inc., Bedminster, NJ) or dry powder form (e.g., Powder-Ject™, PowderJect Pharmaceuticals Plc, Oxford, England) are propelled toward the skin with such velocity that they are able to penetrate the skin, in essence, forming their own channels. Depending on the system, drug can be deposited in the epidermis, the dermis, subcutaneous adipose tissue, or intramuscular tissue. Other devices are based on the formation of multiple pores in the stratum corneum, through which drug can either diffuse passively or be actively driven by iontophoresis. Formation of multiple pores can be achieved either through the brief application of high temperatures to the skin (Altea Therapeutics, Atlanta, GA) or by piercing the stratum corneum with hollow or solid microprojections of uniform shape and length.^[12–15] Both methods allow the control of pore depth and diameter. Use of drug-coated solid microprojections permits drug to be directly deposited into the epidermis, achieving high delivery efficiencies.

System Components

Needleless injection systems

Needleless injection systems are syringelike devices that use mechanical compression force to propel a jet stream of drug solution from a cylinder. The force and surface area of the jet stream determine the depth of penetration (e.g., Antares Pharma). For delivery of dry powder or coated gold particles, a jet stream of an inert gas such as helium is typically used to drive the drug into the skin (e.g., Powderject Pharmaceuticals Plc). A novel mechanism currently in development is based on the rapid depression of a piston through the contraction of shape memory alloy fibers, activated by a brief electrical pulse (Norwood Abbey, Victoria, Australia).

Thermal creation of micropores

The MicroPor™ system (Altea Therapeutics) is composed of three integrated elements: an array of metallic heating filaments, placed directly against the skin, a control unit containing a power source and electrical circuitry, and a drug reservoir. An electrical pulse from the control unit activates delivery of a brief pulse of thermal energy from the heating filaments, resulting in the formation of micropores through the stratum corneum. Drug then passively diffuses from the reservoir through the micropores into the skin.

Creation of pores through microprojections

Microprojections are composed of silicon or titanium. The microprojection systems developed by Becton Dickinson^[12] and at the Georgia Institute of Technology^[13] are produced by etching a silicon substrate. Macroflux® microprojection arrays (ALZA Corporation; Refs. [14–16]) are composed of titanium and fabricated by chemical etching followed by a forming step. The shape of microprojections, which are organized into arrays of up to 1000 projections per cm², is highly uniform within the array. Microprojections are generally less than 200 μm long to avoid penetration into the dermis. They can be used to pretreat a skin site before application of a topical drug formulation or integrated with a drug reservoir for passive or iontophoretic delivery. Alternatively, microprojections can be directly coated with drug and attached to an adhesive backing. For the Macroflux® system (ALZA Corporation), use of a spring-loaded, self-actuated device to apply the microprojection array to the skin helps to ensure uniform and reproducible penetration (Fig. 5).

System Applications

At present, only needleless injection devices are commercially available in the United States for use as an alternative to conventional needle-based injection systems. Development of mechanical microchannel-based transdermal systems may help to overcome transdermal drug delivery challenges for highly charged and high molecular weight drug compounds. In particular, these technologies may enhance the delivery of commercially relevant therapeutic proteins and vaccines, which are currently administered only by parenteral injection.

STRATEGIES FOR ENHANCING BIOCOMPATIBILITY

Several commercially available transdermal systems have been reported to produce local irritation or

Fig. 5 A prototype Macroflux[®] transdermal system.

sensitization.^[17] Since transdermal delivery systems interface with the skin, they are inherently able to cause skin irritation. In addition, transdermal delivery leads to high local drug concentrations that can promote irritation or sensitization at the delivery site. Here, we will briefly outline different types of skin reactions to transdermal drug delivery and the various strategies that have been developed to minimize these local side effects.^[18]

System-Induced Skin Reactions

Transdermal delivery systems rely on occlusion, which causes changes in the pH and hydration state of the skin. These changes may result in increased absorption not only of drug, but also of permeation enhancers or inactive system components. Usually well-tolerated excipients such as propylene glycol and methyl cellulose have been found to cause contact dermatitis in a small fraction of the population. Similarly, ethanol can cause skin reactions when used as a permeation enhancer, particularly in individuals with aldehyde dehydrogenase deficiency. Irritation caused by passive transdermal systems, however, is typically mild and can be avoided by adequate product engineering and judicious choice of the system components, the application site, and the duration of occlusion.

In iontophoretic systems, the electrochemical processes add to the risk of skin irritation. Use of consumable electrodes that minimize the electrolysis of water prevents pH changes that can cause local irritation. All iontophoretic systems, however, cause hyperemia. While the ensuing erythema is usually mild

and self-limited, it increases with length of application and current density. High current densities in areas of low resistance, such as skin defects, can result in focal irritation and ulceration, and care should be taken to apply iontophoretic systems to normal, intact skin. The potential for skin reaction can be further reduced by uniformly lowering skin resistance through creation of artificial transport channels in the stratum corneum (see section on mechanical modification of transdermal transport) or by adjusting the pH of the electrode formulations.

Skin behaves like an ionic exchange membrane with an isoelectric point (pI) of four to five, becoming negatively or positively charged at pH values above or below the pI, respectively. Increasing the pH of the anode formulation was found to decrease skin resistance and erythema during transport of positively charged molecules from the anode. A reduction in erythema was also observed at the cathode site for transport of negative species as the pH of the cathode formulation was decreased.

Drug-Induced Skin Reactions

Even drugs with low systemic toxicity are capable of producing an irritant or allergic skin reaction when delivered transdermally. Many drugs can produce erythema and even edema through their vasoactive properties, which may become evident only at the high concentrations achieved locally by transdermal delivery. Irritation due to generation of reactive or toxic metabolites in the skin is uncommon for most transdermally delivered drugs. Most irritation seems to be

T

related to lipophilicity of a drug, since drugs with an octanol/water partition coefficient of greater than 10^4 were shown to be cytotoxic at concentrations easily achieved in any layer of the skin during transdermal transport.^[19] In addition to irritation, allergic reactions (delayed hypersensitivity) have been reported to occur upon transdermal delivery of clonidine and many other drugs from a wide range of therapeutic classes. Repeated application of transdermal systems over prolonged periods of time increases the likelihood of immune responses.

Control of Local Drug Concentrations

Irritation and, to a lesser extent, sensitization depend on local drug concentration, which is determined by drug flux into and out of the delivery site. Drug flux into the skin depends on skin permeability, which can vary up to tenfold between subjects and up to 100-fold between skin sites. Differences in skin absorption can be minimized through the use of rate-controlling membranes in passive transdermal systems or through use of iontophoresis, in which drug flux directly depends on the current applied. Removal of drug from the delivery site can be accelerated by codelivering a vasodilating agent with the drug, as shown by reduction of the irritation potential of the drug tetracaine upon codelivery of methyl nicotinate. Any decrease in the long-lasting irritation response to the drug, however, comes at the expense of a short-lasting, but visible erythema induced by the vasodilating agent. Another strategy aims at reducing the intracellular accumulation of drug in acidic organelles such as lysosomes. Codelivery of the lysosomotropic agent ammonium chloride or the ionophore monensin with the drug chloroquine inhibited intracellular accumulation of chloroquine and dramatically reduced chloroquine-induced skin irritation.

Drug Modification

Attempts have been made to manufacture a prodrug with reduced lipophilicity and, thus, decreased skin toxicity compared with the original drug. A related approach is to deliver salts of the acid or basic drug instead of its neutral form. These strategies work best for iontophoretic delivery, since passive transdermal transport depends on a drug's lipophilicity. Other approaches include camouflaging the drug by complexing it with cyclodextrins or incorporating it in micelles or liposomes. It is still uncertain, however, if transport of such aggregates is feasible.

Inhibition of Metabolism

Contact sensitization requires binding of sensitizing moieties (haptens) derived from the drug molecule to proteins, which are then processed intracellularly in acidic endosomal compartments and presented in association with major histocompatibility-complex proteins on the extracellular membrane. Since most drugs of interest for transdermal delivery are stable chemical entities, metabolism is thought to be a requisite for haptentization. In concordance with this concept, codelivery of a sensitizing agent with inhibitors of a common metabolic pathway, the monoamino oxidase pathway, reduced sensitization. There also is indication that codelivery of lysosomotropic agents, which raise the endosomal compartment pH, may inhibit sensitization responses by inhibiting intracellular processing of haptentized proteins.

Control of Inflammatory Response

If reduction of the irritation/sensitization potential of a drug or delivery system is not feasible, the skin response can be controlled by codelivery of nonspecific anti-inflammatory agents. A synthetic anti-inflammatory peptide that lacks the side effects typically associated with glucocorticoids was shown to reduce irritation caused by iontophoretic delivery of chlorpromazine. Similarly, passive codelivery of hydrocortisone with chlorpheniramine or benzoyl peroxide inhibited sensitization to these drugs. Hydrocortisone also inhibited erythema and edema resulting from iontophoretic delivery of metoclopramide. Since hydrocortisone has never been observed to cause local side effects such as skin thinning, and only a small fraction of its normal endogenous production is needed to provide local anti-inflammatory effects, this compound may be a good alternative to more potent glucocorticoids for inhibition of mild to moderate inflammatory responses.

CONCLUSION

Transdermal drug delivery is a rapidly developing field due to the advantages it provides over other routes of drug administration. The use of transdermal systems is expected to increase in the future as new methods for maximizing drug transport through skin and minimizing skin irritation are perfected. The transdermal delivery of macromolecules such as proteins, nucleic acids, and vaccines, which cannot withstand the gastrointestinal environment and currently require invasive delivery methods, is of particular research and development interest. Here, we have presented a brief

overview of the theory of transdermal drug transport and the types of systems and strategies applied to different delivery challenges. Further information on the topics presented here can be found in Refs. [20–23]. By incorporating the latest advances in materials science, electronics, microfabrication, and skin biology, transdermal systems of the future will be able to deliver a broader spectrum of pharmaceutical agents and provide more complex delivery profiles.

Transplantation Biology Program, and the Department of Physiology, Mayo Clinic, Rochester, Minnesota, U.S.A.

Jeffrey L. Platt

Transplantation Biology Program, and the Departments of Immunology, Pediatrics, and Surgery, Mayo Clinic, Rochester, Minnesota, U.S.A.

INTRODUCTION

Today nearly 85,000 individuals await organ transplantation.^[1] Some predict that with new developments in medicine and biotechnology this number will increase substantially. This communication will consider how genetically engineered animals might be used to supply organs needed for transplantation.

One new development that may especially increase the demand for transplantation is molecular and genomic diagnosis. Advances in molecular diagnostics, genomics, and possibly proteomics may soon make it possible to predict the onset of disease long before the symptoms are manifest and the course once disease has become apparent. With this information, the physician may be tempted even more than before to recommend “preemptive” transplantation to spare patients from lethal diseases or from adding the risks of organ failure to the risks of transplantation.^[2] As only one example, molecular diagnostics and genomics are approaching the levels of specificity and sensitivity that may make it possible to diagnose cancer before it can be localized by imaging. Extending preemptive transplantation to adults with high likelihood of tumor formation could add as many as 89,000 potential recipients per year to the list of those awaiting kidney transplants. A second development that may change the demand for transplantation is increasing life expectancy. As the population ages, the potential for organ failure increases and hence the demand for organ donors increases.

Clearly, transplanting human organs will not address the ever-increasing demand for organ replacement. One potential solution to this problem is to use animal organs and tissues instead of human organs and tissues for transplantation, that is, xenotransplantation. The potential benefits of xenotransplantation extend beyond addressing the shortage of human organs for transplantation. For example, xenotransplantation might be a preferred way to treat certain diseases that afflict human but not animal organs (i.e., HIV and hepatitis). Xenotransplantation could also offer a way of dealing with acute organ failure due, for example, to new epidemics of myocarditis, viral pneumonia, or

nephritis. Xenotransplantation might also be used to enable the growth of human stem cells into organs in a surrogate animal.^[3] Finally, xenotransplantation could provide an opportunity for manipulation of the donor organ instead of the host to promote organ acceptance. Manipulation of this type might include gene delivery.^[4] Key to the use of xenotransplantation as a way of replacing organs and as a means of gene transfer is genetic engineering. How genetic engineering can be applied toward this end is the central focus of this entry.

HISTORY OF XENOTRANSPLANTATION

The first serious attempts at xenotransplantation were made in the early years of the 20th century. Princeteau and Jaboulay each tried to connect animal kidneys to human blood vessels using a newly developed technique—the vascular anastomosis.^[5–7] Animals were used as a source of organs then because using humans seemed unethical. The animal kidneys grafted to the sick patients functioned only briefly. Failure of the organs was attributed to technical difficulties associated with the surgical procedure. Xenotransplantation and subsequent attempts at allotransplantation (human to human transplantation) always failed; the reasons for failure were hotly debated. Protein incompatibility, infection, technical failure, and immunity were among the postulated causes. In the early 1940s researchers found that the immune system may be prohibiting the success of transplantation, and in the 1960s, the availability of immunosuppressive drugs brought proof that transplantations failed because of immune rejection and this problem could be overcome with immunosuppression.^[8,9]

The advent of immunosuppressive drugs made it possible to undertake organ transplantation for the treatment of disease. However, there remained the question of what source of organs might be used. Early transplants were undertaken using living related donors.^[10] Indeed, the first successful transplant was from an identical twin.^[10] However, most subjects with

renal failure did not have a living donor much less a twin available to provide a kidney. Hence, some turned once again to animals as a potential source of kidneys. In 1963, Reemtsma transplanted chimpanzee kidneys into 13 patients treated with immunosuppressive therapy. One patient survived for nearly 9 mo after receiving the organ, before dying from an electrolyte imbalance (the xenograft appeared normal).^[11–13] This relative success triggered a resurgence of interest in xenotransplantation and led to the performing of 14 kidney transplants, 8 heart transplants, and 11 liver transplants at various centers. Unfortunately, these attempts were less successful, with approximate survival averaging 15 days (Table 1).^[14,15]

Today, the transplantation of animal organs or tissues is needed more than ever but is yet to be routinely applied in the clinical setting due to several hurdles. First, there may be physiological limitations of the animal tissue in a foreign environment. Second, there exists a potential for transmission of microbial organisms that could give rise to novel infections in the

human population [e.g., porcine endogenous retrovirus (PERV)]. Third, and most crucial, the immune system of the recipient causes severe, incessant rejection of the transplant (Fig. 1).^[33,34] This entry will focus especially on the problem of rejection because this problem is the main barrier to xenotransplantation.

IMMUNOLOGIC HURDLES OF XENOTRANSPLANTATION

All xenografts elicit an immune response by the recipient of the graft; however, the impact of the immune response is dictated by the manner in which a xenograft is connected to the recipient. In the case of whole-organ transplants, the blood vessels of organ xenografts are in direct contact with recipient blood and the components of the immune system contained therein. It is primarily the interaction of these immune components with endothelium lining the blood vessels that leads to the distinct types of vascular disease associated with

T

Table 1 Historical summary of whole-organ xenotransplantation

Year	Recipients (surgeon)	Xenotransplant	Survival	Reference
1905	1 (Princeteau)	Rabbit kidney	Brief	[5]
1906	2 (Jaboulay)	Porcine/goat kidney	Brief	[6]

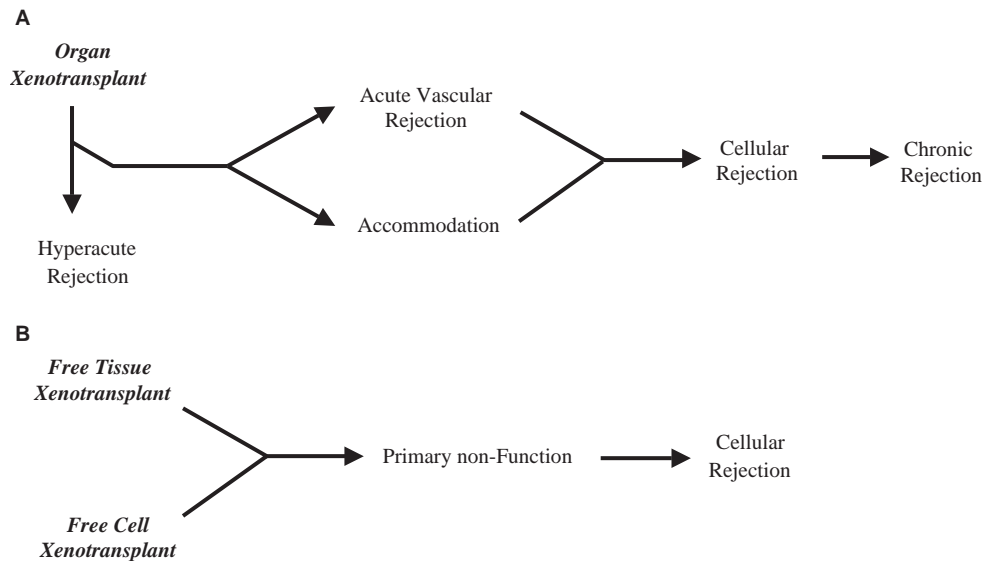

Fig. 1 Biological response to xenotransplantation.

xenogeneic organ rejection. The types of vascular disease seen in this setting are depicted in Fig. 1 and will be described below. Cell and tissue xenografts, in contrast, receive blood supply by ingrowth of blood vessels of the recipient. In this setting the blood vessels of the graft provide a barrier between immune reactants and the transplanted tissue. Below, we describe the types of rejection seen in whole-organ xenografts and how genetic engineering might be used to avert each type of rejection. Rejection of cellular and tissue xenografts is beyond the scope of this communication and so we refer the reader to a recent review.^[3]

The discussion of rejection that follows will focus specifically on the rejection of porcine xenografts. Pigs are the preferred animal for xenotransplantation. Pigs have large litters and a relatively short gestation period (114 days). In addition, porcine organs are very similar to human organs in size and structure. The large litter size and short gestation make housing in “specific pathogen-free” facilities, necessary to avert transfer of pathogens to the organ recipient, economically feasible.

Hyperacute Rejection

Hyperacute rejection is the first and most severe type of rejection seen in xenogeneic organ transplants.^[35] Hyperacute rejection is characterized by immediate bleeding into the graft and by the formation of platelet microthrombi, which in concert lead to graft destruction within several minutes to a few hours. It is very likely that the first xenografts performed in patients with renal failure were destroyed by hyperacute rejection and not by “technical factors.”

Hyperacute rejection is initiated by the binding of xenoreactive natural antibodies to the endothelial lining of donor blood vessels. Xenoreactive natural antibodies are found in the blood of all normal individuals and bind to antigens (i.e., proteins, sugars, etc.) on the surface of cells of other species. Xenoreactive natural antibodies in humans bind especially to one saccharide consisting of terminal Gal α 1-3Gal residues.^[36–38] The binding of xenoreactive antibodies to this sugar activates the complement system of the recipient. The complement system consists of 20 or more proteins in the blood. The primary function of the complement is to attach to foreign organisms and either directly kill or facilitate ingestion of the organism by white blood cells. It is the complement system acting on donor blood vessels that destroys the graft.

Complement is activated in solution and could target one’s own cells. Under normal circumstances, however, activation of complement on a person’s cells is attenuated by regulatory proteins in the plasma and on the surface of cells. These proteins protect healthy cells from inadvertent injury. However, complement regulatory proteins appear to be species specific, operating most effectively in a homologous environment.^[39,40] Thus, in the xenotransplant, complement of the recipient is not adequately controlled and so causes severe, unrestrained injury to the graft.

Several therapies have been used successfully to avert hyperacute rejection. For example, hyperacute rejection can be avoided through depletion of xenoreactive antibodies from the recipient.^[41] Depletion of xenoreactive antibodies can be accomplished by using immunoabsorbent columns in conjunction with immunosuppressive agents such as cyclophosphamide,

mycophenolate, leflunomide, or similar new agents, to prevent rapid antibody resynthesis.^[42] Another way of preventing hyperacute rejection is to inhibit the complement. Systemic inhibitors of complement such as cobra venom factor, soluble complement receptor Type 1 (SCR1), and antibodies against complement component C5 and γ -globulin have been used with relative efficacy.^[43–48] However, these treatments render the treated individual susceptible to severe infection because the complement system is generally incapacitated. A safer, more effective, and more enduring approach has been to genetically alter animals to express human complement regulatory proteins that can provide control of complement in the transplant. Human CD55, CD46 (membrane cofactor protein), and CD59 (protectin) are among the proteins that have been expressed in transgenic animals.^[49–54] Organs from these animals have been shown to control activation of complement in the xenograft. This was the first use of transgenic animals as organ donors. We describe these efforts and discuss future possibilities below.

All of the therapies discussed above—antibody depletion, systemic inhibition of complement, and use of organs transgenic for human complement regulatory proteins—successfully avert hyperacute rejection. Unfortunately, none of these approaches has allowed long-term survival of organ xenografts. In every case the grafts ultimately develop acute vascular rejection over a period of days to weeks.

Acute Vascular Rejection

When hyperacute rejection is prevented, as discussed above, a xenogeneic organ is subject to acute vascular rejection. Acute vascular rejection can destroy a xenograft over days to weeks. It is characterized by focal ischemia, intravascular fibrin deposition, and thrombosis.^[55–57] Because hyperacute rejection can be easily prevented, acute vascular rejection has been thought to be the main barrier to clinical application of xenotransplantation.

Acute vascular rejection appears to be initiated by binding of xenoreactive antibodies to the xenograft. Unlike hyperacute rejection, in which complement is activated in large amounts by these antibodies, in acute vascular rejection complement is activated only sparingly. Activated complement or antibody alone triggers profound changes in the physiology of endothelium, called endothelial activation. Activated endothelial cells express procoagulant molecules such as tissue factor and proinflammatory molecules such as E-selectin and cytokines. The pathogenesis of acute vascular rejection is summarized in Fig. 2.

Fig. 2 Molecular mechanisms of acute vascular rejection.

Developing therapies to prevent acute vascular rejection has been a much more daunting challenge than developing therapies to prevent hyperacute rejection. Part of the challenge in developing therapies for acute vascular rejection is that very low levels of bound antibody or activated complement can initiate disease.^[3] The antibodies that initiate acute vascular rejection include anti-Gal α 1-3Gal antibodies but may also include antibodies against other foreign antigens.^[58] As a corollary, the eradication of one antigen or depletion of antibodies that recognize it may be insufficient to prevent acute vascular rejection. Still, reduction of xenograft antigen expression by genetic engineering and inhibition of the complement cascade may be a reasonable first step in addressing this problem.

Another challenge is that acute vascular rejection may be promoted by direct action of natural killer cells and monocytes on the graft. Natural killer cells and monocytes circulate in the blood and are thought to provide initial defense against some infectious organisms. These cells may act on a xenograft as if it were a foreign organism or parasite. The reason why these cells attack xenogeneic cells is not entirely known but implicated in the process are natural killer cell and monocyte-associated receptors, lectins specific for Gal α 1-3Gal and receptors (i.e., Fc) that recognize bound antibody that triggers activity of the cells. Infiltration of these inflammatory cells leads to synthesis of tissue factor and plasminogen activator inhibitor type 1, which promote coagulation and synthesis of E-selectin and cytokines, which promote inflammation. In this manner the injury triggered by xenoreactive antibodies is further exacerbated.^[59–61]

Steps to overcome acute vascular rejection include induction of tolerance. Tolerance in xenotransplantation implies cessation of the synthesis of xenoreactive antibodies. One approach to achieving this end is the transplantation of donor bone marrow, or bone marrow genetically manipulated, to bring about expression of relevant donor antigens and subsequently the deletion or suppression of B-cells of the recipient, which secrete antidonor antibodies. Bracy, Sachs, and Iacomini used this approach by expressing α 1,3galactosyltransferase in bone marrow cells by gene transfer.^[62] Administration of the Gal α 1-3Gal⁺ bone marrow cells

in α 1,3 galactosyltransferase knockout mice decreased production of anti-Gal α 1-3Gal antibodies.

Another approach for avoiding xenograft acute vascular rejection is to bring about accommodation of the graft. Accommodation is an acquired resistance to humoral injury. It was first observed in the successful transplantation of ABO-incompatible renal allografts.^[63] This demonstrated that if anti-A or anti-B antibodies from the recipient were depleted before placement of an incompatible allograft, prolonged graft survival could be achieved in spite of the presence of an intact complement system and the eventual return of anti-A or anti-B antibodies. The biological mechanisms underlying accommodation are still poorly understood and so while it is known that initial depletion of donor antibodies is necessary, the depletion duration is unclear. Some have suggested that accommodation might be initiated via expression of antiapoptotic genes such as hemoxygenase 1, A 20, and bcl2.^[64-68] If successful, this could offer a period of protection sufficient to trigger accommodation. Careful studies detailing the biochemical nature of accommodation are needed to identify the molecular nature of this process and hence the targets for genetic engineering.

T Cell-Mediated Rejection

The T cell-mediated response to a xenograft is thought to be quite potent, but because acute vascular rejection has yet to be circumvented, the impact of this response is not fully known. T cells can recognize major histocompatibility antigens as they are expressed on pig cells, similar to the T cell-mediated response to allografts.^[34,69-71] However, it is not known whether the cell-to-cell interactions that contribute to T cell recognition occur fully between disparate species. In a related manner, T cell repressor function could be defective in the xenogeneic environment (as discussed in the case of hyperacute rejection). What is known is that nearly every porcine protein can give rise to immunogenic peptides and thus the severity of the T cell-mediated response may be very high.^[58] Humoral immunity raised against the xenograft as discussed above may make cellular rejection more severe.^[72] If the cell-mediated immune response to xenografts is more severe than that to allografts, an important question is whether current immunosuppressive agents used in allotransplantation will be effective in the xenotransplant setting. Studies in experimental animals using cellular xenografts suggest that these regimens will suffice. It is conceivable that genetic engineering might be used to avert cell-mediated rejection, but first molecular targets must be more clearly defined.

GENETICALLY ENGINEERED ORGANS

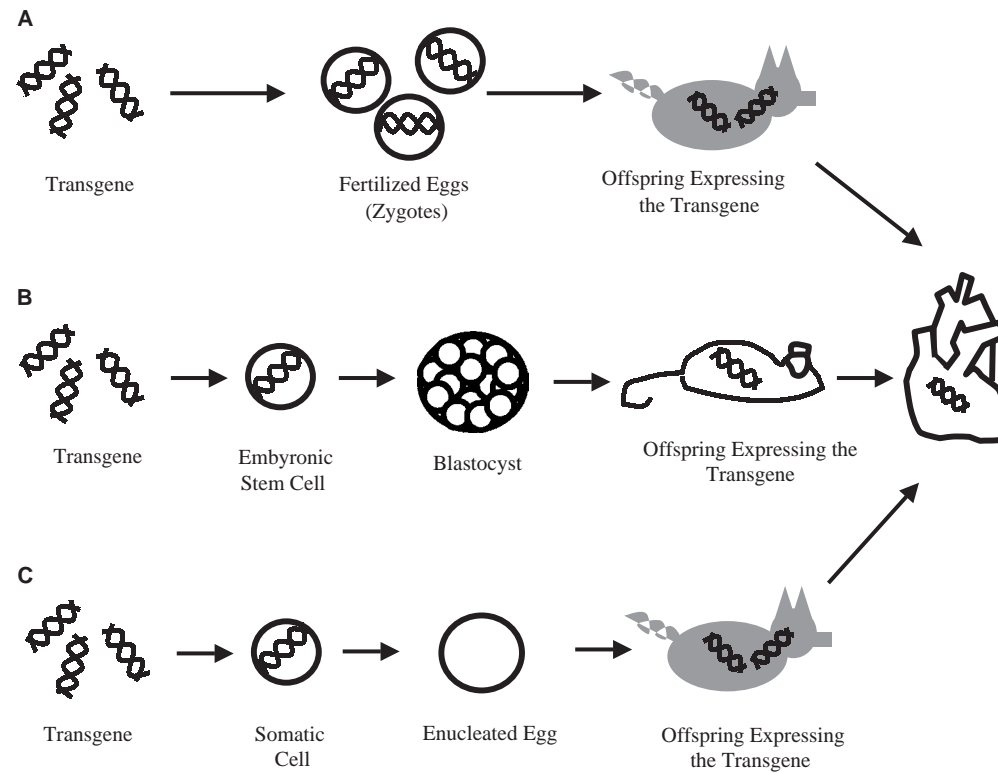

Methods

Genetic engineering provides a means to stably add, delete, or alter the expression of genes in animals. And as discussed above, the organs of transgenic animals may provide a means to avert rejection of transplanted organs. There are several means by which gene expression may be changed in animals. We describe each method below and refer the reader to two reviews of the technology necessary for genetic engineering.^[73,74]

In one approach, a DNA fragment or construct including coding and regulating sequences is micro-injected into the pronucleus of a zygote (Fig. 3A). The injected zygote develops further following its introduction into the oviduct of a pseudopregnant recipient female. The DNA integrates randomly into the chromosome and therefore germ cells may convey transgene expression allowing transmission to subsequent generations. The random nature of the insertion results in variation in the number and location of integrated copies and unpredictable control of expression. Additionally, the length of the DNA is limited.

In a second approach, genetic modification is performed in embryonic stem cells, which are then introduced into preimplantation mouse blastocysts. The genetic modification takes place *in vitro* and may include random integration or homologous recombination (Fig. 3B). The latter involves replacing a wild-type allele with a mutant allele. Embryonic stem cells exhibiting the desired mutation (gene knockout) are selected and subsequently injected into the blastocoele of a recipient blastocyst. The result is a chimeric animal with both the recipient blastocyst cells and the injected embryonic stem cells. If gametes of a chimera develop from the injected embryonic stem cells, the mutant allele present can be transmitted to subsequent generations. Unfortunately, embryonic stem cells are not currently available for pigs.

A third method involves genetic manipulation of cultured somatic cells followed by fusion of a somatic cell or nucleus to an enucleated oocyte, termed nuclear transfer (Fig. 3C). Prior to fusion, donor somatic cells are grown under special conditions to maintain quiescence. At this time it is possible to make genetic modifications (presumably to multiple genetic loci), and select cells with the desired modification. Under the correct conditions, many of which are still dimly defined and poorly understood, the introduced nucleus can lead to the formation of an embryo. This method is very inefficient as seen in the past success rates. Of over 400 manipulated embryos, 1 sheep survived, of 250 embryos, 8 calves survived, and of approximately 2500 embryos, 31 newborn mice survived.^[75-77] Along with

T

Fig. 3 Methods to genetically engineer organs.

the poor rate of success this method is very expensive. However, this is the only effective way to inactivate specific genes in large animals.

Applications

Genetic engineering of organs has been conducted to avert rejection of xenogeneic organs. One way this has been undertaken has been through the generation of lines of pigs transgenic for human complement regulatory proteins. Organs from transgenic pigs expressing human complement regulatory proteins CD55, CD46 (membrane cofactor protein), and CD59 (protectin), either singly or in combination are protected from hyperacute rejection.^[49–54] This result underscores the importance of complement regulation as a determinant of xenograft outcome.

Another way to quench hyperacute rejection using transgenic animals may be to modify expression of xenogeneic antigens. Recent reports describe the successful knockout of the α 1,3 galactosyltransferase gene in pigs using nuclear transfer.^[78–84] The piglets have yet to be extensively tested for expression of the Gal α 1-3Gal antigen. In the interim homozygous (–/–) fetal-pig fibroblast cells have been produced from heterozygous embryos using a novel selection method. These cells express low (~1%) but detectable levels of the Gal α 1-3Gal antigen.^[85] Whether cells expressing low-level antigen are as susceptible to hyperacute rejection as their wild-type counterparts remains to be seen. As cloning technology continues to advance, it is possible that much simpler and less expensive technology will be developed. One possibility proposed by Nottle et al. is the use of the Cre/loxP recombination system to create a transgene acceptor site in the porcine genome.^[86,87]

Table 2 Genetically engineered organs to avert xenograft rejection

Target mechanisms	Genetic manipulation of donor organ
Antibody–antigen interaction	Generation of α -1,3-galactosyltransferase knockout pigs Generation of pigs that overexpress an alternate glycosyltransferase (i.e., H-transferase)
Complement activation	Generation of pigs transgenic for human complement regulatory proteins (i.e., CD55, CD46, CD59)
Activation of endothelium	Suppression of procoagulant or proinflammatory genes

Cloned pigs containing the transgene acceptor site could be used as embryo donor for microinjection. Then, by injecting the transgene and Cre-recombinase construct into the pronucleus of a fertilized egg, it may be possible to achieve single-copy targeted gene insertion.

Another means by which antigen expression may be modulated is by overexpression of an alternate glycosyltransferase (H transferase) such that an H antigen resides at the terminus of some sugar chains instead of Gal α 1-3Gal. To date, these endeavors have shown *ex vivo* decrease in complement-mediated lysis of isolated porcine cells with increased H-transferase.^[88,89] Animal lines transgenic for this glycosyltransferase have not been generated and so complete elimination of hyperacute rejection *in vivo* is still uncertain.

Genetically engineered organs have been proposed and developed to avert rejection of xenografts; however, the use of genetically engineered organs could be extended in many ways. First, genetic engineering could be used to enhance the physical characteristics of an organ. For example, it has been shown that the innervation and overall morphology of the atrioventricular node in pigs is quite different from that of humans.^[90,91] Such differences could alter heart rate and contractility, thereby increasing the potential for arrhythmias. Hence, pig hearts could be genetically engineered to harbor a more similar innervation network to that of humans. Second, animal organs may be altered such that endogenous viruses are knocked out, or mutated and therefore rendered incapable of infecting human recipients.

CONCLUSIONS

The technology for producing genetically modified animals was made possible by the fusion of fundamental discoveries in several seemingly unrelated disciplines including reproductive physiology, molecular biology, and genomics. Genetically modified animals were at first viewed as a tool for investigating disease and studying new therapies. Those in the field of transplantation propose to extend the utility of genetically modified animals by using their organs to address the overwhelming demand for organ replacement. Genetically modified organs have been generated with intent to avert rejection. However, the use of transgenic organs could extend beyond this to provide therapeutic benefit to the recipient.

INTRODUCTION

Tissue engineering is an interdisciplinary field that involves cell biology, materials science, and clinical research for creating functional tissues and organs. Significant advances in tissue engineering have been led by effectively combining living cells including stem cells with materials suitable for cell cultivation. Currently, many types of materials are being investigated for reconstructive bone surgery. For example, calcium phosphate ceramics such as hydroxyapatite (HA) and β -tricalcium phosphate (β -TCP) are widely used as artificial bone graft substitutes.^[1-4] When implanted into bone defects, these materials exhibit bone-bonding properties that enable them to establish chemical bonds between the host bones and the surfaces of the implants. This bone/material interface is very firm and stable, and these materials are known as “bioactive materials.”^[5,6]

Another current attractive technology has been developed for regenerating viable tissues or organs by combining cultured cells with suitable materials. Hydroxyapatite and β -TCP have high degrees of biocompatibility/bioaffinity and stimulate osteoconduction. Thus, these materials are well-known scaffold materials and play important roles in the adhesion, proliferation, and differentiation of cultured cells. We have previously demonstrated the fabrication of regenerative cultured bone tissues with cultured cells by means of tissue engineering.^[7-10] We culture expanded the number of mesenchymal stem cells (MSCs) from fresh bone marrow cells, then further cultured the cells on the HA ceramic and β -TCP ceramic samples.^[11,12] These MSCs differentiated into osteoblasts and produced bone matrices under osteogenic conditions in vitro.^[13] Moreover, the cultured osteoblast/matrix constructs (regenerative cultured bone) show immediate new bone formation capability after in vivo

implantation.^[10,14,15] Based on these results, since January 2002, we have applied the cultured bone tissues fabricated at the cell processing center of our institute to patients suffering from cases such as bone tumors (Fig. 1). We considered that the ceramic surface is very promising for supporting MSC proliferation/differentiation, which has been demonstrated by biochemical or gene expression analyses and observation by scanning electron microscopy (SEM).^[16,17] Usually, cultured cells can be observed with a light microscope when they are cultured on tissue culture polystyrene (TCPS) dishes. However, owing to the opacity of the ceramics, microscopic observation of the cells on ceramics is very difficult. Scanning electron microscopy requires cell fixation by a fixative solution, and the cells are no longer viable. Thus, consecutive observation of the same specimen during the culture periods was impossible.

If the ceramics were transparent, we would be able to observe cellular events including cell adhesion, proliferation, and differentiation cascade with an ordinary microscope. To confirm such cellular events, we attempted to fabricate novel materials for cell culture, specifically, transparent hydroxyapatite (t-HA) ceramics and transparent β -TCP (t- β -TCP) ceramics, which were made by the spark plasma sintering process (SPS).^[18] The SPS is a new process that enables sintering of materials in short periods by charging the spaces between the powder particles with electrical energy and using a high sintering pressure. The SPS systems have many advantages such as rapid sintering, sintering with fewer additives, uniform sintering, low operating expense, and easy operation compared to that of conventional systems using hot press (HP) sintering, hot isostatic pressing (HIP), or atmospheric furnaces. The SPS process can be applied to many materials including fine ceramics. Both the t-HA ceramics and the t- β -TCP ceramics made by the SPS

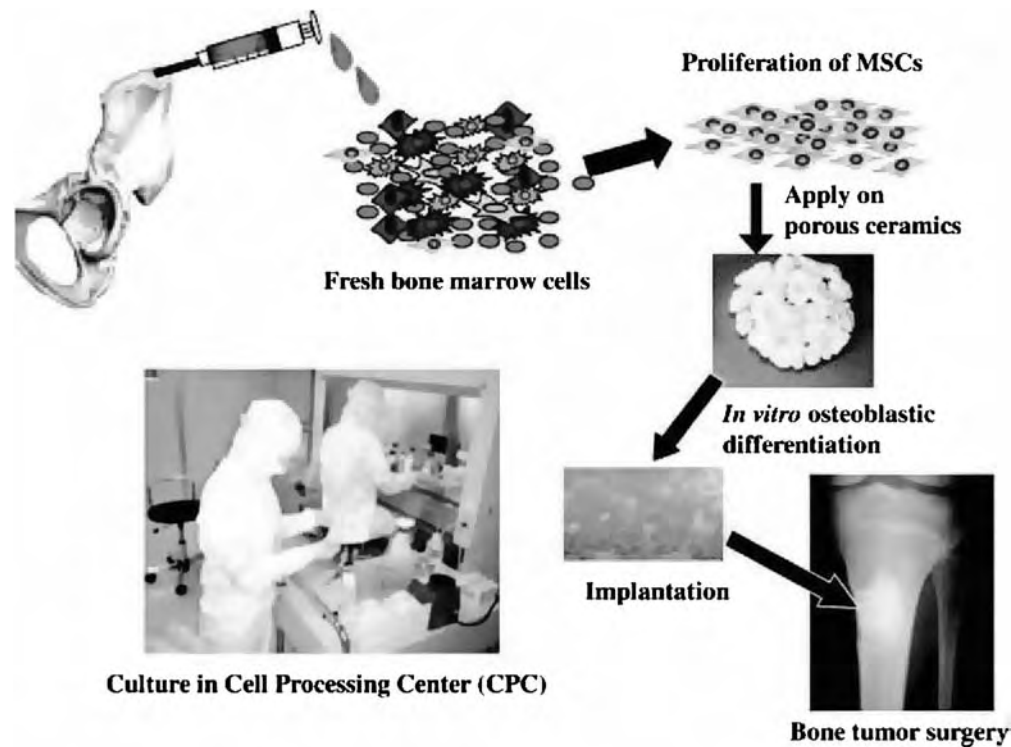

Fig. 1 Schematic representation of clinical application of MSCs to bone tumor cases. Mesenchymal stem cells from fresh bone marrow cells were allowed to proliferate and were then seeded on porous bioactive ceramics. To fabricate regenerative cultured bone, the cell/ceramic composites were cultured under an osteogenic medium. The cultured bone was used for bone tumor surgery in a hospital. The cells were cultured at the cell processing center (CPC) of our institute.

process have enabled observation of the cell behaviors of rat MSCs.^[19,20]

In this entry, we used rat MSCs derived from bone marrow as the cell source and observed cell adhesion, proliferation, and osteogenic differentiation on the t-HA ceramics as well as the t- β TCP ceramics, and conducted a comparative analysis of cell functions.

EXPERIMENTAL PROCEDURES

Preparation of Ceramics

The detailed methods of making t-HA ceramics and t- β -TCP ceramics have been previously reported.^[18] Briefly, a fine powder of HA or β -TCP was utilized as the basic material. One gram of this powder was poured into a graphite mold (inner diameter: 15 mm), then sintered by the SPS process (SPS: Dr Sinter-511S, Sumitomo Coal Mining, Tokyo, Japan). The samples were pressed uniaxially under 10 MPa, then heated at 800°C, 900°C, or 1000°C for 10 min at a rate of 25°C/min. Each ceramic sample was 5 or 20 mm in diameter and 2 mm thick. The ceramic samples were autoclaved for sterilization at 120°C for 20 min.

Surface Characterization

The sessile contact angles (SCA) of the t-HA ceramics, t- β -TCP ceramics, and TCPS dishes were determined using Milli-Q water and a goniometer (Face Contact-Angle Meter, Kyowa Kaimenkagaku Co., Ltd., Tokyo, Japan). A probability (p) value of less than 0.05 was considered significant. To evaluate the surface structures of the materials, a scanning electron microscope (SM-300, Topcon Corp., Tokyo, Japan) was used to analyze the surface of each material.

Cell Culture

Rat bone marrow cells were obtained from 7-week-old male Fischer 344 (F344) rats. Preparation and osteogenic differentiation of MSCs from rat were described by Maniatopoulos et al. and modified by us.^[7,21]

In brief, rat bone marrow cells were flushed out by a culture medium, minimum essential medium (Nacalai Tesque, Inc., Kyoto, Japan) containing 15% fetal bovine serum (JRH Biosciences, Inc., Kansas, U.S.A.), and 1% antibiotics. The bone marrow cells were cultured on T-75 TCPS dishes (Becton, Dickinson and Company, New Jersey, U.S.A.) in a humidified

atmosphere of 95% air with 5% CO₂ at 37°C. The cells adherent to the dishes containing MSCs from rat bone marrow were initially cultured up to 80% confluence and resuspended to 5×10^5 cells/mL in culture medium following harvesting using 0.05% trypsin/0.53 mM EDTA. The cell suspension was applied to the sterilized t-HA ceramic and t-β-TCP ceramic samples (5 or 20 mm in diameter and 2 mm thick), which were placed into a multiwell plate. The cells were cultured with osteogenic medium containing 10 nM dexamethasone (Dex) (Sigma-Aldrich Corporation, Missouri, U.S.A.), 10 mM β-glycerophosphate (Merck, Darmstadt, Germany), and 0.28 mM ascorbic acid 2-phosphate magnesium salt *n*-hydrate (Sigma-Aldrich Corp.) As a control, the same amount of cell suspension was also applied directly in a TCPS well with no ceramic material. The culture medium was changed two or three times a week. During the culture periods, the cell morphologies at different days of cell adhesion, proliferation, and differentiation were detected by phase-contrast (Olympus CK41SF, Olympus Optical, Tokyo, Japan) and fluorescence microscopy (Olympus IX70FL).

Alkaline Phosphatase Activity Staining

The cultured cells on the t-HA ceramics, t-β-TCP ceramics, and TCPS dishes were rinsed with phosphate buffer saline (PBS) and fixed with 4% paraformaldehyde for 10 min at 4°C. The fixed cells were soaked in 0.1% naphthol AS-MX phosphate and 0.1% fast red violet LB salt in 56 mM 2-amino-2-methyl-1, 3-propanediol (pH 9.9) for 10 min at room temperature and washed with PBS.^[7]

Calcium Staining by Alizarin Red S

The cultured cells on the t-HA ceramics, t-β-TCP ceramics, and TCPS dishes were washed with PBS and fixed with 4% paraformaldehyde for 10 min at 4°C. The fixed cells were soaked in 0.5% Alizarin red S/PBS solution for 10 min at room temperature and washed with PBS.^[7] Nonspecific reactions were removed by a washing step using 70% ethanol (EtOH). The stain was used to detect calcium in the extracellular matrix.

Visualization of Mineralized Matrix by Fluorescence Emission During Subculture

During the culture periods, the calcium in the mineralized extracellular matrix was also determined by using calcein, which is a calcium-binding fluorescent dye.^[22] Calcein (1 μg/mL) (Dojindo Laboratories, Kumamoto, Japan) was added to the culture wells

whenever the culture medium was replaced. Before the assay, the medium containing calcein was removed and the wells were washed twice with PBS. The fluorescence of the incorporated calcein was observed by using a fluorescence microscope. After this assay, the cell culture was continued in the osteogenic condition with calcein.

RESULTS

Surface Characterization of t-HA Ceramics, t-β-TCP Ceramics, and TCPS Dishes

It is well known that the surface roughness and wettability of culture substrates influence cellular activity such as cell adhesion and cell proliferation. Therefore, we studied the surface properties of the t-HA ceramic and t-β-TCP ceramic by SEM before cultivation. The surfaces of the t-HA ceramic and t-β-TCP ceramic samples were slightly rough compared with the surface of the TCPS dishes. Nevertheless, the grain structure of the surfaces of the sintered t-HA ceramic and t-β-TCP ceramic samples was fine (less than 1 μm) (data not shown). We also checked the wettability of the t-HA ceramics, t-β-TCP ceramics, and TCPS dishes, which is represented by SCA (Table 1). The SCA of the t-HA ceramics, t-β-TCP ceramics, and TCPS dishes showed no significant difference. The results indicate that surface configuration is not an important factor in comparing the cellular responses on the t-HA ceramics and t-β-TCP ceramics to that on the TCPS dishes.

Cell Adhesion and Proliferation of Rat MSCs Seeded on t-HA Ceramics, t-β-TCP Ceramics, and TCPS Dishes

Next, we observed the cell adhesion and proliferation of rat MSCs on t-HA ceramics, t-β-TCP ceramics, and TCPS dishes. The TCPS dish, which is fabricated from crystal grade polystyrene by a vacuum-gas plasma treatment, exhibits a slightly hydrophilic nature because the plasma treatment introduces carboxyl and hydroxyl groups onto the surface. Under typical

Table 1 Sessile contact angle (SCA)

Material	SCA ± SD (°)
t-HA	73.1 ± 2.36
t-β-TCP	74.7 ± 3.92
TCPS	71.0 ± 3.42

Data show the mean value of eight samples with standard deviation (SD).

(From Hirose, M., et al.)

culture conditions employing TCPS dishes, numerous types of cultured cells are able to attach and proliferate on the surface, while cells could scarcely attach to bare polystyrene because of the high degree of hydrophobicity of its surface. Therefore, TCPS is known as a gold standard substrate for cell cultivation.

Because t-HA ceramics, t- β -TCP ceramics, and TCPS dishes are transparent, cells cultured on these substrates can be observed by phase-contrast and fluorescence microscopy. The shapes of the cultured cells on both ceramics were clearly detected by phase-contrast microscopy; the resolution of the microscopy was almost the same as that on the TCPS dishes (Fig. 2). Even at a very early stage of culture (1 hr after cell seeding), many MSCs had already attached and exhibited initial spreading as evidenced by small, round cells on the t-HA ceramics and t- β -TCP ceramics (data not shown). One day after seeding, almost all the cells were able to adhere to the substrates and exhibit the morphological characteristics of mesenchymal types (spindle cell morphology) (Figs. 2A–C). At culture day 4, the cells were clearly seen proliferating well on all the substrates (Figs. 2D–F). The cascade of the cellular behaviors on the t-HA ceramics and t- β -TCP ceramics was similar to that of the cells seeded on the TCPS dishes (Fig. 2). The results suggested that rat MSCs could attach, spread, and proliferate on t-HA ceramics and t- β -TCP ceramics to the same degree as on TCPS dishes.

Osteogenic Differentiation of Rat MSCs Cultured on t-HA, t- β -TCP, and TCPS Dishes

We investigated the osteogenic differentiation of rat MSCs cultured on these substrates. To evaluate the osteogenic differentiation of rat MSCs on t-HA ceramics and t- β -TCP ceramics, the cells were cultured on both types of ceramics and on TCPS dishes in the presence or absence of Dex, which functions as an osteogenic factor, for 14 days. Cell morphology was observed by fluorescence and phase-contrast microscopy. The cells were cultured in the presence of β -glycerophosphate, ascorbic acid, and Dex [Dex (+)]. The cells differentiated into bone forming osteoblasts, which fabricate extracellular mineralized matrix nodules around the cultured cells.

Recently, we have reported a novel in situ method of monitoring for mineralization by cultured cells by using a calcium-binding fluorescent dye, calcein.^[7,8] Calcein was found to be specifically incorporated and deposited into extracellular bone matrices as evidenced by costaining with Alizarin red S. The advanced characteristics of the method included the monitoring of the mineralization of the same specimens of cultured cells in a time-dependent manner owing to continuous cultivation without the fixation processes of cell layers. To evaluate the degree of mineralization by rat MSCs cultured on the substrates, we added calcein to the culture medium and observed the cells with a

Fig. 2 Cell shape of rat MSCs on t-HA ceramics, t- β -TCP ceramics, and TCPS dishes. The cells cultured on t-HA ceramics, t- β -TCP ceramics, and TCPS dishes are shown in (A, D), (B, E), and (C, F), respectively. Cell shapes were observed by phase-contrast microscopy at culture day 1 (A–C) and day 4 (D–F) after seeding of rat MSCs on each substrate. At culture day 1, the cells had spread completely on all substrates. After 4 days, the cells had proliferated well on all substrates. Original magnification is 100 \times .

Fig. 3 Calcein uptake by rat MSCs on t-HA ceramics, t- β -TCP ceramics, and TCPS dishes. The cells cultured on t-HA ceramics, t- β -TCP ceramics, and TCPS dishes are shown in (A, D), (B, E), and (C, F), respectively. On all substrates, the cells cultured for 14 days in the presence of Dex exhibited extracellular mineralization as indicated by a green fluorescence emission of calcein (A–C). The cells cultured without Dex did not exhibit extracellular mineralization and no green fluorescence emission was observed (D–F). Each inset is a phase-contrast microscopic image of the corresponding field. Original magnification is 100 \times .

fluorescence microscope. When cultured in the osteogenic condition for 14 days, the cells exhibited the same level of mineralized bone matrix on the t-HA ceramics, t- β -TCP ceramics, and TCPS dishes (Figs. 3A–C). Fluorescence microscopy demonstrated that the cells treated with Dex [Dex (+)] could differentiate into osteoblasts and had the capability of mineralization as evidenced by calcein uptake on all of the substrates (Figs. 3A–C). Even after a profuse matrix formation on the t-HA ceramics and t- β -TCP ceramics, the cell shapes could easily be recognized under observation by phase-contrast microscopy (insets of Figs. 3A–C). In contrast, the cells cultured in the absence of Dex [Dex (–)] showed no osteoblastic cell shape but did show a fibroblastic shape (insets of Figs. 3D–F). That the calcein emission was negligible demonstrated no evidence of matrix formation by the cells without Dex (Figs. 3D–F). The findings indicate that rat MSC can easily differentiate into osteoblasts on the surface of t-HA ceramics and t- β -TCP ceramics resulting in the formation of bone matrix under conditions of osteogenic culture. Importantly, the cascade of the differentiation of rat MSCs cultured on t-HA ceramics and t- β -TCP ceramics can be equally detected on TCPS dishes.

To confirm the osteogenic differentiation of rat MSCs on t-HA ceramics and t- β -TCP ceramics, we stained the cells with ALP and calcium staining (Alizarin red S) after 14 days of cultivation by

macroscopic observation. Alkaline phosphatase (ALP), which is a cell surface protein, is known as an early marker for osteoblastic differentiation, and Alizarin red S can identify calcium, which is the major inorganic component of bone matrices. When rat MSCs were cultured with Dex, many clusters of cells were clearly stained with ALP on the t-HA ceramics, t- β -TCP ceramics, and TCPS dishes at almost the same level (Figs. 4A–C). In contrast, the cells cultured without Dex were faintly stained with ALP on all the substrates (Figs. 4D–F). Alizarin red S staining is commonly used to determine calcium deposited into bone matrices. As seen in the ALP staining (Fig. 4), the cells cultured with Dex for 14 days were strongly stained with Alizarin red S (Figs. 5A–C), while the cells cultured without Dex were scarcely stained (Figs. 5D–F). After 14 days of culture, the DNA contents from each substrate were measured. The DNA contents were similar regardless of the culture substrate (data not shown). The biochemical data showed that osteogenic differentiation of rat MSCs cultured in the presence of Dex could occur on t-HA ceramics and t- β -TCP ceramics as well as on TCPS dishes.

DISCUSSION

In this entry, cell behavior including cell adhesion, cell proliferation, and cell differentiation on t-HA ceramics

Fig. 4 Alkaline phosphatase activity staining of rat MSCs on t-HA ceramics, t- β -TCP ceramics, and TCPS dishes. The cells cultured on t-HA ceramics, t- β -TCP ceramics, and TCPS dishes are shown in (A, D), (B, E), and (C, F), respectively. On all substrates, the cells cultured for 14 days in the presence of Dex were actively stained with ALP, indicated in red (A–C). The cells cultured without Dex were faintly stained with ALP (D–F). Single bar and double bars indicate 10 and 1 mm, respectively.

and t- β -TCP ceramics was compared with that on TCPS dishes. Tissue culture polystyrene dishes are considered the gold standard substrate for cell cultivation and were therefore used in the present experiment as a positive control. In the progress of tissue engineering, extreme attention has been focused on the development of new scaffold materials suitable for cell cultivation. If cultured cells, especially stem cells, retain their biological activity within the material, they are expected to have the capability of self-renewal and differentiation into lineage-committed cells after *in vivo* implantation. Therefore, the combination of cultured cells and biomaterials is vital for the successful fabrication of regenerative cultured tissues or organs. Numerous types of materials have been used as artificial bone substitutes. Such substitutes need a high degree of biocompatibility and sufficient mechanical strength. Some kinds of ceramics have frequently been used as artificial bone substitutes and have also been used for tissue engineering as a cell scaffold resulting in good bone formation.^[23–26] Actually, for hard tissue regeneration, we have employed a variety of ceramics such as bioactive β -TCP ceramics, glass ceramics, and bioinert alumina ceramics as well as bioactive HA ceramics.^[9,11,27] Maniatopoulos et al. reported that cultured rat bone marrow cells could form mineralization *in vitro* in the presence of Dex.^[21] We then

reported that rat MSCs treated with Dex showed high levels of ALP activity and demonstrated osteocalcin mRNA expression by northern blot analysis. The localization of the gene expression was identified in the cells surrounding the mineralized area because of *in situ* hybridization.^[7] We also showed that the osteogenic differentiation of rat MSCs could occur on glass and HA ceramic surfaces.^[9,28] Furthermore, we have demonstrated that human MSCs derived from bone marrow have been found to have osteogenic capability both *in vitro* and *in vivo*.^[29–32] These previous results confirm that rat and human MSCs derived from bone marrow can differentiate into active osteoblasts, which produce bone matrices in culture.

In these situations, observation of a cascade of cell behaviors might be an attractive field of research for clarifying cell/material interactions. Usually, cell behaviors are observed using a phase-contrast microscope. Unfortunately, on many types of ceramics, cells are difficult to observe because of the opaque nature of the ceramics. We previously utilized single-crystalline transparent alumina ceramics to observe cell behaviors such as cell adhesion, cell proliferation, and osteogenic potential using human MSCs.^[29,30] However, most other types of ceramics such as HA and β -TCP are not naturally transparent and it is difficult to create single-crystal or transparent ceramics. Alumina ceramics are

Fig. 5 Calcium staining of rat MSCs on t-HA ceramics, t- β -TCP ceramics, and TCPS dishes with Alizarin red S. The cells cultured on t-HA ceramics, t- β -TCP ceramics, and TCPS dishes are shown in (A, D), (B, E), and (C, F), respectively. On all substrates, the cells cultured for 14 days in the presence of Dex exhibited profuse extracellular mineralized matrices heavily stained with Alizarin red S (A–C). The cells cultured without Dex exhibited no obvious extracellular mineralized matrices (D–F). Single bar and double bars indicate 10 and 1 mm, respectively.

bioinert and have no bone-bonding properties. In contrast, HA ceramics and β -TCP ceramics are widely known as bioactive ceramics having bone-bonding properties and are suitable as scaffolds for culturing cells. However, owing to the opaque nature of the ceramics, cell behavior on the ceramics is difficult to observe. To overcome this shortcoming, the SPS process has recently been used for making certain types of transparent ceramics.

It is also well known that the surface characteristics of culture substrates affect cell behavior during culture periods. An appropriate level of surface hydrophilicity is needed for good cell adhesion. As seen in Table 1, the surface wettability of t-HA ceramics and t- β -TCP ceramics is similar to that of TCPS dishes. The optimal wettability for cell attachment is considered to be about 70° (defined by SCA), and the SCA of t-HA ceramics and t- β -TCP ceramics as well as TCPS dishes is nearly 70° . Additionally, the surface of t-HA and t- β -TCP ceramics is very smooth in comparison to that of TCPS dishes as observed by SEM (data not shown). These results indicate that the wettability of t-HA and t- β -TCP is suitable for cell adhesion.

As shown in Fig. 2, both t-HA ceramics and t- β -TCP ceramics exhibited cellular adhesive and proliferative characteristics comparable to those of TCPS

dishes. By using transparent materials, we can use a microscope to monitor the cellular event cascade of the same samples throughout the culture period. Cell adhesion molecules could be considered the reason the ceramics showed high cellular affinity. Although further experiments are required to clarify the mechanisms of the excellent properties of t-HA ceramics and t- β -TCP ceramics, fibronectin (FN) in serum or produced by the cells is thought to be a principal factor for promoting cellular adhesion and spreading on the substrates. In comparison with polystyrene treated for tissue culture (TCPS), the interaction of FN with bare polystyrene (as is commonly used for bacterial agar plates) is weak and about 1/10 as effective in cell binding. Therefore, a TCPS dish is an excellent substrate for cell culture and was therefore used as a positive control in this study. The degree of cell adhesion and cell proliferation on t-HA ceramics and t- β -TCP ceramics was similar to that on TCPS dishes (Fig. 2). The results suggest that the surface properties of t-HA ceramics and t- β -TCP ceramics are equivalent to those of TCPS dishes, which results in the capability of supporting cellular adhesion and proliferation.

The *in vitro* osteogenic differentiation on various types of ceramics can be evaluated by ALP staining or calcium staining with Alizarin red S after fixation, as

shown in Figs. 4 and 5. However, we have not been able to repeatedly monitor the same specimen during the culture period because of cell death caused by fixative solutions. Now, we have developed a new method for clearly monitoring the osteogenic differentiation indicated by fluorescence emission of calcein added to the culture medium (Fig. 3). The fluorescence can be repeatedly detected for the same specimen during the entire culture period. As seen in Fig. 3, we confirmed the osteogenic capability of rat MSCs cultured on t-HA ceramics and t- β -TCP ceramics in a time-dependent manner. The results also showed that the capabilities of t-HA ceramics and t- β -TCP ceramics to support in vitro osteogenic differentiation of MSCs were similar to that of TCPS dishes.

Recently, composites of various types of biomaterials and cultured cells have been used for clinical treatments. In fact, we have succeeded in fabricating regenerative cultured bone tissues by using various types of ceramic scaffolds and MSCs derived from the patients' own bone marrow (Fig. 1). The regenerative cultured bone tissues were then implanted into the same patients. Before implantation, evidence of adequate cellular functions is strongly needed to guarantee the efficacy of cell-based therapy. In the case of bone tissue regeneration, validation of the osteogenic capability of the MSCs on the ceramics is a prerequisite for clinical applications. However, it is difficult to validate this capability in cells cultured on ordinary ceramics by light microscopy because of the opacity of the ceramic material. Here, we demonstrated that transparent ceramics enable direct monitoring of living cells by light microscopy. Therefore, it is suggested that transparent biomaterials could be used as a validation system for culturing cells on such materials because they will be able to give us information such as cell morphology and differentiation. We concluded that transparent bioactive materials could be useful materials for clinical research in regenerative medicine as well as in vitro basic research in tissue engineering.

CONCLUSIONS

We fabricated new bioactive materials, t-HA ceramics and t- β -TCP ceramics as cell culture scaffolds. The ceramic materials enabled the observation of cultured cells by phase-contrast microscopy. Cell shapes on both types of transparent ceramics were clearly observed at almost the same level as that observed on TCPS dishes. In this study, rat MSCs were cultured on the substrates. Cell adhesion, proliferation, and differentiation of rat MSCs on t-HA ceramics and t- β -TCP ceramics were significantly similar to those on TCPS dishes and were confirmed by qualitative

biochemical assays. The observation of living cells on t-HA ceramics and t- β -TCP ceramics could be used as a validation system of cellular behavior in the fields of regenerative medicine and tissue engineering.

INTRODUCTION

Ultra-high molecular weight polyethylene (UHMWPE) is widely used in orthopedics, especially in the fabrication of articular components for arthroplasties, in particular, the acetabular cup or liner in a total hip joint replacement (THJR) and the tibial insert in a total knee joint replacement (TKJR). UHMWPE is used for these applications due to its excellent biocompatibility, high impact strength, remarkable wear resistance, and low friction coefficient. In this article on UHMWPE, we address four topics. The first section presents the procedure of how UHMWPE powder is synthesized and then processed into test specimens (for laboratory studies) and near-final and/or final net-shape components (for orthopedic uses). A key element of this synthesis is the use of a Ziegler-Natta catalyst in the chain polymerization process. The processing methods in current use are compression sintering, ram extrusion, and direct compression molding.

In the second section, the structure and properties of UHMWPE are discussed, with special reference to lamellae structure, plastic deformation of crystallites, microscopic surface morphology, and physical and mechanical properties. The lamellae (crystalline units of UHMWPE) are known to have an important influence on the mechanical properties of the polymer. UHMWPE powder particles have a porous and irregularly shaped surface morphology. However, scanning electron microscopy (SEM) observation at a high magnification reveals a complex and hierarchical structure. These morphological features play an important role in the consolidation of UHMWPE powders during the sintering process and affect the resultant bulk mechanical properties of the polymer.

The focus of the third section is description of the various methods used for sterilizing UHMWPE implants and the resultant structural changes that they produce in the polymer. The special emphasis in this section is gamma irradiation in ambient air. This sterilization method has raised many concerns in

regard to the long-term in-vitro and in-vivo stability of UHMWPE parts, because the gamma irradiation causes progressive and irreversible damage to the polymer, resulting in significant depreciation in its physical, chemical, and mechanical properties.

Some recent developments and future challenges in the field of UHMWPE are discussed briefly in the fourth section.

SYNTHESIS AND PROCESSING

In the early 1950s, Karl Ziegler of the Max Planck Institute in Muhlheim-Ruhr, Germany, developed a method for synthesizing UHMWPE powders. This method uses a Ziegler-Natta catalyst made from titanium chloride and organo-aluminum compounds (triethyl-aluminum or diethyl-aluminum chloride). Because these chemicals are very sensitive to air and moisture, all the steps in the synthesis are carried out in an inert gas environment. Pure ethylene and a suspending agent without polar impurities are important prerequisites for successful synthesis. Catalysts are produced in one vessel and are then diluted in a second vessel. The catalyst suspension is pumped into a polymerization reactor, where it reacts with the ethylene gas to form polyethylene. Polymerization takes place at a temperature of between 65°C and 85°C under a pressure of between 0.5 MPa and 2.0 MPa. The molecular weight of polyethylene can be controlled by adding very small amounts of hydrogen to the ethylene gas or by changing the polymerization temperature.^[1]

In chain polymerization, the ethylene molecules remain attached onto the active sites of the catalyst particles. The polyethylene keeps growing around these particles until the polymer finally encapsulates them. Polymer particles become much larger than the catalyst particles, but the polymerization does not proceed indefinitely. Instead, it has a limit, yielding a polymer with a molecular weight of no more than

Table 1 Nomenclature of ticona and montell UHMWPE resins

Resin	Manufacturer	Mean M.W. (10^6 g/mol)	Calcium stearate included	Maximum conc. of calcium stearate (ppm)
GUR 1150	Hoechst/Ticona	5.5~6.0	Yes	500
GUR 1050	Hoechst/Ticona	5.5~6.0	No	75
GUR 1120	Hoechst/Ticona	3.5	Yes	500
GUR 1020	Hoechst/Ticona	3.5	No	75
1900	Himont/Montell	4.4~4.9	No	NA
1900H	Himont/Montell	> 4.9	No	NA

(Note: Prior to 1998, when Ticona was known as Hoechst, the UHMWPEs that they produced in the United States were designated as GUR 4150, GUR 4050, GUR 4120, and GUR 4020.)

(From Ref. [2].)

between 6×10^6 g/mol and 7×10^6 g/mol. With the polyethylene particles that remain in suspension, a centrifuge separates the suspending agent, and the remaining solvent is removed by steam distillation. Hot nitrogen is used to remove the residual moisture. The final product is a fine white powder. Though the sizes of the powder particles are not the same, most of them are less than 300 μ m in diameter. As an additive, very small amounts of fine calcium stearate may be added to the polyethylene powders to eliminate the residual catalysts, which have the potential for corroding the conversion machines. The calcium stearate has two other functions. First, it acts as a lubricant when a part is to be fabricated using ram-extrusion of the polymer powders. Second, it helps the polyethylene powders to maintain a white color. However, there are concerns about using calcium stearate, as it may cause fusion defects in a fabricated part and, hence, lead to a depreciation of its properties. Fabricators of UHMWPE parts that are used in arthroplasties are now switching their protocols to produce UHMWPE resins with either very small amounts of calcium stearate or none at all (Table 1). The issue of the quality of UHMWPE to be used in fabricating orthopedic articular components is addressed in ASTM F 648-96 (Table 2).^[3] (It should be noted, however, that the standard applies to raw UHMWPE powders and fabricated forms of UHMWPE, and not to packaged and sterilized implants.)

The high melt-flow resistance of UHMWPE makes the processing of UHMWPE powders into bulk products very challenging. There are three fabrication methods in current use. The first is compression sintering. A charge of polymer powder is evenly distributed in a female mold cavity and then covered by a male mold. The system is then subjected to a combination of high temperature and high pressure for a certain amount of time. Then the system is cooled at a slow and uniform rate in order to minimize shrinkage and deformation of the product (the stock). The stock

is then machined into smaller blocks or cylindrical bars from which UHMWPE articular components can be machined. The second method, ram extrusion of the UHMWPE powders, produces cylindrical bar stocks ranging in diameter from 25 mm to 150 mm. In this process, the UHMWPE powder charge is fed into a chamber and then heat is applied (through electrical resistors) to the charge. A ram then compresses and extrudes the plasticized powder charge into a heated cylindrical barrel, where it is consolidated into a cylindrical bar stock. (It should be noted that as the ram moves back and forth, the powder stock in the chamber is refilled.) UHMWPE articular components may then be machined from this bar stock. In the third method, direct compression molding, the UHMWPE powder charge is consolidated into a final or semi-final bulk product using a preshaped mold. Although this process is slow and costly, orthopedic articular components made using this method have very smooth surface finishes and excellent dimensional consistency.

Fabrication method and resin type are known to be two important factors that influence the clinical

Table 2 Requirements for UHMWPE, per ASTM F 648-96

Property or feature	Requirement
Molecular weight	3×10^6 g/mol
Yield strength	19 MPa
Elongation (minimum)	250%
Density	0.927 g/cm ³ –0.944 g/cm ³
Hardness (minimum)	60 D
Impact strength	30 kJ/m ²

performance of UHMWPE articular components. Examinations of retrieved acetabular cups revealed that directly compression-molded components (made using polymer powders that do not contain calcium stearate) showed better wear performance compared to ram-extruded and machined ones.^[4] Another study evaluated gamma-irradiated, in ambient air, and shelf-aged (2 months–16.5 years) tibial inserts made from Himont 1900, GUR 415, and GUR 412 resins.^[5] A significant difference was found in the oxidation rates between these two sets of inserts; specifically, the Himont 1900 inserts oxidized more slowly and possessed better mechanical properties than those fabricated from GUR 415 or GUR 412.

STRUCTURE AND PROPERTIES

UHMWPE is a linear homopolymer (with a repeating unit of CH_2CH_2) that has C—H and C—C covalent single bonds, with the neighboring chains interacting through van der Waals forces (Fig. 1). UHMWPE is a semicrystalline polymer, which means that it has both crystalline and amorphous phases. The regularity of the arrangement of the polymer chains gives the polymer a unique crystalline structure. In the amorphous state, the macromolecular chains are randomly oriented. In the crystalline region of polyethylene, groups of orthorhombic unit cells form a lamella, which is composed of the folded polyethylene chains (Fig. 2). The lamellae are packed together in parallel fashion and are separated from the layers of amorphous polymer chains. The thickness and length of a lamella are, typically, 5–25 nm and 10–50 μm , respectively.

In the folded-chain model, the macromolecular chains form a fold within the lamellae and reenter into the same crystallites. Several models have been proposed to explain the folding of polymer chains into the lamellae from which they emerge. However, a common feature of all these theories is the point that there are molecules that do not fold back into the same lamellae but, rather, become part of the lamellae. Such

Fig. 1 Basic structural unit of polyethylene with the repeating unit in parentheses and an orthorhombic crystal structure of polyethylene with $a = 0.74$ nm, $b = 0.493$ nm and $c = 0.254$ nm. (From Ref. [6].)

Fig. 2 Transmission electron micrograph of the lamella structure of UHMWPE. (Courtesy of Stephen Spiegelberg of Cambridge Polymer Group, Inc., Cambridge, MA.)

molecules are called tie molecules. Formation of tie molecules provides high toughness to the polymer because these molecules link the lamellae together. In the absence of these intercrystalline connections, it would be difficult for UHMWPE to undergo large plastic deformation.

UHMWPE powders have a very intriguing morphology (Fig. 3). At low magnification, the particles have a porous and irregularly shaped, rounded structure. However, at high magnification, the structure is complicated and hierarchical. A nodule is a basic structural unit and these nodules are interconnected by very fine fibrils. Aggregates of the nodules organize into a larger structural form and groups of the aggregates form a single powder particle. These highly developed structural features can contribute to a high sintering time for the UHMWPE powders; for example, 25 min at 180°C for a polymer with mean molecular weight (M_m) of 4×10^6 g/mol, and 90 min at 180°C for a polymer with M_m of 5×10^5 g/mol. It should be noted that the surface morphology of UHMWPE powder particles plays a significant role both in the sintering behavior of UHMWPE powders and in the mechanical properties of the solid polymer.^[7,8]

The deformation mechanism of UHMWPE reflects the relationship between its structure and its mechanical behavior. When a semicrystalline polymer, such as UHMWPE, is subjected to increasing stress, plastic deformation does not occur until the stress exceeds a certain limit (yield strength), at which point elastic response ends and permanent structural damages take place. In the case of UHMWPE, deformation begins with the disruption of the amorphous phase and breakdown of the crystalline phase is followed by a

Fig. 3 Scanning electron micrographs of UHMWPE powder particles at low (A) and high (B) magnification.

large plastic strain. In some cases, the contribution of the amorphous phase is of importance in the interpretation of the viscoelastic behavior of the polymer.^[9] The predominant deformation of UHMWPE occurs through a crystallographic slip within the crystalline regions. In general, a single slip system can lead only to a simple shear deformation of the crystallites, not structural changes. Slip would take place more easily along directions where the dislocation motions require the least energy. When an UHMWPE specimen is loaded in tension, it is elongated without plastic deformation. Beyond the yield strength, however, plastic deformation begins and the polymer elongates further. At this point, more slips are produced and the resultant dislocations interact and, eventually, entangle. These events make further slip difficult, resulting in strain hardening of the polymer. More details about the plastic deformation of polyethylene have been given by many workers.^[6,10]

In some literature reports, UHMWPE is referred to as high-density polyethylene. However, there are many

Table 3 Comparison of physical and chemical properties of high-density polyethylene (HDPE) and ultra-high molecular weight polyethylene, UHMWPE

Property	HDPE	UHMWPE
Molecular weight (10^6 g/mole)	0.05–0.20	2.0–6.0
Melting point ($^{\circ}\text{C}$)	130–137	125–135
Density (g/cm^3)	0.952–0.965	0.930–0.945
Tensile yield strength (MPa)	26.2–33.1	19.3–23.0
Elongation at failure (%)	10–1,200	200–350
Tensile modulus (GPa)	0.4–4.0	0.8–1.5
Izod impact (J/m)	21–210	>1,070–no break
Shore-D hardness	66–73	60–65

(From Ref. [11].)

differences between these two polymers (Table 3). In comparison to conventional polyethylene, the long linear chains of UHMWPE compromise their ability to arrange themselves into crystalline structures such as spherulites, thus limiting the percent crystallinity (%C) and density. The density of UHMWPE is close to that of low-density polyethylene ($0.925\text{--}0.935\text{ g}/\text{cm}^3$). The melting point (T_m) and % C of UHMWPE depend on the resin type. Given the load-bearing duty of UHMWPE articular components in total joint prostheses, the polymer's fracture toughness is one of the many mechanical properties that is of particular importance. For tough polymers, such as UHMWPE, the fracture toughness is determined using the J-integral method. Lewis and Nyman^[12] reported a J-integral fracture toughness of $92.0\text{ kJ}/\text{m}^2$ for unsterilized and unaged UHMWPE and $44.3\text{ kJ}/\text{m}^2$ for gamma-irradiated, in air, unaged UHMWPE.

STERILIZATION METHODS AND STRUCTURAL MODIFICATIONS

Until recently, most orthopedic device companies sterilized UHMWPE articular components by gamma irradiating them, in ambient air. For this purpose, gamma rays from a cobalt-60 source, at a dosage of between 2.5 Mrad and 4.0 Mrad (25–40 kGy), were commonly used. However, it is now widely known that this sterilization method brings about extensive, deleterious, and irreversible structural changes in the polymer; namely, breakage of the C—C bonds (chain scission) and breakage of the C—H bonds to create free radicals, the majority of which remain highly reactive in the polymer structure for extended periods. (It is fair to point out that a few of the carbon radicals

recombine to form cross-links, a structural change that has a positive effect on some of the polymer's properties.) These free radicals can take part in oxidative reactions in the polymer by reacting with oxygen species from one or more of the following sources: 1) dissolved oxygen present at the time of the irradiation; 2) oxygen that has diffused into the component during shelf storage; and 3) for the implanted articular components, dissolved oxygen in the body fluid. There have been numerous reports of oxidative degradation of UHMWPE. In many of these reports, the change in the peak intensity of the carbonyl region (wave number of 1720 cm^{-1}) in the FTIR spectrum of UHMWPE is taken as index of the extent of oxidation (or oxidation index, OI) of the polymer. According to one study, the OI of shelf-aged (2–11 years) UHMWPE acetabular liners increased with shelf aging time and showed a maximum level at a layer positioned between 0.5 mm and 2.0 mm below the surface.^[13] It has also been reported that sterilization using ethylene oxide gas (EtO) or gas plasma leads to a substantially lower level of OI of UHMWPE compared to when gamma irradiation, in ambient air, is used.^[14]

The oxidative degradation of UHMWPE is affected by many parameters, notably sterilization method and poststerilization aging conditions (environment and time). Furthermore, it is widely agreed that the oxidative degradation of UHMWPE causes or substantially contributes to the depreciation of the in-vitro properties and in-vivo behavior of UHMWPE components that are gamma-irradiated, in ambient air. Densities of the gamma-irradiated UHMWPE specimens continuously increased up to a radiation dosage of 16 Mrad but remained unchanged thereafter.^[15] The %C showed a similar trend. The increase in %C is highly associated with rearrangement of the polymer chains. It is believed that the radiation-induced scission of tie molecules in UHMWPE contributes to: 1) an increase of %C, 2) crystallization in amorphous regions, and 3) crystal growth in the crystalline regions.^[16] Gamma irradiation, in ambient air, causes a stiffening of the material, leading to increases in the elastic modulus and the yield strength of UHMWPE. In turn, increased stiffness decreases the polymer's ductility and, consequently, influences its fracture toughness and fatigue strength.

Sutula et al.^[17] reported the side effects of gamma irradiation, in ambient air, of UHMWPE, which altered the polymer's chemical and mechanical properties over time. The results showed high subsurface oxidation, reduced ductility, and decreased strength. A subsurface white band was frequently observed in the gamma-sterilized components and this zone was also where significantly reduced levels of strength and ductility of the polymer were seen. Tensile tests of 23 UHMWPE acetabular components showed that

presence of the subsurface white band adversely affected the mechanical properties of the polyethylene.^[17] Although the ultimate tensile strength (UTS) and % elongation in the absence of gamma sterilization and subsurface white band were 45 MPa and 630%, respectively, the corresponding values for specimens that were gamma irradiated and exhibited the subsurface white band were 20 MPa and 70%, respectively. Fatigue strength of the polymer, a property that is very important for its use in fabricating articular components for arthroplasties, is also adversely affected by gamma irradiation compared to other sterilization methods.^[18] Results of rotating beam fatigue tests found the fatigue limit to be 17.5 MPa for UHMWPE gamma irradiated, in ambient air, and 31 MPa for unsterilized UHMWPE. Even though the patterns of the applied-stress-versus-number-of-cycles-to-failure curve, over the first two million cycles, were the same for these two sets of specimens, the fatigue strength of the gamma-irradiated UHMWPE began to decrease sharply and resulted in more than 40% reduction after ten million cycles. The fatigue strength (28 MPa) for EtO-sterilized UHMWPE was not significantly lower than that for the unsterilized material.

The undesirable outcomes of gamma irradiation, in ambient air, prompted the search for alternative sterilization methods, such as: 1) gamma irradiation, in a reduced oxygen, nitrogen gas, or vacuum environment; gamma radiation, in a vacuum foil package; 2) sterilization using EtO; and 3) sterilization using gas plasma. EtO sterilization of UHMWPE parts is accomplished by the diffusion of EtO gas into the near-surface areas to kill bacteria, viruses, and spores. All residual EtO is then removed from the UHMWPE part. Gas plasma sterilization is accomplished by subjecting the UHMWPE part to ionized gas (peracetic acid or hydrogen peroxide gas plasma) at a temperature below 50°C . Investigations suggest that EtO and gas plasma sterilization methods do not adversely affect the chemical, physical, and mechanical properties of UHMWPE.^[19,20] The alternative sterilization methods all led to materials with lower values of OI and higher UTS compared to the corresponding values for UHMWPE that was gamma irradiated, in ambient air. Furthermore, the clinical performance of UHMWPE articular components that are sterilized using EtO or gas plasma has been reported to be acceptable during short-term use.^[21]

RECENT DEVELOPMENTS AND FUTURE WORK

Progress continues to be made on two fronts, namely: 1) improvement in the quality of the UHMWPE stock material; and 2) use of cross-linking (and associated postcross-linking stabilization regimens) for producing

UHMWPE parts with excellent in-vitro and in-vivo wear performance.

Two examples of the commercially available improved stock materials are ArCom™ (Biomet, Inc., Warsaw, IN, U.S.A.) and Duramer™ (Wright Medical Technology, Inc., Arlington, TN, U.S.A.). ArCom™ uses a very high molecular weight resin followed by sterilizing the stock using gamma radiation, in an argon environment. After further processing, final products are placed in an argon-filled package. The combination of the sterilization and packaging methods used leads to an enhancement of the material's properties, particularly its wear resistance. ArCom™ is used to fabricate the tibial inserts in, for example, AGC and TCCK designs (Biomet, Inc., Warsaw, IN, U.S.A.) of TKJR. Duramer™ is made by an optimized ram extrusion processing of GUR 415 resin followed by sterilization of the final part using EtO.

The introduction of cross-links within the UHMWPE structure has generated great interest due to the significantly improved wear resistance of the polymer compared to the uncross-linked variant. Currently, three methods that are widely used for cross-linking UHMWPE are gamma irradiation, electron beam irradiation, and chemicals.^[22] With gamma irradiation, the dosage used ranges from 5 to 100 Mrad. As for chemical-induced cross-linking, dicumyl peroxide and 2,5-dimethyl-2,5-bis (*tert*-butylperoxy)-3-hexyne (Peroxide 130) have gained the most attention as the chemical. These peroxides, either in liquid or powder form, are typically mixed with UHMWPE powders and then consolidated by compression molding or hot isostatic pressing. The peroxides begin to decompose in the system by chemical reactions, culminating in the formation of the cross-links within polymer network. It should be pointed out that when the gamma or electron beam irradiation method is used, cross-linking occurs in the solid state of the UHMWPE, but when peroxide is used, cross-linking takes place above the polymer's melting temperature. This results in decreased density of peroxide-cross-linked UHMWPE due to a hindered crystallization of cross-linked polyethylene melt. Substantial improvement of wear resistance has been extensively reported with cross-linked UHMWPE. McKellop et al.^[23] reported that, in hip joint simulator tests, the wear resistance of UHMWPE acetabular cups cross-linked by 28 Mrad gamma radiation was excellent. In another study,^[24] it was reported that the steady-state radiographic wear rate was 0.06 mm/year for implanted 100 Mrad gamma-irradiated UHMWPE acetabular cups. This value was substantially lower than the mean of 0.29 mm/year for unirradiated cups. Oonishi et al.^[25] examined retrieved polyethylene acetabular cups that were 100 Mrad irradiated before implantation (in-vivo time of between 15 years and 16 years). Compared to

the unirradiated cups, the UTS and gel content of the retrieved UHMWPE cups did not show significant deterioration in the presence of a high free radical level.

The enhanced wear resistance of cross-linked UHMWPE is associated with the fact that cross-linking contributes to a decrease in the mobility of polymer chains. Edidin et al.^[26] have postulated that, in UHMWPE, plasticity-induced lamellar alignment is believed to be a precursor of wear generation, because this irreversible plastic deformation is a consequence of the structural deformation of the polymer followed by continuous cyclic load. The suppressed chain mobility thus minimizes the depth of the lamellar alignment layer from the articulating surface, which, in turn, produces fewer wear debris. Despite improved wear resistance, there have been many concerns about gamma-irradiation-cross-linked UHMWPE, especially with respect to its decreased ductility, fatigue crack propagation resistance, and fracture toughness.^[18,27] Investigation of the fracture toughness of the cross-linked UHMWPE found a steady decrease of resistance of crack propagation (J_{ss}) with increase in gamma irradiation dosage (116.9 kJ/m² at 0 Mrad; 98.5 kJ/m² at 5 Mrad; and 79.3 kJ/m² at 20 Mrad).^[28] Cole et al.^[29] showed that the reduction of fracture toughness is both radiation dosage- and resin type-dependent. In this study, two different resins were examined (GUR 1050 and Himont 1900). The fracture toughness values were reported to be 40.4 kJ/m² and 15.4 kJ/m² for GUR 1050 at 3.3 Mrad and 10.0 Mrad, and 21.6 kJ/m² and 19.1 kJ/m² for Himont 1900 at the same radiation dosages. Another problem with highly cross-linked UHMWPE is the large amount of free radicals produced after radiation or peroxide cross-linking. These free radicals can accelerate the oxidative degradation of an UHMWPE articular component during shelf storage as well as in vivo. In an effort to eliminate as many of these free radicals as possible, it is now standard practice to subject the cross-linked part to some stabilization treatment; for example, UHMWPE parts that are cross-linked using electron beam radiation are annealed at a temperature above the polymer's melting temperature.^[30]

Although cross-linked UHMWPE parts have been shown to have substantially improved wear resistance (relative to uncross-linked ones), other relevant material properties (such as fracture toughness and fatigue crack propagation rate) are sacrificed. Thus, as far as UHMWPE is concerned, the main challenge facing orthopedic device manufacturers is to develop cross-linking method(s) that will simultaneously enhance the polymer's wear performance with no accompanying depreciation in any of its other important material properties.

Ultrasound and Tissue Interaction

K. Kirk Shung

Department of Biomedical Engineering, University of Southern California, Los Angeles, California, U.S.A.

INTRODUCTION

Ultrasound has been used as a clinical imaging modality since the late 1950s. The primary form of ultrasonic imaging to date has been that of a pulse-echo mode. The principle is very similar to that of sonar and radar. In essence, following an ultrasonic pulse transmission, echoes from the medium being interrogated are detected and used to form an image. Today, ultrasound capable of both anatomic imaging and blood flow imaging based upon the Doppler principle is the second most utilized diagnostic imaging modality in medicine, next only to conventional X ray, and is a critically important diagnostic tool of any medical facility.

Ultrasound, while best known for its diagnostic capability, has also been used for therapeutic purpose. Significant progress has also been made in ultrasound hyperthermia, frequently in combination with chemotherapy or radiotherapy, for the treatment of tumors, in high-intensity focused tissue ablation, and in ultrasound-mediated drug delivery.

FUNDAMENTALS OF ACOUSTIC PROPAGATION

Ultrasound is characterized by acoustic parameters such as pressure, particle (or medium) velocity, particle displacement, density, and temperature. It is a sound wave with frequencies higher than the audible range, i.e., 20 kHz. If an ultrasound source is applied to a medium, the medium is displaced by the external energy. The distance traveled by the medium is called particle or medium displacement, which is extremely small. The velocity of the medium is called particle or medium velocity and is in the order of a few centimeters per second. The medium velocity is different from the rate at which the energy is propagating through the medium. The velocity at which the ultrasound energy propagates through the medium is defined as the phase velocity or the sound propagation velocity, c . In water, c is approximately 1500 m/s. If the displacement of the medium is in the same direction as the direction of wave propagation, this type of acoustic wave is called a longitudinal or

compressional wave. If the displacement of the medium is perpendicular to the propagation direction, this type is called a shear wave. All wave concepts can be applied to ultrasound. Ultrasound wavelength λ , frequency f , and velocity c , are related by

$$f\lambda = c \quad (1)$$

For a plane wave propagating in a medium in the z -direction, the acoustic parameters vary as a function of time and space governed by the wave equation.

$$\frac{\partial^2 W}{\partial z^2} = \frac{\rho}{v + 2\mu} \frac{\partial^2 W}{\partial t^2} \quad (2)$$

where W , ρ , and t denote, respectively, medium displacement in z -direction, density, and time. The two symbols, v and μ , are Lamé constants and μ is also called shear modulus. The solutions for this second-order differential equation has the form of $f(z \pm ct)$, where the negative sign indicates a wave traveling in the $+z$ -direction, whereas the positive sign indicates a wave traveling in the $-z$ -direction. The displacement W is in the same direction as the wave propagation direction, z . This type of wave is called a compressional or longitudinal wave. The sinusoidal solution for this equation is:

$$W^\mp(z, t) = W_0 e^{j(\omega t \pm kz)} \quad (3)$$

where W^- and W^+ denote displacements for positive- and negative-going waves, respectively, ω = angular frequency = $2\pi f$, $k = \omega/c$ is the wave number, and sound velocity, c , is given by

$$c = \sqrt{\frac{v + 2\mu}{\rho}} \quad (4)$$

For a fluid $\mu = 0$,

$$c = \sqrt{\frac{B}{\rho}} = \sqrt{\frac{1}{G\rho}} \quad (5)$$

It is worth noting from this equation that the sound velocity in a medium is determined by the density and

U

the compressibility of a medium. This means that a measurement of velocity may yield useful information about the acoustic or mechanical properties of a medium. For instance, sound velocity in air is much smaller than in water.

For a case where the displacement in x -direction U is perpendicular to the direction of propagation z , the wave equation becomes:

$$\frac{\partial^2 W}{\partial x^2} = \frac{\rho}{\mu} \frac{\partial^2 W}{\partial t^2} \quad (6)$$

The sinusoidal solution is

$$W^\mp(x, t) = W_0 e^{j(\omega t \pm k_t x)} \quad (7)$$

This type of wave expressed by Eq. (7) is called a shear or transverse wave. The wave number for the shear wave is given by $k_t = \omega/c_t$ where c_t is the shear wave propagation velocity given by

$$c_t = \sqrt{\frac{\mu}{\rho}} \quad (8)$$

It is obvious from Eq. 8 that a shear wave can only exist in a medium with nonzero shear modulus, that is, fluid cannot support the propagation of a shear wave.

Both the longitudinal and shear velocities, as apparent from Eqs. (5) and (8) are affected by the mechanical properties of a tissue. Pathological processes that alternate these properties can cause the sound velocity to change. Therefore, if the velocity can be accurately measured, the result can be used to infer or diagnose the pathology. A few ultrasonic devices in the market today for diagnosing osteoporosis are based upon this principle since osteoporosis causes a loss of bone mass.

CHARACTERISTIC IMPEDANCE

For sinusoidal plane wave acoustic propagation, the characteristic acoustic impedance of a medium is defined as the ration of pressure p to medium velocity u :

$$Z^\pm = \frac{p^\pm}{u^\pm} = \pm \rho c \quad (9)$$

The acoustic impedance has a unit of $\text{kg/m}^2\text{-sec}$ or Rayl. The positive and negative signs are for the positive- and negative-going waves, respectively. The acoustic velocity and impedance for a few common materials and biological tissues are listed in Table 1. The acoustic velocity in a medium is a sensitive function of the temperature, but its dependence on frequency is minimal over the frequency range from 1 to 15 MHz. The acoustic impedance is a very important parameter in ultrasonic imaging since it determines the amplitude of the echoes that are reflected or scattered by tissue components. These echoes are acquired by an imaging device to form an image.^[1-3]

INTENSITY

The instantaneous intensity of an ultrasonic wave is the average power carried by a wave per unit area normal to the direction of propagation over time and is given by

$$i(t) = p(t)u(t)$$

For the case of sinusoidal propagation, the average intensity I can be found by averaging $i(t)$ over a cycle.

$$I = p_0 u_0 \cdot \frac{1}{T} \int_0^T \sin^2 \omega t = \frac{1}{2} p_0 u_0 \quad (10)$$

Table 1 Acoustic properties of biological tissues and relevant materials

Material	Speed m/s at 20–25°C	Acoustic impedance, MRayl	Attenuation coefficient, neper/cm at 1 MHz	Backscattering coefficient, $\text{cm}^{-1} \text{sr}^{-1}$ at 5 MHz
Air	343	0.0004	1.38	–
Water	1480	1.48	0.00025	–
Fat	1450	1.38	0.06	–
Myocardium (perpendicular to fibers)	1550	1.62	0.35	8×10^{-4}
Blood	1550	1.61	0.02	2×10^{-5}
Liver	1570	1.65	0.11	5×10^{-3}
Skull bone	3360	6.00	1.30	–
Aluminum	6420	17.00	0.0021	–

where p_0 and u_0 denote peak pressure and medium velocity, and T is the period.

RADIATION FORCE

An acoustic wave exerts a force on any interface across which there is a decrease in ultrasonic intensity in the direction of wave propagation. For a plane wave of intensity I propagating in a medium with a sound velocity c , the radiation force per unit area or radiation pressure f_r is given by

$$f_r = a(I/c) \quad (11)$$

where a is a constant, depending on the acoustic properties of the target and its geometry.^[4] If a target is made of a material of large acoustic impedance, such as steel, and reflects almost completely the ultrasound beam propagating in water, $a=2$. If the target is a perfect absorber, $a=1$.

The radiation force has been used as a means to perturb an object remotely so that from the displacement of the object, which can be measured via ultrasonic imaging, an assessment of the elastic properties of the medium surrounding the object may be made.^[5]

REFLECTION AND REFRACTION

Reflection and refraction of a plane ultrasonic wave occurs at a flat interface between two media, I and II, of different acoustic impedance. The directions of the reflected and refracted waves are governed, just as in optics, by Snell's law. This is illustrated in Fig. 1 where the subscripts i , r , and t refer to incident, reflected and transmitted, or refracted waves, respectively. As in optics,

$$\theta_i = \theta_r, \text{ and } \sin \theta_i / \sin \theta_t = c_1 / c_2 \quad (12)$$

When $\theta_t = \pi/2$, $\sin \theta_t = 1$, and $\theta_{ic} = \sin^{-1} c_1 / c_2$ if $c_2 > c_1$. For any incident angle greater than θ_{ic} , there is

Fig. 1 A plane ultrasonic wave reflected and refracted by a flat interface between two media.

no transmission, that is, total reflection occurs. Therefore, θ_{ic} is called the critical angle.

The pressure reflection and transmission coefficients, R and T , can be easily found by using the boundary conditions that the pressure and particle velocity should be continuous across the boundary.

$$R = \frac{p_r}{p_i} = \frac{Z_2 \cos \theta_i - Z_1 \cos \theta_t}{Z_2 \cos \theta_i + Z_1 \cos \theta_t} \quad (13)$$

$$T = \frac{p_t}{p_i} = \frac{2Z_2 \cos \theta_i}{Z_2 \cos \theta_i + Z_1 \cos \theta_t} \quad (14)$$

As an acoustic wave propagates through an inhomogeneous medium such as biological tissues, part of its energy will be lost due to absorption and scattering, which will be discussed later, and part of its energy will be lost due to specular reflection at the boundary of two adjacent layers of tissues. The ultrasonic images are formed from the specularly reflected echoes due to planar interfaces as well as the diffusely scattered echoes due to small inhomogeneities in tissue parenchyma. Therefore, any change in the elastic properties of the tissues as a result of a disease may be detectable from the ultrasonic image. This has been the principal rationale behind the conventional pulse-echo ultrasonic imaging methods. Since both scattering and reflection depend on the elastic properties of the tissues, which determine the acoustic impedance of the tissue, intuitively, one may postulate that echographic visualizability of tissues is determined mostly by their connective tissue content.^[6] The acoustic impedance of connective tissues and tissues containing high concentrations of connective tissues has been found to be much higher than other types of tissue components such as fat and protein and tissues containing less connective tissues. Because of their higher impedance than surrounding tissues, tissues that contain more connective tissues are more echogenic than those that contain less. However, it must be noted that the attenuation of ultrasound in connective tissues is also much higher. Very little energy can transmit through a mass such as a solid tumor composed of mainly connective tissues. Thus, an acoustic shadow may be created behind such a mass. This has been used as one of the criteria for diagnosing tumors. The origin of the ultrasonic echoes observed in an ultrasonic image for most of the soft tissues has not yet been determined. There are, however, experimental evidences suggesting that, at least in muscle and myocardium, the collagen fibers surrounding the muscle fibers affect, to a great extent, the echogenicity of these tissues.^[7] Although the postulation that tissue echogenicity is largely determined by its connective tissue content may appear to be true, other factors such as cellular dimension and tissue complexity should also play an important role

and cannot be ignored.^[7] There has been a long-standing interest in correlating the acoustic parameters such as scattering, attenuation, and acoustic impedance to the biological composition of the tissues or ultrasonic characterization of biological tissues.^[7,8]

ATTENUATION, ABSORPTION, AND SCATTERING

When an ultrasonic wave propagates through a heterogeneous medium, its energy is reduced or attenuated as a function of distance. The energy may be diverted by reflection or scattering or absorbed by the medium and converted to heat.

The pressure of a plane monochromatic wave propagating in z -direction decreases exponentially as a function of z :

$$p(z) = p(z=0)e^{-\alpha z} \quad (15)$$

where $p(z=0)$ is the pressure at $z=0$ and α is the pressure attenuation coefficient. The attenuation coefficient has a unit of neper/cm and is sometimes expressed in units of dB/cm. Typical values of the attenuation coefficient in some materials are given in Table 1.

The relative importance of absorption and scattering to attenuation of ultrasound in biological tissues is a matter being continuously debated. Investigations to date have shown that scattering contributes little to attenuation, at most a few %, in most soft tissues.^[7] Therefore, it is safe to say that absorption is the dominant mechanism for ultrasonic attenuation in biological tissues.

The energy absorbed by the medium during an ultrasonic propagation is mostly converted to heat. The absorption mechanisms in biological tissues are quite complex and have been assumed to arise from classical absorption due to viscosity and a relaxation phenomenon. Both mechanisms depend on the frequency of the wave. In earlier developments, an ideal fluid with $\mu \sim 0$ has been assumed and this means that the absorption due to the classical viscous loss is ignored. However, in reality, this is seldom the case. Absorption of ultrasound in a lossy fluid has been shown to be proportional to $(\text{frequency})^2$. In media such as air and water, where the dimension of the inhomogeneities of the medium is much smaller than the wavelength, this $(\text{frequency})^2$ dependence of absorption is observed, but in most biological materials, experimental results on attenuation coefficient of ultrasound in biological tissues indicate an approximately linear dependence on frequencies below 15 MHz. As a result, an alternative theory is needed to explain this behavior. It has been theorized that

ultrasonic absorption in biological tissues is dominated by a relaxation process.

When an elemental volume or particle in a medium such as a molecule is pushed to a new position by a force and then released, a finite time is required for the particle to return to its neutral position. This time is called the relaxation time of the particle. For a medium that is composed of the same type of particles, the relaxation time is also the relaxation time of the medium. If the relaxation time is short compared to the period of the wave, its effect on the wave should be small. However, if the relaxation time is comparable to the period of the wave, the particle may not be able to completely return to its neutral state before a second wave arrives. When this occurs, the wave is moving in one direction and the molecules in the other. More energy is thus required to reverse the direction of the particle motion. If the frequency is increased high enough that the molecules simply cannot follow the wave motion, the relaxation effect again becomes negligible. Maximum absorption occurs when the relaxation motion of the particles is completely out of synchronization with the wave motion. Therefore, the relaxation process is characterized by a relaxation frequency where the absorption is maximal and is negligibly small for low-frequency and high-frequency regions illustrated in Fig. 2. Mathematically, the relaxation process can be represented by the following equation:

$$\alpha_r = \frac{Bf^2}{1 + (f/f_R)^2} \quad (16)$$

where α_r = component of the absorption coefficient due to the relaxation process and f_R = relaxation frequency = $1/T_R$, T_R = relaxation time, and B is a constant. In a biological tissue, there are many components, giving rise to many relaxation frequencies. The absorption coefficient in a tissue can be expressed as

$$\alpha_a/f^2 = A + \sum_i \frac{B_i}{1 + (f/f_{Ri})^2} \quad (17)$$

where A is a constant associated with classical absorption and B_i 's and f_{Ri} 's are the relaxation

Fig. 2 Ultrasonic absorption caused by a relaxation process characterized by relaxation frequency f_R .

Fig. 3 Ultrasonic absorption caused by multiple relaxation processes characterized by relaxation frequency $f_{R1}, f_{R2} \dots$

constants and frequencies associated with different tissue components.^[8] A possible scenario for this equation is illustrated in Fig. 3, where many relaxation processes may overlap, resulting in a linear increase in the diagnostic ultrasound frequency range or a constant $\alpha\lambda$. Figure 4 shows the absorption of ultrasound in various biological tissues as a function of frequency. As can be seen, the absorption is more or less linearly proportional to frequency ($\alpha\lambda$ is constant) in diagnostic ultrasound frequency range. Also in this figure, it can be seen that the absorption of ultrasound in water is proportional to f^2 .

As a wave is incident on an object, as shown in Fig. 5, part of the wave will be scattered and part of the wave will be absorbed by the object. The scattering characteristics are most conveniently expressed by a term called scattering cross section.

Assume that the incident pressure is a plane monochromatic wave $p_i(r) = e^{-j\mathbf{k}\cdot\mathbf{r}}$ where $\mathbf{k} = k\mathbf{i}$ (\mathbf{i} denotes a unit vector in the incident direction) and \mathbf{r} are vectors representing the wave number and the position. The scattered wave at \mathbf{r}_s due to a scatterer at \mathbf{r}_0 is given by

$$p_s(\mathbf{r}_s) = \frac{e^{-jkR}}{R} p_i(\mathbf{r}_0) f(\mathbf{o}, \mathbf{i}) \quad (18)$$

where \mathbf{o} is a unit vector in the direction of observation, provided that the observation point is in the far field of

Fig. 4 Ultrasonic absorption in biological tissues as a function of frequency.

Fig. 5 A plane wave incident upon a scatterer.

the scatterer and $R = |\mathbf{r}_s - \mathbf{r}_0|$ if $kR \gg 1$. The term $f(\mathbf{o}, \mathbf{i})$ in Eq. (18) is called the scattering amplitude function, which describes the scattering properties of the object and depends on the directions of incidence and observation. By utilizing the definition of intensity, it can be shown that

$$\sigma_d(\mathbf{o}, \mathbf{i}) = |f(\mathbf{o}, \mathbf{i})|^2 = \frac{I_s R^2}{I_i} \quad (19)$$

where the term $\sigma_d(\mathbf{o}, \mathbf{i}) = |f|^2$ is defined as the differential scattering cross section, which is the power scattered in \mathbf{o} direction with the incident direction \mathbf{i} in one solid angle per unit incident intensity. When $\mathbf{o} = -\mathbf{i}$, $\sigma_d(\mathbf{i}, -\mathbf{i})$ is called the backscattering cross section. By integrating σ_d over the 4π solid angle, the scattering cross section σ_s (defined as the power scattered by the object per unit incident intensity) can be found.

$$\sigma_s = \int_{4\pi} \sigma_d d\Omega = \int_{4\pi} |f(\mathbf{o}, \mathbf{i})|^2 d\Omega$$

where $d\Omega$ is the differential solid angle. Similarly, an absorption cross section, σ_a , can be defined as the total power absorbed by the object. Thus, the attenuation in wave intensity due to the presence of the object is simply

$$2\alpha = \sigma_a + \sigma_s$$

where 2α is the intensity attenuation coefficient. If there are a number of objects, the intensity attenuation coefficient should be:

$$2\alpha = n(\sigma_a + \sigma_s)$$

where n is the object concentration per unit volume. This relation is valid only if n is small or volume concentration given by $n \cdot (\text{object volume}) < 1\%$. As n increases, multiple scattering occurs and there may be particle-particle interactions,^[7] and this relation no longer holds.

It is impossible to solve analytically for the scattering cross section of an object of arbitrary shape, although there are computer-based methods,

such as finite element analysis, which may be used. However, a number of approximations exist, which can simplify the problem considerably. One of these is the Born Approximation, which assumes that the wave inside the object is the same as the incident wave.^[9] This is a valid assumption if the size of the object is much smaller than the wavelength or if the acoustic properties of the scatterer are similar to those of the surrounding medium. By applying this approximation and using the wave equation, the scattering cross section of an object can be found. The scattering cross section for a sphere whose radius is much smaller than the wavelength is given by:^[9]

$$\sigma_s = \frac{4\pi k^4 a^6}{9} \left(\left| \frac{G_e - G}{G} \right|^2 + \frac{1}{3} \left| \frac{3\rho_e - 3\rho}{2\rho_e + \rho} \right|^2 \right) \quad (20)$$

where k is the wave number, a is the radius of the sphere, G_e and G are the adiabatic compressibilities of the particle and the surrounding medium, and ρ_e and ρ are the corresponding mass densities.

In a dense distribution of scatterers like biological tissues, for instance, human blood consisting of $5 \cdot 10^9$ red blood cells in one cubic centimeter, scatterer-to-scatterer interaction cannot be ignored. To take this into consideration, a parameter called backscattering coefficient in a unit of $(\text{cm-steradian})^{-1}$ is often used. It is also sometimes called volumetric backscattering cross section and is defined as the power backscattered by a unit volume of scatterers in one solid angle per unit incident intensity. The physical meaning of the backscattering coefficient can be easily understood simply by replacing the scatterer in Fig. 5 by a unit-scattering volume. Because the tissues are fairly inhomogeneous, the scattered signals acquired may vary greatly at any single frequency and over a band of frequencies, a parameter that is frequently used to describe scattering behavior of a tissue is the integrated backscatter. The integrated backscatter (IB) is defined as the frequency average of the backscatter over the bandwidth of the signal, which mathematically can be expressed as

$$IB = \frac{1}{2\Delta\omega} \int_{\omega_0 - \Delta\omega}^{\omega_0 + \Delta\omega} e(\omega) d\omega$$

where $2\Delta\omega$ is the bandwidth, ω_0 is the center frequency of the spectrum, and $e(\omega)$ is the backscattered signal at angular frequency ω . However, in order to eliminate the dependence of the backscattered signal from tissues on the electrical and acoustic characteristics of the experimental system, the IB is usually expressed in dB by comparing the backscattered signal to a reference signal, e.g., the echo from a flat reflector.

Therefore,

$$IB(\text{dB}) = 20 \log \left\{ \frac{1}{2\Delta\omega} \left[\int_{\omega_0 - \Delta\omega}^{\omega_0 + \Delta\omega} e(\omega) d\omega \right] \div \int_{\omega_0 - \Delta\omega}^{\omega_0 + \Delta\omega} e_r(\omega) d\omega \right\}$$

where $e_r(\omega)$ is the reflected signal from the flat reflector at angular frequency ω . The backscattering coefficient for several tissues is listed in Table 1.

The fact that the acoustic scattering characteristics of an object including angular scattering pattern depend on the shape, size, and acoustic properties of the scatterer has been known for many years. Ideally, the structure and acoustic properties of the scatterers can be deduced from measuring their scattering properties. This problem is of interest to many scientists in such diverse fields as geophysics, oceanography, and communication. It is generally termed as remote sensing or detection. Although the potential of characterizing a tissue structure from its scattering properties was realized in the biomedical ultrasound community almost three decades ago, this field still remains in its infancy, primarily due to the complex nature of biological tissues. Preliminary experimental investigations in vitro so far have shown that different tissues exhibit different angular scattering pattern and frequency dependence.^[7,8] The backscattering coefficient (defined as backscattering cross section per unit volume) of scatterers for five different types of bovine tissues as a function of frequency is shown in Fig. 6.^[7] Experimental results on scattering by red blood cells^[7] are in good agreement with Eq. 20. Scattering from myocardium has been shown to have a third power dependence on frequency.^[7] Based on this evidence and more recent results indicating that ultrasonic scattering increases as the muscle is stretched, it was suggested that the scattering from muscle may be attributed to the collagen fibers in the muscle because the scattering from cylinders whose radius is much smaller than the wavelength is proportional to f^3 . Experimental results on scattering from tissues thus far have been very scanty and inconclusive. The precise origin of ultrasonic scattering from many tissues is still unknown although there are efforts underway to shed more light on this subject.

Because pathological processes in tissues involve anatomical variations, it is likely that they will result in corresponding changes in ultrasonic backscatter. This has been demonstrated by several recent investigations. Figure 7 shows that the backscattering coefficient for regions of infarcted myocardium is substantially higher than that for normal myocardium.^[10] In addition, myocardial ultrasonic backscatter is shown to be related to the contractural state of the tissue (Fig. 8).

Fig. 6 Ultrasonic backscatter coefficient for several bovine soft tissues as a function of frequency.

The myocardial backscatter was found to be the highest at the end diastole and lowest at the end systole during a cardiac cycle and this cyclic behavior was blunted in ischemic heart.^[10]

In summary, the attenuation of ultrasound in biological tissues can be attributed to two mechanisms: scattering and absorption. The question remains, however, as to the relative importance of these mechanisms although absorption is believed to be the dominant mechanism. Attenuation in general is not desirable because it limits the depth of penetration ultrasound into the body. However, it may yield useful information for diagnostic purposes because it carries information about the properties of the tissues if it can be accurately estimated. Extensive work has also been carried out to demonstrate that tissue pathology can affect, to a great extent, the attenuation coefficient of tissues. Infarcted myocardium and malignant tumors in liver and breast were all shown to have an increased attenuation. Unfortunately, measuring attenuation in vivo has been proven to be quite a difficult task. Various schemes have been developed with little success.

NONLINEARITY EFFECTS AND PARAMETER B/A

Because the spatial peak temporal peak intensity I_{SPTP} of modern ultrasonic diagnostic instruments can sometimes reach the level of more than 100 W/cm^2 ,

Fig. 7 Ultrasonic backscatter coefficient for canine myocardium as a function of frequency. Solid, dashed, and dotted lines represent data for normal myocardium, myocardium 5–6 weeks following infarction, and myocardium 15–17 weeks following infarction.

nonlinear acoustic phenomena may not be ignored in treating ultrasonic propagation in tissues.^[11] In fact, it has been shown that in many instances harmonic imaging that utilizes the harmonics generated due to the nonlinear propagation yields better images than conventional ultrasonic imaging.^[12] Other reasons for studying the nonlinear properties are: new tissue parameters may be derived for tissue characterization and nonlinearity can influence, to a significant extent, how the ultrasound energy is absorbed by the tissue.

The nonlinear behavior of a fluid medium can be expressed by a second-order parameter B/A . For an adiabatic process in which the entropy is constant or there is no energy flow, the relation between pressure and density can be expressed as a Taylor series expansion of pressure, p , about the point of equilibrium density, ρ_0 , and entropy, s_0 ,

$$p = p(s_0, \rho_0) + A \left(\frac{\rho - \rho_0}{\rho_0} \right) + \frac{1}{2} B \left(\frac{\rho - \rho_0}{\rho_0} \right)^2 + \dots$$

where A and B are constants and the ratio of B/A is given by

$$B/A = 2\rho_0 c_0 \left[\frac{\partial c(s_0, \rho_0)}{\partial p} \right] \tag{21}$$

Fig. 8 Integrated backscatter from canine myocardium as a function of the cardiac cycle.

This B/A parameter is a primary indicator as to the nonlinearity of a medium and can be estimated from these quantities, which are either known or measurable. Experimental findings show that: 1) B/A is linearly proportional to solute concentration in aqueous solutions of proteins; 2) B/A is insensitive to the molecular weight of the solute at fixed concentrations; 3) B/A ranges from six to 11 for soft tissues; and 4) B/A may be dependent upon tissue structure. The B/A values for a few tissues and relevant materials are given in Table 2.

The nonlinearity of ultrasonic wave propagation can cause the distortion of waveforms as illustrated in Fig. 9, which shows that a sinusoidal waveform becomes a sawtooth waveform as a result of the generation of higher harmonics after propagating in a medium. This is plausible in that the velocity in a denser region of the medium should be greater. It is

Table 2 B/A values for various materials

Material	B/A
Water	5.0 at 20°C
Bovine serum albumin (20 g/100 ml)	6.2 at 25°C
Beef liver	7.8 at 23°C
Human breast fat	9.2 at 22°C

Porcine whole blood	6.2 at 30°C

Fig. 9 Wave distortion resulted from the nonlinear interaction between ultrasound and the medium.

known that the amplitude of the fundamental frequency drops and the amplitudes of higher harmonics increase as the propagation distance increases.^[13]

In addition to heating, high-amplitude ultrasound can also induce cavitation. The term cavitation is used to describe the behavior of gas bubbles in ultrasonic fields. Two different types of cavitation may occur: transient and stable cavitation. Transient cavitation describes the phenomenon in which microbubbles suddenly grow and collapse in a liquid medium. The physical process can be described as follows: Bubbles in a medium are greatly expanded when pressure decreases rapidly. The pressure increases one-half cycle later, causing bubbles to collapse and disappear. For a very large pressure swing, the radius increases markedly, reaching a peak well past the pressure minimum, and as the pressure reaches a peak, the bubble collapses. The internal bubble pressure can become very high—up to 80,000 ATM—with a temperature approaching 10,000°K. Such high temperatures can cause decomposition of water into chemically-active acidic components, causing serious biological effects. A phenomenon called sonoluminescence, in which flashes of light with a duration less than a few picoseconds are generated, may accompany the collapsing of the bubbles.^[14] Stable cavitation, on the other hand, describes a phenomenon in which the bubbles do not collapse as just described. Under this circumstance, the behavior of such bubbles is quite stable and is known as stable cavitation. Stable cavitation is more likely to occur at lower ultrasound intensities.

Cavitation can be suppressed by degassing the liquid, increasing the viscosity of the surrounding medium, or by increasing the external pressure applied to the system. It takes a finite amount of time for the gas bubble to respond to the pressure change. Therefore, cavitation is a frequency-dependent phenomenon. If the ultrasound frequency is high enough, it should disappear.

As ultrasound propagates in a fluid, transfer of momentum to the medium via absorption causes acoustic streaming in the direction of the sound beam. If a discrete object is present in the ultrasound beam, a radiation force is exerted on the object, as discussed earlier. As the object moves, streaming of the fluid near the object may occur. If the object is an air bubble, the

oscillation of the bubble can also cause streaming of the fluid. Because acoustic streaming is related to absorption, nonlinear interaction between ultrasound and a medium may increase the acoustic streaming manifold. Acoustic streaming may induce shear stress on interfaces that border the fluid and the object. These nonlinear ultrasound effects have been used for hyperthermia for the treatment of cancer, high-intensity focused surgery,^[15] and gene transfection and drug delivery.^[3,16]

Ultrasound Doppler

Ding-Yu Fei

INTRODUCTION

The Doppler effect is a physical phenomenon existing with all waves such as electromagnetic and sound waves. The effect is a change in frequency of a wave perceived by an observer, when the wave source, the observer, or both are moving with respect to the other. Many animals such as bats and dolphins use the Doppler effect to detect moving targets, enabling them to find food. The Doppler effect was discovered by the Austrian scientist Johann Christian Doppler in 1842. He derived equations relating the change of the perceived frequency to the relative speed between the wave source and the observer. Since then, the Doppler principle has been used with microwaves, light, and sound waves including ultrasound. Ultrasound is a portion of the sound spectrum with frequency higher than 20 KHz, which is beyond human hearing ability. Ultrasound Doppler has been widely used in industries as well as daily life. For example, sonar systems on ships use underwater ultrasound Doppler to detect and measure movement of fishes and submarines. Home burglar alarms use airborne ultrasound Doppler to detect moving targets in the yard and house.

In biomedical fields, ultrasound Doppler is employed to identify blood flow, measure blood flow velocity in vessels, and monitor the movement of tissues and organs. Several types of ultrasound Doppler instruments and technologies are available for a variety of medical applications. From the perspective of the ultrasonic signals transmitted, there are two types of Doppler instruments: continuous wave (CW) Doppler and pulsed wave (PW) Doppler. Ultrasound Doppler technologies are frequently used in combination with ultrasonic imaging systems or scanners to visualize the site of measurement in order to provide more useful and accurate information. Currently, the major combinations include duplex scanning, Doppler color imaging (DCI), power Doppler imaging (PDI), and tissue Doppler imaging (TDI).

Using the different technologies, the measurement of ultrasound Doppler can be carried out within a single or a few sampling volumes along a specific

ultrasound beam. The measured results may be heard with loudspeakers and/or displayed on the screen of a monitor in real time. Blood flow velocities or tissue movement may be obtained within a relatively large area by using a multiple gate procedure. In this case, color images are usually used to display the results. Signal and image processing technologies are used to extract more useful information from the detected Doppler signals. The results obtained are widely used for evaluating normal hemodynamic function and detecting abnormalities in most large- and middle-sized vessels in humans. By measuring blood flow in small vessels, ultrasound Doppler is also used to detect abnormal tissues and tumors in some organs.

DOPPLER PRINCIPLE

As mentioned previously, the Doppler effect results in a change in frequency of waves perceived by an observer under three possible cases: the source is moving, the observer is moving, or both are moving with respect to the other. When a sound wave travels in a medium, the general relationship among the frequency, f , sound speed, c , and wavelength, λ , can be expressed as

$$f = c/\lambda \quad (1)$$

Assume that a signal source emits a sound wave with a emitted frequency, f_e . An observer at a distance away from the source perceives the same frequency emitted from the source when both the source and observer are stationary. When the wave source is moving toward the observer with a velocity, v , as the wave approaches, the peaks of the sound wave are compressed toward the observer. The intervals between wave peaks or the effective wavelength is reduced to $\lambda - vT$, where T is the period of the wave, i.e., $1/f_e$. The reduction in wavelength translates into an increase in the observer perceived frequency, f_p . The difference between the perceived and the emitted frequencies is called the Doppler frequency or Doppler

Fig. 1 Typical case using ultrasound Doppler instrument to measure blood flow velocity in a vessel.

shift, f_d , and can be expressed as

$$f_d = f_p - f_e \quad (2)$$

If the source is stationary and the observer is moving toward the source, the effective wave speed will increase to $c + v$. The increase of wave speed also translates into an increase of perceived frequency. In both of the preceding cases, the Doppler frequency is a positive value. Conversely, if the source and observer are moving away from each other, the perceived frequency will be lower than the emitted frequency and the Doppler frequency will be negative.

In the case that both the source and observer are moving toward (or away from) each other at the same velocity, v , if the velocity v is much less than the sound speed in the medium, the Doppler frequency for the combining case can be expressed as:^[1,2]

$$f_d = 2vf_e/c \quad (3)$$

where c is the sound speed in the medium.

Figure 1 shows the most popular case of ultrasound Doppler used in medical applications. The transducer consisting of the transmitter and receiver, which may be one or two separate element(s), as discussed in later sections, contacts the skin surface and the transmitted ultrasound beam passes across a vessel in the body. When the ultrasound signals arrive at the vessel, the moving cellular components of the blood pool, consisting mainly of red blood cells, will scatter the

signal in all directions. The signal scattered back (called backscattered signal) to the transducer will be detected by the receiver and the Doppler frequency will then be calculated. Sound speed varies when it travels in different medium. In humans, because the major component of all soft tissues is water, sound speeds in different soft tissues are very nearly the same.^[1] It is reasonable to assume that the sound speed travels in all soft tissues at an average speed of 1540 m/sec. On the other hand, blood velocities observed in the human body are all below a few m/sec, which is much less than the average sound speed in soft tissues. Eq. 3, therefore, is valid for this case. For the situation where the angle between the flow and beam directions is θ , the Doppler frequency perceived reflects the component of the velocity along the beam direction and Eq. 3 is modified to:

$$f_d = 2v \cos \theta f_e/c \quad (4)$$

This is the basic equation usually used for velocity determination in ultrasound Doppler systems. It can be seen from Eq. 4 that if the Doppler frequency is detected and the sound speed is known, the component of the velocity along the beam direction, i.e., $v \cos \theta$, can be calculated. If the Doppler angle, θ , is also known, the flow velocity can be determined. Normally, the range of emitted frequencies used for most medical ultrasound applications is from 2 to 8 MHz. The range of blood velocities in large- and medium-sized vessels is from several cm/sec to a few m/sec. To obtain some idea about the range of Doppler frequencies detected, Table 1 shows a few examples of the perceived Doppler frequencies used in medical ultrasound Doppler devices. In most medical applications, Doppler frequencies are within the audible sound range (below 20 KHz).

SPECIFIC TYPES OF ULTRASOUND DOPPLER

Continuous Wave (CW) Doppler

CW Doppler is one of the earliest modes of ultrasound Doppler technologies. The transducer of the device is

Table 1 Samples of ultrasound Doppler frequency in medical applications^a

Emitted frequency f_e (MHz)	Flow velocity c (cm/sec)	Doppler angle θ (degree)	Doppler frequency f_d (Hz)
3.5	100	0	4,545.5
		60	2,272.8
		70	1,554.7
2.5	50	0	2,272.8
		0	1,623.4
5.0	50	0	3,246.8

^aThe sound speed is assumed to be 1540 m/sec, which is the average of sound speeds in soft tissues.

made of two piezoelectric elements. One serves as the transmitter and emits an ultrasound signal continuously. The other serves as the receiver to detect the reflected or scattered sound signals. Because the transmitting and receiving ultrasound beams may not be the same, the detectable echo signals are the signals coming from the overlapping volume of the transmitting and receiving beams.^[2,3] Normally, the frequency, amplitude, and phase information of the echoes are processed. By comparing with the emitted frequency, the Doppler frequencies and corresponding amplitudes can be determined. A technique known as quadrature phase detection^[3] is often used to determine whether the flow direction is toward or away from the transducer. As mentioned previously, the detected Doppler frequencies usually fall in the audible sound range. In some compact devices such as simple fetal heart monitors, only loudspeakers are used to listen to the Doppler signals. Some devices may use simple methods such as zero-crossing technique to detect the frequencies. Many other devices use fast Fourier transformation (FFT)^[4] to determine Doppler frequency spectrum of the echo signals and display them on the monitor.

CW Doppler can provide velocity information on blood flow and tissue or organ movement. In the human body, Doppler signals from blood flow in vessels have much higher frequencies, but lower amplitudes compared with those from tissue movement. With CW Doppler as well as all other Doppler technologies, if the Doppler mode is designed for measurement of blood flow, a wall filter is usually used to remove the large amplitude but low-frequency Doppler signals generated by vessel wall motion. On the other hand, if the device is designed to measure tissue movement, no filter or a filter removing the high Doppler frequencies generated by the blood flow may be used.

A major advantage of CW Doppler over PW Doppler (see description later in the article) is that CW Doppler has no limitation on the maximum measurable velocity as PW Doppler systems have. The large sample volume in CW Doppler allows detection of the maximum velocity along the entire ultrasound beam. However, because the transmitter emits the ultrasonic signal continuously, the echo coming back from targets at one distance may be mixed with echoes coming back from targets at deeper positions. No distance information is included in the measured results. CW Doppler systems may also give complicated and confusing presentations if two or more different flow regions fall within the path of the ultrasound beam. For a stand-alone CW Doppler system, because no vessel visualization is provided from the instrument, the user must know the basic anatomic structure in order to detect flow in the vessel of interest.

Pulsed Wave (PW) Doppler

A PW Doppler system periodically emits short duration ultrasonic signals and then detects the reflected sound signals in the time interval between two consecutive emitted signals. Because emission and reception of the signals occur at different times, only one piezoelectric element is usually used to serve as both the transmitter and receiver. Each of the short-duration signals includes several cycles at the emitted frequency and is called a burst or pulse train. The frequency of the emitted bursts is called the pulse repetition frequency, or PRF. Using the time of the emitted signal as a reference, the time interval between the emitted and the reflected signals represents the round trip distance along the beam between the transducer and the reflector. This time interval can be used to determine the distance between two reflectors at different depths. By listening for reflected signals during a particular time interval (gate in time), PW Doppler devices can acquire reflected signals within a sample volume at a particular depth or distance from the transducer. This allows measurement of Doppler shifts (hence velocities) within a particular sample volume in space. This process is called range gating. FFT is usually used to determine the Doppler spectrum of returning echoes within the sample volume. The spectrum can be displayed on the screen in real time and the timing of the gate provides the distance information of the reflectors. For a stand-alone PW Doppler device, no image display is available. Therefore, the user must know the anatomy in order to measure flow in the vessel or location of interest.

Aliasing phenomenon is a limiting factor in PW Doppler instruments. Because the echo signals from a specified sample volume are not available continuously, PW Doppler has to determine the Doppler frequencies from timed samples of the echo signal. The sampling rate is equal to PRF of the device. According to the sampling theory,^[4,5] if the signal frequency is higher than half of the sampling rate, aliasing occurs. The calculated flow direction will be reversed and the velocity value would also be incorrect. Therefore, the highest Doppler frequency that can be detected by PW Doppler without aliasing equals one-half of the PRF and is called the Nyquist limit.

In both stand-alone CW and PW Doppler devices, information on the Doppler angle is usually not available because the vessel direction inside the body is unknown, and therefore, the actual velocities cannot be determined.

Duplex Scanning

Duplex scanning combines ultrasonic imaging and Doppler technologies to provide quantitative flow

Fig. 2 Duplex ultrasound image of common carotid artery. Position of pulsed Doppler cursor in 2-D image is seen in upper part of figure. Blood flow velocity spectral pattern is seen in lower part of figure.

information in vessels. A transducer consists of one set of piezoelectric elements for two-dimensional, gray-scale Brightness or B mode imaging, and another set of elements for ultrasound Doppler, although some of the elements may be used for both B mode and Doppler. Either PW or CW Doppler can be used. From the B mode image, the user can move the transducer to find the vessel of interest and locate the ultrasound Doppler beam to the desired portion of the vessel. Figure 2 shows a typical image of the duplex scanning with PW Doppler for a common carotid artery (CCA). The acquired B mode image is shown at the top of the image. In the image, the relatively straight, dark area across the image from right to left is the CCA lumen. The vessel wall and surrounding tissues can also be seen. The position and direction of the PW Doppler beam are displayed as the dotted line in the image. There are two short, parallel lines along the Doppler beam, which represent the gate position and gate length. There is a flow angle indicating line (the broken line) between the two short lines. The orientation of this line can be adjusted around 360° and is used to indicate the flow velocity direction for angle correction. In a relatively straight segment of a vessel, it is reasonable to assume that the flow directions inside the vessel are parallel with the direction of vessel wall. When the user adjusts the angle indicating line parallel with the direction of vessel (as shown in the image), the Doppler angle can be determined by the scanner and displayed in the image (53° in this image). When the Doppler angle is known, the velocity can be calculated from the detected Doppler frequency with Eq. 4. In duplex scanning, the detected Doppler frequency spectrum is normally converted to velocity spectrum and displayed at the lower portion of the screen in real time. When the spectrum image is frozen as shown, further analysis of the image can be carried out. Using

duplex imaging, the velocity spectra at different vessels, locations, and sample volumes can be observed and analyzed.

Because duplex scanning provides additional anatomic information, the measurement site and the sampling volume can be adjusted. Analyzing velocity spectra at specified sites provides valuable information for patient monitoring and for diagnosis of a variety of cardiovascular diseases. The average velocity across a vessel obtained from duplex scanning may also be used for the estimation of blood flow rate.

Doppler Color Imaging (DCI)

DCI or Doppler color flow imaging (DCFI) uses imaging and PW Doppler technologies to acquire flow information within a relatively large area in a flow field. A same set of piezoelectric elements may be used for B mode imaging and PW Doppler flow acquisition. When acquiring flow information, the ultrasonic beam is scanned to form a linear or sector pattern. For each scan line, multiple gates are used to detect the echoes. Each gate corresponds to a small sample volume, and velocities along the scan line can be detected simultaneously. By scanning the ultrasonic beam, the velocity information within a relatively large area is obtained.

In the process of flow velocity estimation, if FFT technology is used, as the regular PW Doppler devices do, a relatively large number (perhaps up to 128) of pulse trains are required for each scan line. Because there will also be a large number of scan lines, a rather long time is needed to complete scanning one frame of the image. This will not be a realistic method for real-time acquisition of flow information. In the current color imaging systems, an autocorrelation technique or an instantaneous frequency estimation technique or combination of these two are used to make fast determination of Doppler shifts.^[6] Using these techniques, as few as three pulse trains are sufficient to determine the mean velocity at each sample volume although larger numbers of pulse trains may provide more accurate results. This makes real-time DCI possible. The mean velocities within a selected area are obtained, color coded, and superimposed on the gray-scale image to form the Doppler color image.

Figure 3 shows a typical Doppler color image of the carotid bifurcation at peak systole. A linear transducer is used. Most ultrasound scanners provide three beam directions for linear transducers. As shown in Fig. 3, the beam direction for the color imaging is toward the right from the transducer. The Doppler beam direction may be adjusted toward the left or central (vertical to the transducer). In the image, the main vessel on the right is the common carotid artery (CCA). The

Fig. 3 Doppler color image of common carotid bifurcation at peak systole using a linear array transducer.

branches on the left are internal carotid artery (ICA) (lower branch) and external carotid artery (ECA) (higher branch). Two color bars to the left of the image are the reference color scale. The bar at the top has red (lower) to yellow (higher) color to represent flow toward the transducer. The lower bar has blue (higher location represents lower velocity) to green (lower location, higher velocity) color to represent flow away from the transducer. By comparing the color in the vessel to the color scale, the measured mean flow velocity at each point can be estimated. In Fig. 3, the color at most portions of the vessel lumen is blue with higher velocity along the inner wall of the ICA. This shows that the blood flows mainly from right to left. The color in a small area at the lower and expanded portion (bulb) is red. It is a reversed flow area in the ICA, which is a normal flow pattern for most healthy persons.

In addition to normal velocity display mode, DCI systems can determine the variance of velocities within each sample volume. The results can be displayed with a variance color scale. High variance represents flow turbulence existing in the corresponding sampling location and can also be used for diagnostic purposes.

The strength of DCI lies in the fact that it can quickly provide a global view of flow in real time superimposed on anatomic structures, thus revealing the direct relationship between flow and anatomy instantaneously. It enhances the chances of determining abnormal flow patterns in a particular area and facilitates comparison of flow in different anatomic regions. Thus, DCI provides flow information faster and from a larger area, thus allowing easier detection of abnormal flow patterns.

Several limiting factors need to be considered when using DCI for flow field observation.^[6] First, the velocity obtained in DCI is the mean velocity within each sample volume. No velocity spectrum can be

determined. Second, the mean velocity is actually the component of the true velocity along the beam direction and therefore, images obtained in DCI are angle-dependent. As seen in Fig. 3, if one changes the ultrasound beam direction to the left, the components of the velocities in the flow fields along the beam direction will all change, and a flow image with totally different color will result. Generally, since blood vessels frequently exhibit curvature and branching in a relatively large flow field, the flow direction may vary significantly within the imaging region and therefore, even though the beam direction is known in linear transducer, one cannot simply use one predicted flow direction as the basis for angle correction over the entire region. If a sector transducer is used, the beam direction continuously varies from line to line and the angle dependence will be a more serious problem. The angle dependence is an important barrier against further exploiting the quantitative information and expanding the clinical applications of the DCI technique. Currently, methods based on multiple beam directions have been developed for reconstruction of angle-independent DCI.^[7-9]

Aliasing is also a limiting factor in DCI. If the color scale selected is too small, Doppler frequencies from a portion of the flow field may be higher than the Nyquist limit, and incorrect color representation of the flow field may result.

Power Doppler Imaging (PDI)

PDI can be considered as a modified mode of DCI.^[5] Similar to DCI, PDI uses PW Doppler and a multiple-gate procedure to collect flow information. Instead of finding the Doppler frequency, PDI detects the Doppler amplitude or power within each sample volume. The results are also color coded and superimposed on the gray-scale image. In other words, DCI is a frequency-coded color imaging and PDI is an amplitude- or power-coded color imaging.

Power Doppler imaging is very sensitive to the Doppler shift and can easily detect flow in small vessels such as blood in the liver and kidney. Power Doppler imaging does not need to calculate flow velocity and therefore, Doppler angle plays much less of a role in the imaging process. DPI is basically angle-independent except at a Doppler angle approaching 90° . At that angle, the Doppler frequency equals zero and no blood flow can be detected by either PDI or DCI. Also, because no velocity is calculated, aliasing will play no role in the detection of blood flow.

To further improve the sensitivity in detecting flow in small vessels, contrast-enhanced agents may be introduced.^[5,10] Studies have shown that the contrast-enhanced PDI can more easily visualize

Fig. 4 Tissue Doppler image of medial mitral valve annulus. Position of Doppler cursor on the annulus is seen in upper right of figure. Velocity spectral of the annulus is seen in lower part of figure.

small vessels and identify soft-tissue masses and abscesses.^[11,12]

Tissue Doppler Imaging (TDI)

TDI is a technique using PW Doppler to detect velocities of tissue movement.^[13] Either single-gate or multiple-gate procedures can be used. As mentioned previously, tissue and wall movements usually generate higher amplitude and lower frequency Doppler signals compared to those from blood flow. Filters to remove the high-frequency signals from blood flow may or may not be used, depending on the design of the device. Figure 4 shows a typical TD image of a normal mitral valve annulus in the heart. A sector transducer and a single-gate procedure are used. Similar to duplex scanning, the ultrasound Doppler beam and gate location are displayed in the B mode image at the upper right of the image. The detected tissue velocity spectrum within the sampling volume as a function of time is displayed at the lower portion of the image. A trace of the electrocardiogram (ECG) is also displayed above the tissue velocity spectrum to serve as a time reference. Velocities of tissue movement within a relatively large area can also be detected using multiple-gate procedure. Same as DCI, the measured tissue velocities will be color coded and superimposed on the gray-scale image.

APPLICATIONS OF ULTRASOUND DOPPLER

Ultrasound Doppler is used extensively in the peripheral vascular system, heart, and abdomen to

determine the presence or absence of blood flow and its direction, velocity, and character.

Carotid Artery Examination

In the United States, approximately 500,000 new strokes occur annually, and about 75% of these are ischemic or result from a decrease in blood flow to a particular area in the brain.^[14] Atherosclerosis, with associated vessel plaque disruption or lumen stenosis (lumen narrowing) is a common cause of stroke, particularly in the elderly. About 75% of the brain is supplied by the two internal carotid arteries. Flow characteristics in the carotid bifurcations also enhance their susceptibility to atherosclerotic plaque formation. Disruption of plaque and exposure of the underlying stroma in the vessel wall can result in thrombus formation and subsequent embolization, leading to stroke. Three large randomized studies comparing carotid endarterectomy with conservative medical therapy clearly demonstrated the superiority of endarterectomy over medical therapy for the reduction of stroke and death in patients with at least 60 to 70% internal carotid artery stenosis.^[15-17] Therefore, it is important to determine the morphology of the carotid bifurcation in many patients with acute stroke or transient ischemic attack (symptoms similar to stroke lasting less than 24 hours) or patients with carotid bruits. Two-dimensional imaging and Doppler ultrasound examination of the carotid bifurcation can provide important information about whether carotid plaque is present, its characteristics, and whether significant stenosis is present. PW Doppler and DCI remain the mainstay of carotid stenosis assessment.

Transcranial Doppler Examination

Transcranial Doppler (TCD) allows examination of the major intracerebral arteries through transorbital, transtemporal, suboccipital, and submandibular approaches.^[18] It allows detection of intracranial stenoses and arterial venous malformations in the major basal arteries of the brain. TCD is often used in conjunction with carotid ultrasound to evaluate the significance of internal carotid artery disease. Relative changes in cerebral blood flow can be measured objectively, immediately, and repeatedly, making TCD an attractive monitoring tool particularly during neurosurgical, vascular surgical, cardiac, and cerebral vascular procedures. Immediate cerebral blood flow information allows adjustments to be made that could reduce the incidence of postprocedural complications.

Arterial Disease of the Extremities

Decreased tissue perfusion in the extremities is usually caused by disease affecting the patency of arteries supplying these affected territories. The degree to which arterial disease produces symptoms and signs depends on the location and degree of arterial occlusion. If arterial disease is suspected, it is important to establish that a stenosis or occlusion is present, its location, and the nature of the underlying disease, i.e., atherosclerosis or thrombosis. Since ultrasound is noninvasive, it provides a low-risk, low-cost means for initial evaluation of patients suspected of having peripheral arterial disease. Therefore, it can help in the planning of more invasive procedures such as arteriography and intervention, both surgical and percutaneous.

One of the most important tests for assessing the patency of the arterial circulation in the lower limb is the ankle systolic pressure, which is done by placing an occluding cuff just above the ankle and assessing blood flow with CW Doppler in the posterior tibial and dorsalis pedis arteries. This is usually compared to the simultaneous brachial systolic pressure measured by brachial artery CW Doppler. The ankle-brachial index (ABI) is a ratio of the ankle systolic pressure divided by the brachial systolic pressure and is considered normal if above 0.90.^[19] The ABI has also been shown to be important in assessing risks for coronary artery disease and all-cause mortality.^[20]

Examination of the morphology of the Doppler spectral flow pattern or waveform in the main arteries of the upper or lower extremity provides additional information for assessing arterial occlusive disease. In this regard, waveforms are analyzed directly over a stenosis and proximal and distal to a stenosis, providing information about the severity of stenosis and the presence or absence of collateral flow.

Cardiac Doppler Examination

The application of ultrasound Doppler in the heart has made measurement of blood flow velocity and intracardiac pressure possible.^[21] Information that previously was only obtainable by cardiac catheterization is now obtainable noninvasively by Doppler ultrasound. This technique therefore allows serial assessment at low cost and minimal risk. A few examples follow that illustrate the application of Doppler ultrasound in cardiac imaging.

Cardiac output

Stroke volume (volume of blood ejected by the heart per beat) may be assessed by measuring the blood flow

velocity at a particular point where the cross-sectional area is known. Typically, this is the left ventricular outflow tract or the main pulmonary artery, and velocities are measured using PW Doppler. Because flow in the cardiovascular system is pulsatile, flow velocity varies during ejection, and the velocity must be integrated over the ejection period to measure the total volume of blood flow during a given ejection. This integration is called the time velocity integral (TVI) and is equal to the area enclosed by the Doppler spectral wave form. Multiplying the TVI by the cross-sectional area yields the stroke volume which, when multiplied by the heart rate, yields the cardiac output.

Valvular heart disease

Doppler ultrasound allows assessment of both valvular stenosis and valvular regurgitation (valvular incompetence). The major strength of Doppler ultrasound is that it allows accurate serial assessment of these lesions so that the hemodynamic data can be continually correlated with patient symptoms. In this way, patients can be initially treated with medical intervention and then mechanical intervention (either surgical or percutaneous valvuloplasty) as symptoms and hemodynamics dictate. Moreover, once medical therapy is instituted, further study can easily be done to assess response to therapy.

In valvular stenosis, the valve orifice is narrowed, causing an obstruction to blood flow. The assessment of the severity of valvular stenosis requires the determination of the transvalvular pressure gradient and valve area. Doppler ultrasound measures blood flow velocities and these may be converted to pressure gradient using the Bernoulli equation:

$$P_1 - P_2 = \frac{1}{2}\rho(V_2^2 - V_1^2) + \rho \int_1^2 \frac{dV}{dt} ds + R(V) \quad (5)$$

where 1 and 2 refer to an upstream (site 1) and a downstream (site 2) position, respectively, P is pressure, V is velocity, ρ is the density of the medium, and s refers to the streamline from site 1 to 2. The equation shows that the pressure drop, $P_1 - P_2$, is equal to the sum of three terms on the right-hand-side of the equation. The three terms represent the effects of convective acceleration, flow acceleration, and viscous friction loss, respectively.

In most clinical situations, flow acceleration and viscous friction can be ignored. When $\rho = 1.07 \text{ gm/cm}^3$ (the average density of human blood), the pressure change across a stenotic valve can be calculated with the simplified Bernoulli equation: $P_1 - P_2 = 4(V_2^2 - V_1^2)$, where the unit of P is mmHg and the unit of V is m/sec. Usually, flow velocity proximal (site 1) to

a narrowed valve orifice (site 2) is much smaller than the peak flow velocity at the orifice site, such that V_1 can be ignored as well. Thus, the pressure change across a stenotic valve is easily obtained by measuring the velocity across the valve with either PW Doppler or CW Doppler.

The valve area can be assessed using the continuity equation, which is an expression of conservation of flow. In a vessel, the volume of flow through a cross section at the upstream site 1 must equal the flow at the downstream site 2, i.e., $Q_1 = Q_2$ and thus, $A_1 \times V_1 = A_2 \times V_2$, where A = area. Rearranging $A_2 = (A_1 \times V_1) / V_2$. If the velocity and area at site 1 can be determined as well as the velocity at site 2, the desired stenotic area can be calculated.

In aortic stenosis, volume flow across the aortic valve at site 2 is equal to the volume flow across the left ventricular outflow tract at site 1. Velocities V_1 and V_2 can be measured by PW or CW Doppler. If it is assumed that the outflow tract is circular, the area may be calculated from the diameter measured from the B mode image, and then the stenotic valve area (A_2) can be determined.

Intracardiac pressure

Application of the Bernoulli equation to regurgitant valves allows estimation of intracardiac pressures. For example, the peak tricuspid valve regurgitant jet velocity measured usually with CW Doppler reflects the peak systolic pressure difference between the right atrium (RA) and right ventricle (RV). The RA pressure can be estimated from a physical exam of the jugular vein in the neck and in healthy individuals, usually varies between 5–10 mmHg at rest. It is elevated when pulmonary hypertension or right ventricular failure is present. Thus, the RV systolic pressure is equal to the peak systolic pressure difference between the RA and RV plus the estimated RA pressure. It follows that the pulmonary artery peak systolic pressure is equal to the peak RV systolic pressure when there is no obstruction to RV outflow. This can be assessed by measurement of Doppler velocities in the RV outflow tract and pulmonary valve. Thus, pulmonary pressures can be estimated by measuring tricuspid regurgitant jet velocities.

Abdominal Doppler Examination

Normal duplex scanning waveforms and color flow patterns have been investigated for vessels in the abdomen. These include the abdominal aorta, the inferior vena cava (IVC), and portal, hepatic, renal, splenic, and mesenteric vessels. Abnormalities can be diagnosed by comparing the spectral flow waveforms or

color flow patterns in the vessel of interest with normal patterns. Ultrasound Doppler has been used for diagnosis of abdominal aortic stenosis due to atherosclerosis, aortic aneurysms, and inferior vena cava filters.^[5,22] PDI can detect flow in small vessels in organs such as the liver, kidney, and heart, and hence assess perfusion. PDI and contrast-enhanced PDI have been used to detect tumors and masses in these organs as well.^[23]

CONCLUSION

Ultrasound Doppler is a rapidly developing technology with numerous applications in biomedical fields. It is used to quickly identify and differentiate vascular from nonvascular structures. It is employed to determine flow direction, velocity distribution, and their temporal variation. Blood flow supply to different organs may be determined. Ultrasound Doppler permits the diagnosis of a variety of abnormalities, including stenosis, aneurysms, and vessel occlusion in the cardiovascular system. Abnormal tissues, including tumor masses in different organs, may also be identified. With the development of new imaging and signal processing technologies, the applications of ultrasound Doppler will be further expanded in biomedical fields.

Ultrasound Therapy, Bone Healing

Özgür Erdoğan

Department of Oral and Maxillofacial Surgery, Faculty of Dentistry, Çukurova University, Balcali, Adana, Turkey

INTRODUCTION

Bone healing is a complex process with several overlapping steps. Because bone is a dynamic tissue affected by systemic or local factors, bone healing is also associated with a variety of biochemical, biomechanical, cellular, hormonal, and pathologic events. Therapeutic approaches aim to accelerate bone healing in order to shorten treatment time or treat non-healing injuries caused by systemic or local diseases. Numerous therapeutic methods for bone healing have been described in the literature. These applications are systemic or local drug deliveries or physical treatments like low-intensity laser, electromagnetic fields, extracorporeal shock, mechanical stimulation, and ultrasound (US) therapy. The use of US as a therapeutic approach in bone healing has a history of more than half a century. This chapter discusses the current understanding of the molecular mechanism of US therapy, surveys the findings of the literature, and evaluates the future of the application.

Historical Perspective

The piezoelectric effect was invented by brothers Jacques and Pierre Curie in 1880 when they realized that some crystals produce acoustic waves if alternate electricity is applied in resonance frequency. The piezoelectric effect refers to the generation of an electrical response to an applied pressure. Langevin used this principle in submarine detectors in the first years of World War I. Industrial use of US began in 1928 to detect hidden flaws in materials. The biological effects of US were first discovered at that time. The therapeutic use of US in medicine was first reported by Pohlman et al. in 1939. The authors used US for the treatment of back pain, neuralgia, and myalgia. They reported improvement in the symptoms when US was applied at a frequency of 800 KHz, with US energy transmitted at 4–5 W/cm² intensity to biological tissues for 10 days. The daily US treatment lasted 10 min. Although this dose of US treatment created some increased heat, it did not cause any kind of thermal injury. Diagnostic application of US began in the late 1940s. US was used as a therapeutic tool in the treatment of many diseases until the 1950s. The general

recognition was that US caused damage and its use in bones should be avoided. Halsscheidt et al. reported in 1949 a patient with osteomyelitis in the alveolar bone who received US treatment for a lesion in the lower lip.^[1,2]

The first study concerning the effects of US on bone healing was published in 1950 by Maintz.^[2] This study was a cornerstone, because it demonstrated for the first time the positive effects, but not the harmful effects, of US on bone. In that study, the author created bilateral osteotomies in the radius of 3-month-old rabbits. One limb of the rabbit received 0.5, 1.0, 1.5, or 2.5 W/cm² US treatment. According to histological and radiological evaluations, although US treatment in high intensities could cause thermal damage in bone, lower doses led to new periosteal bone formation. A placebo controlled study by Corradi and Cozzolino^[3] demonstrated that US application stimulates new callus formation in the fracture line in the radial bones of rabbits. After this study, the authors used the application in the clinic and reported that US treatment led to periosteal callus formation in eight patients.^[4]

Shiro advocated the use of lower doses and pulsed US application to decrease thermal damage to bones.^[5] The author used pulsed US application at 0.2 W/cm² intensity and reported increased osteoblastic/chondroblastic activity in osteotomized tibiae of rabbits in the experimental group. Twenty years after Shiro's study, Dyson and Brookes created bilateral fibula osteotomy in rabbits and applied US signals at 0.5 W/cm² intensity to one side. The authors reported increased ossification in the experimental group compared with the control group.^[6] In the same year, Xavier and Duarte applied lower doses of US (30 mW/cm²) to 26 patients with lower extremity fractures with nonunion after conventional treatments.^[7] They reported 70% healing after 20 min of daily US application. After that study, Duarte demonstrated an increase of 28% in ossification in the osteotomized fibulae of rabbits that received low-intensity-pulsed-ultrasound (LIPU) application compared with the control group.^[8]

In a placebo controlled study, Pilla et al. osteotomized the tibiae of rabbits bilaterally and applied LIPU (1.5-MHz pressure wave administered in pulses of 200 msec with an average temporal and spatial intensity of 30 mW/cm²) to rabbits in the experimental group.^[9] The authors reported that the osteotomized legs in the

U

LIPU group gained the mechanical properties of the non-osteotomized legs on the 17th day, whereas the osteotomized legs in the control group gained the mechanical properties of the non-osteotomized legs on the 28th day.

In 1998, Jangushi et al. reported that LIPU positively affects all phases of endochondral ossification and the optimal frequency of US pulses is 1 Hz, which corresponds to 200-msec intervals. Another study by Azuma et al. similarly demonstrated that LIPU has positive effects on ossification in all phases of fracture healing.^[10]

After successful reports in fracture treatment, the efficiency of LIPU was studied in relation to other orthopedic surgical procedures. Positive effects of LIPU were demonstrated in spinal fusion and distraction osteogenesis procedures in rabbits.^[11,12]

As a result of these *in vitro* and *in vivo* studies, US treatment was used in clinical applications for accelerating bone healing. In a randomized, double-blind controlled study by Heckman et al., the effects of LIPU on fresh tibia fractures were evaluated. In this multicenter study consisting of 67 patients, LIPU treatment was applied to 33 patients, with 34 patients in the control group. The authors reported that LIPU application accelerates the fracture healing at a rate of 38%.^[13] After 3 years, accelerated healing of fresh dorsal radius fractures was reported by Kristiansen et al. by means of LIPU treatment. The average healing time for the fractures in the experimental group was 61 days, whereas the healing time was 98 days for the control group.^[14]

The Sonic Accelerated Fracture Healing System (SAFHS; Smith and Nephew, Exogen, Memphis, TN) is a commercially available therapeutic US device that allows home application by the patient (Fig. 1). The US signals generated by the device consist of a 1.5-MHz sine wave, administered in bursts of 200 μ sec, followed by a pause of 800 μ sec with a repetition rate of 1 KHz. The average temporal and spatial intensity is 30 mW/cm². The US is administered for 200 min daily. The SAFHS was initially cleared for marketing by the Federal Drug Administration in 1994 as a treatment for fresh, closed, posteriorly displaced distal radius fractures and fresh, closed, or grade I open tibial diaphysis fractures in

skeletally mature individuals when these fractures are orthopedically managed by closed reduction and cast immobilization. In 2000, the indications were expanded to include the treatment of established non-unions, excluding the skull and vertebrae.

Bone Healing

Bone is a dynamic, well-organized tissue that can remodel itself in response to environmental mechanical stress and hormonal activity. Mature bone consists of three major components: marrow, periosteum, and bone tissue. At the microscopic level bone can be classified into two types: lamellar and woven bone. Woven bone is usually found in growing bones, regenerating bones like fracture callus, and some specific regions such as ear ossicles and tendon or ligament attachments. The microscopic appearance of woven bone is easily distinguishable from that of lamellar bone, because the orientation of collagen fibers is not uniformly formed as in lamellar bone.

Regarding porosity and architecture, bone can be in trabecular (cancellous) or compact (cortical) forms. Cortical bone and trabecular bone have the same matrix component. However, the density is increased in cortical bone and decreased in trabecular bone because of increased marrow space.

Bone matrix is composed of organic components, inorganic components, and water. The major organic component is collagen. It provides elasticity and thus resistance to external forces. Type I collagen is predominantly present in bone tissue. The inorganic components are mainly calcium phosphate, calcium carbonate, magnesium fluoride, and sodium. These inorganic components give stiffness to the bone tissue and serve as an ion reservoir for the body.

The unique design of living parts of bone facilitates bone remodeling according to the type and direction of external forces. Osteoblasts, osteocytes, osteoclasts, and undifferentiated mesenchymal cells constitute bone tissue. The mediators present in extracellular matrix organize the transformation of hematopoietic stem cells to osteoblasts or undifferentiated mesenchymal cells to

Fig. 1 Equipment of the Exogen 2000™ device.

osteoblasts. Osteocytes are the main type of bone cells in the human skeleton. They reside in and are surrounded by mineralized bone matrix. They are connected through canaliculi and communicate between themselves and the matrix. Osteoblasts build bone matrix and osteoclasts resorb bone matrix. The actions of these cells play a role in bone healing.

Bone formation may occur through transformation from cartilage tissue (endochondral ossification), a calcification surrounding the organic matrix (endochondral ossification) or formation of new bone on existing bone (appositional ossification). The three types of ossification occur throughout the formation of new bones, the regeneration process of the skeleton after injury, and surgery or formation of bone tumors.

Remodeling of bone is regulated by a combination of resorption and bone formation. The primary cells involved are osteoblasts and osteoclasts. There is a close anatomical and functional relationship between resorptive and formative cells at the remodeling sites. These cells demonstrate their action within a temporary anatomic structure called the basic multicellular unit (BMU).^[15] A mature BMU consists of a leading front of osteoclasts followed by osteoblasts, blood supplies, and the associated connective tissues. In the remodeling process the entire BMU moves forward; osteoclasts resorb bone and die by apoptosis. The resorbed bone is replaced by osteoblast, bone-forming cells, and new bone formation.

Bone metabolism is constantly regulated by hormonal activity. Major hormones that affect bone metabolism are parathyroid hormone, vitamin D, calcitonin, estrogen, glucocorticoid, and growth hormone. Parathyroid hormone regulates the calcium level in extracellular fluids by increasing the calcium flow from the intracellular compartments. Vitamin D stimulates renal calcium-binding proteins and facilitates active calcium transport. Calcitonin is secreted by parafollicular cells in the thyroid glands. It serves to decrease the levels of plasma calcium and phosphorus. Estrogen is produced by the ovaries; deficiency or absence of estrogen causes an increase in bone turnover, negatively affecting bone healing. Glucocorticoids inhibit formation of osteoblasts and synthesis of collagen by osteoblasts. Growth hormone plays a major role in the maturation of the skeletal system and increases intestinal calcium absorption.

Some proteins or growth factors released from platelets are associated with bone healing. Most well-known proteins are bone morphogenetic proteins, which induce mesenchymal stem cells that differentiate into bone cells. Other known proteins and growth factors that influence bone healing are insulin-like growth factor, transforming growth factor, platelet-derived growth factor, fibroblast growth factor, osteonectin, fibronectin, and osteocalcin.

Bone healing or fracture healing is the repair of injured bone. It has three distinct but overlapping stages: the early inflammatory stage, the repair stage, and the late remodeling stage.^[16] In the inflammatory stage, hematoma develops and inflammatory cells and fibroblasts infiltrate the injured area. A granulation tissue forms, ingrowth of vascular tissue occurs, and mesenchymal stem cells migrate in this stage. In the repair stage, fibroblasts serve as a stroma for vascular ingrowth and are responsible for synthesis of collagen matrix and angiogenesis. Collagen matrix ossifies and consequently callus tissue develops. Bone healing is completed during the remodeling stage. Woven bone is differentiated to lamellar bone and bone gains its original strength after completion of this stage.

Ultrasound Physics

Acoustic waves are vibrations that are transmitted mechanically. This means that a solid material, which consists of particles, is required for generating and transmitting the ultrasonic waves. It is not possible to transmit the ultrasonic waves in vacuumed spaces, which do not have particles. The number of impulses generated in each particulate is an important feature in determining characteristics of acoustic waves. Acoustic waves show a sinusoidal propagation when propagating in the medium.

Acoustic vibrations that are transmitted over 20-KHz frequency are called ultrasonic. Ultrasonic waves are longitudinal waves, which have compression and expansion bands. Ultrasound waves are transmitted through mechanical vibrations, unlike electromagnetic energy, which is transmitted through photons (Fig. 2).

Piezoelectric crystals are used for generating ultrasound waves. The particles in the piezoelectric crystals are stimulated and start to produce waves and transmit the waves to other particles mechanically. Piezoelectric crystals are present in the transducer of the US device. These crystals are part of the US devices and are in contact with the tissues. The crystals are deformed in response to electrical voltage applied to them and ultrasonic waves are generated on the other side of the crystals. The piezoelectric crystals used in the therapeutic US devices are usually lead–zirconium–titanate crystals. Quartz, barium–titanate, and Rochelle crystals are also used for this purpose.

The number of complete oscillations each particle undergoes in a second is called the frequency. A wave that has 100 cycles in 1 sec means that a 0.01-msec time interval exists between the cycles. The unit of frequency measurement is Hertz. Hertz defines the number of cycles per second. Higher frequencies are abbreviated as follows: 1,000,000 Hz = 1000 KHz = 1 MHz. The

Fig. 2 A pressure/time sinusoid occurring as a result of pressure to a medium. This type of sinusoid develops when a constant vibration is administered.

frequency interval of the acoustic waves of the human hearing limit is between 20 Hz and 20 KHz, which corresponds to 10 octaves of interval. It is a considerably high interval when compared to visible light interval, which has only 2 octaves (Fig. 3). Frequencies employed in therapeutic US applications generally range from 1 MHz to 3 MHz. Higher US frequencies tend to generate narrower beam width waves.

The efficiency of piezoelectric crystals is dependent on the amount of generated ultrasonic waves, which are transformed from the electrical energy applied to them. Piezoelectric crystals are active at their particular resonance frequency. The resonance frequency of a piezoelectric crystal depends on the thickness of the crystals. A scheme of a typical US transducer is illustrated in Fig. 4.

Power and intensity are measures of the strength of US waves. In physics, power (P) is defined as the amount of energy passing through a surface per unit time and is expressed in watts. The formulation for the calculation of power is

$$P = (F \times l)/t,$$

where P is the power, F is the force, l is the distance, and t is the time.

Medical ultrasound focuses on a small area and the term "intensity" is used to define the power of ultrasound. It is the rate of energy delivered per unit area (W/cm^2). The output of the device is expressed in watts divided by the effective radiating surface area of the transducer resulting in the power. The intensity changes depending on the width of the ultrasound beam. Therefore, in focused sound beams, the intensity is greatest at the focus where the beam width is the

Fig. 3 Frequency intervals of acoustic waves.

narrowest. In pulsed ultrasound beams, the greatest intensity value occurs during the pulse and is zero between pulses. Therefore, acoustic intensities must be specified as to whether they are temporal-average or temporal-peak values and whether they are spatial-average or spatial-peak values. Therapeutic ultrasound may be classified as low intensity or high intensity according to the energy output. Low-intensity US has an output value as low as 20 mW/cm^2 , which is comparable to diagnostic US. It is mainly used for stimulation of the tissues in order to increase healing capacity, as in treatment of fractures. High-intensity US corresponds to intensities higher than 5 W/cm^2 and its thermal effect is utilized for physical treatments like decreasing joint stiffness following surgical procedures like ablation or excision of tissues.

Velocity is the rate of energy transmitted in a specified direction of propagation. Velocity of ultrasound waves depends on the physical properties of the medium in which the wave is transmitted. The waves are transmitted faster in solid media compared with liquids and air. For example, the velocity of

Fig. 4 A typical US transducer.

US is 1500 m/sec in saline and 350 m/sec in air. The velocity in bone is between 3000 and 5000 m/sec.^[17] Velocity of propagation does not depend on the frequency of US.

Wavelength is the distance between two corresponding points of a wave. It is dependent on frequency and velocity and formulation of calculation is

$$\text{Wavelength } (I) = \text{Velocity } (V) / \text{Frequency } (F).$$

As the US wave travels through the tissue, it continually loses energy. The decrease in energy per unit distance is called attenuation. Attenuation occurs through absorption, scattering, and transmission. Energy is lost to reflection or scattering of the sound beam when it strikes a reflecting surface or is lost to absorption as it overcomes the internal friction that exists in tissue while traveling through it. The frequency of the US beam and properties of the tissue determine the attenuation of the energy. For example, a 1-MHz US wave loses half of its energy after propagating 9 mm in muscle tissue, whereas it loses half its energy after 50 mm propagation in fat tissue.^[18] In general, the tissues comprising more protein absorb more energy compared with tissues comprising more water. The attenuation of US in bone occurs through absorption and scattering. When energy impinges on bone, some of the energy is transformed to shear, which is rapidly attenuated at the front surface of the bone.^[17]

Therapeutic ultrasound applications are performed in pulsed mode in order to reduce the thermal effect and increase the stimulation level. Pulsed ultrasound may be applied at different frequencies and pulse lengths. Intervals between the pulses may also be adjusted. In 1:1 mode, after a 200- μ sec pulse duration there is a 200- μ sec pause period. In 1:4 mode, the pause is 800 μ sec after every 200- μ sec pulse period.

In order to conduct the ultrasound waves to tissues, a coupling medium in liquid, gel, or cream form is put between the transducer and the tissue. An ideal coupling medium should fill the space, have some viscosity in order to stay in place, have similar acoustic resistance with the tissue with which it is coupled, and cause minimal energy absorption in order to transmit the waves with minimal energy loss. High water-comprising gels have been developed as coupling media for this purpose.

Interaction of Ultrasound with Bone Tissue

Despite the complex characteristics of bone healing and multiple effects of ultrasound on biological tissues, much is known today about the mechanism of action of US therapy. Several theories have been proposed to explain these effects. The combination of physical, piezoelectric, and biologic effects of US plays a role in the interaction of US with bone healing.

Physical effects

Ultrasound waves generate vibrations in all tissue components, including intracellular and extracellular fluids and cell membranes, when penetrating tissues. They cause movements or displacements of particles when transmitted in tissues. Because of these motions, US treatment produces a micromassage effect in tissues, which produces mechanical stimulation.

Acoustic vibrations have thermal and non-thermal effects on biologic tissues. The energy attenuated by tissues leads to thermal increase. US signals at high intensities create considerable heat increase. However, ultrasound therapy utilized for bone healing uses intensity as low as 20–50 mW/cm². Vibrations at these intensities generate a heat increase below 1°C, which is negligible in terms of thermal damage. However, this small increase in temperature may affect some enzymes such as matrix metalloproteinase 1.^[19] This enzyme is very sensitive to small variations in temperature. In terms of biologic effects, the thermal and non-thermal effects of US are not separable and it is assumed that non-thermal effects of US are usually accompanied by some heat increase. The observed non-thermal effects of US are stable cavitations, microstreaming, acoustic streaming, and direct effects to the cell membrane.

Stable cavitation defines the presence of gas bubbles in fluids as a result of US energy. These bubbles may be in different shapes and sizes depending on the type of US signals and lead local movements in the fluid. These movements in fluids are called microstreaming. Ter Haar et al. demonstrated that US signals of 1.5-MHz frequency and 150 mW/cm² intensity generate bubbles bigger than 10 μ m in the body fluids of pigs. Acoustic streams are localized high-velocity streams of fluid created by US signals in a liquid.^[20] These mechanisms cause movements and transfers of intracellular and extracellular ions. An increase in intercellular ion transfers leads to changes in membrane permeability, resulting in alterations of the electrophysiological properties of the cells. US application increases ion conductivity up to 22% and decreases the need for ATP consumption by sodium–potassium channels.^[21]

Piezoelectric effect

An increase in electrical potential occurs when pressure is applied to bone tissue. This effect is called the piezoelectric effect. Piezoelectricity affects the arrangement of bone resorption and bone healing. Bone as a dynamic living tissue remodels itself according to environmental forces. US application generates a piezoelectric effect on the bone, thus increasing the electric potential within the tissue. An increase in electric

potential may induce bone remodeling, thereby assisting in fracture healing.^[22]

Biologic effects

As US signals travel in bone, a biologic response develops in the tissue. There are many *in vivo* and *in vitro* studies regarding the biologic effects of US on bone healing.

In vitro studies on human or animal cell cultures demonstrated several cellular effects of US, which may be related to acceleration in bone healing or fracture repair. LIPU application stimulates aggrecan mRNA expression and proteoglycan synthesis by chondrocytes, increases prostaglandin E₂ synthesis by osteoblasts, and increases platelet-derived growth factor synthesis. US signals induce conformational changes in the cell membrane and alter ionic permeability and second messenger activity. Changes in second messenger activity lead to downstream alterations in gene expression, resulting in acceleration of the fracture–repair process by up-regulating cartilage and bone-specific genes. Others demonstrated effects of LIPU on bone healing as increased expression of transforming growth factor- β , increased efflux of potassium ions from intracellular spaces, and increased calcium ion incorporation.^[2,4]

Increased blood flow to the fracture site promotes delivery of key components, such as growth factors and cytokines necessary for the normal healing process. Capillary formation occurs in the injured area in the inflammatory phase of bone healing. US application increases the synthesis of angiogenesis-related cytokines such as interleukin-8, fibroblast growth factor (FGF), and vascular endothelial growth factor.^[23] A power Doppler sonography-based study demonstrated that low-intensity ultrasound delivered over a 10-day period stimulated a greater degree of vascularity at the site of ulnar osteotomies in dogs.^[24]

Several studies addressed the question of which phase of fracture healing is influenced by US therapy. Controversial studies have been published regarding this issue. Yang et al. reported that aggrecan gene expression was significantly higher in the LIPU-treated group on the 7th day but significantly lower on the 21st day in a rat femur fracture model.^[25] Similarly, some studies indicated that LIPU influences the early phases, consisting of inflammatory and callus formation phases of fracture healing^[9,26,27] but not the remodeling phase. Azuma et al. reported controversial results indicating that LIPU treatment affects all phases of fracture healing, including the bone remodeling phase.^[10]

According to studies concerning the mechanism of stimulation of bone healing by US, US application mainly affects endochondral bone formation. The studies reveal that US application stimulates chondrocyte

proliferation or maturation, which causes an increase in bone healing. The number of chondrocytes or osteoblasts was not increased by US application. There is no strong evidence available regarding the stimulation of intramembraneous bone healing by US therapy. From these studies it may be concluded that US therapy causes the fracture callus to gain its original strength in a shorter period of time through faster maturation of chondrocytes. Stimulation of the proliferation of chondrocytes occurs by several mechanisms such as unregulated cartilage, bone, or vascular gene expressions.

Clinical Applications

Clinical use of therapeutic US for bone healing is mostly concerned with fracture management. Most clinical studies regarding the effects of US treatment for bone healing are based on fresh fracture models. US treatment reduced the healing time of fresh fractures of tibial, distal radius, and scaphoid bones.^[13,14,28] Although fresh fractures heal without complications with standard fracture care, low-intensity ultrasound treatment may be considered for the treatment of fresh, closed fractures with closed reduction for patients with codiseases associated with bone metabolism such as diabetes, steroid therapy, osteoporosis, and smoking.

An open fracture is defined as one in which there is communication with a break in the integument, usually near the fracture site.^[29] Delayed union corresponds to a slower than expected healing process. Non-union is defined as cessation of healing for more than 3 months, as documented by serial radiographs including multiple views.^[29] Treatment of delayed unions or non-unions may be complicated because of some systemic or local conditions like osteoporosis or radiotherapy. US was beneficial in the treatment of delayed unions and non-unions. Mayr et al. utilized the application in 951 patients with delayed unions and 366 patients with non-union. They reported successful healing in more than 86% of patients in both groups.^[30] Nolte et al. applied the treatment to 29 patients with non-union after conventional therapies. The fractures were located in the tibia, femur, radius/ulna, scaphoid, humerus, metatarsal, and clavicle. They demonstrated complete healing in 86% of patients on average in 22 weeks.^[31] The efficiency of LIPU treatment on open fractures has not yet been proven by randomized clinical trials. Evidence of acceleration of bone healing is weaker compared with treatment for fresh closed fractures of long bones because of the design of the published studies concerning the treatment of delayed union or non-union. However, this patient group constitutes the main group needing US therapy.

Distraction osteogenesis is another clinical procedure that utilized US therapy. Few clinical studies

demonstrate the positive effects of LIPU on distraction callus. In a study by Tsumaki et al., 21 patients with osteoarthritis underwent bilateral tibial hemicallotaxis. One limb of every patient received ultrasound treatment for 20 min daily for 4 weeks. The authors demonstrated increased callus bone mineral density in the LIPU-treated limbs.^[32] Another study by El-Mowafi and Mohsen demonstrated accelerated healing of distraction callus of tibiae in LIPU-treated patients.^[33] Clinical studies are mainly in favor of LIPU application for distraction osteogenesis procedures. However, the number of studies and patients are limited and more clinical studies are needed in this area.

Spinal arthrodesis is another orthopedic procedure that may benefit from LIPU treatment. Although several animal studies demonstrated positive effects of LIPU treatment on spinal arthrodesis procedures, no clinical report is available so far.

Because of altered bone turnover rate, implant osseointegration is compromised in osteoporotic patients. Management of fractures is complicated in osteoporotic patients for the same reason. Although US treatment stimulated bone growth in tantalum implants in dogs, no clinical use has been reported so far.^[34]

U.S. therapy and maxillofacial bones

Maxillofacial bones differ from extremity bones in their embryologic genesis, their growth, and their histologic appearance. Most clinical and preclinical studies were conducted on long bones and the number of studies concerning the effects of LIPU on maxillofacial bones is limited and controversial. The first clinical report was published by Harris et al. in 1992.^[35] The author applied US treatment with 3-MHz frequency at 1.0 W/cm² intensity for 60 days for the treatment of osteoradionecrosis of the mandible. He reported positive progress in 10 of 21 patients.^[35] In vitro studies conducted on mandibular osteoblast and fibroblast cultures indicated that US signals increase proliferation of cells, synthesis of cytokines like interleukins and FGF, and synthesis of nitric oxide and prostaglandins, which are important mediators in angiogenesis and bone healing. The first animal study on mandible was published by El-Bialy et al.^[36] The authors demonstrated enhanced bone formation on the distraction site stimulated by US application. A clinical study reported that LIPU application provides better repair for orthodontically induced root resorption.^[37] Another clinical study by Schortinghuis et al.^[42] indicated that LIPU has no effect on ossification in the distraction gap of vertically distracted mandible. A listing of animal and clinical studies concerning maxillofacial bones is presented in Table 1.

It is mainly accepted that US treatment enhances endochondral bone formation. The fact that maxillofacial

bones have intramembraneous ossification makes the use of US therapy questionable in this particular region. The close relationship to important anatomic locations like the brain, parotid gland, and eyes, in which the effects of US are not known, is another drawback for the use of US in maxillofacial bones. Another drawback is the thicker soft tissue layer compared with tibial, ulnar, or scaphoid bone regions, which makes the penetration of US signals weaker, thus reducing the effectiveness of US treatment. The treatment of most maxillofacial fractures requires intermaxillary fixation. Long duration of intermaxillary fixations causes many problems like impairment in feeding, temporomandibular joint problems, or dental–periodontal problems. Shortening the intermaxillary fixation time may be one main indication for LIPU applications in the maxillofacial area. One animal study conducted on rabbits demonstrated increased fracture healing in a mandibular fracture model.^[38] However, more studies are needed to determine the optimal dosing and treatment modality before utilizing the procedure in clinical settings.

Complications and Side Effects

Ultrasound treatment as an aid to bone healing generates low-intensity energy, which is comparable to diagnostic US doses. Pulsed signals and low energy minimize the thermal effect of US on biological tissues. No serious complication has been reported regarding the clinical use of US therapy. Reported adverse effects as a result of US treatment include muscle spasm at the treatment side, mild erythema, and mild swelling. US signals do not interfere with metal objects and its use in sites with implanted metal biomaterial is safe. One disadvantage of the home application type of US treatment is patient dependency on the treatment. In such situations patient cooperation affects the success of the therapy. The effects of US therapy on growing bones and brain tissue are not clear. Thus its use in pediatric patients and in skull bones should be avoided. The use of US in sites of suspected neoplasia and acute infection is contraindicated because of possible accelerated progress of the disease. Patients should be evaluated by allergic reactions against the coupling gel. Patients on cardiac pacemakers should avoid US treatment because of the possible interaction with US signals.

Future of Ultrasound Therapy for Bone Healing

The minimal complication rates and adverse effects of US therapy for acceleration of bone healing make it possible to use this therapy in clinical settings. Although many clinical and animal studies demonstrate

Table 1 Clinical and animal studies concerning the effects of ultrasound therapy on maxillofacial bones

Author/year	Indication	Animal/clinical (No.)	US intensity	Conclusion
Fedotov et al., 1986 ^[39]	Mandibular fracture	Rabbits (36)	0.2–0.6 W/cm ²	Stimulated reparative process at fracture site

El Bialy et al., 2006 ^[45]	Mandibular growth modification	Baboon (14)	30 mW/cm ²	Enhanced mandibular growth in growing baboons when US treatment was combined with functional appliances

the positive effects of US, controversial results also exist. Most fresh fractures or surgical approaches associated with bone tissue, such as bone distraction, heal eventually with conventional treatments. However, in cases when faster healing is desired by the patient or the physician, US therapy may be considered as an alternative approach.

There is evidence of successful treatments of non-unions and delayed unions with LIPU therapy.^[30,31] One main indication of US treatment may be this group of patients in the future. Osteoporosis is a major disease affecting bone tissue, especially in developed countries, which have an intense elderly population. Integration of biomaterials may be compromised in osteoporotic patients. Tanzer et al. demonstrated increased bone growth in porous intramedullar tantalum implants in the ulnae of dogs.^[34] One potential use of US treatment is to accelerate osseointegration of implants (in the treatment of fractures or dental implants) in osteoporotic patients. More animal and clinical studies are

needed in this area. US treatment also positively affects soft tissue wound healing.^[46] Complicated fractures that involve soft tissue and bone injury combined may benefit from US therapy.

Osteoradionecrosis is an avascular necrosis of bone, which develops as a consequence of radiotherapy. It is characterized by hypoxia and hypovascularity. The conventional treatment approach is surgical debridement with additional antibiotic and hyperbaric oxygen therapy. US treatment increases vascularity by inducing synthesis of angiogenesis-related cytokines.^[2] One study demonstrated that supportive US application helped considerably in the treatment of osteonecrosis of the jaw.^[35] US therapy may be considered a supportive treatment option for the treatment of osteonecrosis. Hypovascularity and hypoxia as a result of radiotherapy impair the success of reconstructive procedures in oncologic surgeries. One potential use of US is as a supportive procedure after reconstructive surgery in sites that receive radiotherapy.

Experimental and clinical studies are being conducted continuously to understand the mechanism of action and the effectiveness of US in clinical settings. Although the indication of use in clinical settings may be limited for a small group of patients, US therapy poses a significant treatment option in the management of bone pathologies and injuries mentioned above.

CONCLUSION

The use of US in medicine started for therapeutic but not for diagnostic purposes. Several theories explain the mechanism of action on bone healing. The studies mostly indicate that US therapy accelerates endochondral bone healing. Therapeutic US therapy in clinical settings is a non-invasive application and has no serious complications or side effects. It is an acceptable treatment of choice in fractures with delayed unions or non-unions. Although it does not seem possible to treat osteoporosis itself because of difficulties in application and a low penetration rate, its use in acceleration of osseointegration of metal biomaterials in osteoporotic patients has a promising future in orthopedic surgery and oral-maxillofacial surgery. The use of US in the treatment of fresh fractures or surgical interventions associated with bone tissue like spinal arthrodesis or distraction osteogenesis in healthy patients may not be worthwhile, because bone healing usually occurs uneventfully in these situations. Although much is known about the molecular effects of US treatment on bone healing, more studies are needed to fully understand the mechanism.

Urinary Prostheses

Daniel Eberli
Anthony Atala

Wake Forest Institute for Regenerative Medicine, Winston Salem, North Carolina, U.S.A.

INTRODUCTION

Modern urologic prostheses include artificial sphincters, penile prosthesis, testicular implants, catheters, and stents. The urological use of artificial materials has a long history, starting in 3000 B.C. when Egyptians used papyrus and gold catheters to treat urinary retention. Over the next decades catheters were made from lead, treated paper, and, after the turn of the 19th century, from natural rubber. Only in the early 1970s were more sophisticated hydraulic prosthesis for the treatment of erectile dysfunction and urinary incontinence introduced.

A biomaterial used for urologic prostheses should incorporate certain features, such as biocompatibility and stability after placement, resistance to infection, chemical stability in urine, no carcinogenicity or antigenicity, ability to sterilize, and availability at an affordable price. Although not perfect, silicone and polyurethanes are the biomaterials currently used for urological implants. Both silicone and polyurethanes have excellent biocompatibility and have been successfully used in clinics for over 30 years. However, the use of hydraulic implants for the treatment of erectile dysfunction and incontinence are still considered the last treatment option if pharmacological treatment fails. Serious complications, including infection or malfunction, require instant removal or replacement of the prosthesis. On the other hand, patients with successfully implanted prostheses report the highest satisfaction scores. Careful patient selection is crucial for the success of the implanted device, since the patient has to learn how to use his prosthesis.

This chapter will critically discuss urological prosthesis in regard to biomaterials, indications, surgical treatment, and future perspectives. Furthermore, it will emphasize current clinical problems associated with the use of prostheses in the hope that upcoming research might help to overcome these obstacles.

BIOMATERIALS FOR URINARY PROSTHESES

Urological implants are made of a relatively small variety of materials including silicone and polyurethanes.

Other materials such as latex, polytetrafluoro ethylene, or hydrogels are commonly used in stents and catheters, often as coatings. Generally speaking, polyurethanes have good mechanical properties and poor stability in the body, while silicones have poor mechanical properties, but excellent stability in the body. Therefore, both materials have to be modified to meet the requirements for use as urinary prostheses. This can be achieved by chemical modification of the polymer, by mixing with additives or by using a multilayer design.

Biomaterial–Tissue Interaction

Contact of any biomaterial with tissue leads to an inflammatory reaction in varying degrees. The body reacts by activating the innate and specific immune system, the complement system, and coagulation cascades. This inflammatory response is influenced by surface characteristics of the biomaterial, the reaction to denatured proteins adsorbed on the surface of the biomaterial, and the products of degradation.

In the early phase, the adsorption of albumin, fibrinogen, and other proteins trigger the host defense. This adsorption of protein further decreases the surface tension allowing for more protein to adhere. Some urologic prostheses reduce the tissue response by utilizing a hydrophilic coating and a smooth finish to decrease the adherence of protein. Nevertheless, all biomaterials become encapsulated over time. Encapsulation is a chronic inflammatory response of the host towards any biomaterial. The fear that this chronic inflammation might trigger malignancy is discussed later in this chapter.

In summary, silicone and polyurethanes show excellent biocompatibility with minimal effect on surrounding tissue, and are therefore preferred biomaterials for urologic prostheses.

Silicone

Silicone has been chosen for the majority of urologic prosthetics because it is relatively inert, easily sterilized, maintains its strength in vivo. Silicone, or the more scientific name, Siloxane, was first discovered as a waste product during the synthesis of other polymeric

materials and has been known for over 100 years. The driving force behind the exploration was the exceptional stability in the biological environment, compared to other elastomers showing more degradation when left in vivo for long periods. The first commercial production began in 1943.^[1]

The general molecular formula for silicone polymers is R_2-SiO , where R is a carbon based side group, and the polymer chain consists of a $-(SiO)-$ backbone. The viscosity of silicone can be tailored by changing the chain length, from liquid to gum. In prostheses, silicone polymers are used in three major forms, including oils, gels, and elastomers. Silicone oils consist of mixtures of short chain polymers. Silicone gel is a mixture of silicone oil and crosslinked elastomers. Elastomers are made by combining long chains of silicone and ethyl cross-links between the chains.

Compared with other commercially available polymers, the mechanical properties of silicone are relatively poor, but the preservation of its properties in vivo has led to its widespread use. Typical tensile strength of silicone used in medical devices is 4.9–7.4 MPa, and the tensile modulus is 2.2 MPa.^[1]

Polyurethanes

The second most used material for urological prosthesis is polyurethane (Bioflex[®]). Polyurethane has a tensile strength of 52 MPa and a tensile modulus of 3.4 MPa,^[1] thus is far stronger than silicone. The elongation of silicone and polyurethane is comparable, allowing for 600% elongation before tearing.

The backbone of polyurethanes contains the urethane linkage $-OC(O)NH-$. The characteristics of the polymer are given by the functional groups such as polyethers, polyesters, ureas, silicones, and hydrocarbon groups. The exceptional mechanical properties are due to excellent secondary hydrogen bonding. Generally speaking, polyurethanes have good mechanical properties and poor stability in the body. Therefore, polyurethanes have to be modified to meet the criteria for urologic implants. The composition of polyurethanes used in medical devices (Bioflex[®]) is proprietary. Therefore, details about the formulation are not known to the public. In general terms, Mentor describes the improvement as due to two factors: a changed polyurethane chemistry and additives that optimize in vivo durability. Studies have shown that the polyurethane used by Mentor is more durable and less elastic than silicone.^[2]

Possible Reactions to Silicone and Other Thermoplastic Elastomers

The issue of the possible relationship between various diseases and silicone has been, and continues to be, the

subject of great scientific and medical debate. The legal battle is mainly focused on implants for augmentation and reconstructive mammoplasty, but since the same biomaterial is used for urologic prostheses, the problematic situation applies here as well. The medical literature has raised the possibility that there may be an association between certain immunological-based diseases and silicone implants. The diseases most commonly mentioned include scleroderma, rheumatoid arthritis, and systemic lupus erythematosus. Neurological problems have been reported in a small number of breast implant patients who also exhibit immunological symptoms. Available information does not permit precise quantification of risk. In addition, women with connective tissue disorders have reported a reduction in symptoms after their breast implants were removed. More scientific studies are needed to prove a link between the implants and immunological or neurological problems.

Even more formidable is the association of biomaterials and tumor development. The literature suggests that in vivo degradation and particle shedding of silicone elastomers may play an important role in maintaining chronic inflammatory response and encapsulation.

Since certain malignancies can be clearly linked to chronic inflammation, including gastric cancer and esophageal cancer, this problem needs serious attention. Case reports in the medical literature have associated tumors with the presence of silicone mammary implants. However, the number of tumors found in the vicinity of implants is only one to two cases globally every year.^[3] This number is very small in relation to the millions of implants performed every year. Although, the individual cancer risk is minimal, concerns among patients still remain. During the past two decades of clinical use, the medical literature generally indicates that silicone prostheses are not carcinogenic, but the debate is still ongoing.

In summary, an association between silicone and the aforementioned conditions and complications has not been verified by controlled scientific studies. Urological devices made from silicone and polyurethane should be labeled safe for clinical use. Nevertheless, patients concerns must be included in the decision-making process before surgery to ensure a favorable outcome.

PENILE PROSTHESES

Overview

The National Institute of Health estimates that 10–20 million American men are impotent. The treatment options today include oral therapy, vacuum devices,

penile injection therapy, and prosthetic surgery. Penile prosthesis is usually offered if pharmacological therapy fails. Historically, the first penile prosthesis used cartilage and bone to improve rigidity. The approach was inspired by the observation that the “penis bone” of certain species consists of cartilage. A report of 1948 Bergman et al. described the use of a rib cartilage implant placed into a tube of skin graft.^[4] Despite initially high success rates, the use of cartilage had many disadvantages, including substantial harvest site morbidity, difficulty getting the right size, and variable absorption. Therefore, rib cartilage was replaced with the first synthetic rods made of perforated acrylic or polyethylene. The material of these early artificial implants was later replaced by silicone, an inert biomaterial with the desired flexibility and rigidity. A hydraulic inflatable prosthesis allowing for adjustment of the rigidity, from flaccid to firm, was introduced in 1973.^[5] Further research and development was needed to decrease the high rate of mechanical failure of these early inflatable implants. Modern prostheses are able to resolve the rigidity problem and penetration difficulties, with no change in libido or orgasm characteristics, and there is no increase in size. These facts have to be clearly communicated to the patient to prevent an unsatisfactory outcome of the procedure. With careful patient selection and successful implantation, penile prostheses are associated with a high rate of patient satisfaction.^[6]

Types of Penile Prostheses

There are currently two types of penile prostheses available on the market, including semirigid and inflatable prostheses with one, two, or three volumes.

Semirigid Prostheses

The most commonly used semirigid implants (Fig. 1) are the Mentor Acu-Form (Mentor, Santa Barbara, CA) and the AMS 600–650 (American Medical Systems, Minnetonka, Minnesota). During surgery, a pair of these malleable silicone elastomer rods are directly placed into the corpora cavernosa. These implants consist of twisted stainless steel or silver wires wrapped in a synthetic fabric surrounded by a silicone jacket. One major drawback of this design is the problem of “spring-back” after bending. Newer models reduce the elasticity by increasing the number of cable strands reducing the “spring-back” and improving mechanical reliability. All implants are offered in various diameter and lengths to fit the anatomical specifications of each patient.

In comparison to inflatable implants, semirigid prostheses are easier to insert since there is no pump or

Fig. 1 Mentor genesis Semirigid implants with malleable silicone elastomer rods. (Courtesy of Mentor Corporation, Santa Barbara, CA).

reservoir to place. Furthermore, the semirigid implants are more widely accepted internationally because they are substantially less expensive than the inflatable implants.

AMS recently presented a more advanced semirigid implant (Dura-II). This device consists of a series of articulating polypropylene discs connected with a metal cable running through the center of the discs, resembling to a gooseneck lamp.

This positional memory allows the implant to be rigid during intercourse and to remain concealed when placed along the leg.

Inflatable Implants

Inflatable implants are manufactured as two- or three-piece prostheses. The two-piece implants include a pair of inflatable cylinders implanted in the corpora cavernosa and a small pump for scrotal implantation. The three piece prostheses (Fig. 2) are supplemented with an additional fluid reservoir, which is typically positioned intraperitoneally. All components are connected by tubes. Currently medical implants have nylon reinforced tubing to make kinking virtually impossible and are equipped with patented locking connectors for easy connections.

In order to increase rigidity of the penis, saline solution is moved from the reservoir to the cylinder shafts by squeezing and releasing the scrotal pump several times. Modern inflatable implants, like the AMS 700CX, are designed in a three layer fashion containing a core made of elastic silicone, a middle layer of woven monofilament (90% polyethylene and

Fig. 2 AMS 700 CX™ penile prosthesis Inflatable three piece prostheses, including a pair of inflatable cylinders implanted in the corpora cavernosa, a small pump for scrotal implantation and fluid reservoir which is typically positioned intraperitoneally. (Courtesy of American Medical Systems, Inc., Minnetonka, MN).

10% polyurethane) and an outer silicone layer for tissue interaction. The middle woven monofilament knitted layer is designed to permit controlled expansion of the cylinders. The fibers can either be woven bidirectionally, permitting length and girth expansions, or unidirectionally, permitting only girth expansion. Cylinders that expand more in girth than in length tend to straighten penile curvature better and are recommended for use in patients with significant scarring, such as that caused by priapism (prorogued erection), Peyronies disease (disorder with local corpora fibrosis) or reimplantation of a prosthesis. Finally, the inner elastic silicone core provides rigidity if filled with fluid.

The implants manufactured by Mentor are very similar in design and function to the AMS prosthesis. The main difference is that Mentor uses a polyether urea urethane elastomer called Bioflex[®], which has a higher tensile strength and is more resistant to abrasion compared to silicone.

In an effort to simplify surgical placement, both manufacturers presented two-piece inflatable prostheses that combine the reservoir with one of the other components. The AMS Ambicor prosthesis has the reservoir located at the proximal end of the cylinder. For activation, saline is pumped from the proximal reservoir to the distal inflatable chamber using the pump located in the scrotum. The Mentor Mark II has a different design and combines the pump and the reservoir. To conceal the relatively large pump reservoir, the device can be implanted between the testicles. Both models are prefilled with saline and require no tubing connections, reducing operation time and infection risk.

The original Mentor two-piece prosthesis was prone to early mechanical malfunction due to tissue

encapsulation of the pump-reservoir system and subsequent contracture of the capsule. The newer Mentor models have a textured surface added to the reservoir pump to reduce capsule formation.

In a further effort to reduce the number of volumes needed, AMS introduced a self-contained inflatable prosthesis in 1985, usually referred to as a one-piece penile implant. Unfortunately, mechanical failure rate of the original one-piece prosthesis was reported to be 79%, and the long term patient satisfaction was only 43%. The overall explantation rate of the self-contained inflatable prosthesis was as high as 55%. Studies comparing one piece prosthesis with multi-component inflatables noted a higher patient satisfaction and lower revision rate for the multi-component prosthesis. The multi-component inflatable prosthesis is the device of choice for patients requiring prosthetic surgery for erectile dysfunction.

Indications

The introduction of oral therapy (phosphodiesterase inhibitors) radically changed the management of the treatment for erectile dysfunction, leading to a reduced surgical indication. Penile prosthesis still remains the treatment of choice for patients with organic-factor related erectile dysfunction, including unsatisfactory results with other therapy modalities, contraindications to oral treatment, and rejection by the patient.

Out of the 25% nonresponders to oral pharmacotherapy, approximately 15% will be offered intracavernosal injection therapy, a modality with a high drop-out rate. Therefore, approximately 15% of patients seeking treatment for erectile dysfunction have severe and irreversible damage of the erectile mechanism and are candidates for implantation surgery.^[7] Candidates for treatment with penile prostheses should be psychologically stable, in good general health and fully informed. This is particularly important since implantation surgery is associated with significant risk of complications and is irreversible.

Success and Problems

Outcome

Among all treatment options for erectile dysfunction, penile prostheses are associated with the highest success rates. The overall published rates of satisfied patients and partners are 70%–85% and 60%–70%, respectively. A recent study compared erectile function and satisfaction rates in patients who received treatment for erectile dysfunction with sildenafil (Viagra[®]), intracavernosous prostaglandin E1 injection therapy or penile implant surgery.^[6] The Erectile Dysfunction

Inventory for Treatment Satisfaction (EDITS) and the erectile function domain score of the IIEF were used to assess the outcome. After a mean follow-up of almost two years, patients who underwent penile implant surgery had significantly higher scores than patients treated with sildenafil or intracavernous injections. Further studies using a psychosexual questionnaire found a significant alleviation of concerns about achieving and maintaining an erection during intercourse after penile implant surgery.

In summary, these results show that penile prostheses can be highly successful in improving erection, ejaculation, orgasm and sexual satisfaction.

Infections

Infection associated with the penile prosthesis is a serious event that usually necessitates the immediate removal of the device. Most infections occur as a result of contamination of the operative wound and subsequent colonization of the prostheses at the time of implantation. The most common bacteria found on infected prosthesis is *Staphylococcus epidermidis* and *Staphylococcus aureus*,^[7] both common skin inhabitants. Fortunately, the infection rates with more aggressive organisms such as methicillin-resistant *S. aureus* or *Pseudomonas aeruginosa* are relatively low, in the range of 1%–10% of cases.

Recent studies found the overall incidence of infection to be approximately 10% for primary implants. Patients with deficiency of the immune system are more prone to infection. Therefore, patients under treatment with immunosuppressive drugs or patients with poorly controlled diabetes mellitus should postpone their surgery until the underlying condition has stabilized.

Surprising results were revealed in a prospective study analyzing the infection rate of removed prostheses. Seventy percent of patients with clinically uninfected penile prostheses had culture positive bacteria; most of them were a *Staphylococcus* species.^[8]

This study shows that colonization of prostheses is far more common than clinically expected. Unfortunately, we do not yet understand why some patients develop a fulminate infection while others show no clinical signs even though the implant is colonized with bacteria.

Both manufacturers of penile prostheses made significant efforts to reduce the high rate of infected implants. AMS added a coating called InhibiZone™ containing a sustained release formula of Rifampicin and Minocycline to inhibit bacterial growth. Rifampicin shows a significant decrease after one day, while Minocycline decreases after seven days. The InhibiZone™ coating proved to be most efficient against *S. epidermidis* and *S. aureus*, both bacteria commonly found

on infected prostheses. The conclusion of a recent study including more than 4000 patients was that InhibiZone™ lowers the infection rate significantly by 60% compared to noncoated prostheses.^[9] It is important to understand that both antibiotics do not reach labeled doses for active infection, and therefore a conventional prophylactic antibiotic protocol should be administered before surgery.

Mentor has chosen a different cause of action and changed the surface structure of their penile prosthesis to reduce bacterial adherence. The extremely hydrophilic coating called Resist™ has been shown to decrease bacterial adherence in vivo.^[10] Furthermore, this coating can absorb antibiotics and release them over 24–72 h. An antibiotic-soaking solution, composed of 100,000 Units of Bacitracin and 2 g Gentamicin in 1000 ml of saline has been successfully tested and is in clinical use.

In general, it is important that the introduction of microbe-resisting coating does not result in the surgeon reducing his vigilance or sterile technique. Procedures which already have been established to reduce the incidence of infection are still of crucial importance. Therefore, administering of prophylactic antibiotics two hours prior to surgery, thorough shaving in the immediate preoperative period, and opening of the prosthesis package as late as possible should still be practiced.

Future Perspectives: Regenerative Medicine

The shortcomings of synthetic biomaterials have led to the application of regenerative medicine and tissue engineering to the field of penile reconstruction. Regenerative Medicine encompasses various areas of technology, such as tissue engineering, stem cells, and cloning. Tissue engineering, one of the major components of regenerative medicine, follows the principles of cell transplantation, materials science, and engineering towards the development of biological substitutes that can restore and maintain normal function. Tissue engineering strategies generally fall into two categories: the use of acellular matrices, which depend on the body's natural ability to regenerate for proper orientation and direction of new tissue growth, and the use of matrices with cells. Acellular tissue matrices are usually prepared by manufacturing artificial scaffolds, or by removing cellular components from tissues via mechanical and chemical manipulation to produce collagen-rich matrices. These matrices tend to slowly degrade on implantation and are generally replaced by the extracellular matrix (ECM) proteins that are secreted by the ingrowing cells.

When cells are used for tissue engineering, a small piece of donor tissue is dissociated into individual cells.

These cells are expanded in culture, attached to a support matrix, and then reimplanted into the host after expansion. The source of donor tissue can be heterologous, allogeneic, or autologous. Ideally, both structural and functional tissue replacement will occur with minimal complications. The preferred cells to use are autologous cells, where a biopsy of tissue is obtained from the host; the cells are dissociated and expanded in culture, and the expanded cells are implanted into the same host.^[11-14] Although, it may cause an inflammatory response, the use of autologous cells avoids rejection. Thus, the deleterious side effects of immunosuppressive medications can be avoided.

The first successful studies, applying the methods of tissue engineering to the treatment of erectile dysfunction, engineered human cartilage rods that could be used in patients requiring a penile prosthesis.^[15] These human cartilage rods were created by transplanting chondrocytes harvested from a small biopsy of the cartilaginous part of a human ear on polymer scaffolds. Mechanical tests showed that the engineered cartilage rods exhibited the appropriate mechanical properties required for use as natural penile prostheses. In consecutive studies the same research group started to engineer functional corpora tissue. After establishing the cell expansion technique for penile endothelial cells and smooth muscle cells^[16] a segmental replacement of corporal tissue was successfully performed in a rabbit model.^[17] Autologous endothelial cells and smooth muscle cells were seeded on acellular tissue matrices and the constructs implanted into a penile defect. This study demonstrated the possibility of engineering autologous penile corpora cavernosa tissue in a rabbit model. The engineered tissue was able to achieve adequate structural and functional parameters as proven in histology and functional measures (Cavernosometry). A study evaluating the total penile replacement is currently ongoing. Preliminary data presented at international meetings are very promising.

In summary, tissue engineering might offer a novel treatment option for patient requiring a penile prosthesis and phallic reconstruction. The use of the patient's own cells to engineer a functional corpus would clearly present a major medical breakthrough.

ARTIFICIAL URINARY SPHINCTER

Overview

Urinary incontinence is associated with impairment of quality of life, social isolation, and depressive symptoms.^[18] A conservative estimate is that urinary incontinence affects approximately 20% of women. However, the prevalence may be as high as 50% in elderly women with a peak at 47 years of age.^[19-21] In

the United States the estimated annual direct cost of caring for patients with urinary incontinence is over \$16 billion.^[22]

In women, trauma during childbirth is the main reason for developing severe urinary incontinence requiring an artificial urinary sphincter. In male patients, the main cause of incontinence is surgery for prostate disease.

In general, treatment plans are usually directed toward the specific type of urinary incontinence; the treatment option with the lowest risk for adverse complications is usually offered. Lifestyle intervention, pelvic floor muscle training, vaginal devices (pessaries), and pharmacological treatments are usually considered prior to surgical intervention.^[18] Surgical treatment options include the endoscopic injection of bulking agents, colposuspension (e.g., Burch), sling operations, traditional transvaginal needle suspension, tension-free vaginal tape (TVT), and artificial urinary sphincter.

The first non-hydraulic artificial urinary sphincter composed of silicone and stainless steel was introduced in 1973. Since then major design changes have significantly improved effectiveness and patient satisfaction. At first, the four-component model consisted of an inflatable cuff, a fluid reservoir, and two pumps: one to inflate and the other to deflate. Due to the large number of components, this first device was difficult to implant and prone to mechanical failure.^[23]

Types of Artificial Urinary Sphincters

Currently, one type of artificial urinary sphincter is dominating the market (Fig. 3). American Medical Systems (Minnetonka, Minnesota) manufactures the three-piece artificial sphincter (AMS 800) consisting of a deflation pump, a pressure regulating reservoir, and an inflatable cuff. The pump is usually placed in the scrotum, and the reservoir is placed in the lower abdomen. Finally, the cuff can be implanted either at the bladder neck or the bulbous urethra. All pieces are interconnected with reinforced silicone tubing and the system is filled with sterile saline solution. To initiate micturation, the pressure in the cuff is released by squeezing the deflation pump located in the scrotum. The pump is constructed to allow for slow return of fluid to the cuff and automatically raises the pressure around the urethra after micuration, usually within 3 min. By choosing one of the three different pressure regulating reservoirs, the pressure within the system can be adjusted. The surgery is usually done under general or spinal anesthesia and is completed within 90 min. Following surgery the device is locked in an open condition (deactivated) to allow proper healing of the wound. Four to six weeks after surgery, the device

Fig. 3 AMS 800™ artificial urinary sphincter Three-piece artificial sphincter consisting of a deflation pump, a pressure regulating reservoir and an inflatable cuff. (Courtesy of American Medical Systems, Inc., Minnetonka, MN).

is usually activated and the patient educated in the handling of the device.

Indications

The current artificial urinary sphincter is suitable for difficult incontinence in both sexes. More than 90,000 men worldwide received an AMS 800 within the last 30 years. The majority of implants were used for the treatment of incontinence after removal of the prostate due to prostate cancer. The anatomical proximity of the urinary sphincter and the prostate makes it difficult to remove the entire cancer without harming the sphincter muscle. The indication in woman is severe urinary stress incontinence with involuntary urinary leakage in a lying position. Numerous reports indicate that the artificial sphincter implantation is well tolerated and provides satisfactory results for the treatment of severe urinary incontinence in both genders.

Success and Problems

Artificial sphincters face the same problems as penile implants, including malfunction, erosion, and infection. These complications are severe since they require immediate surgical revision, often including explantation of the prosthesis. The level of mechanical malfunction of the improved AMS 800 series have been reported as 7%–16%.^[24,25] Early reports in

female patients with stress urinary incontinence described urethral erosion rate around the cuff at 10%–26%.^[26,27] More recent reports suggest that, if care is taken during implantation, the erosion rate can be minimized.^[27] The overall surgical revision rate is reported to be 29% with a follow up of 7.7 years.^[25] Therefore, patients have to be fully informed that up to one-third will need revision surgery in the years to come.

However, the artificial sphincter is associated with a high long-term success rate. A recent study evaluating men who received a prosthesis found that after seven years 80% were still satisfied with the device and achieved a social continence (requiring zero to one pad per day).^[28] Another long-term study evaluated the use of artificial sphincters for the treatment of post-prostatectomy incontinence and found that 90% of patients reported satisfaction and 96% would recommend the device to a friend.^[29]

Future Perspectives: Regenerative Medicine

Many of the current surgical treatment options are limited by the postoperative complications, including infection, graft erosion, bladder and bowel perforation, prologued catheterization, and vascular injury.^[21] In addition, 5%–10% of patients undergoing surgery for stress urinary incontinence will have worsening due to new onset of detrusor over activity, causing urge incontinence.^[21] The pelvic diaphragm prevents urinary incontinence by providing both resting urethral tone via slow-twitch fibers and rapid re-rectory contraction via fast-twitch fibers if the abdominal pressure rises. Therefore, the external striated urethral sphincter is primarily responsible for preventing stress urinary incontinence. The potential use of injectable cultured myoblasts (muscle precursor cells, MPC) for the treatment of stress urinary incontinence has been investigated and has the potential to become the first treatment to restore sphincter muscle function.^[30] Labeled myoblasts were directly injected into the proximal urethra and lateral bladder walls of nude mice with a micro-syringe in an open surgical procedure. Tissue harvested up to 35 days post-injection contained the labeled myoblasts, as well as evidence of differentiation of the labeled myoblasts into regenerative myofibers. The authors reported that a significant portion of the injected myoblast population persisted in vivo.^[31] A subsequent study demonstrated a significant improvement in leak point pressure when sciatic nerves transected rats were treated with myoblast injections.^[32] The fact that myoblasts can be labeled and survive after injection and begin the process of further myogenic differentiation supports the feasibility of using cultured cells of

muscular origin as an injectable bioimplant. Muscle precursor cells are the quiescent satellite cells found in each myofiber that proliferate to form myoblasts, and eventually myotubes and new muscle tissue. Intrinsic MPC have previously been shown to play an active role in the regeneration of injured striated urethral sphincters.^[33] In a subsequent study, autologous MPC were injected into a rat model of urethral sphincter injury, and both replacement of mature myotubes, as well as restoration of functional motor units, was noted in the regenerating sphincteric muscle tissue.^[34]

Preclinical trials for the application of this technology are currently being conducted in large animals. Sphincteric derived muscle cells have been used for the treatment of urinary incontinence in a pig model.^[35] The damaged sphincter was visualized by transurethral ultrasound and the MPC and fibroblasts injected into the damaged zone. Our institution is performing a preclinical study in dogs; animals that received a muscle precursor cell injection after damage of the sphincter showed a significant improvement in leak point and sphincter pressure compared to controls.

In summary, these results are promising and the first clinical trials are within reach. Muscle precursor cells may be a minimally invasive solution for urinary incontinence in patients with irreversible urinary sphincter muscle insufficiency.

TESTICULAR PROSTHESIS

Overview

Testicular loss occurs for various reasons, including orchiectomy for cancer, torsion, or agenesis. The scrotum plays an important psychological role in the male body image. Therefore, prosthetic devices have been developed to restore the normal appearance of the scrotum and to improve quality of life and psychological well-being. The first testicular prosthesis was implanted in 1939 using a metal alloy vitalium 1939.^[36] Over the years, glass spheres, polymerized methyl methacrylate, methacrylate, and polyurethane foams were introduced with the goal to be a cosmetically more acceptable testicular prosthesis. The use of silicone-gel filled silicone implants in the early 1970s was a major improvement,^[37] providing similar touch as a native testicle. Silicone polymer prostheses were then widely used for over 20 years. The production stopped in 1995 because of the concerns over the association of silicone implants with connective tissue disease.^[38] Although the expert panels in the United States (The National Science Panel and the Institute of Medicine) failed to find evidence for any causal linkage, the manufacturer designed a silicone-gel free testicular prosthesis. This saline-filled testicular prosthesis

Fig. 4 Mentor testicular prosthesis Saline filled testicular prosthesis with a silicone polymer shell and recessed suture tab, which allows the device to be fixed in place during surgical placement. (Courtesy of Mentor Corporation, Santa Barbara, CA).

with a silicone polymer shell (Mentor) remains the gold standard up to date (Fig. 4). The manufacturer offers four different sizes XS (5 ml), S (8 ml), M (11 ml), and L (15 ml). The silicone polymer shell has two reinforced regions. At the upper pole, the silicone shell is thicker to prevent leakage after filling the prosthesis, and at the lower pole there is a recessed suture tab that allows the device to be fixed in place during surgery. This prosthesis should not be considered a lifetime implant but can often remain without exchange or removal for decades.

Indications

Testicular implants should be offered to any patient with agenesis of a testicle or surgical removal due to cancer or torsion. An implant can restore the normal appearance of the scrotum and can improve self-esteem. It clearly remains a patient's choice whether he

wants an artificial implant or prefers to live with only one testis. In our experience, older men tend to deny the implant more often, while younger men decide to have a prosthesis implanted. Despite the excellent results and improvement of quality of life, every foreign body carries the risk of infection even years after implantation.

There are no strong contraindications except the presence of a soft tissue infection at the time of placement. In addition, the manufacturer mentions the possibility of persistent pain in patients with preexisting varicoceles, a disease where venous backflow causes dilatation of the venous plexus surrounding the testicle.

The placement can be performed on an outpatient basis. To prevent device infection the patient is given perioperative antibiotics, which are repeated for several days after surgery. Additionally, the prosthetic device is bathed in antibiotic solution and then filled with normal saline. The prosthesis is placed into the scrotal pouch and usually fixed to the surrounding fascia through the suture tab.

Success and Problems

Silicone polymer testicular prostheses have a wide acceptance and are used around the world. A recent study^[39] evaluated, prospectively, 149 patients with testicular implants. After a follow up of one year, only three patients (2%) required additional surgery due to major complications, including device extrusion and device migrations. Additionally, this study was able to show a significant improvement in self-esteem measured by a well-accepted questionnaire. The prosthesis infection rate in this group was zero and only one patient had a superficial wound infection. This might be due to the strict antibiotics regime, the low complexity of the device, and the surgical procedure. In summary, testicular prosthesis is safe and should be offered to any patient with testicular agenesis or surgical removal. Numerous investigators have reported the cosmetic benefits provided by testicular implants, which lead to psychological benefits and high levels of patient satisfaction.

CONCLUSION

Urologic prostheses range from complex hydraulic penile prostheses or artificial urinary sphincters to rather simple-saline filled testicular prosthesis. Biomaterials used for these implants are silicone and polyurethane, both materials with exceptional biocompatibility. The more complex hydraulic prostheses have a high rate of surgical revisions due to mechanical

failure, erosions, and infections. Manufacturers are constantly seeking to decrease the revision rate by improving surface texture, adding antibiotics, and improving the overall design. If implanted successfully, urological prostheses are associated with very high satisfaction rates.

Vascular Fluid Dynamics

Stanley A. Berger

Departments of Mechanical Engineering and Bioengineering, University of California, Berkeley, California, U.S.A.

INTRODUCTION

The term *vascular* is defined “as relating to or containing blood vessels.” In this article, we discuss the circulatory systems whereby blood in the human body is distributed to the various organs and tissues of the body. The principal ones are the systemic and pulmonary circulations, and it is these that we discuss in most detail. The velocities in these flows are relatively low, with two immediate consequences: 1) the flows generally are incompressible and 2) the Reynolds numbers are low, ranging from much less than one to the low thousands, and not millions typical of industrial and aeronautical flows. As a result of the latter, the flows are typically laminar, at least under normal physiological conditions. The fact that the flows are laminar and incompressible presents an enormous advantage in their analysis. Complicating factors are that the flows 1) are mostly unsteady, e.g., pulsatile blood flow in the arteries; 2) occur in complex geometries, e.g., bends and junctions. Additional complications arise because the fluid, blood, is a complex suspension, and exhibits non-Newtonian properties under certain flow conditions or in parts of the circulation. Hemodynamic analyses and studies, in addition to contributing insight into the operation of one of the basic functional systems of the body, provide important information relevant to the pathogenesis of vascular diseases and malfunctions, and the means to evaluate the efficacy of palliative interventions to treat these.

BACKGROUND

Shown in Fig. 1 is a schematic of the flow in the systemic and pulmonary circulations, the major blood circulatory systems in the body. In the systemic circulation, contraction of the left ventricle ejects blood through the aortic valve into the aorta, the largest artery, whereupon the blood divides as it moves through many generations of junctions and bifurcations, passing through progressively smaller arteries and arterioles, until it finally reaches the capillaries, the smallest blood vessels in the body, across whose walls the gaseous and mass transfer processes necessary for life occur. The return circuit is through the venules, the

veins, the vena cavae, and finally into the right atrium. Deoxygenated blood is then ejected through the tricuspid valve into the right ventricle and pumped into the pulmonary arteries, ultimately reaching the pulmonary capillaries surrounding the alveoli in the lung, where it is reoxygenated, returning then to the left atrium. Ejection through the mitral valve into the left ventricle then completes one cycle of this pulsatile motion.

Table 1 lists some properties of the circulation and of the blood. While blood has about the same density as water, it is about three times more viscous, primarily as a result of the large number of suspended red blood cells (RBCs). Average Reynolds numbers are sufficiently low for the flow to be laminar throughout the circulation, and are very low in the microcirculation (arterioles, capillaries, and venules). Mean pressure falls from a relatively high value of 100 mmHg in the largest arteries to values of the order of 20 mmHg in the capillaries and even lower in the return venous circulation. To accommodate this, the arteries and arterioles are relatively thick walled, whereas the capillaries, venules, and veins are thin walled. This is schematically illustrated in Fig. 2, which also shows the mixture of the four basic tissues in each of the blood vessel types. The proportionally large amount of elastic tissue in the larger arteries means that these vessels act rather passively in response to the pressure pulse, whereas the arterioles, with a proportionally much larger fraction of smooth muscle can, by dilating or contracting, as controlled by the autonomic nervous system, actively affect the amount of blood flowing through them. This feature of the circulation provides the basis for the dominant flow control mechanism in the systemic circulation, as illustrated in Fig. 3. Note the relatively small pressure drop in the arteries, with most of the pressure drop, as much as 50 mmHg, occurring in the arterioles. It is this that makes it possible for the body to so effectively shunt blood to different organs—for digestion, physical exertion, etc.—as needed.

That changes in arteriolar diameter can so dramatically affect the pressure can be explained by using, approximately, the Poiseuille law, according to which the pressure drop varies inversely with the fourth power of vessel radius, therefore, for example, a decrease in diameter by a factor of two results in a

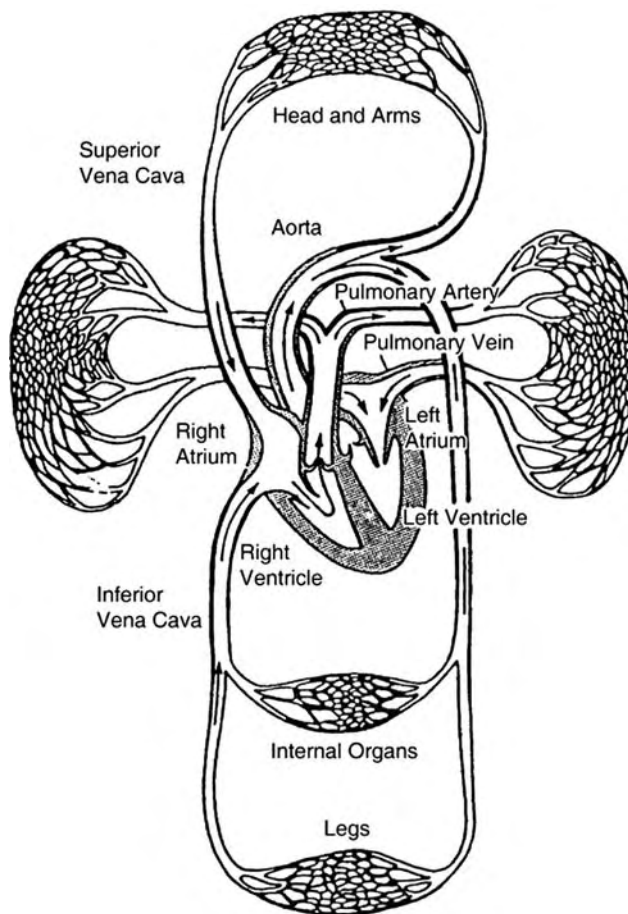

Fig. 1 Schematic of the systemic and pulmonary circulations.

16-fold increase in the resistance to flow, and vice versa. Fig. 3 shows that at the capillary level, there is little or no pulsatility in pressure; this was believed to be true with possibly some exceptions for the systemic circulation, less so for the pulmonary circulation. Recent evidence shows residual pulsatility in the systemic capillaries, with intermittent flow being common.

We now discuss in turn and in some detail each major part of the circulatory vascular system, starting with the arteries and progressing down to the capillaries.

FLOW IN THE SYSTEMIC CIRCULATION

The Arteries

The most obvious feature of blood flow in the arteries is the pulsatile nature of the flow, as evidenced by the existence of a pulse at sites remote from the heart. Our discussion of pulsatile blood flow begins with an analysis of pulse-wave propagation in the arteries.

Inviscid analysis

The analysis is based on an idealized artery, assumed to be an infinitely long, circular, cylindrical elastic tube isolated from its surroundings and subject to a pressure pulse. The blood flowing through this tube is assumed to be a homogeneous, incompressible, inviscid fluid, and the pulse-wave amplitude and tube radius are both assumed to be small compared with the wavelength. These assumptions allow the flow to be modeled as

Table 1 Some properties of the circulation and blood

Vessels	Diameter (mm)	Length (cm)	Wall thickness (mm)	Contained volume (cm ³ or ml)	Mean pressure (mmHg)	Average velocity (cm/sec)	Reynolds number	
							Average	Maximum
Aorta	25.0	40.0	2.0	100	100(av.)	40(av.)	3000	8500
Arteries	15–0.15	15.0	0.8	350	90(av.)	40–10	500	1000
Arterioles	0.14–0.01	0.2	0.02	50	60	10–0.1	0.7	—
Capillaries	0.008	0.05	0.001	300	30–20	<0.1	0.002	—
Venules	0.01–0.14	0.2	0.002	300	20	<0.3	0.01	—
Veins	0.15–15	18.0	0.6	2500	15–10	0.3–5	150	—
Vena cava	30.0	40.0	1.5	300	10–5	5–30	3000	—

Number of red blood cells (per mm³), 5×10^6 .

Number of white blood cells (per mm³), 10^4 .

Blood volume (L), 5–6.

Viscosity of whole blood (mPa sec; cP), 3–4 (in the larger vessels).

Specific gravity, 1.06.

Heart rate (per min), 60–70.

Cardiac output (L/min), 5–6.

Stroke volume (ml), 70.

Fig. 2 Variety of sizes, thickness of wall, and admixture of the four basic tissues in the walls of different blood vessels. The figures directly under the vessel name are the lumen diameter and the wall thickness, respectively. *End.*, endothelial cells; *ela.*, elastic fibers; *mus.*, smooth muscle; *fib.*, collagenous fibers. (From Ref. [1].)

one-dimensional, with a single velocity component $u(x, t)$, where x is the coordinate in the direction of the axis of the tube, u is the velocity in this direction, and t is time.

The differential form of the mass conservation, or continuity, equation is

$$\frac{\partial A}{\partial t} + \frac{\partial(uA)}{\partial x} = 0 \quad (1)$$

where A is the cross-sectional area of the tube. Conservation of momentum is expressed by

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + \frac{1}{\rho} \frac{\partial p}{\partial x} = 0 \quad (2)$$

We need a relationship describing the dependence of the tube radius, a , on the internal pressure, p , in the tube. The simplest elastic model is a linear relation

$$da = \frac{\gamma}{2} dp, \quad (3)$$

where γ is the compliance of the tube.

The above constitute three equations for the three unknowns u , p , and $A (= \pi a^2)$. Linearizing them for small disturbances, we can then combine them to obtain the single equation

$$\frac{\partial^2 p}{\partial x^2} = \frac{1}{c^2} \frac{\partial^2 p}{\partial t^2}, \quad \text{where } c^2 = \frac{a}{\rho \gamma} \quad (4)$$

This is the wave equation, the wave speed being c .

For blood flow in the arteries, an important example of such an elastic tube is a thin-walled tube whose material satisfies Hooke's law. Consider a small change in radius da owing to a pressure change dp in half of the cross-sectional element. The increase in the circumference is $2\pi da$, so the associated circumferential strain is $2\pi da/2\pi a = da/a$. Then, according to Hooke's law, the circumferential stress is $E(da/a)$, where E is Young's modulus of the wall material. A force balance for equilibrium on the upper half of the vessel gives, per unit axial length,

$$2adp = 2 \left(E \frac{da}{a} \right) h, \quad \text{or } da = \left(\frac{a^2}{Eh} \right) dp \quad (5)$$

Fig. 3 Pressure variation in the systemic circulation, showing mean pressure and temporal variation about the mean in the different vessels.

where h is the tube wall thickness. Comparison of this with Eq. (3) yields the compliance of the tube as $\gamma = 2a^2/Eh$, so the pulse-wave propagation speed is, from Eq. (4),

$$c = \sqrt{\frac{a}{\rho\gamma}} = \sqrt{\frac{Eh}{2\rho a}} \quad (6)$$

This expression for the wave speed in an inviscid, incompressible fluid in a thin-walled simple elastic tube, one of the most important formulas in arterial fluid dynamics, is called the Moens–Korteweg formula. It is a good approximation to the wave speed in the larger arteries even when the viscosity of blood is taken into account.

Viscous analysis

A more realistic model of blood flow in the arteries considers wave propagation in an arbitrarily *distensible* tube containing a *viscous*, incompressible fluid. This requires more space than available here, so we simply outline the analysis. The fluid is assumed to be Newtonian, this being generally a good approximation in the arteries. The tube is again assumed to be an infinitely long, freely moving, circular cylinder. Wall displacements owing to passage of the wave are assumed to be small, and the wall material is assumed to have linear response, and behave in a purely elastic, viscoelastic, or more complicated manner. Finally, the tube is taken to be either thin- or thick walled. Based on these assumptions one obtains two partial differential equations for the axial and radial displacements of the wall, the independent variables being t and x , and the radial coordinate, r (Fig. 4). (The problem is axisymmetric, so there is no dependence on the azimuthal coordinate.)

The fluid motion is characterized by three dependent variables: the pressure and the axial and radial velocities; the three governing equations are the continuity equation and the axial and radial momentum equations (Fig. 4). For a viscous fluid, the momentum equations, the Navier–Stokes equations, are highly nonlinear because of the presence of convective acceleration terms. In the arteries, the pulse-wave speed is much larger than typical fluid velocities, so these nonlinear terms are small and are dropped.

There are five governing equations, two for the wall motion and three for the fluid motion, i.e., linear partial differential equations in three independent variables, time and the axial and radial spatial coordinates. Specification of boundary conditions completes the formulation of the problem; some of these relate to the fluid only, others require that the motion

Fig. 4 Vessel geometry and coordinate system.

and state of stress in the fluid and wall match at their interface.

The solution is obtained in terms of a traveling wave solution, of the form

$$\begin{aligned} v_x &= \hat{v}_x(r) \exp[i\omega(t - x/c)] \\ v_r &= \hat{v}_r(r) \exp[i\omega(t - x/c)] \end{aligned} \quad (7)$$

where v_x and v_r are the corresponding velocity components (given by the real parts of the expressions on the right-hand side), and ω and c the frequency and wave speed of the pulse wave, respectively. The system is dissipative because the fluid is viscous, so c is complex, so also are $\hat{v}_x(r)$ and $\hat{v}_r(r)$, which turn out to be Bessel functions of complex arguments. The details of the analysis are quite elaborate; we highlight here only some features of the solution. The analysis, as we have described it, is primarily owing to Womersley.^[2]

The solution depends on the Womersley, or frequency, parameter

$$\alpha = a\sqrt{\frac{\omega}{\nu}} \quad (8)$$

where a is the vessel radius and ν is the kinematic viscosity. The Womersley parameter represents the ratio in the Navier–Stokes equations of the unsteady inertial term to the viscous term, and as such is the fundamental parameter in unsteady viscous flows. It corresponds to the Reynolds number, Re , which represents the corresponding ratio of inertial to viscous forces for a steady flow (the formal definition is $Re = UL/\nu$, where U and L are the characteristic velocity and length). Corresponding to “Reynolds” similarity, similitude modeling considerations require that if two such flows are to be “similar,” α should have the same value for both. Values of α decrease linearly with vessel radius as the flow progresses from larger to smaller arteries. For humans, α is of $O(15)$ in the aorta and $O(3)$ in the smaller femoral artery.

Among quantities of interest is the ratio c/c_0 , where c is the actual pulse-wave velocity and c_0 the Moens–Korteweg velocity for an inviscid fluid [Eq. (6)]. The variation of c/c_0 with the Womersley parameter α (Fig. 5) shows that for values $\alpha \geq 5$, appropriate for the larger arteries, the actual wave speed is very close to the inviscid wave speed (about 6 m/sec in the aorta and

Fig. 5 Variation of wave speed c/c_0 with α .

8–10 m/sec in the femoral), justifying the inviscid analysis for the pulse-wave propagation given earlier. Attenuation of the pulse wave in one wavelength is found to be quite high, suggesting an inefficiently designed system, until one realizes that corresponding to a fundamental pulse frequency f of 1 Hz, the wavelength is $\lambda = c/f = (6 \text{ m/sec})/(1 \text{ Hz}) = 6 \text{ m}$, about four times the distance from the heart to the furthest extremity, so the actual attenuation is small (wavelengths for higher values of α are shorter, but not until the fourth harmonic of the fundamental is an entire wavelength encompassed within the body). Fig. 6 shows the ratio of the maximum flow rate in the artery to the steady Poiseuille value for the same pressure gradient.

Fig. 6 Variation of flow rate ratio $Q_{\max}/Q_{\text{steady}}$ with α .

Calculated velocity profiles for a “rigid” tube at various time increments in the cycle for a sinusoidal pressure gradient for a range of values of α are shown in Fig. 7. These show that for a relatively low value of α , the flow is quasisteady, with roughly parabolic Poiseuille velocity profiles, while for larger values of α , the profiles are relatively flat, with the core flow lagging behind the rapidly responding wall (Stokes) layers—results consistent with the physical interpretation of the Womersley parameter given above.

General comments

Comparison of the results of the Womersley^[2] viscous pulsatile arterial flow analysis with canine experiments^[3] showed significant discrepancies. Womersley,^[2] accordingly, modified his original analysis,

Fig. 7 Velocity profiles in a straight “rigid” tube at various points in the cycle of a sinusoidal pressure gradient for different values of α .

incorporating additional factors such as tethering—the attachment of the artery to the surrounding tissue—and allowing for internal viscous damping in the arterial wall. These substantially improved the agreement between theory and experiment. Other factors play a role in accurately modeling arterial flows, such as arterial taper, but probably none more so than incorporating more realistic arterial wall models.^[4,5] There is also nonlinearity to consider: 1) convective acceleration terms in the Navier–Stokes momentum equations; 2) finite strain of the vessel wall; and 3) nonlinear wall viscoelasticity. To account for such nonlinearities requires extensive numerical calculations, unlike for linearized theories.

Notwithstanding all these additional complications, it is interesting that the results for pulsatile flow in an infinitely long, uniform, rigid circular tube (e.g., as in Fig. 7) reasonably well describe the flow in the arteries for different values of α .

Electrical analogues of the arterial system

The arterial system is a complex multigenerational system of branching, bifurcating, distensible vessels. Modeling the flow in an entire circulatory system or some significant part of it is formidably computationally demanding. Although much progress along these lines has been made,^[6,7] the traditional approach to modeling large segments of/or the entire circulatory system has been to use the analysis for a single arterial segment in conjunction with ideas from AC circuit theory. The integrated, linearized, continuity and Navier–Stokes momentum equations are equivalent to the equations for signal transmission through a uniform cable, the “telegraph” equations, with the correspondence between fluid mechanical and electrical quantities as shown in Table 2. Human arterial anatomical atlases allow the calculation of the arterial parameters on the left-hand side of the table, such as

resistance and compliance, for each arterial segment. This determines their electrical analogues, the entries on the right-hand side. After modeling each segment of the arterial tree using this correspondence, the equations for this complex AC circuit are solved, determining the voltage V and current I in each segment, from which the corresponding values of pressure p and flow Q are determined. From these results, one can calculate the various impedances useful for understanding the gross dynamics of flow in each vessel, and most importantly, the input impedance for each vessel, a measure of the actual effective resistance the blood encounters as it enters that segment, located as it is, in a complex arterial tree.^[8]

It is important to account for the many branchings and junctions, which occur as the blood flows from larger to smaller vessels. The simplest of such branching is a simple bifurcation of a parent vessel into two daughter vessels, as shown in Fig. 8, which can be treated with a one-dimensional flow model (in the spirit of Rayleigh for acoustic waves). The total cross-sectional area of the daughter vessels at arterial tree branchings is generally slightly larger than the parent vessel.

A traveling pressure wave encountering such a bifurcation is partly transmitted and partly reflected. Continuity of volumetric flow and pressure at the junction is sufficient to determine the magnitudes of the reflected and transmitted waves. The analysis shows that reflections cause a slight increase in the pressure wave as long as the increase in total area of daughter vessel is not too great. It is the reinforcing effect of all the reflected waves from each of the multitude of bifurcations in the arterial tree that explains why, in the face of dispersive, dissipative effects of the fluid and wall, the pressure-pulse shape becomes “peakier” as it moves further from the heart into the smaller arteries.

For comprehensive discussions of the circulation, see Caro et al.,^[9] Pedley,^[4] Fung,^[10] and Berger.^[5]

The Microcirculation

The term *microcirculation* is usually reserved for those vessels of the arterial and venous system that are smaller than roughly $180\ \mu\text{m}$, which includes the arterioles, capillaries, and venules. Arterioles are those vessels whose diameters lie between those of the smallest arteries and the true capillaries (diameter $10\ \mu\text{m}$ and smaller). They have proportionally the largest amount of smooth muscle, which makes them principal mediators of vascular control of the circulation. The capillaries have diameters $10\text{--}3\ \mu\text{m}$, and it is at their level that the important gaseous and mass transfer processes between the RBCs and the tissues occur. The venules are the vessels in the venous circulation corresponding to the arterioles. The microcirculatory bed is different in different organs and tissues, with different numbers of other microcirculatory vessels, such as metarterioles, preferential or thoroughfare channels, arteriovenous anastomoses, and precapillary sphincters, together with terminal arterioles, playing a role in the regulation of flow.^[11,12]

Pulsatility exists in the arterioles, although to a much lesser degree than in the arteries (Fig. 3), becoming more attenuated as one moves distally. Nonetheless the flow in these vessels is exceedingly hard to analyze because their diameters range from approximately 20 times greater than red cell diameters to slightly larger than red cell diameters, so it is generally not valid to treat blood as a rheologically simple, homogeneous, single-phase Newtonian fluid. Until recently, experimental observations and data were most lacking for this group of blood vessels. Non-Newtonian models have been successfully used in the microcirculation, particularly in the arterioles. This section therefore begins with a brief consideration of blood rheology, first with a discussion of rheological instruments to determine the behavior of blood, and then moves on to rheological laws to model this measured behavior.

Rheology of blood

Viscometry. There are two broad groups of instruments used to measure the viscosity of blood: 1) tube and 2) rotational instruments.

1. *Tube viscometers:* In these viscometers, also known as capillary-tube viscometers, the test fluid is made to flow from a reservoir down a narrow tube of precisely known caliber and either a) the total volume that passes within a fixed time, or b) the time necessary for a given volume to pass, under a given pressure gradient, is measured.^[13] Tubes with diameters less than $100\ \mu\text{m}$ are generally used. For a Newtonian fluid, from Poiseuille's law, the absolute (dynamic) viscosity μ is given by

$$\mu = \left(\frac{\pi d^4}{128LQ} \right) \Delta p \quad (9)$$

where d is tube diameter, L tube length, Q volume flow rate, and Δp the pressure head. The bore of the tube must be known with great precision, and corrections are needed for end effects. Viscosity values are commonly reported as relative viscosities—usually to that of water. The rate of shear is not constant in tube viscometers, so they should, strictly speaking, be used only for Newtonian fluids, although this injunction is often breached.^[13]

2. *Rotational viscometers:* These consist of two elements, separated by the liquid being tested, that rotate relative to one another about a common axis. Viscosity is determined by the relationship between the rotational velocity of the rotating element and the torque developed on the other. The two principal subgroups of instruments are: coaxial cylinder and cone-plate types (Fig. 9).

In the *coaxial cylinder* instrument, two coaxial circular cylinders, of radii R_1 and R_2 (where, $R_2 > R_1$), are made to rotate relative to one another (Fig. 9A), usually with the inner one fixed, the outer one rotating at a constant angular velocity, Ω . If the fluid in the annulus between the cylinders is Newtonian, the torque transmitted to the inner cylinder is given by

$$T = \left(\frac{4\pi R_1^2 R_2^2 h \Omega}{R_2^2 - R_1^2} \right) \mu, \quad (10)$$

determining the viscosity μ in terms of the geometry of the instrument and the measured torque T . In the *cone-plate* instrument, the space between a cone of a large apex angle and a flat surface normal to the cone axis is filled with the test liquid (Fig. 9B), and one of these

Fig. 9 Schematics of rotational viscometers: (A) coaxial cylinder; (B) cone plate.

elements is rotated, with the torque measured on the other. The rate of shear in the fluid is constant throughout the fluid.^[13]

Rotational viscometers, particularly for biomedical applications, are made with the gap between the rotating and stationary elements as narrow as possible. This has two advantages: 1) the volume of test fluid required is small; 2) the narrower the gap, the closer is the rate of shear to being constant across the gap, a necessary requirement when, using a range of rotational speeds, these instruments are used to determine the relationship between stress and rate of shear for a non-Newtonian fluid.

Stress–Shear-Rate Laws. We consider now some simple stress-rate-of-shear relations, including, wherever possible, the usual mechanical models used to represent them.

1. *Newtonian fluid:* The relationship between stress τ and shear rate D is linear,

$$\tau = \mu D \quad (11)$$

The mechanical model is a simple dashpot.

2. *Power-law fluid:* This is in the form of the empirical relationship

$$\tau = \mu D^s, \quad s = \text{const.} \quad (s = 1, \text{Newtonian}) \quad (12)$$

There is no simple mechanical model.

3. *Bingham plastic:* The mechanical model is a dashpot in parallel with a friction coupling. Friction between the sliding surfaces in the coupling makes extension impossible unless the applied force F is greater than some frictional force. If the rate of extension beyond this value is proportional to the applied stress, the material is called an ideal Bingham plastic; otherwise it is a generalized Bingham plastic. In the former case,

$$\tau - \tau_y = \mu D \quad \text{or} \quad \tau = \tau_y + \mu D \quad (13)$$

where τ_y is the yield stress.

4. *Casson plastic:* There is no mechanical model. This is an empirical extension of the law for a Bingham plastic, of the form

$$\sqrt{\tau} - \sqrt{\tau_y} = \mu \sqrt{D} \quad (14)$$

Fig. 10 shows these various laws for τ as a function of D .

Blood Viscosity; Stress–Shear-Rate Laws. Blood is a complex heterogeneous suspension. The suspended material includes white cells and platelets, but their

Fig. 10 Stress vs. shear rate for different rheological models.

Fig. 11 Viscosity of whole blood as a function of shear rate for different hematocrits (temperature 37°C).

numbers are small. The principal contributors to the rheological behavior of blood are the erythrocytes, the RBCs, their numbers measured in terms of the hematocrit, H , the volume percentage of red cells.

Using one of the rotating viscometers described above, one obtains the results shown in Fig. 11 for the viscosity of whole blood as a function of shear rate for different hematocrits. The viscosity increases significantly as the hematocrit increases, with the curves all asymptoting to constant values of viscosity for large values of D . Blood with a normal male hematocrit of about 45% has a constant viscosity of about 3–4 mPa sec (3–4 cP) for values $D \geq 100 \text{ sec}^{-1}$. Mean shear rates in the arteries being generally much higher than 100 sec^{-1} , to a very good approximation, blood behaves in the arteries as a Newtonian fluid with a constant viscosity (This is generally only true for normal vessels; for diseased or injured arteries, or for certain geometries, there may be regions of lower shear rates owing to flow separation and recirculation so that non-Newtonian models are more appropriate. Various models have been used, often power-law models, with exponents reflecting the shear-thinning (*pseudo-plastic*) nature of blood, and including, or not, a yield stress. Popular ones are the Herschel-Bulkley, Walburn-Schneck, and Carreau models.^[14]).

Although nominal shear rates in the arterioles may be much larger than 100 sec^{-1} , the rheological behavior of blood in the arterioles is not well modeled as Newtonian. Among the models discussed above, the traditional ones used are the power-law [Eq. (12)] and the Casson equation [Eq. (14)]. For the power-law, s lying in the range $0.68 \leq s \leq 0.80$ was found to provide a good approximation for shear rates lying in the range $5\text{--}200 \text{ sec}^{-1}$ ^[13] (values of $s < 1$ reflect the shear-thinning property of blood as the shear rate increases).

The rheological formula equations [Eqs. (13) and (14)] include a yield stress, reflecting the formation at very low velocities of rouleaux, broad face-to-face

aggregations of two, and generally many more, RBCs. Their formation has been ascribed to various mechanisms. In any event, the yield stress τ_y is the (small) value of stress [$\tau_y < 0.01 \text{ Pa}$ (0.1 dyn/cm^2)] necessary to break up these aggregates before flow commences.

Rheological and hematocrit anomalies of blood^[15–18]

Effect of Tube Size^[16–18].

1. *Fåhræus–Lindqvist effect*: For tube-viscometer capillary diameters greater than 1–2 mm, the relative viscosity of whole blood remains the same. For narrower tubes, the apparent viscosity decreases with diameter, continuing to decrease until diameters reach values as low as $8 \mu\text{m}$, after which it increases sharply as the very much different capillary flow regime is entered. This Fåhræus–Lindqvist effect is one of the most significant features of microcirculatory flow. Although a number of factors contribute to the effect, the primary physical reason is the well-known tendency of RBCs to migrate away from the wall, leaving a cell-depleted, lower viscosity region near the wall, thereby reducing the overall viscosity of the blood in the tube.
2. *Fåhræus effect*: This other important characteristic of the microcirculation is related to the Fåhræus–Lindqvist effect, being a further consequence of the migration of RBCs from the tube wall. The resulting increased concentration of cells in the higher velocity part of the flow reduces on average the transit time of RBCs through the tube. As a result, the *tube hematocrit*, H_T , the hematocrit within the tube (measured, e.g., by stopping the flow and emptying the contents) is less than the hematocrit of the fluid exiting the tube, the *discharge hematocrit*, H_D .

Another important influence on hematocrit variation in the microcirculation is associated with the presence of a cell-depleted wall layer. When blood flows through a diverging microvascular bifurcation, a disproportionate fraction of RBCs flow into the branch receiving the higher flow rate, resulting in a higher hematocrit in that branch, the lower-flow branch primarily “skimming” plasma from the peripheral layer of the flow.

Cell Migration. Cell migration has very important effects on the flow and rheological behavior of blood in the vessels of the microcirculation. As the velocity increases, there is an increasing tendency of the red cells to move toward the axis of the tube, increasing the hematocrit there and lowering it near the wall. To aid

understanding of the mechanisms involved, migratory paths of rigid and deformable particles in slow viscous flow at very low Reynolds numbers, for which inertial effects are negligible, and in viscous flows at larger Reynolds numbers, for which inertial effects are not negligible, have been determined.^[15] In most cases, the particles drift to the axis or to some annular location between the axis and tube wall. Migration of neutrally buoyant rigid spheres to an annulus owing to inertial effects is called the “Segré–Silberberg effect.” These observations, based on model experiments and calculations, are only suggestive of the behavior of real RBCs, because the importance of cell flexibility and flow inertia will depend on flow state and vessel geometry. In addition to these migratory patterns, individual red cells also rotate and deform in sheared flows.

Flow in the microcirculation

Arterioles. The arteriolar network is typically organized in two general patterns: an arcade arrangement in vessels of diameter of the order of $25\ \mu\text{m}$ and larger, and a sequential branching pattern in more distal vessels. These are the vessels that control the distribution of blood to organs and tissues of the body by changing their diameters by vasodilation or vasoconstriction. A variety of methods have been used to measure velocity profiles and pressures in the arterioles and venules of various tissues. Some of these findings were discussed above. In terms of modeling flow in the arterioles, although much progress has been made, it remains presently impossible, computationally or otherwise, to analyze anything as complex as the motion of a concentrated suspension of real, deformable, red cells in narrow tubes whose diameters range from a few to 20 times the diameter of these cells, spanning the domain of particulate to continuum flow. In addition, there are structural and geometrical differences between arterioles in different tissues. In the absence of a theory of flow as simple and universal as for arteries, results for the arterioles are necessarily, in part, empirical, phenomenological, and analytical. Generally for flows in individual microvessels of the microcirculation, the Reynolds, Re , and Womersley, α , numbers are small, so inertia does not play a significant role, and the momentum balance is between pressure and viscous forces (*Stokes flow*). Complications, however, are that the viscosity, μ , cannot generally be taken as a simple constant, as for a Newtonian fluid, and that the arteriole is distensible, the diameter, d , generally depending on the pressure, $d = d(p)$, differently for different tissues. Non-Newtonian viscosity models, in the context of single and multiple-phase analyses, have been employed to deal with the former of these

complications, in formulations that are different depending on the size of the arteriole. Examples of multiple-phase analyses are two-phase continuum models, consisting of a core Newtonian viscous fluid, representing a concentrated RBC suspension, surrounded by an annulus of a less viscous Newtonian fluid, representing the cell-depleted layer, which give results in reasonable quantitative agreement with experimental data on blood apparent viscosity in tubes with diameters of $O(30\ \mu\text{m})$ and larger (for the details of these, see Refs. [16–18]).

Note, unlike the arterial system where the flow in individual arteries is often sought in its own right, individual arterioles are of interest primarily to the extent that they are part of a microvascular network, and are involved in the regulation of flow in such a network.

Capillaries. In these vessels, ranging in size from 10 down to $3\ \mu\text{m}$, the motion of individual RBCs must be taken into account. The typical normal red cell is a biconcave disk, $8\ \mu\text{m}$ in diameter and $2\ \mu\text{m}$ in thickness, consisting of a thin, flexible membrane filled with a viscous Newtonian-like fluid, hemoglobin. The flow may or may not be pulsatile. The extreme flexibility of red cells is most evident in these vessels, e.g., a red cell is readily able to move through a $3\ \mu\text{m}$ -diameter micropipette by folding about an axis through its center into a “crêpe suzette” shape. In wider, $5\text{--}7\ \mu\text{m}$, tubes, it may take on a “parachute” shape. In the largest capillaries, the cells may move down relatively undeformed, their broad face perpendicular to the flow direction. They move down in single file, one following the other.

The motion of undeformed individual red cells in the larger capillaries was early to receive attention. One such generic configuration is shown in Fig. 12. The usual analysis idealizes the cells as rigid circular disks moving steadily with constant velocity in a rigid circular tube surrounded on all sides by plasma. Because of the very small lengths and low cell velocities, the Reynolds numbers for capillary flow are exceedingly small (of the order of 10^{-3}), so these flows fall into the category of Stokes or “creeping flows.” The governing differential equations for such flows are linear and, for

Fig. 12 Rigid disks in a tube as a model of red cell flow in a capillary.

simple configurations such as that shown in Fig. 12, may be solved in closed form.

In somewhat narrower capillaries, in which the cells must deform, e.g., into the parachute shape, to fit in the vessel, the flow in the narrow gap between the cell and the capillary wall can be analyzed as a *lubrication flow*, with due account taken of cell deformability. This is a special, difficult, creeping flow, which has been resolved by the application of sophisticated perturbation analysis.

Both of the above are axisymmetric flows. There have been advances in recent years in treating non-axisymmetric configurations, there being evidence that red cells commonly enter capillaries edge on, resulting in significant cell deformation and a “tank treading” of the cell membranes.^[10,17]

Resistance to flow depends strongly on the capillary diameter, and in the larger capillaries, it is very much greater than it would for Poiseuille flow in the same-sized tube of a fluid with the overall whole blood viscosity.

As to the nature of the flow in the plasma region between red cells, in a frame moving with the velocity of the cells, the streamlines of the plasma region follow closed circulatory paths, a pattern called “bolus flow.” Speculation, on qualitative grounds, that this recirculatory flow pattern might beneficially facilitate mass transfer of gases between the cells and the surrounding tissues has not been borne out.

The effect of the thin capillary endothelial glycocalyx layer on the motion of RBCs has been of great recent interest^[17] [the glycocalyx and its associated macromolecules are referred to, collectively, as the endothelial surface layer (ESL)].

Venules. These are postcapillary venous side vessels corresponding to the arterioles on the arterial side. They are about the same length as corresponding arterioles, but with larger lumens. The shear stress values in them are low, increasing RBC aggregation, which tends to produce a more blunted velocity profile, increasing the apparent viscosity. With aggregation, however, there is greater axial cell migration, resulting in a thicker cell-depleted layer at the wall, providing a compensatory reduction in viscosity. The blunting of the velocity profiles, which are sometimes asymmetric, may be associated with as much as a doubling of the resistance, which is also very much affected by the ESL.

Flow in venules with diameters of $O(25\ \mu\text{m})$ and larger have been modeled with two-phase continuum models, similar to those used for arteriolar flows, or with multiphase, non-Newtonian formulations. For narrower venules, there is no available theory. White blood cell (WBC)–endothelial interactions occur mainly on the venous side of the microcirculation. A

large number of experimental studies have been done, including direct observations of WBCs adhering to, rolling on, and transmigrating across venular endothelium, and in vitro and in vivo investigations into the molecular mechanisms of these interactions. There has also been a good deal of theoretical modeling and computational studies. See Ref. [18] for a discussion of this work, and, more generally, the flow in venules and the microcirculation as a whole; this review also discusses how the results for individual microvessels are integrated to model blood flow in microvascular networks.

The Veins

The veins draining a vascular bed tend to have larger lumens than the corresponding arteries supplying it. They are thin walled, with a much smaller ratio, 0.1, of wall thickness to diameter (Fig. 2), making them much more distensible than arteries, and there are greater numbers of them. These features give the venous system a much greater volumetric capacity than the arterial system, able to hold as much as 70% of the total blood volume. Their walls also contain much less smooth muscle and elastic fibers than arteries (Fig. 2), and are easily stretched. They are often elliptical, rather than circular, in cross section. Venous pressures are generally low, 12 mmHg or so, about 10% of the peak arterial systolic pressure (Fig. 3). The venous system is free of any heart-induced pulsations, the slight unsteadiness in the largest veins, near the heart, is primarily caused by respiratory pressure changes (and possibly cross talk with nearby parallel arteries). As there are no significant pressures and pressure gradients on the venous side of the circulation, blood is forced back to the heart by the squeezing action on the thin-walled veins of surrounding tissues (e.g., skeletal muscles), with the assistance of valves in the veins to prevent backflow. This motion is much less regular than arterial flows, and plays a much lesser role in the dynamics of the circulation; it has thus received much less attention.

Another very important difference between arterial and venous flows is that because the latter is a low-pressure system, the transmural pressure in the veins is sometimes negative, the result of hydraulic pressure gradients, muscular action, intrathoracic pressure changes, etc. When the pressure outside a vein exceeds that inside, there is a tendency for the vessel to collapse. This phenomenon arises in other areas of physiological flow in flexible vessels: in some circumstances for systemic arterial flow, in the pulmonary circulation, in the respiratory airways, in peristaltic transport, etc. It is part of the more general physiological problem of strong fluid–structure interaction,

and leads to important and complex physics, such as multiple geometric modes of vessel collapse, flow-induced instabilities, etc. A rich literature has emerged on flow in collapsible tubes (see Ref. [19] for an early account and Refs.^[20,21] for recent accounts).

THE PULMONARY CIRCULATION

This circulation comprises the passage of all the deoxygenated blood exiting the right ventricle through the pulmonary arteries to the alveolar capillaries and its return, oxygenated, via the pulmonary veins to the left atrium. A secondary, much smaller, circulation, the bronchial circulation, fed by the thoracic aorta, nourishes the lung itself.

The pulmonary circulation, although similar to the systemic circulation in the types of vessels, arteries, capillaries, and veins, shows important differences:^[10]

1. The pulmonary circulation is a low-pressure, low-resistance system, with a time-average pressure in the arteries of about 15 mmHg being one-sixth of that in the systemic arteries.
2. Pulmonary arteries are much thinner walled than systemic arteries, consistent with the lower pressures; they have the same Young's modulus as the latter, but are more distensible because they are thinner.
3. The pulmonary vascular bed is not regionally specialized.
4. Vasomotor control is relatively unimportant under normal conditions; unlike the systemic arteries, the pulmonary vessels do not undergo large active changes in their dimensions; the arteries and arterioles have primarily elastic tissue, but little smooth muscle.

To a great extent, the mechanics of the pulmonary circulation are affected by the mechanics of the lung and the thoracic pressure changes over the respiratory cycle. Arterial branching is very similar to that in the systemic circulation. The shape of the pressure wave in the main pulmonary arteries is like that in the aorta, but there is no significant change in shape along the pulmonary arterial system because it is so short—the total length from the beginning of the pulmonary trunk to the capillaries being only 20 cm—that the pulse occurs simultaneously along the entire length. Velocity profiles in the arteries are relatively flat because $Re \gg 1$ and $\alpha = a\sqrt{\omega/\nu} \gg 1$, and the vessels are so short that new boundary layers begin on each flow divider and never fill the vessels.

The pulmonary microcirculation has a number of features that contrast sharply with the systemic microcirculation:^[10]

1. There is less vasomotor activity in precapillary vessels (or elsewhere) than in the systemic circulation, with resistance to flow occurring mainly in the capillaries (there is some local flow regulation, and hence oxygen regulation, in the lung by vasodilation and constriction of the pulmonary arterioles).
2. The capillaries have lengths comparable to their diameters, are flattened, and are arranged like two-dimensional channels passing between pairs of alveoli, the walls of which are flexible and held apart by posts (typical thickness $\approx 4 \mu\text{m}$), so the blood flows as a sheet of fluid between almost parallel alveolar membranes held apart by frequently occurring posts of connective tissue.
3. Pulsatility of the flow is more pronounced.

As in the systemic microcirculation, $Re \ll 1$, velocities are typically about 0.005 m/sec, and $\alpha \ll 1$. Fluid inertia is therefore negligible, the force balance in the capillary sheet being between pressure and viscous forces, and the flow is quasisteady, i.e., the flow rate is in phase with the pressure gradient at all parts of the sheet at all times. In the case of a Newtonian fluid flowing in a rigid sheet, it would then follow that $Q \propto dp/dx$, i.e., the flow rate is directly proportional to the pressure gradient, but, because the sheet here is elastic, the sheet thickness, h , depends on dp/dx . This implies, as h affects the fluid resistance, that resistance depends on dp/dx . Based on these ideas and assumptions, a simple theory for flow in such a sheet can be developed.^[10] Because the alveolar pressure, p_{alv} , the pressure outside the sheet, plays a major role in determining the width of the sheet, the nature of the flow depends on the relative magnitudes of three pressures: the arterial, venous, and alveolar pressures. An increase in p_{alv} , leading to a decrease in sheet width, particularly to values as small as 2–3 μm , has a major effect on the rate of flow, for, even in a Poiseuille flow of a Newtonian fluid in such a channel, the resistance to flow increases, strongly, as h^4 , where h is the channel width, and the increase should be so much greater for whole blood with 8 μm red cells that must be deformed to flow through the sheet.

Dependence of the flow in the pulmonary microcirculation on the relative magnitudes of the arterial, p_a , venous, p_v , and alveolar pressure, p_{alv} , combined with the hydrostatic variation of pressure, leads to nonuniform perfusion over the height of the lung,^[10] as sketched in Fig. 13. The height of the lung is about 30 cm, so the total hydrostatic head between the top and bottom of the lung is 30 cm H₂O or 22.5 mmHg. The pulmonary arteries enter the lung about halfway up, and because p_a is on average about 15 mmHg, arterial pressures are about 26 mmHg at the bottom and 4 mmHg at the top of the lung. As there is a 7–8 mmHg

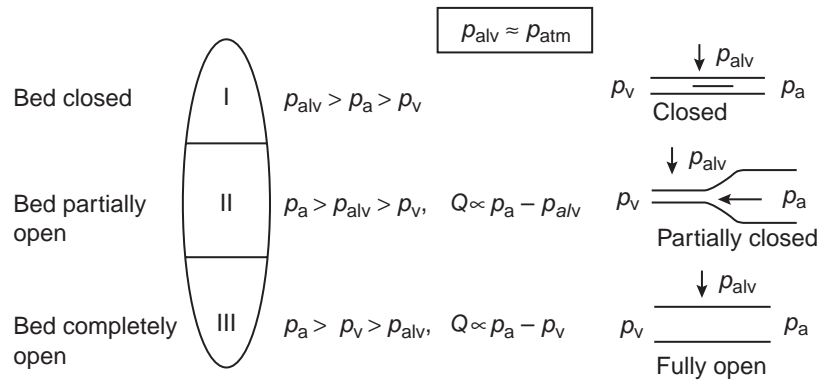

Fig. 13 Schematic of human lung showing the relationship of p_a , p_v , and p_{alv} at different heights.

drop in pressure across the pulmonary circulation, the mean pressure is normally subatmospheric in the microcirculation at the top of the lung! If the pressure in the tissue surrounding a blood vessel exceeds that in the vessel, i.e., the transmural pressure is negative, there will be a net force acting to close the vessel. Because the pressure external to the pulmonary microvessels, p_{alv} , is approximately atmospheric, the relative magnitudes of p_a , p_v , and p_{alv} at different levels in the lung will be as shown in Fig. 13, with vessels fully open near the bottom of the lung, partially open in the middle, and fully closed at the top. The flow rate, Q , in the lowest, fully open capillaries (zone III) is proportional to $p_a - p_v$, while that in zone II is proportional to $p_a - p_{alv}$ (the latter zone thus behaves as a so-called “Starling resistor,” or waterfall, because like a waterfall, the flow rate does not depend on the total height of fall, in this case the overall pressure drop $p_a - p_v$). The levels at which these zones blend into one another depend on the alveolar pressure, and therefore vary over the breathing cycle and with the arterial pressure, which increases, e.g., during exercise.^[10,21]

The above considerations suggest grossly unequal perfusion and ventilation in the lung, because air enters the lung near the top and does not normally make it to the lower recesses of the lung, whereas, from the discussion above, blood flow is greatest at the bottom and least at the top. Partly because of the highly deformable lung structure, however, there is a much closer balance of air and blood over the length of the lung than would be deduced from these considerations.

FLUID MECHANICS AND VASCULAR DISEASE

This article has thus far exclusively considered the normal vasculature. Clearly, knowledge of the normal behavior of any system or part of it is preliminary to understanding its malfunctioning. The few comments here, for lack of space, will address primarily the principal disease of the vasculature, particularly the arteries. But first, we briefly note that the patency of

arteries may be compromised for congenital reasons, by injury, or by disease. Patency may be restored or maintained, or nonpatent vessels bypassed, by the use of vascular grafts, stents, or stent grafts. They are also used for treating aneurysms. These as well as other interventions are widely used clinically. Fluid mechanics is used to determine the efficacy of various designs of these prostheses and where to site them.

The biology of, and flow in, the microcirculation was thought to be most in need of research progress, whereas the study of the arteries was regarded as a mature subject. It is therefore ironic that, increasingly, arterial flow has been a central focus of research in biofluid-dynamics, motivated by the belief that hemodynamics plays an important, perhaps critical, role in the pathogenesis and pathophysiology of atherosclerosis, the leading cause of death, via heart attack or stroke, in the developed world.^[22] Atherosclerosis is a focal disease and research has shown that atheromatous lesions are preferentially located where there are sudden changes in arterial flow geometry in unsteady flow. Among the important ways fluid mechanics affects the arteries is its effect on endothelial cell morphology and cytoskeletal organization, as well as in its helping to provide pathways and facilitate transport of low-density lipoproteins through the arterial walls, the key first step in atherogenesis. Seminal studies in recent years have elucidated many of the pathways by which mechanical forces, primarily wall shear stresses, are transduced to effect changes in the arterial wall at various levels: the cellular, subcellular, genetic, and molecular.^[22–24]

Whereas low values, or rapidly changing values, of wall shear stress are associated with atherogenesis, less is known about the role or effect of shear stresses, or fluid mechanics in general, on plaque growth and remodeling. Disruption of “older” plaque has been identified as a key pathophysiological event in coronary thrombosis and carotid thromboembolism. Factors in plaque fracture and rupture are believed to be in large part hemodynamic in origin, normal stresses, shear stresses, and long term effects such as fatigue,

perhaps all playing a role.^[24] Very much more remains to be done in this area.

CONCLUSIONS

Flows in the circulation, principally the systemic and pulmonary, are discussed. Since these flows are typically laminar, and the fluid, blood, is incompressible, they are often reasonably amenable to analytical or computational analysis, at least for the larger vessels. Complicating the flows even in these vessels are unsteadiness (pulsatility), complex geometries (bends, junctions, bifurcations, etc.) and branching networks, non-Newtonian blood rheology, vessel deformability (leading to fluid-structure interaction), etc. In the smaller vessels, those in the microcirculation, the finite size of the suspended material, especially the red blood cells, must be taken into account, making analysis of the flows in them much more difficult. The relevance of such hemodynamic analyses and studies to vascular disease and its treatment is briefly considered.

Vascular Grafts

Deon Bezuidenhout

Peter Zilla

Cardiovascular Research Unit, University of Cape Town Medical School and Grootte Schuur Hospital, Cape Town, Western Cape, South Africa

INTRODUCTION

The integrity and function of the estimated 100,000 miles of blood vessels in the human body may be compromised by various pathological conditions and traumatic injuries. Although many cases are treated by alternative methods, severe pathologies or injuries may require the surgical replacement or bypassing of the injured vessels to restore adequate blood flow to the distal vasculature. This article will focus on the vascular grafts (substitute vessels) used in replacement and bypass surgery. It will discuss the need for vascular grafts, the different types of experimental and commercially available grafts, the healing responses elicited by grafts, the need for alternative grafts, and efforts to develop grafts able to provide good long-term outcomes in challenging, small-diameter applications.

THE NEED FOR VASCULAR GRAFTS

The total demand for vascular grafts used to augment the insufficient functioning of blood vessels has been estimated to be from over a million cases worldwide^[1] to 1.4 million in the United States alone.^[2] Figure 1 shows a breakdown of the cardiovascular procedures performed between 1990 and 1999 in the United States that required vascular grafts.^[3] The procedures are grouped into three categories based on graft diameter and listed in descending number of procedures performed:

- Coronary artery bypass grafts (CABGs, 1–4 mm diameter), used in aortocoronary bypass procedures. The National Center for Health Statistics (NCHS) reported an increase from 392,000 to 571,000 of these procedures performed between 1990 and 1999, despite the exponential increase observed in alternative treatments (coronary obstruction removal and stenting).
- Small-diameter grafts (4–6 mm), used for peripheral grafts to relieve lower-extremity ischemia and for vascular access grafts (VAGs) to treat end-stage renal disease (ESRD). The combined need for these two graft types is evident from the roughly 180,000 procedures performed each year.

- Large-diameter grafts (>7 mm), for use in the thoracic and abdominal cavities (mostly for the replacement of aortic sections), were required for a total of 40,000 procedures.

TYPES OF GRAFTS

Vascular grafts may be classified into two broad groups: bioprosthetic and synthetic. Bioprosthetic grafts are of biological origin and composed of autologous, homologous, or heterologous tissue. These tissue grafts may, in some cases, be stabilized by cross-linking with various fixatives and/or by reinforcement with synthetic materials. The second group comprises vascular prostheses fabricated entirely (or mostly) from synthetic materials.

Bioprosthetic Grafts

Autologous grafts (auto-grafts)

Fresh, viable autologous veins (especially saphenous veins) have been demonstrated to be the preferred grafts for use in relieving lower-extremity ischemia (e.g., femoropopliteal bypass grafting).^[4] Depending on its exact nature and position relative to the position of the bypass, the graft vein may either be excised and reimplanted in a reverse configuration (to prevent obstruction of flow by valves) or left in situ with only the proximal and distal ends repositioned and anastomosed to the occluded artery. The in-situ use of veins for arterial bypassing requires the removal of venous valves to allow unrestricted blood flow. Autologous veins (saphenous and jugular veins, and veins of the upper extremities) may further be used for coronary, carotid, renal, and other sites. The use of vein grafts may, however, be compromised by deterioration when exposed to arterial hemodynamic forces.^[5] In addition, the number of veins that can be transferred without causing venous disturbances is limited, and veins may be unsuitable due to preexisting conditions.

Autologous arteries may be considered the ideal arterial graft. In coronary artery bypass surgery, the

Fig. 1 Graphic representation of the number of clinical procedures involving vascular grafts performed from 1990 to 1999 in the United States. (From Ref. [3].)

pedicled left internal mammary artery (LIMA) has long been the superior conduit, but its application is generally limited to the left anterior descending (LAD) coronary artery. Depending on the anatomical position of the graft, the age of the patient, and other factors, further stenoses may be bypassed with either the pedicled or free right internal mammary artery (RIMA), radial arteries, and gastroepiploic arteries. Other specific examples of the use of autologous arteries include the application of resected autologous iliac arteries (which are subsequently replaced with a suitable synthetic prosthesis) to a more critical location, and the use of radial arteries in coronary positions of young patients. Apart from these specific severe cases, however, dispensable autologous arteries are even less readily available than dispensable veins.

Homologous grafts (allo-grafts)

Prior to the development of successful synthetic prostheses, homologous arterial tissue was the standard clinical large-bore material. This tissue type has been used in various forms: fresh, frozen, refrigerated in physiological solution, freeze-dried, glycerin preserved, alcohol preserved, dried, and preserved in formalin.^[4] Although arterial homografts are rarely used today, they might still find application as aortic arch replacements.

Glutaraldehyde-fixed homologous umbilical veins have found some application as bypass grafts for small-diameter arteries in the lower extremities. These grafts are typically externally supported with a light Dacron mesh to enhance structural integrity, and may offer a reasonable alternative to autologous veins when the latter are not available.^[6]

The shortcomings of arterial homografts, as evident from the changes that occur during the healing response, include slow wall lysis, compaction and loss of elastic tissue, ulceration, mural thrombosis, and calcification. Such changes resemble atherosclerosis^[7] and result in a poor longterm outcome. Although few nonarterial homograft tissues have been used in arterial positions, experiments evaluating homologous veins for aortic replacement show late fibrotic stenosis. Glutaraldehyde-fixed homologous umbilical veins have found some use in lower-extremity applications, but the general consensus is that they are not as reliable as autologous vein grafts.

Heterologous grafts (xeno-grafts)

Tissue fixation procedures similar to those used for the cross-linking of heterologous bioprosthetic heart valves have been used with some success to preserve heterologous arterial tissue. Typically, bovine carotid arteries were fixed in dialdehydes to reduce the antigenicity, reinforced with Dacron mesh to improve mechanical strength, and used as vascular access grafts.^[4] The use of heterologous vein grafts has not been reported to any great extent.

Heterologous arterial tissues demonstrate a decidedly accelerated tissue response, due to antigenicity, and are heavily subject to aneurysm formation and rupture. The antigenicity may be reduced by certain chemical modifications, such as cross-linking, but these grafts remain prone to aneurysmal dilation. This shortcoming has been corrected by Dacron reinforcement, and although studies have shown superior long-term fate compared with freeze-dried homografts and some textile

prostheses, the use of fixed heterologous arterial tissue is limited mostly to arteriovenous shunts.^[8]

Synthetic Grafts

The synthetic vascular graft market is dominated by two graft types: expanded polytetrafluoroethylene (ePTFE) grafts and textile polyethylene terephthalate (PET) grafts. Considerable effort has, however, been put into the development of grafts from alternative polymeric materials. Of these alternative materials, by far the most extensively reported are polyurethanes^[9] and bioresorbable polymers such as poly(glycolic acid) and poly(lactic acid).^[10] The latter type of grafts (bioresorbable) will be discussed with the alternative tissue engineering approaches.

Biostable grafts

The biostable approach to synthetic vascular grafts is based on the permanent incorporation of synthetic materials into the body. Initial investigations into the use of polymeric materials for vascular grafts concentrated on fibrillar materials that showed a high degree of in-vivo stability. These studies led to the acceptance of PET and PTFE (initially fibrillar, now expanded) as materials of sufficient stability to be used in commercially available vascular grafts. It has since been recognized that no material is completely inert in the hostile environment found in the human body, and even materials that are recognized as being extremely stable (gold, platinum, titanium) are corroded in vivo. Nonetheless, the demands placed on the polymeric materials used in durable vascular grafts require them to be chemically stable to a degree that ensures structural integrity and that prevents the generation of toxic or inflammatory breakdown products.

PET grafts

Polyethylene terephthalate (PET) is a semicrystalline polymer that is readily melt-spun and drawn into highly

crystalline filaments of high modulus and tensile strength. These filaments (10–20 μm in diameter) are typically bundled into multifilament yarns (24–108 filaments per yarn) and then woven or knitted to produce tubular or bifurcated grafts. The simplest configuration is a 1:1 or taffeta weave, in which the warp and weft of yarns are interwoven at right angles (in a one-to-one fashion), as seen in Fig. 2b. The warp yarns are aligned in the longitudinal direction of the graft (horizontal direction in Fig. 2), while the weft yarns run orthogonal to that direction. The taffeta weave results in the strongest construction, the highest fabric density, and the best dimensional stability, and is less prone to kinking than knits. Drawbacks of woven grafts include poor compliance, limited elongation (in the uncrimped form), and a tendency to fray. Woven prostheses are typically used in large-diameter emergency situations such as aortic aneurysms.

Knitted grafts contain yarns that are looped around each other as opposed to the interlacing found in woven grafts. If the yarns lie predominantly in the circumferential direction, the structure is termed a “weft knit.” The “jersey knit” is typical of this type of construction. To eliminate the dilation and unraveling found in weft-knit materials, warp knits, where the yarns lie predominantly in the longitudinal graft direction, were introduced (Fig. 2a). Many warp-knit configurations are possible; the most common ones are the two-bar warp locknit and the tricot warp knit. Warp knits have good dimensional stability and handling/suturing characteristics, and are less prone to fraying than their weft-knit counterparts. The surfaces of some knitted grafts are often roughened by the addition of textured yarns or by napping with wire brushes. This results in velour-type grafts that are reported to improve interlocking of tissue and thus improve healing. After knitting, chemical or heat treatment is used for compaction of the structure in order to decrease the water permeability of grafts to acceptable levels.^[11] PET grafts are generally sterilized by ethylene oxide gas or ionizing radiation, as dry or moist heat may further change the properties.

Fig. 2 Scanning electron micrographs of (a) the luminal surface of a Gelseal triaxial warp-knit Dacron vascular graft, 26 mm internal diameter, Sulzermedica (gelatin sealant removed by protease degradation for visualization of knitted structure) ($35\times$, bar = 500 μm); (b, c) the abluminal surface of a DeBakey 6010-S woven Dacron graft, 6 mm internal diameter, USCI, Division of CR Bard, Inc., with (b) showing the taffeta weave ($100\times$, bar = 100 μm) and (c) showing the crimped structure of the graft ($15\times$, bar = 1 mm).

Both woven and knitted grafts are often crimped to improve radial strength (to reduce kinking and collapse) and increase elongation potential (see Fig. 2c). To eliminate the need for surgeons to pre-clot large-diameter PET grafts, they are often sealed with collagen, albumin, or gelatin to completely eliminate blood permeability.^[12]

PET (Dacron) is the material of choice for large-diameter, high-flow vascular graft applications such as aortic replacements. The manufacturing techniques used in the production of PET grafts also lend themselves to the inclusion of side branches and bifurcations, and PET grafts are used as aortofemoral replacements. A secondary patency rate of 93% at 10 years can be achieved with large-diameter grafts of this type.^[13]

PTFE grafts

Polytetrafluoroethylene is a highly crystalline, inert material with high molecular mass, low coefficient of friction, and low surface tension. Although PTFE is not as readily processed by conventional melt and solution techniques as other thermoplastic materials, processing into fibers and subsequently into textile prostheses (similar to those obtained from PET fibers) is possible. Textile PTFE grafts were, however, withdrawn by many manufacturers due to unraveling and false aneurysm formation.

Expanded PTFE (ePTFE) grafts are produced by ram-extrusion of PTFE powder (with a lubricant), removal of the lubricant, longitudinal stretching at very high strain rates, and subsequent sintering. The resultant structure, consisting of solid nodes connected by interconnecting fibrils, may be seen in Fig. 3a. Some manufacturers use a less dense outer PTFE wrap (Fig. 3b) and either circular (Fig. 3c) or helical reinforcement (not shown). Sterilization of ePTFE grafts should be effected by ETO gas, steam, or dry heat, as ionizing radiation may cause polymer degradation.

Expanded PTFE is favored in medium-bore (6–12 mm) applications when autologous veins are unavailable or unsuitable, even though there is no

difference in the patency between ePTFE and PET of similar size.^[5] Patency rates of 40–50% after four years of implantation in femoro-popliteal reconstructions are lower than the rates achieved by using reversed saphenous veins (70–80%).^[14] ePTFE grafts fail to perform satisfactorily, however, in smaller-diameter applications (<6 mm) due to occlusion caused by thrombosis and intimal hyperplasia.

Polyurethane grafts

A wide range of segmented, thermoplastic polyurethanes (TPUs) have been developed specifically for medical applications. Their biocompatibility and elastomeric properties, combined with the fact that they may be processed by conventional melt and solution techniques, have been exploited over the past three decades in the search for a successful small-diameter vascular graft.

Polyurethane grafts may be classified into fibrillar (Fig. 4a) or foam-type (Fig. 4b and c) structures. Fibrillar grafts have been produced by conventional weaving and knitting, solution or melt spinning, electrostatic spinning, and other nonwoven techniques, whereas replamineform, thermal inversion, blowing/reticulation, gas expansion, and phase inversion have been employed in the production of foamed structures.^[9,15] Extractable porogens may be used in conjunction with phase separation techniques to introduce larger pores, with premixing of irregularly shaped porogens generally resulting in irregularly shaped pores, limited pore interconnectivity, and residual porogens remaining in the structure.^[16] A variation of the phase inversion/porogen extract method has, however, been developed to produce scaffolds with well-defined, dodecahedral pores with high interconnectivity and no residual porogen retainment (see Fig. 4c).^[15]

Although a number of polyurethane prostheses have been developed to the extent that they have been evaluated in clinical trials as A–V shunts and femoropopliteal grafts,^[17,18] they have not gained widespread acceptance or clinical use.

GRAFT PROPERTIES

The success of a synthetic vascular graft depends on many factors pertaining to its preimplant properties, its properties during implantation, and its ability to perform its vital function after implantation. The Association for the Advancement of Medical Instrumentation (AAMI) provides guidelines of graft standards and measurement techniques.^[19] Graft production should use cost-effective, environmentally acceptable processes that allow high and consistent quality. They should then allow for sterilization by conventional techniques and packaging/storage in a sterile state. The surgeon should be able to choose a graft of suitable diameter, wall thickness, and length and must then be able to trim the graft without undue fraying of the edges. During implantation, the graft should not only withstand the rigors of handling, trimming, and suturing, but also be of sufficient initial mechanical strength to withstand the blood pressure without excessive hemorrhage. In addition to the demand that toxic, carcinogenic, or excessively inflammatory products not be released, postimplantation properties of grafts (specifically synthetic grafts) are discussed in the following sections.

Porosity

Early investigations into the replacement of arteries with solid synthetic tubes (glass, aluminum, siliconized rubber, etc.) were unsuccessful due to thrombotic occlusion.^[20] Voorhees et al. were the first to recognize the importance of porosity when they performed a successful arterial replacement using a synthetic fabric in 1952.^[21] The importance of porosity was confirmed when a variety of synthetic materials, unsuccessful as solid-wall prostheses, were shown to be successful in porous configurations.^[22] Okoshi et al. extended the porosity principle to microporous polyurethane grafts by also showing a positive correlation between porosity and patency.^[23]

Dacron manufacturers often define the porosity of their grafts in terms of water permeability. Grafts are thus not only distinguished on the basis of the type of knit or weave, but are further characterized as being of high porosity ($1500\text{--}4000\ \text{ml}\cdot\text{cm}^{-2}\cdot\text{min}^{-1}$) or low porosity ($200\text{--}1000\ \text{ml}\cdot\text{cm}^{-2}\cdot\text{min}^{-1}$).^[24] The porosity of ePTFE grafts, on the other hand, is characterized by the average distance between the centers of adjacent nodes (internodular distance or IND). For most commercially available ePTFE grafts this value is typically in the order of $30\ \mu\text{m}$, although larger sizes have been produced. The morphology of foam-type porous scaffolds used in experimental polyurethane grafts is also generally expressed either in terms of water permeability or, where applicable, indirectly by stating the average size of the porogens used in their production. Although water permeability is a useful parameter for other reasons, it is not useful in the prediction or evaluation of the permissiveness of the material toward tissue ingrowth. Likewise, internodular distance is often a misleading dimension, as the actual space available for tissue ingrowth, namely the interfibrillar distance, is typically in the $4\text{--}5\ \mu\text{m}$ range.^[24] Thus, if one attempts to gain a better understanding of the relationship between porosity and healing, an additional parameter—average pore size available for tissue ingrowth—is required.

Mechanical Properties

The most basic function of a vascular graft, to provide a conduit for blood flow, necessitates two mechanical attributes: 1) the structural integrity to withstand internal pressure (both in the wall and at the suture line), and 2) sufficient resistance to kinking and flattening in order to retain an open lumen. Natural blood vessels exhibit further mechanical attributes, namely regulation of blood flow in response to physiological demands, and dilation and contraction in sympathy with the pulse pressure. The latter property, termed compliance, may be defined in terms of the diameter

change of a vessel between diastolic and systolic pressures, and is usually expressed as %/100 mm Hg.^[25] Equation 1 relates the diameter compliance (C_D) to the diameter (D) and pressure (P) changes, and to the radius (r), wall thickness (t), and bulk modulus of the wall (E_w):

$$C_D = \frac{(D_s - D_d)}{(P_s - P_d) \times D_d} = \frac{r}{t} \frac{1}{E_w} \quad (1)$$

where subscripts s and d denote systole and diastole, respectively. Convenient units for C_D are %/100 mmHg. In porous walls, the constitutive elements defining the wall (e.g., fibers) fill only a fraction of the wall volume. Additionally, these elements are not completely aligned in the circumferential direction, and the deformation is not purely tensile. In such cases the modulus of the vessel also depends on the frictional forces involved in the relative movement between individual elements, as well as the flexural and shear moduli of the elements themselves. It is for this reason that prostheses constructed from very stiff materials such as PET (high E_w) fibers may exhibit some, but not adequate, compliance.

As the structure and function of blood vessels change along the vascular tree, so do their mechanical properties. The larger elastic arteries are highly compliant—so much so that the ascending aorta ($C_D = 30\%/100$ mm Hg^[26]) stores approximately 40% of the cardiac output volume during systole and then releases that volume during diastole. This “windkessel” effect is responsible for the smoothing out of the pressure pulse and contributes to the diastolic pressure. The compliance decreases as one moves away from the heart, and a typical value for the compliance of a femoral artery is 7 to 14%/100 mm Hg.^[27] It is also important to note that, in addition to the variation of compliance between healthy individuals within the same age group, the compliance is a function of age and may be further influenced by disease (notably arteriosclerosis, hypertension, or diabetes). The limited compliance of ePTFE ($C_D = 1.6 \pm 0.2\%/100$ mm Hg) and Dacron ($C_D = 1.9 \pm 0.3\%/100$ mm Hg) grafts has long been indicated as a contributory factor in small-diameter graft failure. A significant correlation between patency and compliance supports this view.^[25] Increased impedance and decreased capacitance, causing disturbed flow patterns, have been cited as causes for intimal hyperplasia that results in the failure of undercompliant grafts.

Although various researchers have attempted to mimic natural vessel compliance by using elastomeric polyurethanes,^[17] the fact that very few of these grafts have progressed past clinical trials indicates that, although compliance may be an important factor, it is not a sufficient factor in the determination of graft success.

Biocompatibility

The nature of the reaction elicited by the implantation of a synthetic graft determines not only the short-term fate of the implant, but also its long-term stability and function. The sequence of events that follows implantation of medical devices—namely injury, acute and chronic inflammation, the formation of granulation tissue, foreign body reaction, and finally fibrosis and fibrous encapsulation—are described by Anderson.^[28] Complete inertness, a property, that has been shown to be unattainable with current materials, may actually be an undesirable property, as it may cause incomplete functional incorporation and healing of the device due to limited interaction with the living tissue. It is for this reason that biomaterials are now being rendered “bioactive” by a variety of surface and bulk modification techniques in order to promote constructive interaction between the implant and the host tissue.

Surface modification is a useful tool that allows the alteration or masking of the chemical nature of the implant that is exposed to the surrounding tissue, as it may be used to alter this property without undue influence on physical properties that may have been optimized for the intended application. In addition to synthetic hydrogels, modification agents include materials of biological origin that may render the material bioactive, i.e., that actively interact with the host tissue by mimicking naturally occurring materials. Other approaches rely on the immobilization of oligopeptide sequences (identified as being the active binding sites in proteins) to obtain the desired effect.

The surfaces of biomaterials may be modified for a number of reasons, all intended to improve the biocompatibility of the material. The reasons include decreasing the adhesion of proteins and/or inflammatory cells, decreasing the thrombogenicity of the material, and increasing the adhesion, proliferation, or migration of desired cell types on or in the material. Leucocyte and macrophage adhesion (and differentiation of macrophages into FBGCs) plays a pivotal role in the inflammatory response. The adhesion of these cell types has been shown to depend on several factors, including surface chemistry, hydrophilicity, and protein adsorption.^[29]

Polyethylene glycols have been shown to be very versatile polymers in surface modification applications. They have been shown not only to decrease protein and macrophage adhesion and bacterial adhesion,^[30] but also to be effective antithrombotic agents.^[31] Thrombotic events on vascular grafts have also been decreased by the immobilization of a number of active antithrombotic agents. These include acetyl salicylic acid (ASA or aspirin),^[32] hirudin,^[33] dipyridamole,^[34] phosphorylcholine,^[35] and heparin.^[36]

The improved incorporation of synthetic devices may be facilitated by the immobilization of extracellular matrix materials such as collagen.^[37] Collagen and other extracellular matrix materials contain distinct peptide sequences that have been identified as the adhesion sites for certain cells. These include the well-known RGD sequence, as well as the YIGSR and IKVAV sequences. These oligopeptides (with flanking sequences) have been covalently immobilized on biomaterials with the aim of improving tissue interaction.^[38,39]

Graft Healing

In order to understand the in-vivo response to vascular grafts, it is important to distinguish between transanastomotic and transmural healing. In the past, very little distinction was made between these modes of healing, and healing patterns were described without specific reference to the source of the tissue. Due to the differences in healing responses observed in different animal models, knowledge about the tissue source is of critical importance. A graft that may show complete surface healing (and even complete surface endothelialization) in one model due to transanastomotic outgrowth, will not show the same favorable response in clinical applications.

Transanastomotic healing

Shortly after implantation of a vascular graft, smooth muscle (and other) cells in the media of the native artery start to proliferate and migrate through the damaged internal elastic lamina into the intima.^[40] This hyperplastic tissue subsequently migrates and proliferates onto the graft (from each anastomosis) toward the midgraft area, forming a “tongue” of tissue generally referred to as the pannus.

Three major factors influence the extent of pannus growth. The first two, the porosity of the graft and the presence of tissue under the inner fibrinous capsule, may be closely interrelated. The third factor affecting transanastomotic outgrowth is the animal model. Although the proliferative capacity of human endothelial cells does not differ significantly from that of experimental animals,^[41] there is a marked difference in the extent of endothelialization observed in vivo between the human and experimental animal models. For reasons unknown, transanastomotic endothelialization stops after only a short distance from the anastomosis in humans.^[42] On standard-porosity ePTFE (30 μm), the coverage achieved in humans in 56 weeks occurs in dogs, the yellow baboon, and the chacma baboon in 3.5, 5.6, and 7.6 weeks, respectively.^[24] Thus, the chacma baboon, in which transanastomotic outgrowth

is 2.1 times slower than in the most commonly used model (the dog), seems to be the best choice for the evaluation of transanastomotic endothelialization of grafts intended for man.

Transmural healing

Peripheral vascular grafts used to alleviate lower-extremity ischemia (femoropopliteal) may be up to 60 cm long. This fact, combined with the very short distance the endothelium is able to migrate (in humans) onto the surfaces of such grafts by transanastomotic surface healing, indicates that future grafts intended for clinical use should rely more on transmural healing. If full transmural healing could be achieved, it would not only lead to the formation of a viable endothelium, but would also result in the formation of viable tissue in the graft wall, and thus to improved incorporation of the prosthetic material by the host. The mural tissue should consist, as previously indicated, not only of smooth muscle cells and accompanying extracellular matrix, but also of a fully developed vasa vasorum capable of sustaining the viability of the cells.

The ability of tissue to migrate through the graft wall is, again, dependent on both the structure of the graft and the proliferative and migratory capacity of the cells of the host. The need for sufficient porosity to accommodate cellular ingrowth has been discussed. Standard-porosity ePTFE, due to its restricted ingrowth spaces, does not allow for significant transmural ingrowth, irrespective of the animal model used. In 60 μm ePTFE, transmural ingrowth of capillary vessels leads to the surface endothelial in as little as two weeks in the yellow baboon, whereas the perigraft tissue does not even penetrate the outer two-thirds of these grafts in the chacma baboon within the same time frame.^[24]

The healing of Dacron grafts is also greatly affected by porosity. Low-porosity Dacron prostheses (woven) show similar perigraft incorporation as standard (30 μm) ePTFE during the initial period after implantation. Subsequently, some fibroblast and capillary infiltration into the narrow spaces between the Dacron yarns is observed.^[4] Even if the tissue does manage to grow through the tight interfibrillar spaces, however, it is unable to penetrate the compact inner fibrin layer deposited on the graft surface.^[43] In high-porosity Dacron (knitted), transmural tissue reaches the compact luminal fibrin layer within three to four weeks in animals and three to six months in humans.^[42] The complete endothelialization of long prostheses, comparable to that in highly porous ePTFE grafts, is occasionally seen in knitted prostheses. However, in contrast to high-porosity ePTFE grafts, it remains unclear whether this endothelium is derived from

transmural tissue ingrowth, facilitated transanastomotic outgrowth, or fall-out healing.^[44]

Alternative Approaches

In-vitro tissue engineering

Recent advances in cell culture techniques have created an opportunity for the in-vitro reconstitution of organs from living cells. Weinberg and Bell^[45] were the first to apply such techniques to produce a completely biological tissue-engineered blood vessel (TEBV) from collagen gels and cultured bovine endothelial cells (ECs), smooth muscle cells (SMCs), and fibroblasts. These grafts did not, however, display the required mechanical strength, even when reinforced with Dacron mesh. Similar results were obtained by the group of Auger with human collagen and vascular cells,^[46] and by Hirai and Matsuda,^[47] who used a canine model.

An alternative method entails the production of tissue-engineered blood vessels from cultured human cells without the use of any exogenous biological material, by allowing the cells to create their own extracellular matrix in the presence of ascorbic acid.^[48] The method involved wrapping successive layers of acellular and cellular materials onto a mandrel, removal of the mandrel, and subsequent EC seeding to produce a neo-artery. The vessels were shown to have undergone histological organization and displayed burst strengths comparable to those of natural blood vessels.

Niklason and Langer^[2] used temporary synthetic scaffolds of poly(glycolic acid) (PGA) to produce tissue-engineered blood vessels by seeding tubular nonwoven meshes of PGA with high densities of smooth muscle cells. Maturation of the cells in a bioreactor resulted in the proliferation of the cells and the degradation of the PGA mesh. Pulsatile stretch was employed to facilitate proliferation and enhance the contractile properties of the cells. Although the mechanical stretching did improve the physical strength over that obtained during static culture, the vessels were not able to withstand physiological arterial pressure.

Endothelial cell transplantation

The failure of small-diameter, synthetic, vascular grafts may be attributed mostly to surface thrombogenicity and anastomotic intimal hyperplasia. The surface thrombogenicity, in turn, can be ascribed to a persistent lack of endothelial cell coverage, even after extended implant periods. The basic concept behind endothelial cell transplantation is the lining of

autologous endothelial cells (ECs) on contemporary synthetic grafts before implantation in order to mask the thrombotic nature of the underlying synthetic material.

Single-stage venous EC seeding

This early method involved the single-staged seeding of endothelial cells harvested from subcutaneous veins onto Dacron prostheses, and the subsequent clotting of the cells into the wide-meshed porous structure of the synthetic graft.^[49] The general trend at the time toward the use of ePTFE grafts in peripheral reconstructions prompted researchers to attempt the application of this approach to an alternative material. The narrow interfibrillar spaces of the ePTFE, however, resulted in the cells being clotted onto the luminal surface of the graft instead of into the graft structure. Seeding with cell numbers that were too low for the large surface area of long grafts needed for human implantation, together with the high detachment rate of cells after the restoration of blood flow, resulted in suboptimal seeding densities. Although this probably led to partial endothelialization and moderate decrease in thrombogenicity, the procedure did not result in an improved clinical patency rate.^[50] Newer approaches to circumvent the problem of low seeding densities due to low cell numbers include the mass culture of venous endothelial cells and the mass harvest of capillary endothelial cells from fat tissue.^[51]

In-vitro endothelialization

In-vitro endothelialization was pioneered in the 1980s by a number of groups.^[52] This is essentially a two-stage method, the first stage of which is the mass culture of endothelial cells isolated from a suitable source (e.g., a section of jugular or cephalic vein). The large quantity of endothelial cells cultivated in this step is subsequently seeded at a high density onto the luminal surface of a suitable synthetic prosthesis, typically an ePTFE graft. Precoating of the graft prior to seeding improves the adhesion of the seeded cells. Post-maturation allows for the recovery from injury caused by the seeding procedure, the maturation of the cells' cytoskeletons to better withstand the shear forces exerted on it by the bloodstream, the formation of a confluent layer of cells on the luminal surface, and the reduction of the inflammatory activation of the endothelium.^[53]

Clinical trials utilizing in-vitro endothelialized grafts for femoropopliteal bypass commenced in 1989.^[54] Since then, a number of groups have reported their experience with clinical trials with follow-up periods of up to nine years. The overall success of the procedure is

evident from the excellent improvement achieved in patency rates when endothelialized grafts are compared to unendothelialized controls. Control groups typically have a five-year patency rate of 42% for above-knee ePTFE grafts, whereas patency rates in excess of 65% could be achieved when endothelialized grafts were used.^[52] This compares favorably to the 70% patency rate achieved by Veith with the use of reversed autologous saphenous veins in the same position.^[14] Multicenter clinical trials aimed at the verification of these results are currently under way in Europe.

In-vivo tissue engineering

The in-vivo approach to vascular grafts typically involves the use of degradable materials that allow tissue ingrowth and remodeling in order to produce a neo-artery. Synthetic materials used in such constructs include poly(glycolic acid) (PGA), poly(lactic acid) (PLA), PLGA copolymers, polycaprolactone (PCL), and polydioxanone (PDS). As these materials are generally nonelastomeric (and thus have limited compliance), elastic degradable materials composed of PLGA/PCL/PLGA tri-blocks, PLA/PGA blends with polyurethanes,^[55] hydrolytically degradable polyurethanes,^[56,57] and enzymatically degradable polyurethane^[58] are being developed.

Researchers in this field endeavor to effect the generation of a new vessel by the degradation of porous scaffold after ingrowth of sufficient cellular and extracellular materials (before degradation resulted in failure of the graft), followed by complete (or partial) resorption of the polymeric material.^[10,55] A major challenge in this approach is to ensure that the breakdown products are not excessively toxic, allergenic, thrombogenic, inflammatory, or carcinogenic.^[59]

Naturally occurring materials such as collagen have also been employed in the in-vivo approach. Previous use of collagenous materials as vascular grafts typically involved the use of extensive cross-linking to achieve a durable, permanent implant. In contrast, Sullivan and Brockbank^[60] describe the use of water-soluble carbodiimide (EDC) to minimally cross-link porcine intestinal collagen layers (ICLs), thereby reducing the antigenicity of the material without preventing in-vivo cell ingrowth. Explanted carotid interposition grafts in rabbits showed excellent patencies, and preliminary histology exhibited signs of remodeling of the graft by host cells. Van Wachem et al. cross-linked reconstituted type I bovine collagen to various degrees using EDC and were able to achieve decreased antigenicity and variable degradation rates in vivo.^[61]

An novel approach by Campbell et al. involved the growth of a graft within the recipient's peritoneal

cavity.^[62] This method required no synthetic or biologic matrix, apart from a piece of Silastic tubing that was implanted in the peritoneal cavity and acted as a temporary mandrel. After removal of the mandrel from the explanted mesothelium-covered myofibroblast capsule, and inversion of the construct to position the mesothelium on the luminal surface, the living grafts were successfully implanted in both the rat aortic and rabbit carotid models. More information on vascular tissue engineering may be found in an editorial by Edelman.^[63]

CONCLUSION

Autologous arteries and veins remain the best conduits for replacing or bypassing diseased and injured vessels, and are used in preference to other prostheses. Limitations on their use, caused by lack of availability of dispensable vessels and unsuitability due to preexisting conditions, necessitate the use of alternative grafts. Inherent problems associated with the use of fixed homologous or heterologous grafts imply that synthetic grafts (ePTFE and Dacron) are currently the only viable alternatives. The failure of contemporary Dacron and ePTFE grafts to perform optimally in small-diameter applications may be attributed to the poor healing response exhibited by the body toward the implanted prostheses. This lack of healing, in turn, may be attributed to a number of factors that prevent the graft from being incorporated into a viable composite of synthetic material and living tissue. Although endothelial cell transplantation onto (or into) conventional synthetic prostheses has been successful in improving the patency rates of such grafts, the negative aspects associated with both in-vitro cell culture and conventional synthetic grafts are maintained.

The in-vitro tissue engineering approaches, as well as the in-vivo approaches that require the growing of the vessel prior to graft implantation, offer the possibility of having vascular grafts "made to order" from autologous cells. Although these approaches offer invaluable insight into the conditions required to produce neo-arteries, the turnaround times from initiation to functional graft implantation may limit the application of these techniques. Thus it seems that the holy grail of vascular grafting will remain a device that is "ready to use" or "off the shelf," that would immediately be able to perform the basic functions of a graft, and that would further provide the complex and interrelated chemical, physical, and biological properties required to effect remodeling to a fully functioning neo-artery. Whether this graft will turn out to be made from synthetic or biological degradable materials, or whether durable materials may be used in vivo to form a living, composite tissue/polymer

construct, is the question that fuels research in this exiting field.

INTRODUCTION

Vinyon-N, developed in 1952 by Voorhees, was the first successful artificial vascular graft.^[1] Since then, polyethylene terephthalate (Dacron) and expanded polytetrafluoroethylene (ePTFE) have become the most widely used prosthetic vascular grafts. However, the development of completely nonreactive substances has been unsuccessful. Both Dacron and ePTFE react with blood components and perigraft tissues in a manner that is both beneficial and detrimental. Investigations of the vascular response in both physiological and pathological conditions, along with parallel developments in the field of biomaterials, have led to a more sophisticated strategy—namely, optimizing the tissue–biomaterial interaction to produce desirable results. Synthetic grafts can be coated with proteins, anticoagulants, and antibiotics to improve graft function. Similarly, synthetic polymers or biologically-derived structural proteins can be bonded to various growth factors to induce favorable host responses. Resorbable polymers comprise another type of graft material in which extensive in-vivo tissue ingrowth constitutes the biochemical and functional integrity of the vascular conduit. After more than twenty years of intensive research, a better understanding of the clinical value of endothelial cell (EC) seeding is beginning to emerge. Using tissue engineering techniques, a biologically viable vascular substitute is becoming feasible. In addition, genetic manipulation of vascular cells may enhance the potential function of these biologic grafts.^[2]

STRATEGIES FOR THE DEVELOPMENT OF VASCULAR GRAFTS

To improve the long-term patency of bioprosthetic grafts, the following approaches have been pursued:

- 1) modification of the blood contact surface to maximize the thromboresistance of synthetic grafts;
- 2) manipulation of in-vivo graft-host histologic responses by controlled delivery of bioactive substances;
- 3) development of bioresorbable vascular prostheses;
- 4) endothelialization of the graft blood contact surface; and
- 5) development of completely tissue-engineered vascular substitutes.

Surface Modifications

The simplest modification of a graft is to coat the inner surface with a relatively inert polymer. Carbon coating has been found to decrease surface thrombogenicity due to its negative charge and hydrophobic nature. Carbon-impregnated prosthetic grafts were found to reduce platelet deposition, demonstrate improved primary and secondary graft patency, and raise limb-salvage rates at 12 months in clinical comparative studies.^[3,4] Silicone polymer coating—which produces a smooth surface devoid of the usual ePTFE graft permeability and texture—followed by plasma glow discharge polymerization effectively abolished pannus tissue ingrowth and graft surface neointimal hyperplasia in baboon and canine models.^[5]

Protein coating was used to decrease the porosity of Dacron grafts as an alternative to blood preclotting. Degradation of the impregnated protein by the host immune system and other proteases results in tissue ingrowth.^[6] Albumin, gelatin, and collagen are most commonly used. Large-diameter, knitted Dacron prostheses coated with each of these three proteins are currently available for clinical use. Albumin coating, developed in the 1970s, was found to diminish platelet and leukocyte adhesion.^[7] In a canine thoracoabdominal aortic model, knitted Dacron grafts impregnated with albumin had less transinterstitial

blood loss at implantation, and significantly thinner inner capsules at 20 weeks.^[8]

Native collagen is intrinsically thrombogenic, whereas cross-linked collagen has shown an improved thrombogenic profile. Collagen coating establishes a good matrix for cellular ingrowth and induces neointimal formation, which theoretically should improve long-term graft patency. Promising initial results have been reported by several groups.^[9] However, a recent clinical study reported no significant improvement of graft patency with collagen impregnation of knitted Dacron aortoiliac grafts.^[6]

Gelatin is a derivative of collagen that degrades readily when utilized as a graft coating. Different coating techniques—including alkylation, plasma discharge, nonspecific cross-linking, covalent binding, and application of thin polymer films—have been developed to improve the gelatin degradation time.^[9-16]

Anticoagulants have been affixed to synthetic grafts. Heparin binding to Dacron grafts has been shown to reduce its thrombogenicity.^[17] In canine studies, heparin bound to polyurethane and polydimethylsiloxane surfaces improved graft patency rates.^[18] Thrombolytic agents such as urokinase have also been bound to bioprosthetic surfaces with promising results. Little is known about the long-term efficiency of these modifications.^[19]

Manipulation of In-Vivo Healing Process

Tissue incorporation occurs in all implanted bioprosthetic grafts. Excessive cell proliferation and extracellular matrix (ECM) deposition result in neointimal hyperplasia, leading to vascular graft failure. The ideal healing sequence would be rapid endothelialization of the blood contact surface with spatially and temporally limited subendothelial smooth muscle cell (SMC) growth, followed by phenotypic and functional maturation of cell components, as well as remodeling of the ECM. Recent developments in the study of mechanisms responsible for the migration and proliferation of endothelial cells (ECs) and SMCs provide clues to the efficacious manipulation of the healing process, thereby optimizing the microenvironments of the graft and perigraft tissue.

Fibroblast growth factors (FGFs), notably FGF-1 (acidic FGF) and FGF-2 (basic FGF), which are known to be potent mitogens, also possess potent angiogenic activities. Both factors have been experimentally applied to grafts alone and in combination with heparin. Heparin potentiates the mitogenic activity and protects FGFs from proteolytic degradation.

Achieving a controlled healing response requires a defined delivery system that can apply bioactive

substances to the graft surface and predictably release them with preserved bioactivity over an extended period of time. Greisler has evaluated the affixation of FGF-1 to synthetic graft surfaces.^[20,21] FGF-1 was applied to various synthetic grafts by sequential application of fibronectin, heparin, FGF-1, and a second heparin layer, utilizing known binding affinities between successively applied agents. Growth factor retention was 44% in Dacron grafts and 23% in polydioxanone (PDS) grafts. In addition, full growth factor bioactivity was observed. However, no significant increase in endothelialization was observed *in vivo*.^[22]

Utilizing a fibrin glue delivery system, FGF-1 and heparin-impregnated ePTFE grafts were evaluated in both canine aortoiliac and thoracoabdominal aortic models.^[23-26] A significant increase in endothelial cell proliferation was observed, along with rapid development of a confluent endothelial layer at 28 days. Extensive transinterstitial capillary ingrowth throughout the graft wall was also observed. In addition, a significant increase in subendothelial myofibroblast proliferation was observed at 1 month.^[25,26]

Coimmobilization of FGF-2 and heparin in a microporous polyurethane graft by cross-linked gelatin gel has been demonstrated to accelerate tissue regeneration. It was associated with a greater extent of endothelialization via perianastomotic and transmural capillary ingrowth in a rat aorta model.^[27] A consistent 40- μ m thick neointima with intermittent endothelialization, and an underlying layer of SMCs and fibroblasts, were observed in the midportion of the treated grafts, compared with control grafts that were covered with only a fibrin layer.^[27]

In response to exogenous stimuli, ECs, SMCs, and fibroblasts turn over and enter the cell cycle. Transformed cells divide, synthesize EMC, and produce growth factors with effects induced by autocrine and paracrine mechanisms. A number of growth factors and cell cycle proteins are involved in this process. Intimal hyperplasia is caused by excessive ECM production and cellular proliferation. Fine control of this proliferative process is the key to successful manipulation of these processes.

Bioresorbable Grafts

Currently clinically available synthetic vascular grafts—either ePTFE or Dacron—are permanent prostheses in the host after implantation. Tissue-graft reaction, ultimately resulting in graft failure at times, is inevitable as long as the graft persists. Theoretically, it may be possible to stimulate a rapid and controlled ingrowth of tissue, assuming the load-bearing material resists dilation and incorporates cellular components with

desirable physiologic characteristics, forming a neoartery. The synthetic material itself may no longer be necessary following tissue ingrowth, and may thus form the basis of another strategy in the design of vascular grafts—namely, the use of bioresorbable materials. Bioresorbable grafts' key advantage is that after tissue ingrowth has occurred, prosthetic material is no longer present to continue stimulating a foreign-body reaction or harbor bacteria leading to graft infection.

Wesolowski and Ruderman were the first to propose the concept of a slowly absorbable vascular graft that could induce a host-regenerative process producing a new functional artery.^[28,29] These early partially resorbable grafts were made of fibers composed of Dacron and catgut or Dacron and polylactide. The first report of a completely bioresorbable graft was in 1979 by Bowald, who described the use of a rolled sheet of Vicryl (a copolymer of polyglycolide and polylactide).^[30,31] Unfortunately, these early grafts were prone to aneurysmal dilation and rupture.

Woven polyglycolic acid (PGA) grafts were evaluated by Greisler in a rabbit model.^[32,33] Four weeks after implantation, the grafts contained an inner capsule composed of a confluent layer of endothelial cells and smooth muscle-like myofibroblasts amid dense collagen fibers. Similarly constructed Dacron grafts demonstrated an inner capsule containing only a fibrin coagulum with minimal cellularity. Macrophage infiltration and phagocytosis were in parallel with the resorption of the PGA, which was no longer present at 3 months. Initial experiments showed that aneurysmal dilation occurred in 10% of grafts, at the time of prosthetic material resorption and before ingrowth of tissue with adequate strength to resist hemodynamic pressures. Later studies evaluated grafts composed of PDS, a more slowly resorbed material. PDS grafts demonstrated a similar endothelialization of the regenerated luminal surface. Compared to PGA, which is completely resorbed within 3 months, PDS remains present for up to 6 months. Only 1 of 28 PDS grafts exhibited aneurysmal dilation with explant times as late as 1 year. The explanted specimens of these PDS grafts demonstrated biomechanical characteristics similar to native arteries, which were able to withstand static bursting pressures of 6000 mm Hg and mean pressures of 2000 mm Hg without fatigue.^[34]

As a requirement for clinical efficacy, a bioresorbable graft must regenerate a tissue complex of sufficient strength prior to loss of prosthetic integrity to minimize the development of aneurysmal dilation. There are several theoretical approaches to achieve this goal. One approach combines the bioresorbable material with a nonresorbable material that remains behind as a mechanical strut. Another approach involves the combination of two or more bioresorbable materials with different resorption rates such that the more

rapidly resorbed material evokes rapid tissue ingrowth whereas the second material provides temporary structural integrity to the graft. A third approach utilizes growth factors or cells that can be applied to the graft to enhance tissue ingrowth and organization.

Partially resorbable grafts have been studied by Greisler et al.^[35] Composite grafts constructed from fibers containing 69% resorbable PG910 and 31% nonresorbable polypropylene were evaluated in rabbit and canine models. Remarkably, these grafts demonstrated 100% patency with no aneurysmal dilation 1 year after implantation.^[36] In another study, completely resorbable composite grafts woven from fibers of 74% PG910 and 26% PDS also demonstrated 100% one-year patency with no aneurysms in a rabbit aorta model.^[37,38] In addition, the regenerated arteries withstood 800 mm Hg of pulsatile systolic pressure *ex vivo*. Furthermore, a confluent, functional, endothelial cell layer over circumferentially oriented smooth muscle-like myofibroblasts was present in the inner capsule of these grafts.

Wildevuur and van der Lei evaluated grafts prepared from a 95% polyurethane/5% polylactide mixture, and found that only relatively compliant grafts that induced circumferential smooth muscle development contained elastin and remained stable without dilating.^[39,40] They concluded that modifications of the graft preparation and smooth muscle cell (SMC) seeding may help enhance optimal orientation of the SMCs and may prevent aneurysm formation.^[40]

Further work and development may produce a small-diameter, completely resorbable vascular graft that may ultimately improve the currently dismal long-term patency rates of small-caliber bioprosthetic grafts.

Endothelial Cell Seeding

Endothelial cells (ECs) perform a series of important physiological functions, one of which is the maintenance of blood vessel thromboresistance. Endothelial cells possess a negative surface charge that helps prevent platelet adherence. Glycosaminoglycans—which bind antithrombin III, prostacyclins, and tissue plasminogen activator—are produced by the endothelial cell and contribute to its antithrombotic activities. From a theoretical standpoint, the presence of a confluent monolayer of endothelial cells on the luminal surface of a prosthetic graft should improve graft thromboresistance and help prevent the development of pseudointimal hyperplasia.

The first report of enhanced graft survival as a result of endothelial cell seeding came from Herring in 1978.^[41] Considerable progress has been made since that original report. Initial technical problems

associated with cell harvesting, seeding and adhesion, and prevention of desquamation have for the most part been overcome.^[42,43] The ideal seeded graft should have a confluent endothelial cell lining at the time of implantation. Endothelial cells should be able to resist shear stress after the restoration of blood flow, and retain all of their physiologic functions while present on the graft surface.

Adequate endothelial cell density is a requirement for successful graft seeding. The density of endothelial cells lining a normal artery is approximately 10^3 ECs/mm².^[44] At minimum, an attachment of at least 5×10^3 ECs/mm² is required for immediate confluent human EC coverage of a small-caliber vascular graft. In order to achieve high enough cell densities, a two-stage seeding procedure has been developed. Endothelial cells are harvested, allowed to proliferate *in vitro*, and then seeded and grown to confluence on the vascular graft prior to implantation.^[45-47] The major disadvantages of this technique are the potential for contamination and infection, alteration of the EC phenotype and function, the requirement of a 3-4-week waiting period for expansion of the cell population, and the need for two operative procedures. An alternative method utilizes microvascular endothelial cells in which small-diameter Dacron or ePTFE grafts are seeded with cells harvested from the omental microvasculature in a single stage. This technique resulted in confluent endothelial linings, a larger thrombus-free surface area, and improved patency rates at 1 year in a canine model.^[48]

Endothelial cell adhesion and retention is another key issue for prosthetic graft seeding. Endothelial cells adhere very poorly to synthetic graft materials. Therefore, adhesive proteins such as fibronectin, collagen, fibrin, and laminin have been applied to graft surfaces to improve seeding efficiency. Nitrogen-containing plasma treatment—a novel, recently developed surface modification technique—generates basic groups on the graft surface and enhances the ability of ECs to resist shear stress.^[44,49] Studies on the kinetics of EC seeding showed a 20% loss of seeded cells during the first hour, followed by continued loss up to 60% within the first 24 hours.^[50-52] Longer incubation times prior to exposure to blood flow allow maturation of the cytoskeleton and improve cell retention on the graft surface.^[53-55] Preconditioning the seeded EC monolayer with graded shear stress has been shown to promote the reorganization of the EC cytoskeleton and production of extracellular matrix, which in turn results in higher EC retention after exposure to blood flow.^[56]

Intrinsic properties of the bioprosthetic material also affect EC attachment. Dacron has a higher level of cell attachment compared to ePTFE when both types of grafts are coated with a similar matrix.^[54-57]

Polyurethane also showed better cell attachment than ePTFE.^[58] The negative surface charge present on ePTFE is an important characteristic that helps limit platelet deposition. On the other hand, the negative surface charge also prevents negatively-charged ECs from accessing the graft surface because of natural repulsive forces.

Numerous animal studies have demonstrated decreased platelet deposition and increased patency rates in EC-seeded Dacron and ePTFE grafts.^[59-64] Resistance to bacterial contamination has also been shown in seeded grafts.^[65] Endothelial cell seeding does not appear to reduce the formation of pseudointimal hyperplasia in a canine model, in which 4-mm Dacron grafts were seeded and implanted in the aortoiliac position.^[66] In fact, higher levels of PDGF and bFGF have been measured in endothelial seeded grafts, which is of particular concern given their potential role in the development of pseudointimal hyperplasia.^[67,68]

Clinical data evaluating EC-seeded synthetic grafts have been limited and have had mixed results. Magometschnigg reported a twofold increase in early graft patency and a twofold decrease in late amputation rates of femoral-tibial bypasses, using cultured endothelial cells seeded onto fibrin glue-coated ePTFE grafts.^[69] Herring reported increased 1-year patency rates for seeded ePTFE femoral-popliteal grafts.^[70] However, later studies using the same single-stage seeding technique failed to demonstrate any significant long-term advantage of seeded grafts.^[71] Utilizing the two-stage seeding technique, Zilla reported decreased platelet deposition and increased 5-year patency rates in seeded ePTFE femoral-popliteal bypass grafts over a 9-year period.^[72,73] In addition, intimal thickening and subsequent stenosis of seeded grafts have been reported.^[74,75]

Recent advances in molecular biology have allowed the seeding of genetically-manipulated endothelial cells to synthetic grafts. The first report of this approach was by Wilson et al. in 1989, in which Dacron grafts were seeded with retrovirally-transduced ECs containing the lacZ marker gene. These grafts were implanted into a canine carotid artery model, and lacZ gene expression was detected for a period of 5 weeks.^[76] Tissue plasminogen activator (tPA) has also been successfully transfected into endothelial cells, and expression of tPA activity has been detected in cells seeded onto synthetic grafts.^[77,78] Endothelial cells may be manipulated to secrete specific growth factors and inhibitors to allow optimal EC proliferation and migration and to prevent smooth muscle cell hyperplasia. Varying results have been reported regarding the proliferation, adhesion, and retention of genetically-modified ECs on the surface of synthetic grafts.^[70,79,80] Genetically-modified ECs also appear to have decreased retention on graft surfaces *in vivo*.^[81-85]

Because of these difficulties, little data have thus far been reported showing an in-vivo advantage of genetically-modified EC-seeded grafts.

The introduction of genetic engineering offers considerable potential to manipulate the function and physiology of seeded cells on graft as well as perigraft cells. These cells may in turn further augment the efficiency of EC seeding.

Tissue Engineering

It has been suggested that endothelial cells alone cannot produce a stable intima without the presence of underlying SMCs or fibroblasts.^[86] Tissue fragments containing multiple cell types—including venous tissue, adipose tissue, and bone marrow—have been seeded onto grafts and have been found to accelerate the graft-healing process.^[86] Interestingly, bone marrow cell seeding was reported to induce abundant capillary growth in the graft wall and a rapid, complete endothelialization of the inner surface without intimal hyperplasia. Multipotent stem cells in the bone marrow have the potential to differentiate in response to their microenvironment. Stem cells proliferate and secrete cytokines necessary for their survival and may represent a significant cell source for tissue engineering.

In the quest to develop the ideal vascular substitute, several attempts to construct a neoartery have been reported. Vascular cells were seeded onto a three-dimensional ECM or polymer scaffold. After implantation, the cells proliferated and produced ECM, whereas the scaffold degraded and was replaced by native tissue. The newly formed conduits were viable vessels with the ability to remodel in response to the hemodynamic environment and to maintain the cell components' normal functions.^[87] Shinoka et al. produced a graft from autologous mixed vascular cells from carotid artery explants.^[88] The cells were expanded in vitro and then seeded onto polyglactin or PGA scaffolds. After 7 days in culture, the grafts were implanted as pulmonary artery interpositions in lambs. The scaffolds were no longer present at 11 weeks, and the newly generated conduit resembled native artery architecture with ECs lining the luminal surface. In addition, the development of ECM including collagen and elastic fibers was also observed.^[88]

The first attempt at creating a totally biologic vascular conduit in vitro without a synthetic polymer was made by Weinberg and Bell.^[89] They constructed a three-layered blood vessel model with collagen matrix as a scaffold for ECs, SMCs, and fibroblasts. Similar efforts have been made by other groups.^[90–96] These early models failed to achieve sufficient mechanical strength, requiring reinforcement with Dacron mesh. This weakness is presumed to be due, at least in part, to

the lack of organization of the ECM. L'Heureux et al. generated a vessel exclusively from cultured vascular cells that produced ECM with an organization resembling that present in natural vessels.^[91] SMCs were cultured in vitro to form a cellular sheet, which was then wrapped around a tubular support to produce the media. Subsequently, a similar sheet of fibroblasts was placed around the media to compose the adventitia. After maturation, the tubular support was removed and ECs were seeded onto the luminal surface. This constructed vessel displayed a bursting strength of over 2000 mm Hg. The SMCs produced desmin, expressed circumferential and longitudinal orientations, and even demonstrated contractile responses when challenged with vasoactive agonists. Abundant ultrastructurally organized collagen and elastin fibers were present in the ECM. However, in short-term studies, after being implanted in canine femoral arteries, intramural blood infiltration was observed. Although much work will be required to conquer the technical obstacles and optimize the manufacturing system, these efforts will create possibilities to produce viable substitutes for vascular replacement.

CONCLUSION

Much progress in the development of vascular substitutes has been seen over the past several decades. Investigations into the underlying biochemical and cellular mechanisms involved in the graft-healing process have yielded a firm understanding of graft physiology and the pathological processes involved in graft failure. Utilization of numerous biochemical, molecular biological, and tissue-engineering techniques—with the goal of improving long-term graft patency—will result in the development of novel vascular substitutes and allow continuing increase in our understanding of the graft-healing process.

INTRODUCTION

Approximately 550,000 vascular bypass procedures are performed annually in the United States. Autogenous vein remains the conduit of choice for infrainguinal arterial reconstruction and is the most commonly used conduit for coronary artery bypass surgery. However, in situations where autogenous vein is unsuitable or unavailable, artificial vascular grafts are utilized. Long-term patency rates of artificial vascular grafts are inferior to those observed with autogenous vein grafts; therefore, the development of vascular substitutes remains a continuing priority.

Initial graft research was directed at developing inert materials that passively transported blood and minimally interacted with blood and tissue. Vinyon-N was the first successful artificial vascular graft developed in 1952 by Voorhees.^[1] Since then, polyethylene terephthalate (Dacron) and expanded polytetrafluoroethylene (ePTFE) have become the most widely used prosthetic vascular grafts. However, the development of completely nonreactive substances has been unsuccessful.^[2] Both Dacron and ePTFE react with blood components and perigraft tissues in a manner that is both beneficial and detrimental.

The success of a vascular graft depends upon the intrinsic properties of the graft material and the hemodynamic environment in which the graft is placed. Patient variables, which include clinical indication, outflow resistance, underlying disease processes and other comorbidities, also contribute to the long-term performance of a synthetic vascular graft. A firm understanding of graft physiology and its pathological processes is critical to the development of efficacious vascular substitutes.

GRAFT-HOST INTERACTIONS

All grafts, regardless of their composition and structure, evoke complex but predictable host responses beginning at the blood-biomaterial interface. Protein adsorption begins immediately after restoration of blood flow, followed by cellular and humoral responses to synthetic materials. Host responses include plasma protein deposition, platelet activation, infiltration of neutrophils and monocytes, and migration of endothelial and smooth muscle cells. Even the most inert artificial graft materials thus far developed are still recognized as foreign. The tissue-graft-blood interfaces are highly complex microenvironments that are ultimately responsible for graft patency.

Protein Adsorption

The most abundant serum proteins, albumin, fibrinogen, and immunoglobulin G (IgG), along with other serum proteins, adsorb to the graft almost instantaneously following exposure to the systemic circulation. Redistribution of serum proteins according to the Vroman effect occurs next, where each protein's local concentration and relative biochemical and electrical affinity for the graft surface determines its distribution.^[3] Because platelets and blood cells interact predominantly with bound proteins and not the prosthetic material itself, the constitution and concentration of bound protein largely determine the interaction of blood components with the graft, and therefore affect graft survival.

Fibrinogen, laminin, fibronectin, and vitronectin all have an RGD sequence (arg-gly-asp) region that binds to the GP IIb/IIIa receptor complex on platelet membranes. Thus, platelet deposition and activation is

influenced by prior protein adsorption. The binding of the RGD sequence to β_2 integrins expressed on the cell surface also contributes to graft–leukocyte adhesion. Neutrophils bound to immobilized IgG and fibrinogen demonstrate a reduction in their bactericidal properties, which may in part be responsible for the susceptibility of artificial grafts to infections.^[4] Additional plasma proteins, including complement components, are activated by synthetic surfaces to varying degrees.^[5] The rapid accumulation of coagulation proteins such as thrombin and Factor Xa on the luminal surface after implantation contributes to graft-associated procoagulant activity.^[6]

Platelet Deposition

Early platelet deposition occurs primarily via receptor-mediated interactions with adsorbed proteins and, to a lesser extent, by direct adherence to the graft. The platelet/protein complex is mediated through von Willebrand's factor and platelet membrane glycoproteins. After adherence, platelets undergo conformational changes and degranulate, releasing variety of bioactive substances that include serotonin, epinephrine, adenosine diphosphate, and thromboxane A₂. These substances further activate additional platelets, resulting in increased thrombin generation. Growth factors platelet-derived growth factor (PDGF), epidermal growth factor (EGF), and transforming growth factor β (TGF- β) are also released by activated platelets. These factors modulate smooth muscle cell (SMC) migration and proliferation and extracellular matrix synthesis. In addition, monocyte chemoattractants platelet factor 4 and β -thromboglobulin, which mediate the recruitment of monocytes into the graft, are also released. Platelet deposition and activation continues long after graft implantation. Animal experiments have demonstrated increased levels of thromboxane and decreased systemic platelet counts one year after Dacron graft implantation.^[7] Human studies have also revealed increased platelet adhesion to grafts long after implantation.^[8–10]

The thrombogenic nature of the synthetic graft surface is a major determinant of early and late graft patency. Attenuation of platelet deposition, aggregation, and activation has long been the goal of numerous interventions aimed at improving graft patency. Antiplatelet agents acting on the platelet surface glycoprotein IIb/IIIa ($\alpha_{IIb}\beta_3$ integrin) and on functional domains of thrombin have been shown to decrease platelet accumulation on Dacron grafts.^[11,12] Techniques used to alter surface thrombogenicity without compromising the graft material's bulk properties have been developed. These include the application of antiplatelet or anticoagulant substances to

biomaterial surfaces, alteration of surface electro-negativity, and radio frequency glow discharge of plasma polymerized monomers to graft surfaces.

Neutrophil and Monocyte Infiltration

Leukocyte chemoattractants C5a and leukotriene B₄ (LTB₄) mediate the acute inflammatory response through recruitment of neutrophils to the synthetic graft surface. These cells bind to fibrinogen within the fibrin coagulum on the inner graft surface through cell surface β_2 integrins (mainly CD11b/CD18), which mediate adhesion-dependent chemotaxis and promote cell transmigration. IgG is also important for neutrophil binding to artificial graft surfaces. IgG binds to neutrophils through Fc receptors present on the neutrophil cell surface, resulting in a series of effector functions. This recruitment of phagocytic cells does not confer infection resistance to the synthetic graft surface. On the contrary, neutrophils adherent to biomaterial surfaces have been shown to have reduced phagocytic and bactericidal properties. Neutrophil binding via the Fc receptor to immobilized IgG on graft surfaces may account for this deficiency.^[4] Neutrophils also interact with other deposited proteins such as C3bi and Factor X.

Neutrophils strongly adhere to endothelial cells in the perianastomotic region through selectin and integrin-mediated mechanisms.^[13,14] Activated neutrophils release oxygen free radicals and various proteases, resulting in matrix degradation and inhibition of both endothelialization and tissue incorporation of the vascular graft.

Circulating monocytes are attracted to areas of injured or regenerating endothelium and to areas pre-activated by interleukin-1 (IL-1) and tumor necrosis factor- α (TNF- α). Additional monocyte recruitment and activating factors include LTB₄, platelet factor 4, and PDGF.^[15,16] In response to these factors, monocytes differentiate into tissue macrophages, becoming the major participant in the host's chronic inflammatory response. Like neutrophils, macrophages also release proteases and oxygen free radicals, which have long-term effects on the tissue–graft–blood interfaces.

Inflammatory cells activated by synthetic graft materials release a variety of cytokines. Macrophages grown in the presence of polygalactin 910 (a bioresorbable material readily phagocytized by macrophages) release fibroblast growth factor 2 (FGF-2), which stimulates the proliferation of quiescent SMCs, ECs, and fibroblasts.^[17,18] Monocytes and macrophages grown in the presence of Dacron or ePTFE have been shown to produce interleukin-1 β (IL-1 β), interleukin-6 (IL-6), and TNF- α .^[19] Proliferation of SMCs caused by leukocyte–biomaterial interactions is

mediated by TNF- α , whereas SMC proliferation caused by leukocyte-EC interactions is mediated by IL-1.^[20] IL-1 also induces the upregulation of insulin-like growth factor-1 expression on ECs.^[21] IL-1 β has been shown to stimulate PDGF release from human umbilical vein ECs.^[22] Because the inflammatory reaction elicits a cascade of growth responses, approaches aimed at attenuating this initial inflammatory reaction may improve the long-term graft patency.

Endothelial and Smooth Muscle Cell Ingrowth

Native uninjured blood vessels possess an endothelium that continuously releases bioactive substances that inhibit thrombosis, promote fibrinolysis, and inhibit SMC proliferation to help maintain normal blood flow. After synthetic graft implantation, tissue ingrowth originates from the cut edge of the adjacent artery. Unlike many animal models in which there is often complete endothelialization of synthetic grafts, those implanted into humans exhibit only limited EC ingrowth confined to the first 1–2 cm of the graft at the anastomotic ends. Occasional islands of ECs present in the midportion of implanted grafts at significant distances from the anastomosis have been described and suggest that other mechanisms of graft endothelialization may be important. Interstitial tissue ingrowth, accompanied by microvessels from perigraft tissue, is one proposed mechanism for graft endothelialization on high-porosity ePTFE and bioresorbable prostheses.^[23–26] Deposition and proliferation of circulating ECs or stem cells is another mechanism supported by the finding of discrete isolated islands of ECs without transmural microvessels present on the inner surface of impervious Dacron grafts in a canine model and in a 24-month human Dacron graft explant.^[27–29]

ECs growing onto prosthetic graft surfaces undergo phenotypic modulation. These phenotypically altered activated cells secrete bioactive substances that may promote thrombogenesis and SMC growth. Activated ECs increase PDGF synthesis and secretion. Subintimal SMC proliferation occurs predominantly in areas with an endothelial lining, namely, the perianastomotic area.^[30] This region is an area of chronic EC injury, with highly complex biomechanical activity and chronic inflammation. SMC proliferation begins as early as two days post implantation, which then peaks at two weeks and tapers down thereafter. On the other hand, neointimal volume continues to increase by synthesis of extracellular matrix material, which ultimately on occasion may result in the formation of a stenotic lesion.^[31] Neointima formation in the middle portion of a graft is dependent on transmural ingrowth from surrounding perigraft tissue. Like ECs, SMCs grown onto prosthetic grafts are functionally altered,

producing significantly higher amounts of PDGF, which may contribute to the development of intimal hyperplasia.^[32] In addition, inflammatory mononuclear phagocytes and foreign body giant cells produce a variety of growth-modulating substances including PDGF, FGF, and TGF- β , all of which perpetuate SMC proliferation and production of extracellular matrix components.

GRAFT CHARACTERISTICS AFFECTING VASCULAR HEALING

Chemical composition, construction parameters, and biomechanics are the intrinsic characteristics of a vascular graft that predominantly influence its interaction with its host and, in turn, determine its fate.

Porosity

A direct correlation between porosity and tissue ingrowth has been well established in textile grafts where greater tissue ingrowth is seen in high-porosity grafts such as knitted Dacron versus low-porosity grafts such as woven Dacron.

The rate of tissue ingrowth on ePTFE is dependent upon graft permeability. Clowes has shown in a baboon model enhanced tissue ingrowth with complete endothelialization in ePTFE grafts with a 60- to 90-micron internodal distance.^[23] Transinterstitial capillary ingrowth did not occur in 30-micron internodal distance ePTFE grafts. In a canine model, 90-micron internodal distance ePTFE grafts demonstrated greater endothelial cell coverage and higher patency rates compared with similarly treated 30-micron internodal distance ePTFE grafts.^[33] In contrast, a small preliminary human trial using the more widely expanded ePTFE failed to show any significant advantage in platelet deposition over standard 30-micron internodal distance ePTFE grafts.^[34] In addition, transinterstitial ingrowth may differ between biomaterials with equal porosity, e.g., PGA versus Dacron.^[35] Greisler has demonstrated significantly greater transinterstitial capillary ingrowth and subsequent endothelialization in lactide/glycolide woven grafts compared to Dacron grafts implanted in rabbit and canine models.^[26,36] High-porosity grafts have the practical disadvantage of requiring preclotting to avoid transmural blood ooze after implantation.

Compliance

Atherosclerotic arteries have a wide range of compliance characteristics. The compliance mismatch between arteries and grafts results in flow disruption,

which is thought to influence pseudointimal hyperplasia at the anastomosis.^[37] Numerous attempts at improving graft compliance have focused on increasing biomaterial flexibility. Polyurethane grafts have compliance characteristics more similar to normal arteries, compared with ePTFE.^[38] Its corrugated structure significantly reduces graft stiffness and improves compliance.^[39] Placement of a vein cuff at the distal anastomosis between prosthetic graft and native artery has been shown to improve the compliance mismatch, possibly contributing to improved long-term patency rates.^[40–42] Decreased neointimal thickness in the perianastomotic area has also been shown in animal models.^[43] Use of the distal vein cuff has gained popularity in femoropopliteal arterial reconstructions utilizing prosthetic material, especially in below-knee bypasses.

Arterial compliance variability changes over time, resulting in the development of a hypercompliant zone in the region of the anastomosis.^[44] In addition, elastic grafts lose their compliance over time due to a fibroplastic reaction that occurs following implantation.^[44]

Flow Surface Characteristics

The interfacial reactions between blood and the graft biomaterial surface are dependent on surface chemical and physical properties. These properties include surface charge, surface energy, and the degree of roughness. A negative surface charge inhibits thrombosis, whereas a positive charge and heterogeneity of charge density distribution are thought to be thrombogenic. Several approaches to modifying flow surface characteristics have been developed that stabilize the thrombotic reaction. These approaches include the modification of surface properties and incorporation of antiplatelet and/or anticoagulant substances onto the graft surface, resulting in the endothelialization of the blood contact surface.

GRAFT FAILURE AND GRAFT INFECTION

Synthetic vascular graft occlusion has several etiologies. Immediate graft failure is often the result of technical problems during implantation or of a host hypercoagulable state. Failure in the first month following graft placement is likely the result of thrombosis in the setting of high distal flow resistance. Anastomotic pseudointimal hyperplasia is the most common etiology of graft failure six months to three years post graft placement. Later graft occlusions are usually due to the progression of distal atherosclerotic disease. Thus, thrombogenicity and intimal hyperplasia represent the most common intrinsic causes of graft failure amenable to intervention by manipulation

of graft construction, composition, and/or by induced alterations in blood and tissue reactions to the implanted graft.

Clinical stenosis and patency rates reflect these intrinsic problems of synthetic grafts. Aortic reconstruction involves the placement of large-caliber Dacron or ePTFE grafts. Because of the relatively high flow rates and low outflow resistance, these grafts have an 85–95% five-year patency rate.^[45,46] Compared with smaller caliber grafts used in the infrainguinal and infrapopliteal regions, the results are less than optimal with one- and three-year patency rates for ePTFE grafts used in infrapopliteal bypasses of 43% and 30%, respectively.^[47] These small-caliber grafts are especially susceptible to anastomotic intimal hyperplasia and are more prone to early thrombosis due to lower flow rates and higher resistance outflow vessels.

Prosthetic graft infection is reported to occur in 1–5% of implanted grafts. These infections are often catastrophic, resulting in amputation rates as high as 50% and 25–75% mortality.^[48,49] Development of prosthetic materials resistant to bacterial infection remains an active area of research.^[50] Penicillins and cephalosporins have been noncovalently bound to Dacron and ePTFE surfaces with subsequent increased resistance to *Staphylococcus aureus* infection. Rifampin-bonded gelatin-sealed Dacron grafts have also been shown to provide increased protection against bacterial colonization.^[51,52]

CONCLUSION

A firm understanding of graft physiology and its pathological processes is critical to the development of efficacious vascular substitutes. Investigations into the underlying biochemical and cellular mechanisms involved in the graft-healing process has yielded a firm understanding of graft physiology and the pathological processes involved in graft failure. Utilization of numerous biochemical, molecular, biological, and tissue-engineering techniques, with the goal of improving long-term graft patency, will result in the development of novel vascular substitutes and allow a continued increase in our understanding of the graft-healing process.

Department of Radiology, University of Washington, Seattle, Washington, U.S.A.

INTRODUCTION

The term vascular imaging describes the use of different imaging modalities to visualize the arterial and venous system for the diagnosis of various diseases involving the vascular system. In 1929, Dos Santos reported the first iodine-based contrast arteriogram in a patient, approximately 34 years after the discovery of the X ray and almost simultaneously with the description of the first iodinated contrast medium. For the first time, it was possible to visualize arteries in a living human being. Since then, not only has the number of imaging methods increased, but each one continues to undergo improvement and refinement of its use in medical diagnosis. The classical angiography was aimed at identifying luminal changes due to vascular disease. These techniques, generally referred to as angiograms, do not provide extraluminal information. Newer applications like ultrasound, computer tomography, and magnetic resonance tomography are not only able to noninvasively image lumen from arteries such as the aorta (2.5 cm in diameter) as well as arteries as small as 1 mm in diameter, but also provide additional information about the arterial wall. This is especially important, as vascular disease starts in the wall (extraluminal), and only advanced vascular disease leads to severe lumen narrowing.

The need for vascular imaging is immense. In the western world, atherosclerosis is the most common cause of death, resulting in coronary heart disease, myocardial infarction, stroke, and peripheral vascular disease. Vascular imaging is able to provide important information about the extent of the disease and has become an irreplaceable tool in the clinical practice, not only in atherosclerosis imaging. Vascular imaging is routinely used before liver and renal transplantation, for surgical procedure planning of solid tumors, in the diagnosis of thrombosis or congenital heart disease, and many more. In this article, we will give an oversight of the currently used techniques in vascular imaging, their advantages and disadvantages, and future perspectives of the techniques.

ANGIOGRAPHY

Angiography was the first vascular imaging modality that entered the clinical practice. In ordinary X-ray projection images, blood vessels are hardly visible due to the very low contrast between vessels and the surrounding tissue. This contrast is enhanced by the injection of a radiopaque contrast medium into the vessels to be diagnosed. Currently, nonionic iodinated contrast agents are used. Typical reactions to contrast media include nausea and/or vomiting, scattered to extensive urticaria, bronchospastic reaction, hypotension (isolated) with compensating tachycardia, anaphylactoid reaction, vagal reaction, cardiovascular collapse, convulsion, and seizure. The rate of side effects is 0.2% with deaths occurring approximately 1 in 100,000 applications.^[1] Conventional arteriography uses small flexible catheters that are placed in the arterial system usually via puncture of the femoral artery in the groin. With the use of fluoroscopy for guidance, catheters of various sizes and shapes can be manipulated selectively into virtually every major artery. Contrast injection is performed by hand or by mechanical injector and is accompanied by a timed rapid-sequence filming or digital computer acquisition of the fluoroscopic image. The result is a timed series of images depicting the contrast flow through the artery injected and the tissues that the artery supplies. Conventional venography is performed by contrast injection of veins via distal puncture or selective catheterization.

Before the introduction of digital techniques, film angiography was the method used for all X-ray angiography. According to Mistretta,^[2] film combines excellent spatial resolution (five- or six-line pairs per millimeter) with a large available field of view (FOV), and high temporal resolution is available in cine mode.

Disadvantages of X-ray film angiography^[2] include increased imaging time due to film development requirements, the need for larger contrast agent doses than required for digital systems, and the absence of real-time subtraction capabilities so that in clinical practice, digital subtraction angiography (DSA) is the method of choice. DSA is a powerful technique for the

visualization of blood vessels in the human body and is able to depict blood vessels with a diameter of 500 μm . In DSA imaging, a sequence of images is taken to show the passage of a bolus of injected contrast material through one or more vessels of interest (see Fig. 1). The contrast distortions in these live or contrast images are largely removed by subtracting an image taken prior to the arrival of the contrast medium (referred to as the mask image). Intraarterial (IA)-DSA is used for an increasing number of X-ray angiographic procedures, e.g., stent placement or percutaneous angioplasty for the treatment of stenosis in various vascular beds, thrombolysis or mechanical thrombectomy for treatment of thrombosis, and embolotherapy to stop or prevent bleeding or to destroy/occlude neoplasm or vascular abnormalities.

The advantages of IA-DSA according to Mistretta,^[2] include reduced contrast agent requirements and smaller catheters relative to conventional angiography. It has good spatial and temporal resolution and facilitates diagnostic and interventional procedures in which the immediate availability of subtracted images and road-mapping capabilities are helpful. Selective imaging of vessels can be accomplished. The overall frequency of catheterization-related complications is about 7–9%; the risk of a major complication is about 3 to 6%.^[3] Aside from its invasiveness, the visual interpretation of angiograms exhibits significant observer variability and correlates poorly with post-mortem examination.^[4] Angiography depicts arteries as a planar silhouette of the contrast-filled lumen and any arbitrary angiographic projection can misrepresent

Fig. 1 Angiography of the aortic arch in DSA technique; bones are subtracted. The chevron shows the tip of the intraarterial catheter. The cross marks a pseudoaneurysm that developed after traumatic injury. (Courtesy Dr. E. Hoffer, Harborview Medical Center, Seattle.)

the true extent of luminal narrowing. Mechanical interventions may increase lumen irregularity, impairing the accuracy of angiography.^[5] An assessment of lesion severity requires the measurement of luminal diameter and an uninvolved normal segment. Angiography does not provide information about the arterial wall and is confounded by outward remodeling of the vessel wall, which may conceal early atherosclerosis.

COMPUTED TOMOGRAPHY ANGIOGRAPHY (CTA)

Early development of X-ray computed tomography (CT) took place in the 1960s and the first head CT scanner was introduced in 1972. For their groundbreaking work in CT, Godfrey Hounsfield of Britain and Allan Cormack of the United States earned the Nobel Prize for medicine in 1979. CT images are derived from hundreds of thousands of measurements of the X-ray attenuation through a thin (0.5–10 mm) section of the patient. A narrow, well-collimated beam of X rays is generated on one side of the patient and as the X-ray beam passes through the patient, it is attenuated by absorption and scatter. The net attenuation of the slice is then measured by sensitive X-ray detectors on the opposite side of the patient. After repeatedly measuring attenuation from many different directions by rotating the X-ray tube around the patient, CT numbers are extracted for each pixel in the image by a computer algorithm.^[6] CT numbers reflect the local attenuation coefficient and are expressed in Hounsfield units (H), named for the inventor of CT. Voxel dimensions are determined by the computer algorithm chosen for reconstruction and the thickness of the scanned slice.

In CTA, as in conventional X-ray angiography, intravenous radiopaque contrast agents are needed to demonstrate vascular anatomy and vessel patency. Currently used slice thickness depends on the vascular bed and is 0.5 mm for the coronary arteries up to 5 mm sections for the aorta. The most common indications for CTA are the evaluation of the thoracic and abdominal aorta, the diagnosis and follow-up of pulmonary embolism, and for surgical therapy planning.

A distinct benefit of CTA over DSA is the ability to obtain a three-dimensional (3D) reconstruction of vascular anatomy (see Fig. 2). Conventional (non-helical) CT obtains 3D image data one slice at a time. The patient holds his or her breath, a slice is taken, the patient breathes, the table moves, and the sequence is repeated. Such sequential acquisition and reconstruction of multiple parallel sections constituted the first truly three-dimensional (3D) medical imaging modality. This technique is, however, time-consuming, and multislice spiral CT is currently the state of the art

Fig. 2 Three-dimensional computer tomography angiography from the aorta and renal and iliac arteries in volume-rendering technique. The aorta (cross) has a large aneurysm and a dissection membrane (chevron) is visible.

CT unit. Helical CT, also called spiral CT, is performed by moving the patient table at a constant speed through the CT gantry while scanning continuously with an X-ray tube rotating around the patient. A continuous volume of image data is acquired during a single breath-hold. Multislice CT is based on the acquisition of more than a single slice at a time with the use of multirow detector systems. Multislice CT dramatically improves the speed of image acquisition, enables scanning during optimal contrast opacification, and eliminates artifacts caused by misregistration and variations in patient breathing.^[7] Volume acquisition enables retrospective reconstruction of multiple overlapping slices, improving visualization of small structures, and allowing high-detail three-dimensional CT angiography.^[7]

Advantages of CTA^[2] include the ability to retrospectively reproject from arbitrary angles (vs. X-ray angiography). The information obtained is anatomic and is not subject to the problems of spin saturation and intravoxel dephasing that poses difficulties in MR angiography. Scan times are shorter compared to MRI. The intravascular injection offers a reduction in invasiveness relative to IA-DSA. Spiral CT also provides extraluminal information that IA-DSA does not. Disadvantages of this technique^[2] are radiation

exposure, worse soft tissue contrast compared to MR angiography, and more side effects of the nonionic iodinated contrast agent used for CTA compared to the paramagnetic contrast agents used for MR angiography.

ULTRASOUND (US)

Vascular Ultrasound

Ultrasound (US) has come into widespread use in clinical practice for the assessment of the vascular tree since the parallel development of Doppler US and real-time two-dimensional B-mode US, beginning around 1975. Duplex US is a combination of 2-D gray-scale imaging and Doppler velocity spectral measurements obtained in a selectable region of interest (ROI) on the gray-scale image. This technique, primarily because of its noninvasiveness and low cost, is used or is under investigation for a wide variety of diagnostic screening applications, including intra- and extracranial vessels, the coronary arteries, abdominal vessels, and peripheral vessels. A duplex US examination involves two components:^[8]

(I) Real-time, B-mode imaging, which results in a two-dimensional gray-scale image that is continuously updated (hence the term real-time). The term B-mode is a shortened form of the term brightness modulation, which describes how the two-dimensional image is produced as a result of the brightness of each individual pixel in the image display (see Fig. 3). This brightness is in turn dependent on the intensity of the reflected US signal. The basic physics is well described elsewhere.^[9] Essentially, different tissues have varying acoustic properties and reflect sound differently. The US detectors in the probe receive signals reflected from these different tissues and an image is produced from this information by computer processing. Advances in gray-scale US have resulted in much improved anatomic definition, and the extent and nature of intimal thickening and plaque formation can be well seen. Calcification and air may prevent a satisfactory B-mode image from being produced, because sound energy is nearly completely absorbed at interfaces between soft tissue and bone/air, causing an acoustic shadow. Typical spatial resolution for a 3.5-to-5 MHz transducer is 0.5-to-1 mm axial and 2-to-5 mm lateral. Higher frequencies have smaller wavelengths and provide better axial resolution; however, the imaging depth is reduced. Lateral resolution is determined by the beam diameter emanating from the transducer element(s) and varies greatly with depth.

(II) Doppler assessment. The physics is well described elsewhere.^[9] Basically, moving blood generates a Doppler frequency shift in the reflected sound from

Fig. 3 (A) B-Mode ultrasound image showing a heterogeneous plaque with calcific shadowing (arrow) in the carotid artery. ICA = Internal Carotid Artery, DCCA = Distal Common Carotid Artery. (B) At the top, B-Mode ultrasound image that shows the flow in color Doppler mode of the left carotid artery, and at the bottom, corresponding duplex waveform of the internal carotid artery. The peak systolic velocity is increased to >300 cm/s, suggesting a 50–79% diameter reduction. (Courtesy of B. Mraz, J. Wigen, and J. Primozych, Diagnostic Vascular Service, University of Washington Medical Center, Seattle.)

insonated red blood cells and this frequency shift can be used to calculate the velocity of the moving blood. Low resistance vessels such as the internal carotid and renal arteries are characterized by high diastolic flow, whereas high resistance vessels such as the external carotid and lower and upper limb arteries are characterized by low or absent diastolic flow with early diastolic flow reversal. Stenosis in any vessel is characterized by both an increased range of velocities due to turbulent flow (spectral broadening), as well as an increase in systolic and diastolic velocities (see Fig. 3B). Tables have been produced and modified with experience to relate the systolic and diastolic velocities at the stenosis with that in the disease-free proximal vessel to accurately quantitate the percentage stenosis. Although there are many sources of error and artifact, the single most important technical aspect is that the interrogating angle must be <60 degrees or major errors will result.

An additional degree of convenience is provided by color Doppler flow imaging, in which average blood velocity is color-coded and superimposed on a gray-scale image. Regions of complex flow are demonstrated by irregularities in the color pattern. The most common indications of vascular ultrasound are the evaluation of the carotid, intracranial, and peripheral arteries; diagnosis of venous thrombosis; and evaluation of liver and renal transplants. Advantages of vascular US^[2] include absence of ionizing radiation and real-time noninvasive imaging that provides intra- and extraluminal information in a relatively inexpensive and widely available package. Ultrasound is accurate in diagnosing carotid artery stenosis compared to DSA,^[10] although it has been demonstrated to have lower discriminatory power compared with MRA in diagnosing 70–99% stenosis.

One of the principal limitations of US is the need for an appropriate acoustic window. Regions of

intervening air or bone prevent acquisition of diagnostic information in a substantial number of potential vascular sites. Other disadvantages include limited FOV, dependence on Doppler angle, dependence on operator skill, and less morphological information about the arterial wall compared to MRI.^[11]

Intravascular Ultrasound

In order to obtain the high spatial resolution possible at ultrasonic frequencies of 30–40 MHz (ca. 0.1 mm), the transducer is mounted at the tip of an intravascular catheter so that the blood vessel walls and associated pathologies can be examined at close range. This minimizes loss due to attenuation of ultrasound.

Nissen et al.^[4] reported on intravascular US of the coronary arteries, which they found to be a promising technique without significant risk. In a study of angiographically normal sites in coronary artery disease patients, Nissen et al. found that more than 75% had atherosclerotic abnormalities by US, emphasizing that coronary disease is often more diffuse than indicated by angiography, and undermining the need of imaging modalities that provide intra- and extraluminal information. One of the limitations of intravascular US of the coronaries (besides its invasiveness) is that the catheter size is limited to about 1 mm, which does not permit imaging of tight stenosis and precludes examination of many lesions before angioplasty.^[4]

MAGNETIC RESONANCE ANGIOGRAPHY (MRA)

Paul C. Lauterbur and Peter Mansfield earned the Nobel Prize for medicine in 2003 for their discoveries in magnetic resonance (MR) imaging in the 1970s. MR is a potent technique that produces tomographic

images by means of magnetic fields and radiowaves. Although CT evaluates only a single tissue parameter—X-ray attenuation—MR analyzes multiple tissue characteristics including hydrogen (proton) density, T1 and T2 relaxation times of tissue, and blood flow within tissue. The soft tissue contrast provided by MR is substantially better than for any other image modality. Differences in the density of protons available to contribute to the MR signal discriminate one tissue from another. The complicated physics of MR is beyond the scope of this article.

MRA was experimentally introduced in the mid-1980s to visualize major blood vessels of the neck, abdomen, and thigh. Since the introduction, three principal MRA techniques have been used in clinical imaging of vascular disease. These are time-of-flight MRA (TOF-MRA) and phase-contrast MRA (PC-MRA)—where no injection of contrast material is needed—and more recently, the contrast-enhanced MRA (CE-MRA), using intravenous injection of gadolinium contrast. These so-called bright-blood techniques enhance the signal intensity of flowing blood; thus, the lumen appears hyperintense relative to the adjacent vessel wall. Black-blood techniques refer to MR techniques that suppress the signal from flowing blood.^[12] The most common indications for MRA are the evaluation of the thoracic and abdominal aorta, as well as the evaluation of cranial and peripheral blood vessels.

Time of Flight (TOF)

TOF relies on inflow enhancement. Here, static tissue within a 2-D slice or 3-D slab gives a low signal due to the saturation effect of the long train of closely spaced (short TR) excitation pulses used in forming the image.^[13] On flowing into the imaging volume, unsaturated blood appears hyperintense relative to the static surrounding. Unfortunately, this bright-blood appearance depends on flow velocity, and the path of the vessel through the image volume (i.e., the number and strength of excitation pulses experienced). Efforts in the early 1990s focused largely on maximizing the contrast between blood and parenchyma. This involves reducing the saturation of blood by the succession of excitation pulses experienced while in the imaging volume and simultaneously maximizing the saturation of background tissue signal. This is notable in 2-D acquisition where a large flip angle minimizes the static tissue signal. Whereas this gives maximal inflow effect, segments of the vessel lying within the plane rapidly become saturated, causing signal loss. Using a lower flip angle and a 3-D acquisition, the rate at which blood becomes saturated is slowed, although the degree of background saturation is also

reduced. An intermediate design is that of a series of thin 3-D volumes (e.g., multiple overlapping thin slab angiography—MOTSA) rather than a single thick slab.

Phase-Contrast Magnetic Resonance Angiography

In PC-MRA, the contrast between flowing blood and the surrounding stationary tissue is generated by the flow-induced phase shift of the moving blood. When a magnetic spin in flowing blood is subjected to a gradient magnetic field, it acquires a phase shift that is proportional to its velocity. In the presence of a pair of bipolar gradient lobes, the stationary spins do not develop a net phase shift. Because the flow-induced phase shifts are proportional to the signal intensity, flow direction and velocity can be derived directly from PC data.

Contrast-Enhanced Magnetic Resonance Angiography

Both TOF and PC-MRA techniques are essentially noninvasive and rely on inflow enhancement or phase shift to generate contrast between flowing blood and stationary tissues. There are several disadvantages associated with these techniques. One is inplane saturation, which can be a problem with slow flowing or tortuous arteries. A second is turbulence-induced signal loss in a region of narrowing. Imaging times also tend to be long, especially for covering a large vasculature. A powerful means of maximizing blood signal intensity is through the administration of a T1 shortening contrast agent. This means the inflow pressure is not as essential as in TOF-MRA or conventional contrast arteriography. First-pass contrast-enhanced studies have become widely accepted for abdominal, thoracic, and peripheral MRA since their first demonstration by Prince in 1993^[14] (see Fig. 4). With the T1 of blood reduced to less than 50 ms (i.e., shorter than fat), very heavily T1-weighted images can be acquired in which blood will appear white because of its high signal intensity relative to the saturated surrounding tissues. As with conventional angiography, background suppression can be improved by the subtraction of a precontrast mask from the enhanced study.^[15] Following venous injection, maximal arterial enhancement is achieved by a short bolus delivery. The period of arterial enhancement before the arrival of contrast agent in neighboring veins or its uptake in surrounding tissue forms the effective time window for contrast enhanced arterial imaging.^[16] Three-dimensional CE-MRA with short echo times reduce the examination time,

Fig. 4 Contrast-enhanced magnetic resonance angiography as a multiplanar reconstruction. The cross shows the ascending aorta; the chevron shows the descending aorta. This image also shows the inferior (up arrow) and superior caval (down arrow) vein.

minimize clip artifacts and artifacts caused by movement. Breathheld data acquisition did become possible with the use of improved gradient systems permitting considerable reductions in the minimum repetition (TR) and echo times (TE). The implementation of fast 3-D gradient echo sequences on higher-performance systems permit the acquisition of complex 3-D data sets within the confines of a comfortable breathhold interval under 30 s;^[16] in some of the newer generation systems, even under 10 or 5 s. This kind of dramatic shortening of scan times has even allowed collecting temporally-resolved 3-D data sets. Temporal information regarding the transit of the paramagnetic contrast agent through the vascular system can be harvested.

Black-Blood Techniques

These sequences are ideal for plaque imaging because the conspicuity of the vessel wall is increased when adjacent to a hypointense lumen, and the echo and repetition times can be varied to optimize visualization of specific plaque components.^[17] Black-blood, fast spin-echo-based methods offer particular advantages in cardiac imaging compared to white-blood imaging,^[18] including an exclusive visualization of the coronary lumen, reduced susceptibility to turbulent flow in the regions of focal stenosis, a reduced sensitivity to artifacts induced by metallic implants, and a high contrast-to-noise ratio.

Advantages and Disadvantages of MRI

Advantages of MRA according to Mistretta include its noninvasiveness, ability to image vessels in a broad range of sites, absence of radiation (compared to CTA), ability to obtain retrospective projections (compared to DSA), and the possibility of obtaining flow and velocity information. Additionally, MRI is able to provide information about the composition and morphology of the arterial wall, information that is crucial in the assessment of atherosclerosis. Side effects of the paramagnetic contrast agent are rare (ca. 0.06%,^[11]). Paramagnetic contrast agents are non-nephrotoxic and have a low incidence of allergic reactions. Hence, they are safe for use in patients with renal insufficiency as well as patients with a history of allergic reactions to iodinated contrast media.

Disadvantages include artifacts due to surgical clips or metallic stents, patient motion, and pulsatility. Typically, trade-offs must be made because of the inability to choose imaging parameters that simultaneously maximize FOV, signal-to-noise, and spatial resolution. Contraindications are pacemaker, intracranial aneurysm clips, intraocular metal, recent stents (less than three weeks), and claustrophobia (relative contraindication).

ANGIOSCOPY

Angioscopy is an intravascular imaging method in which a fiberoptic device is placed within the arterial lumen to provide a view of the vessel lumen and internal wall. This technique relies on high-pressure flushing with saline solution to provide a temporary FOV free of blood. Although spatial resolution is high (up to 200 μm), the information is limited to the surface and the technique is invasive, highly operator-dependent, and currently not approved by the Food and Drug Administration for use in the United States.

IMAGE PROCESSING

Developing in parallel with improvements in image acquisition technology have been computer graphics hardware and software tools that enable sophisticated image processing and display. Currently, besides the axial (cross-sectional) view, four image reconstruction techniques have been used: maximum intensity projection (MIP), curved multiplanar reconstruction (MPR), shaded-surface display, and volume rendering.^[19] Postprocessing of CT or MRA image data is almost a necessity in clinical applications for demonstrating spatial positioning, connectivity of vessels, and correlative MR/CT imaging. These algorithms have

the advantage that projection angles can be arbitrary. Hence, the 3D data set can be viewed from multiple angles. The full three-dimensionality inherent to the technique can be exploited only if the data are viewed on a work station. Analysis of the images should, however, exploit the fact that truly three-dimensional data sets are acquired. Analysis should therefore not be limited to viewing maximum intensity projections or surface shaded display, but instead should include thorough evaluation of reformatted source images in all three planes.

FUTURE DIRECTIONS

Angiography

In an article recently published by Katzen,^[20] the author made the following predictions regarding catheter-based angiography:

(I) Most diagnostic angiography will be performed with noninvasive methods. MRA will be the predominant method in the peripheral circulation, with CTA having an important role in aortic imaging and coronary imaging. MRA will have increased use for elective diagnosis and in clinical emergencies.

(II) Catheter-based angiography will have an important role as an adjunct or preliminary procedure related to interventions. This is significant for planning catheter development and functionality of future angiographic equipment.

(III) The need for angiographic therapy will increase as a result of a variety of factors, including aging population, early diagnosis, and increasing acceptance of less invasive therapy.

(IV) Interventionists should be considering and planning for vascular imaging devices (MRA, CTA, and US) to be included as part of the interventional sections and the workload.

Computer Tomography Angiography

It is expected that CTA with multidetector CT scanners will result in better image quality than with the single detector CT scanners, because smaller detector elements improve resolution and faster scan rotation and multiple detectors increase the coverage and/or decrease the scan duration.^[21] The advantages of a shorter scan duration are threefold: 1) less contrast material (30–50%) can be used; 2) the injection rate can be increased with a concomitant better enhancement of the vessels; and 3) most of the data can be acquired during a determined phase (arterial phase in CTA).^[21] The latest multislice CT system^[22] offers simultaneous acquisition of up to 16 submillimeter

slices and gantry rotation times of less than 0.5 s. Large scan ranges in short examination times with reduced amounts of contrast agents can be covered by 16-slice CT systems. Owing to submillimeter slice width and optimized in-plane resolution, almost isotropic voxel sizes of $0.5 \times 0.5 \times 0.6$ mm can be realized for vascular imaging.

Duplex Ultrasound

Newer developments include the use of power Doppler, three-dimensional imaging, contrast agents, and harmonic imaging. Power Doppler is the depiction of flow based on the integrated power of the Doppler spectrum rather than the mean Doppler frequency. It is therefore more sensitive in flow detection than is standard color Doppler and permits detection of low flow. Three-dimensional imaging uses advanced computer technology to produce a three-dimensional image of the area scanned. The role of these latter techniques is not yet established.^[23] Contrast agent has recently become available and consists of biodegradable microbubbles. They enhance vascularity and may prove useful in improving accuracy in certain areas such as assessment of the renal arteries. Harmonic imaging promises to improve sonographic imaging, particularly of structures that are degraded by movement, such as the heart and proximal renal vessels. With harmonic imaging, the US machine transmits the sound beam at a certain frequency, but receives at the resonant (harmonic) frequency, which is twice that of the transmitting frequency. Consequently, the signal-to-noise ratio is improved because, in theory, only the structures being imaged will produce the resonant frequency.^[24]

Magnetic Resonance Imaging (MRI)

Of all the described noninvasive imaging modalities, MRI is the most promising tool for vascular imaging. Although similar in principle to spiral CT angiography, contrast-enhanced MRA holds considerable advantages. Beyond the absence of ionizing radiation and the ability to depict large vascular territories in 3-D imaging volumes, paramagnetic contrast agents are usually better tolerated than iodinated contrast media. It is accurate in diagnosing stenosis compared to DSA and provides extraluminal information. Whole body MRA of the entire vascular tree from the supraaortic to the pedal arteries using a moving table is feasible in 72 s.^[16] There will be further improvement in scan time and/or resolution with the new high-field scanners (3T). Currently, the focus of research is directed to: 1) MRI-contrast agents; 2) plaque imaging; and 3) interventional MRA.

MRI contrast agents

Currently, extracellular nonbinding gadolinium (Gd) chelates that have regulatory approval for use in humans have been the contrast agents of choice for MRA. Modified paramagnetic Gd-based agents with varying degrees of protein as well as superparamagnetic compounds are currently under clinical evaluation.^[25] Some new agents have higher relaxivity and different routes of excretion, but still distribute into the extracellular spaces. Blood pool or intravascular contrast agents are large enough or bind to large enough molecules when injected that they do not leak out of the capillaries, but stay within the intravascular compartment.

In view of the rapid progress of techniques based on the use of extracellular agents, the future of intravascular contrast agents for morphologic imaging of the arterial vascular tree remains doubtful. At this time, it appears likely, however, that these agents will enhance imaging of the venous system and of the coronary arteries.^[16]

Plaque imaging

Traditionally, the degree of luminal stenosis has been used as a measure of atherosclerotic disease severity. In 1988, however, Ambrose et al.^[26] demonstrated in an angiographic study that mild-to-moderate coronary stenosis may lead to acute myocardial infarction, and suggested that luminal narrowing was not the sole predictor of clinical events. Over the past decade, notable advances have been made in our understanding of vascular biology. It is now commonly accepted that factors other than the degree of luminal narrowing, such as plaque burden, plaque morphology, and plaque composition, are objective noninvasive measurements in the assessment of atherosclerotic disease. Currently, the predominant noninvasive imaging modalities being investigated for this purpose are US and MR imaging. Although carotid US is the most widely performed noninvasive test in the evaluation of a patient suspected of having carotid arterial disease, the modality is highly operator-dependent, and presently is not capable of consistent demonstration of plaque morphology.^[11] In contrast, high-resolution MRI seems to be a promising noninvasive tool to evaluate plaque burden, morphology, and composition. For instance, a protocol generating four contrast-weighted images (TOF, T1W, PDW, T2W; best-in-plane pixel size $0.25 \times 0.25 \text{ mm}^2$) has been used successfully to identify the lipid-rich/necrotic core^[27] and the status of the fibrous cap^[28] (see Fig. 5).

Fig. 5 High-resolution magnetic resonance plaque imaging with four contrast-weighted images from the same location. The arrow shows the normal lumen and wall from the external carotid artery; the cross shows the highly stenosed internal carotid artery; the chevron shows the arterial wall that is massively enlarged.

Interventional MRA

Magnetic resonance imaging—with its superior soft tissue contrast, multiplanar imaging capabilities, and specific vascular applications—is a promising modality in vascular interventions, such as percutaneous transluminal angioplasty, stent implantation, or arterial chemoembolization. It requires high spatial resolution with an optimized real-time imaging.^[29] Numerous technical, hardware, and software developments will be needed before interventional vascular MRA reaches clinical practice.

CONCLUSIONS

Vascular imaging is a dynamic field with a variety of imaging modalities, and each of these modalities has its value in the clinical practice. The current developments are directed at the acquisition of even more detailed intra- and extraluminal information to obtain clinically adequate information in a minimally invasive way. For each clinical indication, it should be considered which image modality is best suited to satisfy the clinical needs in a cost-effective way. Whereas some imaging techniques need only limited training and experience and can be applied almost anywhere, others require specific training and experience and can only be

performed in specialized centers. New developments in soft- and hardware will further improve our understanding of vascular disease and might open new areas for diagnosis, prevention, and treatment.

INTRODUCTION

Tissue engineering is touted as the new medical alchemy. Using a combination of cells, especially stem cells, and scaffold matrices, it offers a novel approach that mimics embryological regeneration and promises not only a substitute for conventional reconstructive procedures, but for prostheses and organ transplantations. Frenzied hype and hope blur the line between science and commercial opportunism. Failed biotechnology companies have taught the market salutary lessons. At the moment, the only approved laboratory-prepared tissue engineering products are cartilage and relatively thin structures such as skin, which either do not require a blood supply or can be rapidly revascularized upon implantation.

A pivotal problem facing tissue engineers is that three-dimensional tissues require a functional vasculature. All cells must have access to a microcirculatory system perfused by circulating blood, in order to supply sufficient oxygen and nutrients to sustain their survival, proliferation, and maintenance of biological functions and to remove wastes. Few studies have investigated the production of a microcirculation in engineered tissues *in vitro*; the bulk of work addressing this issue has been undertaken *in vivo*. The current inability to vascularize large transplantable engineered tissues has resulted in two *in vivo* approaches. One approach is to vascularize constructs by the extrinsic derivation of a microcirculation, resulting from ingrowth of capillaries from the recipient vascular bed.^[1,2] The second approach favored by our Institute is to engineer constructs that develop and grow with their own independent capillary network, i.e., an intrinsic microcirculation that derives from a centrally placed macrovascular arteriovenous (AV) loop^[3,4] or flow-through pedicle^[5] placed in a chamber. An intense angiogenic sprouting occurs around the extraluminal surface of the AV loop or flow-through pedicle, probably in response to its ischemic environment. Depending on the anatomical site of the chamber and the addition of exogenous matrix, cells, or

differentiating agents, the developing product can be manipulated to recreate the full complexity of a tissue that would be appropriate for specific reconstructive or organ replacement purposes. To date, we have been able to produce living flaps of fibrous tissue,^[3,4,6] adipose tissue,^[5] skeletal muscle, and organoids of pancreas and liver (unpublished observations).

In this article we will define the major processes involved in new blood vessel growth in adults and the growth factors that control these processes. The use of these growth factors in tissue engineering applications will also be discussed. Our main aim is to describe the work that has been undertaken *in vitro* and *in vivo* in constructing vascularized tissue constructs. The *in vivo* discussion will explore both extrinsic and intrinsic modes of vascularization.

MECHANISMS OF VESSEL GROWTH

In vivo vascularization in general can proceed via four mechanisms: angiogenesis, vasculogenesis, intussusception, and inosculation, all of which are applicable to tissue-engineered constructs. When a new capillary network is required, a complex, coordinated sequence of events involving a complicated interplay of spatial and temporal signals of both genetic and microenvironmental origin guides the vascular assembly process^[7] and may involve any or several of the four mechanisms listed earlier.

The most commonly recognized process is that of angiogenesis, which involves preexisting capillaries, extracellular matrix (ECM) components, growth factors, and signaling molecules. Angiogenesis plays a vital role in a variety of physiological processes including human development, female reproduction, and wound healing, and in various pathological conditions such as tumor growth, rheumatoid arthritis, and inflammation.^[8] Angiogenesis commences with basement membrane degradation around a preexisting vessel,

often a venule, allowing the migration of endothelial cells from the existing vessel. The endothelial cells proliferate, secrete new extracellular matrix, and form solid capillary sprouts. While the sprouts are developing a lumen, the recruitment of pericytes and synthesis of a basement membrane around the endothelial cell/pericyte complex takes place. This heralds the end of the angiogenic process and formation of a fully functional microvessel.^[9]

Vasculogenesis describes the formation in the embryo of a vascular plexus from the mesoderm by differentiation of endothelial precursor cells or angioblasts, into cell clusters known as blood islands and then into endothelial cells.^[10] Vasculogenesis was previously thought to be restricted to embryogenesis, but in recent years, the existence of endothelial progenitor cells (EPC) in the adult peripheral blood, and their participation in ongoing neovascularization have been reported.^[11] Therefore, rather than being solely due to angiogenesis, adult blood vessel growth is the result of a combination of angiogenesis and vasculogenesis, and a similar range of growth factors controls both processes. In addition, two other forms of blood vessel growth—intussusceptive angiogenesis and inosculation—may contribute to vascularization of a tissue-engineered construct. Intussusceptive angiogenesis involves the division of a formed capillary by repeated insertions of new transcapillary tissue pillars (connective tissue cells and extracellular matrix) that push from outside the capillary wall, forcing it against the opposite capillary wall and dividing a single capillary in two. This process of formation of capillary meshes leads to a rapid expansion of the capillary network.^[12] Inosculation is the process by which the microvasculature of transplanted tissue or a tissue-engineered construct connects to the preexisting vasculature of the recipient site.^[13]

GROWTH FACTORS

A plethora of growth factors acting at different stages of vessel development have been identified to have a vital role in new blood vessel development. Significant vascular growth factors are:

- Vascular endothelial growth factor (VEGF)—a potent endothelial cell mitogen.
- Basic fibroblast growth factor (bFGF or FGF 2)—also a significant stimulator of endothelial and other mesenchymal cell proliferation.
- Angiopoietins 1 and 2 (Ang 1 and 2)—thought to control maturation/stabilization of growing capillaries and continued vascular sprouting or vessel regression depending on VEGF levels.^[14]
- Platelet-derived growth factor beta (PDGF β)—involved in pericyte recruitment.^[14]
- Transforming growth factor beta (TGF β)—a multifunctional growth factor with effects on proliferation, differentiation, adhesion, migration, and extracellular matrix production.^[14]

Although much is known about the roles of growth factors in normal and pathophysiological angiogenesis, their use in tissue engineering has been limited. Only VEGF and FGF 2 and, to a lesser extent, PDGF β and TGF β ^[15] have been used as angiogenic agents in tissue engineering. However, application of a single growth factor may be too simplistic an approach^[16] when endeavoring to initiate, develop, mature, and halt blood vessel growth as required in tissue engineering.

VEGF and Its Utilization in Tissue Engineering

VEGF, also known as vascular permeability factor,^[17] is a significant endothelial cell mitogen that promotes angiogenesis in three-dimensional *in vitro* models, resulting in the formation of capillarylike structures from confluent microvascular endothelial cells.^[18] In 1992, Shweiki et al. demonstrated that the expression of VEGF was upregulated by hypoxia.^[19] The examination of possible mechanisms involved in the regulation of this process resulted in elucidation of the transcriptional and posttranscriptional mechanisms of VEGF mRNA upregulation^[20] with a connection to Hypoxia-inducible factor 1 (HIF-1).

VEGF's potency in promoting vascular permeability, proliferation, and migration of endothelial cells,^[21] as well as its ability to induce the expression of interstitial collagenases,^[22] makes it an attractive target for the enhancement of vascular development in tissue-engineered constructs. Several techniques including direct injection and gene delivery of VEGF to ischemic tissues *in vivo*^[23] have been successful in promoting vascularization. There are significant issues associated with promotion of blood vessel growth using VEGF^[24] including its short half-life^[21] and physiological overproduction, leading to events such as vascular hyperpermeability, edema, and hemangioma formation. Tissue engineering applications involving VEGF have utilized slow-release delivery systems and include incorporation into alginate beads^[25] and porous degradable copolymer scaffolds.^[26] Elcin et al.,^[25] in an *in vitro* and *in vivo* study using VEGF incorporated into calcium alginate beads, found significantly increased angiogenesis in rat epigastric groin fascia at 3–8 weeks implantation. Lu et al.^[27] administered recombinant VEGF by implanting bioartificial muscle tissues (BAM), utilizing genetically modified primary skeletal myoblasts. When implanted subcutaneously in syngeneic mice, a 30-fold increase in CD31 positive capillary cells occurred within the BAM. In ischemic hindlimbs, implantation

of this construct, resulted in a two- to threefold increase in capillary density of neighboring host muscle at one week. Biologically active VEGF has been incorporated into poly(glycolic acid) (PLG) matrices containing human microvascular endothelial cells (HMVECS). VEGF was released in a sustained manner for several weeks when the construct was transplanted into severe combined immunodeficient (SCID) mice. A 260% increase in SCID mouse capillaries invaded the matrix at seven days compared to control, and HMVECS with VEGF produced a 16% increase in human-derived blood vessels at 14 days.^[26] Lee et al.^[28] used alginate hydrogels for localized delivery of VEGF and FGF 2 in subcutaneous tissue of SCID mice. Although both growth factors caused an increase in vascular density compared to control, maximal vascular density occurred with VEGF.

FGF 2 and Its Utilization in Tissue Engineering

Fibroblast growth factors have been implicated not only in angiogenesis, but also in fibroblast and smooth muscle cell proliferation and regulation of several other cytokines. The most important in wound healing and angiogenesis is FGF 2, which is released at wound sites by macrophages and injured endothelial cells^[29] and the extracellular matrix and acts as a potent angiogenic cytokine, leading to endothelial proliferation and subsequently, capillary formation.^[30] FGF 2 has also been implicated in hematopoiesis,^[31] suggesting that this growth factor could be involved in the development and/or regulation of the hemangioblast. Like VEGF, FGF 2 has a short half-life and is also considered to have the potential to cause significant side effects when administered therapeutically.^[24] Most tissue engineering applications have utilized FGF 2 using slow-release delivery techniques.

Subcutaneous plugs of Matrigel[®], a biological mouse basement membrane material, with added FGF 2 are known to significantly promote vascularization, which does not occur in the absence of FGF 2.^[32] Recently, our Institute has incorporated FGF 2 into Matrigel[®] in a vascularized flow-through mouse chamber model with small amounts of autologous fat added. Increased vascularization and adipose tissue growth compared to chambers without FGF 2 were observed (Findlay M., personal communication). Kawai et al.^[33] used artificial dermis with incorporated gelatin microspheres impregnated with FGF 2 inserted into full-thickness skin defects on the back of guinea pigs. Fibroblast proliferation and new capillary formation were increased as the dose of incorporated FGF 2 increased and was more effective than that seen with free FGF 2 at doses over 50 µg. Tabata^[34] has investigated the controlled release of FGF 2 from bioabsorbable

gelatin hydrogel microspheres. Neovascularization around the implantation site occurred when the microspheres were placed subcutaneously in mice. Neovascularization did not occur if the gelatin microspheres were added without FGF 2 or if FGF 2 was injected free. Additionally, not only does this technique promote vascularization, but also, depending on the site of FGF 2 plus gelatin microsphere implantation, can accelerate specific tissue regeneration (nerve and adipose tissue). Rinsch et al.^[35] genetically engineered myoblasts to produce FGF 2 or VEGF and encapsulated them in hollow, microporous polymer membranes, which were evaluated in an in vivo model of acute skin flap ischemia. Only encapsulated myoblasts producing FGF 2 improved flap survival. Recently, Perets et al.^[36] constructed a porous alginate scaffold that incorporates tiny (<10 µm in diameter) poly(lactic-co-glycolic acid) microspheres capable of controlled release of FGF 2. In vivo implantation of this construct in rat peritoneal mesentery produced four times more capillaries than scaffolds without growth factor.

IN VITRO VASCULARIZATION OF TISSUE-ENGINEERED CONSTRUCTS

In Vitro Creation of a Microcirculation

The properties of the individual cellular components of the circulatory system, i.e., macrovascular and microvascular endothelial cells, vascular smooth muscle cells, fibroblasts, and pericytes have been extensively studied in two- and three-dimensional culture systems. More complex coordinated functioning microcirculatory systems have rarely been created in vitro. Presumably this is because in vitro tissue-engineered constructs receive adequate nutrition via the culture system in which they are placed, be that a simple culture dish, bioreactor system growing cells on, or in three-dimensional scaffolds or cell encapsulation systems.^[37]

There are three relatively recent studies that have achieved creation of microvessels within an in vitro tissue engineering environment. The first of these was by Black et al.^[38] who demonstrated that in vitro assembly of microvessels is possible by fabricating a collagen biopolymer in which three human cell types—keratinocytes, dermal fibroblasts, and umbilical vein endothelial cells (HUVECS) were cocultured. Spontaneous formation of capillary-like structures occurred that were positively identified as endothelial by the inclusion of Weibel-Palade bodies within the capillary endothelium. Interconnected capillaries and fluid flow within the capillary-like structures were not demonstrated. Interestingly, it was noted that capillary-like structures only formed in this coculture system when proliferating fibroblasts were present, synthesizing new

extracellular matrix. Frerich et al.^[39] explored in vitro creation of a microcirculation in a soft-tissue model, in which HUVECS and human adipose tissue stromal cells were placed in a fibrin microcarrier scaffold including VEGF. Initially, a significant angiogenic response resulted, but the long-term stabilization of these vessels only occurred when Insulin-like Growth Factor-1 was added to the in vitro construct. In a totally different approach, Kaihara et al.^[40] utilized micromachining technologies on silicon and Pyrex surfaces, generating complex interconnecting trenches similar to that of a microcirculatory system. Hepatocytes and endothelial cells were cultured on these templates and then lifted as single-cell monolayers and folded into compact three-dimensional tissues. The endothelial cells formed branched vascular networks.

In Vitro Creation of Macrovascular Conduits

There is a potential need for macrovascular vessels to supply and drain blood from the microcirculation of tissue-engineered constructs and connect this engineered microcirculation to the systemic circulation, particularly in tissue engineering models that promote intrinsic development of the microcirculation within the construct. Traditionally, autologous vein grafts and more recently, autologous arterial grafts have been used for surgical vascular grafting, as they achieve high long-term patency rates (over 95%). Unfortunately, autologous grafts of the appropriate length and diameter are not always available and additionally, create an undesirable donor site scar.

The need for replacement vascular grafts has prompted research into a variety of biologically-derived or synthetic vascular grafts in the last 50 years. The vast majority have not transferred to the clinical setting due to poor patency rates in experimental in vivo settings, resulting from pathological or pathophysiological processes including aneurysm formation, allograft rejection, calcification, and most commonly, neointimal hyperplasia and/or thrombosis. Dacron and expanded polytetrafluoroethylene (ePTFE) greater than 6 mm internal diameter are the only examples of man-made synthetic vascular grafts that have been used routinely in the clinical setting, particularly as ileo-femoral bypass grafts.^[41]

Utilization of a scaffold, either biological^[42] or synthetic, into which vascular cells can be seeded to create a composite vascular graft has been a predominant focus in recent attempts to manufacture in the laboratory off-the-shelf vascular grafts. The range of biological scaffolds used is enormous and includes the connective tissue framework of intestinal submucosa^[43] and ureter,^[44] decellularized arterial and venous grafts,^[45] and mechanically conditioned tubular collagen gels

containing living smooth muscle cells (SMCs).^[17] Several studies have also combined biological and synthetic scaffold elements.^[46,47]

Initial cell seeding studies of synthetic scaffolds were onto Dacron and ePTFE. In the last few years, in vitro seedings of endothelial and/or vascular smooth muscle cells or fibroblasts have been onto biodegradable scaffolds such as PGA/polyhydroxyalkanoate,^[48] poly(L-lactic acid) (PLLA), and PGA,^[49] chitosan,^[50] and poly(carbonate-urea)urethane.^[51]

Recent in vitro advances are incorporating endothelial precursor cell seeding,^[52] retroviral transfection techniques to alter the properties and enhance the survival and function of seeded endothelial and smooth muscle cells, and adhesion materials to enhance endothelial attachment to engineered scaffolds.

In 1998, L'Heureux et al.^[53] created a completely biological tissue-engineered human blood vessel (TEBV) in vitro. Commencing with an acellular inner membrane wrapped around a tubular support, a cohesive layer of cultured human vascular SMCs followed by a fibroblast layer created the media and adventitia. After eight weeks in vitro, the tubular support was removed and endothelial cells were seeded onto the inner membrane. This TEBV produced extracellular matrix proteins including elastin, vWF, prostacyclin, incorporated acetylated low-density lipoproteins, strongly inhibited platelet adhesion, and had a burst strength of 2000 mmHg. Niklason et al. in 1999^[54] defined the concept of bioreactor production of TEBVs. Cultured bovine aortic SMCs were pipetted onto tubular biodegradable PGA scaffolds in a bioreactor and subjected to pulsatile radial stress for eight weeks prior to bovine aortic endothelial cell seeding. The SMCs produced collagen and elastin and the endothelial cells produced vWF and platelet endothelial cell adhesion molecule (PECAM). Burst strength was within physiological range at 2150 mmHg. These exciting results illustrate the potential of complete in vitro manufacture of functioning arterial-like vascular grafts. However, in both cases, vessel growth was time-consuming (2–3 months) and only very preliminary in vivo experiments have been reported.

Summary of In Vitro Vascularization of Tissue-Engineered Constructs

The number of studies addressing the creation of a microcirculatory system in vitro is limited. In vivo implantation and extensive follow-up studies to determine function, connection to the preexisting vasculature by inosculation, and long-term survival have not been undertaken. Although the tissue-engineered macrovascular blood vessels reviewed here have advanced our knowledge of the optimal in vitro conditions required to

seed, adhere, orient, and promote extracellular matrix production of/by endothelial cells, SMCs, or fibroblasts in a biological or synthetic scaffold, few researchers have placed their vascular constructs *in vivo*. Previous *in vivo* implantations have been limited to short- or medium-term studies in which patency rates fall well short of those achieved by autologous grafts. It is only under rigorous, long-term *in vivo* testing incorporating large numbers of TEBV at a variety of sites and flow conditions that properties such as the biodegradability, burst strength, elasticity,^[55] vasoactivity,^[56] compliance mismatch and consequent neointimal ingrowth,^[55] thrombogenicity, foreign body, allograft or xenograft rejection reactions, and long-term patency of TEBV will be determined.

In addition to the problem of growing a macrovascular conduit or microcirculatory system in concert with other seeded cells, laboratory-based tissue engineering must also address issues associated with placing their constructs *in vivo*. These include connection to the preexisting vasculature, immunological rejection, serum-free and animal-free media for cell culture prior to implantation, differentiation protocols, and possible cancerous transformation of stem cells, especially if genetically manipulated.

To avoid many of the problems of laboratory-based tissue engineering, tissue engineering *in vivo* has many attractions. Using our own body as the conductor and given the appropriate cues, the construct can orchestrate its own endogenous cascade of factors that will sequentially lay down the correct biological and structural matrices, adhesion molecules, growth factors, etc. to attract and differentiate key cells for tissue regeneration.

EXTRINSIC AND INTRINSIC IN VIVO VASCULARIZATION

The ultimate test of any complex, three-dimensional construct is survival and function *in vivo*. For this to occur, engineered tissues require a functional vasculature. This may be derived extrinsically by ingrowth of capillaries from the recipient vascular bed, or intrinsically from a centrally-based macrovascular conduit.

Extrinsic Vascularization

Many *in vivo* tissue engineering applications employ either synthetic or naturally occurring biomaterials to support cells when inserted *in vivo*. Synthetic or naturally occurring biomaterials can be separated into two broad groups: matrices and scaffolds that can be characterized by the presence of open pores, and the hydrogels.^[57] The most common approach to

vascularize these biomaterials is to insert thin constructs into a region where they are surrounded by vasculature. This is typically in a subcutaneous position, under the kidney capsule, or in mesenteric or adipose tissue locations. In addition, angiogenic growth factors are often added to the microenvironment to enhance vascularization.

With respect to synthetic matrices, the tissue response is generally that of encapsulation by a foreign body reaction. The capsule thus induced develops into three layers such that a macrophage layer or foreign body cell is in direct contact with the implant. A dense, relatively avascular collagenous layer (up to 100 μm thick) surrounds this layer and is in turn surrounded by a loose collagenous vascular layer. Studies carried out in the 1990s indicate that it is the microarchitecture, in particular the pore size of these matrices, that determines the nature of the encapsulation and infiltration and the extent and degree of vascular infiltration into the matrix itself. Generally, a small pore size induces production of a thick capsule with little vascular infiltration into the matrix. The capsule thickness and the proximity of capsule vessels to the implant decrease, and the degree of vascular infiltration increases as the matrix pore size increases.^[58] In the late 1990s, Sharkawy et al.^[59] characterized the vessels that encapsulate and infiltrate subcutaneous polyvinyl alcohol (PVA) implants, with respect to density, porosity, and diffusivity and showed that a PVA porosity of 60 μm was superior to both smaller and larger pore sizes. He concluded that “implants with pores large enough for cell and tissue infiltration, but not large enough to allow fibrous deposits (scar) induce optimal vascular induction.” However, Yamamoto et al. showed a significant fibrovascular ingrowth into PVA sponge only at a pore size of 250 μm , and only when incorporated with FGF 2 impregnated gelatine microspheres.^[60] These divergent reports and others not cited here indicate that pore size is important, but that all new scaffolds need to be investigated individually for specific vascularization properties.

The hydrogels do not generally induce a foreign body reaction, but do induce a granulation tissue reaction directly surrounding the gel.^[28] A fibrovascular ingrowth occurs when angiogenic growth factors are added. The most widely studied hydrogels are Matrigel[®], gelatin, and alginate.

In 1992, Passaniti et al. demonstrated an intense angiogenic response was elicited by host tissue when Matrigel[®] and FGF 2 were injected subcutaneously.^[32] Kawaguchi et al.^[61] later showed that this angiogenesis created an environment favorable to migration and differentiation of host adipogenic cells. At about the same time, Tabata's group refined a growth factor release system in which FGF 2 was incorporated into gelatin microspheres.^[34] When injected subcutaneously,

the FGF 2 incorporated into gelatin microspheres induced angiogenesis. When incorporated into Matrigel[®], the microspheres with FGF 2 enhanced both the angiogenesis and adipogenesis previously observed with FGF 2 combined in Matrigel[®] without gelatin microspheres. As an extension of these studies, prevascularization utilizing hydrogels capable of controlled release of FGF 2 from gelatin beads has been recently employed to prepare the site of cell implantation prior to cell seeding. Both pancreatic islets and hepatocytes have subsequently been transferred into prevascularization sites successfully.^[63,64] Fibrotic overgrowth was absent around these constructs. More recently, this group has investigated using the FGF 2 microspheres with a collagen sponge scaffold rather than Matrigel[®], which, being a mouse-derived extracellular matrix, cannot be used in humans.^[65]

There is also a recent trend to incorporate endothelial cells into constructs placed *in vivo*. Some of these studies have been referred to earlier.^[26] Nor et al.^[66] seeded human dermal microvascular endothelial cells onto a 1-mm-thick PLGA scaffold in Matrigel[®] in SCID mice where they differentiated into functional human vessels that anastomosed with the mouse vasculature. Recently Koike et al.^[67] seeded HUVECS and 10T1/2 mesenchymal precursor cells in a three dimensional fibronectintype 1 collagen gel which was placed in a transparent window in a mouse. The HUVECS and 10T1/2 cells initially formed long branching interconnected tubes. Connections to the mouse circulatory system were then formed and the new microcirculatory system became perfused with blood. This tissue engineered microcirculation remained stable for one year *in vivo*.

Prefabrication

A well-known technique in plastic surgery termed prefabrication enables three-dimensional tissue to be endowed with a vasculature and later undergo transfer to another part of the body as living tissue. This involves placing a source of angiogenic tissue, in the form of a vascular pedicle or loop, within the tissue to be transferred. Over a period of weeks, these constructs undergo an intense angiogenic response, which links the underlying blood vessels to the overlying tissue, producing a new vascularized flap, which can then be raised on its own pedicle and transferred to the defect site by standard microsurgical techniques.^[68] The principle of vascularization used in prefabrication has applications in tissue engineering. Of particular relevance is the advantage that the newly formed vascular bed is derived from a major vessel. Thus, the tissue can be said to have its own unique vasculature, loosely resembling the

scenario present in major organs where each is served by a main artery and vein. This feature also permits transfer of the construct.

Intrinsic Vascularization

The rationale used in prefabrication, combined with the findings of angiogenesis emanating from a surgically created arteriovenous (AV) shunt loop created in the rat groin,^[3] led us to create an *in vivo* AV loop chamber model for application in tissue engineering. In a rat and pig model, a microsurgically created blood vessel loop or pedicle is placed in the base of a plastic chamber (Fig. 1). The lid of the chamber is secured, leaving a semisealed chamber of up to 1.5 ml (rat) or 80 ml (pig) around the vessels. A small hole in the rim permits entry and exit of the artery and vein that are continuous with the systemic circulation. In a variation of this model, adapted to accommodate use of small blood vessels in a mouse (Fig. 2), the chamber is composed of a silicon tube that is wrapped around an artery, vein, and nerve, and then sealed at the ends, except where the vessels enter and exit. A semi-sealed chamber of approximately 30 μ l surrounds the vessels.

In all three animal models, in the first few days, a fibrin-rich serum seeps into the chamber with a concurrent infiltration of inflammatory cells (Fig. 3). Angiogenic sprouts are evident between 3–7 days (Fig. 4). In the next few weeks, a vigorous angiogenic process proceeds and the chambers are filled with a remarkably dense plexus of both mature and immature vessels embedded in a loose extracellular matrix (Fig. 5). The tissue matures over the ensuing weeks to produce a stable connective tissue flap, which is living on the implanted AV loop.^[4,5] This angiogenesis occurs without added exogenous growth factors in the rat chamber model.^[6] Added ECM in the form of Matrigel[®] enhances the angiogenesis considerably in the mouse model. Altering the chamber microenvironment by addition of scaffolds (Fig. 6), ECM, or growth/differentiation factors modulates the naturally occurring angiogenic process.

Application of this neovasculature to the field of tissue engineering lies in its ability to produce or support vascularized, differentiated tissue products. Using combinations of extracellular matrices with or without an added cell source, these models have been used to produce vascularized skin flaps,^[3] adipose tissue,^[5] and skeletal muscle, bone, as well as pancreatic and liver tissue (Fig. 7). These observations indicate that the spontaneous angiogenesis induced in this model is able to expand with and support added cells to form mature three-dimensional tissue. Recent experiments in the pig have shown that this technique can produce sufficient

Fig. 1 Diagram of a rat arteriovenous loop, which has been placed in the base of a polycarbonate chamber (C). The femoral artery (A) and vein (V) are anastomosed to a vein graft (VG). Several cauterised branches can be seen projecting outside the chamber area. When the lid of the chamber is fitted over these branches they act as anchors stopping movement of the AV loop. three-dimensional, vascularized tissue to potentially 1) grow a standard-sized organ, or 2) repair a human breast that has undergone mastectomy. As with the pre-fabricated grafts, this flap can be transferred micro-surgically, if required.^[3]

Fig. 2 A whole mount of a six week mouse flow through chamber filled with Matrigel[®]. The silicon chamber has been removed. (P) indicates the epigastric pedicle including an artery and vein which flow through the chamber and which are cleared of all surrounding connective tissue at the time of chamber creation. (M) indicates Matrigel[®] areas and the (arrows) display new blood vessel growth from the pedicle extending to the sides of the chamber. Original figure taken at 2× magnification. (Figure courtesy of Dr. Michael Findlay).

CONCLUSIONS

Although the creation of macrovascular conduits in vitro has been extensively studied, little work has been undertaken on the in vitro creation of a microcirculatory system. Even if a microcirculatory system could be readily created in vitro, it will require a minimum of several days for such a system to connect to the systemic circulation when implanted. It would appear that vascularization of tissue-engineered constructs is more easily achieved in vivo.

A number of fundamental differences between the extrinsic and intrinsic modes of in vivo vascularization of engineered tissues merit specific mention. The intrinsic model, utilizing a chamber, permits new tissue to be grown as an individual entity on its own vascular pedicle. This is an ideal therapeutic concept when

Fig. 4 Section through a rat arteriovenous loop and surrounding tissue 7 days after insertion. Adjacent to the vein graft (VG) is newly generated vascularized connective tissue. (Arrows) indicate new capillaries. Asterisk (*) indicates proliferative area where migrating endothelial and fibroblast-like cells are moving into the surrounding fibrin clot. Toluidine blue stained 5 μ thick paraffin section. Original figure taken at 10× magnification.

contemplating the generation of de novo organoids in vivo and the capacity for the tissue to grow over time to meet increasing demands. The use of a chamber allows the creation of a naïve space around the vessels into which the new tissue can grow unhindered. It could be expected that this mode of generating vessels might be more able to support the growth of tissues with a complex structure and high metabolic demand. The chamber-grown constructs are mobile and retrievable by virtue of their containment in a chamber and a microsurgery-friendly vascular pedicle, enabling

Fig. 6 Section through a rat arteriovenous loop 2 weeks following creation of the loop. This AV loop was inserted in a chamber surrounded by PLGA, which does not stain after processing for paraffin embedding and appears as empty spaces (P) in the figure. (VG) indicates a section through the vein graft of the arteriovenous loop. (T) indicates newly generated vascularized tissue derived from the loop, which has grown around the PLGA and through its pores. Haematoxylin and eosin stained 5 μ thick paraffin section. transfer or transplantation with immediate reanastomoses to the circulatory system. In contrast, the source of extrinsic vascularization is diffuse and generally immobilizes the tissue construct at the implant location.

Both intrinsic and extrinsic models have the apparent disadvantage that it takes at least several days for new capillaries to grow into the construct. Undoubtedly, seeded cells die during this hypoxic period, but researchers using both models have demonstrated survival of seeded cells that must derive their nutrition via diffusion during this early period. Only Wang et al.^[63] and Balamurugan et al.^[64] have been able to overcome this problem, utilizing a prevascularization technique.

Both intrinsic and extrinsic vascularization require diffusion to provide nutrition in the first few days. This factor dictates that only small pieces of tissue or tissue and scaffold, or relatively small numbers of stem cells in scaffolds should be implanted. Implanted tissues or cells must grow in parallel with their supplying vasculature. It is obvious at our current state of development that tissue engineering of any body part or organ will take many weeks or months to create the desired tissue.

INTRODUCTION

Coronary artery disease is the leading cause of death in the western world and by-pass grafting is the current therapy of choice to alleviate this disease. The development of a synthetic small diameter graft continues to be a challenge, and vascular tissue engineering appears to be a promising solution. A combination of several factors—scaffold materials, cell source, seeding methods, bioreactors, and in vivo remodeling—is necessary to achieve clinical viability of a tissue-engineered vascular graft (TEVG). This article reviews the current state-of-the-art for these factors and their role in future clinical applications.

CLINICAL NEED FOR VASCULAR TISSUE ENGINEERING

According to the American Heart Association,^[1] almost one million lives are claimed from cardiovascular disease every year in the U.S.A. alone, and more than 50% of those are caused by coronary artery disease—the leading cause of death in the western world. After Favaloro's^[2] first successful implantation of a saphenous vein graft as a coronary artery bypass graft (CABG) in 1968, the number of procedures performed annually in the U.S.A. alone to alleviate this disease has increased to over 500,000. However, almost 30% of vein grafts become occluded in the first year and one half of those occlusions occur within the first month.^[3] Moreover, only 69% of patients can reach a 10–12 yr period free of reoperations or percutaneous transluminal coronary angioplasty.^[4] Many attempts have been made to improve the results obtained with saphenous vein grafts by modifying the harvest methods, preservation, and early antithrombotic therapy. Arterial grafts are a valid alternative for CABG, but they are limited by their short size, small diameter, and availability, as many patients require multiple grafts.^[5] Synthetic grafts have had only limited success,

mainly in larger diameter vessels.^[6] It is clear that new solutions for CABG are needed.

Another related clinical problem is arteriovenous (AV) fistulae failure. The AV fistulae placement is a common procedure for vascular access for hemodialysis. These access grafts often fail within a short period of time, and this is the leading cause of hospitalization for patients suffering from end-stage renal disease. Infection and early thrombosis of synthetic grafts such as those made from expanded polytetrafluoroethylene (ePTFE) and intimal hyperplasia of AV fistulae are the common failure modes.^[7,8]

The clinical shortcomings of current vascular bypass grafts and access grafts have guided new approaches in the development of alternative solutions.^[9] However, a highly successful alternative that can remain patent for an extended period of time has yet to be discovered. A TEVG appears as a promising solution that could meet all requirements needed for that purpose.^[10,11] In the past several years, many groups have investigated different approaches to engineer the biological and biomechanical properties of TEVGs to mimic the native vascular tissue. We review in this article the key components that we believe are required to develop a successful TEVG, including scaffolds, seeding techniques, cell source, in vitro culture with bioreactors, and in vivo remodeling. We also discuss current and future perspectives for the clinical application of TEVGs.

SCAFFOLDS

One of the heaviest areas of investigation in vascular tissue engineering has been the development of an optimal tubular scaffold to foster cell adhesion, integration, and functionality, as well as to provide the necessary mechanical integrity to withstand physiologic pressures and flows.^[10] In 1954, Vorhees was the first to suggest that a synthetic material (Vinyon-N cloth) could be used to repair arterial defects. Since then, several polymeric materials including polyethylene terephthalate (Dacron) and ePTFE have been

utilized successfully in large diameter vascular replacements (>6 mm). One of the earliest approaches that can be considered an attempt to engineer a blood vessel was the *in vitro* endothelial seeding of synthetic grafts to prevent thrombus formation and fibrous deposition in small diameter constructs.^[12] Although success rates were limited, it formed the basis of most approaches in vascular tissue engineering that have relied on some form of natural or synthetic scaffold. To be clinically viable, the design of these scaffolds must meet several requirements including having mechanical properties and material strength similar to that of the replaced native vessel, as well as having sufficient biocompatibility and bioactivity. Regarding mechanical properties, suitable elastance is important to avoid compliance mismatch with the native vessels, which is a common cause of failure of current synthetic grafts.^[13,14] Because strength is critical to withstand systemic pressure, degradation rates of bioerodable scaffolds should be controllable to adapt to the *in vivo* remodeling time. The polymer and its degradation products must also be biocompatible to avoid cytotoxicity or increased inflammatory response and to support cell growth. Desirable bioactive features include low thrombogenicity, selective cell-adhesion, promotion of angiogenesis, control of cell-mediated extracellular matrix (ECM) production, cell proliferation, and incorporation of growth factors.^[15] The materials currently used as scaffolds have varied, ranging from biodegradable synthetic polymers to natural biopolymers such as collagen, elastin, fibrin, glycosaminoglycans, or decellularized grafts.^[16–20] Surface modification of these materials is an expanding research field to foster cell-material interaction.

Synthetic Biodegradable Materials

Synthetic materials have the advantage of being highly reproducible and controllable in terms of mechanical and chemical properties and degradation behavior. Porosity and pore connectivity can be controlled, allowing cell and tissue ingrowth in a short period of time. Mechanical properties can be tuned to mimic native vessels and scale-up would not be a concern for a synthetic product. The main pitfall that this approach faces from a clinical standpoint is the lack of biocompatibility of the polymer and its degradation products.^[21] Although *in vitro* assays indicate good cell survival, the *in vivo* inflammatory response cannot be avoided and that might, in itself, prevent cell survival upon implantation. The most investigated class of synthetic biodegradable biomaterials have been the polyesters poly-L-lactic acid, polyglycolic acid (PGA), polycaprolactone, and related copolymers. Recently, a highly porous biodegradable scaffold and poly(ester

urethane)urea and poly(ether ester urethane)urea have been shown to support cell adhesion and growth, and to provide mechanical and flexural properties suitable for vascular tissue engineering.^[22,23]

Natural Polymers

Natural polymers are desirable because they provide a better environment for cell growth and support, and the inflammatory response to these polymers is significantly reduced. Within this category, three different approaches for vascular tissue engineering can be identified: fashioning of materials derived from natural matrix into a tubular construct, formation of a tubular construct from decellularized ECM materials, or utilizing intact, decellularized blood vessels.

Tubular constructs fabricated from molded matrix/cell suspensions undergo cell-mediated compaction from water release within days of gelation. This phenomenon typically confers improved mechanical properties to the construct and can induce cell alignment in the presence of physical constraints such as a rigid mandrel within the tube.^[24] However, biological gel-based matrices are often limited by reduced mechanical properties and poor reproducibility.^[17,25] Type I collagen cross-linked with enzymes such as transglutaminase^[25] or temporarily supported by a silicone sleeve^[24] have shown potential for vascular tissue engineering applications but suboptimal mechanical properties still remain problematic. Hybrid constructs obtained with mixtures of collagen and fibrin gel or elastin have shown significant improvement in mechanical properties over collagen alone.^[26,27] These approaches are limited by the length of the process—a common roadblock to clinical feasibility. Using a different construction technique, mixtures of collagen and elastin have been electrospun on mandrels to obtain tubular three-layered fibrous constructs that mimic the natural morphology and structure of arteries and have demonstrated good cell integration.^[28]

Another alternative for natural polymers are those derived from decellularized tissue ECM such as small intestinal submucosa or urinary bladder matrix.^[29,30] This approach has been extensively studied in several tissue engineering applications and the ease of processing and biocompatibility have led to a wide acceptance in the clinical community.^[30] During the process of tissue regeneration, the implanted ECM-derived scaffold is gradually degraded until, eventually, only the cells and tissues that have been deposited by the host remain in place of the scaffold. The scaffold consists of a collection of both structural and functional proteins, which fundamentally alters the healing response.^[30] The ECM serves as an inductive scaffold for deposition of organized tissues, rather than

simple scar tissue formation, similar to that which occurs during fetal development. The acellular nature of the scaffold removes the antigenic stimulus that would otherwise cause an adverse immune response.^[31] Although cell loading might be an alternative to enhance regeneration, the nonporous nature of these scaffolds makes cell incorporation *in vitro* difficult. Furthermore, thrombogenic issues in small diameter vascular constructs remain a concern for this type of approach.^[30]

A third type of scaffold for vascular tissue engineering, which has been investigated, is intact decellularized veins and arteries. In this approach, a native vessel is harvested and processed to extract all the cellular components, either mechanically or by means of a detergent solution. The acellular nature of the scaffold eliminates the immune response as in the ECM-derived scaffolds but the mechanical integrity of the original vessel is greatly preserved because collagen and elastin contents remain undisturbed by the decellularizing process.^[18,32] Although different animal species can be used as sources to obtain the grafts, the procedure is labor intensive, and difficult to scale-up. Clinically relevant features for the scaffolds described above are ranked and summarized in Table 1.

Surface Modification

The surface of most scaffolds can be engineered to interact with cells at the molecular level. For example, covalent incorporation of cell adhesion-promoting oligopeptides such as RGD, YIGSR, or REDV on the surface of polymers can increase the steric availability of these ligands to cell-membrane integrin receptors.^[15] The concentration and distribution of adhesive ligands influence the strength of cell attachment, extent of cell spreading, and the speed of cell migration,^[33] and allows for the modulation and control of these parameters. Cell-specific ligands can be used, for example, to foster cell adhesion of targeted cell types in desired locations while inhibiting the adhesion of undesirable cell types.^[34]

Enhancement of adhesion can also be obtained with deposition of self-assembled films. Nanopolyelectrolyte films made of poly(D-lysine) or poly(allylamine hydrochloride) have been shown to increase adhesion of endothelial cells (ECs) in a controllable manner without protein precoating.^[35] Another desirable feature of such films is their ability to incorporate enzymatic recognition sites to give to the scaffold a specific proteolytic sensitivity that can help direct the desired remodeling of the scaffold upon implantation.^[34]

Incorporation of growth factors into the scaffold is another strategy to direct cell attachment and regulate cell proliferation, migration, differentiation, and protein expression. For example, collagen matrices covalently incorporated with heparin and loaded with vascular endothelial growth factor (VEGF) have been shown to significantly enhance angiogenesis in the collagen matrices, thereby increasing EC proliferation.^[36] More recently, polymeric gene delivery has been considered to induce the expression of functional proteins avoiding the cytotoxicity and immunogenicity issues related to the use of viral gene delivery systems.^[37] This approach might allow a controlled overexpression of anticoagulant and anti-inflammatory proteins such as thrombomodulin and/or inhibitors of procoagulant and proinflammatory proteins such as vascular cell adhesion molecule-1 (VCAM-1) and intracellular adhesion molecule-1 (ICAM-1).

SEEDING TECHNIQUES

Cell seeding constitutes a key step in those tissue engineering approaches that incorporate cells into or onto scaffolds for culture or implantation. Desirable features for any seeding technique include preserving cell viability, providing a uniform cell distribution, and attaining a high seeding efficiency, with reduced seeding time. Mechanical forces (e.g., centrifugal forces, shear stress, etc.) are often involved in seeding procedures and can be responsible for force-mediated membrane lysis or triggering of apoptotic pathways.^[38,39] It is therefore important to minimize the

Table 1 Ranking of scaffolds for four key considerations of clinical viability for use in creating a TEVG

	Mechanical properties	Cell seeding	Biocompatibility	Scale-up
Synthetic polymers	Very good	Very good	Fair	Very good
Biological gels (fibrin, collagen)	Fair	Very good	Very good	Fair
Decellularized ECM scaffolds	Good	Poor	Very good	Very good
Decellularized vessels	Very good	Poor	Very good	Fair

Mechanical properties were ranked based on published work. Cell seeding was ranked based on off-the-shelf availability. Biocompatibility was ranked taking into account cell incorporation and the inflammatory reaction triggered after implantation. Scale-up was based on the feasibility to industrialize the construction process.

mechanical stress that cells undergo during the procedure. Uniform seeding of tissue-engineered conduits is desired to achieve homogeneous tissue formation. This is particularly true for the endothelial layer, as failure to accomplish a uniform monolayer can lead to thrombosis, jeopardizing the patency of the construct.

Two common classifications regarding cell seeding exist. One-stage seeding refers to the use of freshly isolated cells, while two-stage seeding refers to cells that are previously expanded *in vitro* to obtain the desired cell number. Another distinction needs to be made between surface and bulk seeding. While surface seeding usually implies coating the luminal layer with cells, bulk seeding attempts to incorporate cells throughout the entire wall thickness. The vast majority of seeding techniques for vascular tissue engineering involve surface seeding. Bulk seeding is harder to accomplish (particularly in tubular constructs) and usually requires an active method of deployment.^[40] Surface seeding techniques on tubular scaffolds typically deliver high-density cell suspensions within the luminal side of the graft and take advantage of sedimentation/rotation, electric fields, or vacuum as driving forces to entrap the cells.^[41–44]

Even though several techniques and devices have been investigated for seeding cells into or onto scaffolds, the literature to date lacks both a complete quantitative analysis of any seeding technique and an accurate predictive model for cell distribution following seeding.

CELL SOURCE

The cellular components of a TEVG are also an important consideration. Cell sourcing is, many believe, the single most rate-limiting step in the development of a TEVG.^[10] A blood vessel comprises three primary cellular components: ECs, smooth muscle cells (SMCs), and fibroblasts. The ECs make up the inner lining of the blood vessel, and are primarily responsible for maintaining hemostasis. They play other roles such as maintaining a selectively permeable barrier to the blood and the underlying SMCs and sensing and responding to various flow environments. For example, they play a role in the initiation of the coagulation and inflammatory cascades by producing factors such as ICAM-1, VCAM-1, platelet-endothelial cell adhesion molecule, thrombomodulin, tissue plasminogen activator, and tissue factor, as well as signaling molecules to the underlying SMCs to alter vascular tone and regulate blood flow such as nitric oxide (NO) and prostaglandins (PGI₂).^[45]

The SMCs, which comprise the media of a blood vessel, are an exquisitely complex continuum of phenotypes, ranging from an active contractile

phenotype to a more passive, matrix-producing phenotype (Fig. 1).

Their phenotype can be described in terms of the specific contractile proteins they produce [e.g., α -smooth muscle actin (α -SMA), SM22 α , calponin, myosin heavy chain (MHC), smoothelin, and caldesmon], ion channels, cell junction proteins (e.g., connexin 40 and connexin 43), adhesion proteins (e.g., metavinculin, and vascular adhesion protein-1), and the types and amounts of various ECM components they produce (e.g., collagen, elastin, and proteoglycans) (Table 2).^[46–48] For in-depth information on these proteins, the reader is directed to an excellent review by Owens.^[49]

The SMC phenotype is predominantly dictated by environmental cues such as mechanical forces, inflammatory molecules, growth factors, and oxygen tension. Thus, not only do SMCs within a single vessel express a range of proteins that determine their function, but also SMCs in different blood vessels express widely different amounts of these proteins coincident with the primary function of that vessel.^[46] Fibroblasts make up most of the adventitial portion of the vessel wall, and mainly act as ECM-secreting cells. Because fibroblasts can be induced to express various markers of SMCs by mechanical and chemical stimulation, it may be possible to think of these cells as SMCs at the completely synthetic end of their spectrum.

In the design of a TEVG, there are two approaches currently available for cell source: terminally differentiated cells and progenitor cells. Both offer certain advantages over the other. The main advantage of using terminally differentiated cells is the possibility of building a TEVG with the same cellular constituents of a native artery and thus potentially increasing the chances of reproducing functionality. However, the use of terminally differentiated cells for the construction of a TEVG presents a number of pitfalls. Owing to the high number of cells required for seeding a TEVG, the isolation may be difficult to accomplish without a highly invasive procedure for the patient, in the case of an autologous approach. Nonautologous grafts, which could be derived from donor cell sources, would require immunosuppression or other intervention owing to rejection issues.

Several investigators have attempted to seed TEVGs with different types of isolated ECs to achieve a functional endothelial layer. Human umbilical vein ECs cells are the most commonly utilized cell type, though bovine and porcine aortic ECs have also been used.^[50–52] Dermal fibroblasts have been used to construct a “self-assembled” TEVG, using extensive cell culture and relying on accelerated ECM production by the cells.^[53,54] SMCs have also been utilized in several approaches to create a TEVG, including seeding on biodegradable scaffolds,^[55] culture in biological

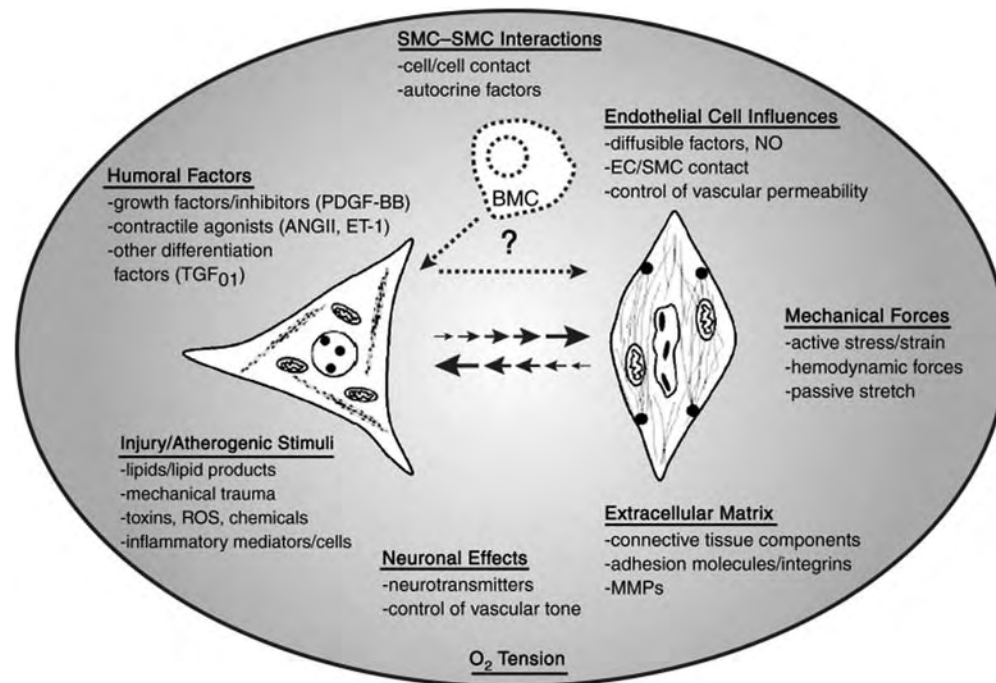

Fig. 1 SMC phenotypes exist as a continuum between the synthetic and contractile phenotypes. The particular position in this continuum is governed mostly by the external environment of the cell, and includes soluble factors (growth factors, hormones, and toxins), mechanical and neuronal stimulation, ECM, oxygen supply, and interaction with ECs. The end result of these signaling milieus will finely tune the response of the SMC to adequately adapt to changes in its environment or respond to injury. Perturbations in these signals are responsible for pathologic processes such as atherosclerosis and intimal thickening through mechanisms that have yet to be elucidated. (From Ref. [46].)

gels,^[17] or as part of cell-based constructs.^[54] Like a native vessel, engineered vessels must possess both a physical and functional component, with the physical component defined by the presence of an organized ECM, and the functional component defined by contractile SMCs.^[16] Dynamic culture of SMCs is thought to be required to avoid a phenotypic change from contractile to synthetic,^[56] though a synthetic phenotype may be a desired feature during TEVG development because it provides greater proliferation and ECM production. Therefore, modulation of SMC phenotype can be a powerful tool in vascular tissue engineering.^[57] Consequentially, it is important to be able to trace the differentiation process that SMCs undergo in different culture conditions,^[47] and this can be achieved by evaluating the levels of expression of contractile proteins, ion channels, cell junction proteins, ECM proteins, and secondary signaling proteins (Table 2).

One of the main concerns with the use of adult autologous SMCs for tissue engineering applications is their limited proliferative capability, which may be related to the enzyme telomerase.^[58] Telomerase is responsible for maintaining the length of DNA after replication.^[59] Its function is greatly diminished in adults, and research investigating the ectopic expression of telomerase has yielded cells capable of

more than 100 population doublings.^[50] Although oncological mapping was performed in these studies, clinical acceptance of this approach to develop a TEVG might be low as telomerase is not constitutively expressed in adult cells and has been shown to be active in most cancer cells.^[60]

Progenitor cells show great potential for use in tissue engineering applications and may circumvent many of the shortcomings associated with other solutions to cell sourcing. Progenitor cells are easier to harvest, and usually display a rapid, almost limitless expansion capability. They can also be viewed as being untouched by the disease state that required intervention. Extensive research has been performed on progenitor cell differentiation in vitro. Bone marrow and embryonic stem cells are the most studied, but embryonic stem cells carry with them an inherent ethical dilemma. The bone marrow contains different types of progenitor cells at various stages of differentiation. Classification of bone marrow progenitor cells (BMPCs) has been performed by specific gravity and the expression of different clusters designation markers, membrane receptors, integrins, and ECM molecules (Table 3).^[61,62]

The main division for bone marrow has been along the marker for CD34, with CD34⁺ cells being considered hematopoietic progenitor cells and the CD34⁻ cells

Table 2 Protein expression in contractile SMCs

Protein	Exclusive to SMCs	Contractile	Synthetic/developmental	Expression in other cells
SMA	N	++	++	Fibroblasts, myoblasts, inducible in ECs
H1-Calponin	Y	++	+/-	
Caldesmon	N	++	+/-	Skeletal myoblasts
Myosin heavy chain (SM-1 and SM-2)	Y	++	--	
SM22 α	Y	++	++	
γ -Vinculin	N	++	++	Cardiac
Metavinculin	N	++	++	Cardiac, skeletal muscle
α -Tropomyosin	N	++	+/-	Embryoid bodies
Vimentin	N	+/-	++	All cell types
Desmin	N	+/-	+/-	Cardiac, skeletal muscle
Angiotensin receptors (AT1 and AT2)	Y	++	Unknown	
Muscarinic receptors (M1, M2, M3)	N	++	Unknown	Neurons, fibroblasts, epithelial, cardiac
Vasopressin receptors (V1, V2)	N	++	Unknown	Neurons, epithelial, hepatocytes
Adrenergic receptors (α and β)	N	++	Unknown	Neurons, epithelial, cardiac

The ability to identify functional, contractile SMCs would be ideal for tissue engineers utilizing progenitor cells to build their constructs. However, of all the markers expressed by SMCs, very few are exclusive to SMCs, and of those that are exclusive to SMCs, only MHC (isotypes SM-1 and SM-2) appears to be limited to the contractile phenotype. The presence of MHC does not necessarily imply functionality. A functional SMC requires abundant K^+ and Ca^{2+} ion channels, as well as the receptors for vasoconstrictors and -dilators. To determine the true contractile/functional state of a presumed SMC, one needs to perform a multitude of protein assays to elucidate the phenotype and suitability for a TEVG. ++ indicates definitively positive expression; +/- indicates transient expression or conflicting reports; and -- indicates definitively negative expression.

being considered mesenchymal progenitor cells. Mesenchymal progenitor cells have high proliferative rates, and can differentiate into many different tissues including bone, fat, tendon, neural, cartilage, and muscle cells.^[63–70] Recently, a small caliber artery was reported

as being created from BMPCs that were differentiated into endothelial and SMCs in vitro.^[18] These grafts remained patent for more than eight weeks as carotid interposition grafts. Bone marrow is also thought to supply distant tissues with progenitor cells that can be

Table 3 The specific antigens, cytokines, cytokine receptors, adhesion molecules, and matrix molecules reported to be expressed or produced by BMPCs

Marker type	Designation
Specific antigens	SH2, SH3, SH4, STRO-1, α -smooth muscle actin
Cytokines and growth factors	IL- 1, 6, 7, 8, 11, 12, 14, and 15, LIF, SCF, Flt-3 ligand, GM-CSF, G-CSF, M-CSF
Cytokine and growth factor receptors	IL-1R, IL-3R, IL-4R, IL-6R, IL-7R, LIFR, SCFR, G-CSFR, IFN- γ R, TNF- α 1R, TNF- α 11R, TGF- β 1R, TGF- β 11R, bFGFR, PDGFR, EGFR
Adhesion molecules	Integrins subunits: α 1, α 2, α 3, α 4, α 5, α v, β 1, β 3, β 4, β 5 Surface adhesion molecules: ICAM-1, ICAM-2, VCAM-1, ALCAM-1, LFA-3, L-selection, endoglin, CD44
ECM	Collagen types I, III, IV, V, and VI, fibronectin, laminin, hyaluronan, proteoglycans

(From Ref. [61].)

committed for a specified purpose.^[63] Although this theory has been repeatedly challenged, it still remains a major focus of research.^[71,72] Furthermore, Reyes et al.^[67] have postulated that the blood transports these progenitor cells to their destinations, and therefore may be a more easily accessible source of progenitor cells. In fact, specific populations of progenitor cells including smooth muscle progenitors have been isolated from peripheral blood.^[73] Other sources of progenitor cells apart from the bone marrow are being investigated and may have a great potential in vascular tissue engineering. Human preadipocytes have been reported to differentiate into smooth muscle cells^[74] and ECs.^[75] Additionally, muscle-derived stem cells are being isolated from skeletal muscle, and these cells exhibit multipotentiality and self-renewal capabilities that may be exploited in vascular tissue engineering.^[76–78] While significant progress has been made in the past decade regarding the controlled differentiation of progenitor cells *in vitro*, further work is necessary to understand how progenitor cells might behave in tissue-engineered constructs.

BIOREACTORS AND IN VITRO DEVELOPMENT OF TISSUE-ENGINEERED BLOOD VESSELS

Because most tissue-engineered constructs lack the complete mechanical and functional properties necessary for a successful *in vivo* implantation immediately following seeding, bioreactors and their design have become a major focus of tissue engineering technology. The goal of a bioreactor is to replicate, as accurately as possible, the biochemical and biophysical stimuli that will ultimately guide the development of the construct into a fully functional tissue capable of *in vivo* implantation. Bioreactors have been utilized for several engineered tissues including cartilage, bone, heart valves, and blood vessels, and have varying levels of complexity and design. Here we will focus on bioreactors for TEVGs, and how biochemical and biophysical stimuli can be used to control the development of an engineered tissue.

The most basic types of bioreactors include spinner flasks and rotational culture of the vessels. These systems enhance tissue culture by improving transport of nutrients and gases. Because blood vessels exist in a dynamic environment, it is important to ensure that TEVGs are mechanically stimulated during *in vitro* development. The mechanical forces that are generally employed include shear stress and radial strain. Kanda, Matsuda, and Oka^[79] were among the first to recognize that mechanical stimulation was necessary for the development of a TEVG with sufficient mechanical properties for *in vivo* implantation. Subsequently, several bioreactor designs have centered

around a silicone tube running through the lumen of a construct to provide a passive means for imparting cyclic stretching—a key force experienced by all layers of a blood vessel.^[16,24] Such mechanical stimulation has been combined with bioactive chemicals such as ascorbic acid, copper sulfate, proline, alanine, and glycine, which are the building blocks of ECM molecules and can enhance matrix cross-linking.^[16,80] Using this approach, accelerated ECM deposition and polymer resorption can be achieved to yield TEVGs with a burst strength equivalent to that of the saphenous vein.^[16] Studies have demonstrated that both the frequency and magnitude of cyclic stretching have effects on tissue inhibitors of matrix metalloproteinase and collagen deposition, and that higher frequency stimulation on the order of fetal or neonatal heart rate (165 bpm) may enhance vessel development.^[81] There is a delicate balance between matrix metalloproteinases (MMPs) (in particular MMP-2) and matrix deposition that occurs under cyclic stretching, and this may be ultimately responsible for the increases seen in the mechanical properties of TEVGs under such stimulation.^[20,82] However, these systems are limited by media diffusion in the luminal surface because of the silicone sleeve. In addition, most systems can only provide radial distension, whereas many arteries in the body also undergo other cyclic deformations, e.g., the coronary arteries.^[83] Therefore, bioreactors that mimic these deformations may be important for TEVGs to be used in such locations.^[84]

The use of perfusion systems to provide stimulation directly to the luminal surface via pressurized culture media as well as the subsequent radial distension has been employed by several researchers to alleviate the nutrient diffusion issues, as well as to provide direct stimulation to an EC layer. Shear stress applied at physiologic arterial levels sustains the expression by ECs of vasodilators [nitric oxide synthase (NOS) and NO], SMC proliferation inhibitors [transforming growth factor (TGF- β), and antithrombotic factors (cyclooxygenase-2, thrombomodulin, and tissue factor plasminogen inhibitors)], while depressing expression of vasoconstrictors (endothelin-1), procoagulation proteins (protease activated receptor-1), and inflammatory proteins (monocyte chemoattractant protein-1).^[45] Shear stress coupled with radial strain may also play a role in increasing cell number and collagen deposition.^[85]

In addition to the potentially beneficial effects of mechanical stimulation, bioreactors impart a means for the delivery of the important growth factors necessary for the proper *in vitro* development of a TEVG such as platelet-derived growth factor (PDGF), TGF- β , basic fibroblastic growth factor (bFGF), and VEGF. Vascular cells, with the exception of ECs that do not generally express PDGF receptors, respond to each of

these molecules through receptor signaling.^[86] The beneficial effects of each of these growth factors on the *in vitro* development of a TEVG are discussed individually below.

Basic fibroblastic growth factor is a strong mitogen and morphogen for most cell types.^[86,87] The mitogenic effects on SMCs and ECs is particularly important for wound healing and angiogenesis, where these cells are needed to grow to fill a defect or void around the injured tissue.^[88] The increase in proliferation consequently causes a decrease in collagen I and III production in SMCs,^[89] but the effects of bFGF in concert with other factors, such as ascorbic acid may prove useful in tissue engineering because their concerted effects induce proliferation *and* matrix production in SMCs.^[90]

PDGF is also a mitogen for SMCs, EC progenitors, and microvascular ECs, but not quiescent ECs. PDGF induces proliferation by allowing cells to pass through G₀ into G₁ phase,^[91] and also has an effect on SMC phenotype.^[49] Several researchers have reported that a specific isoform of PDGF—PDGF-BB—not only induces SMC proliferation, but also suppresses the expression of their contractile machinery^[49,57] through the destabilization of mRNA as it leaves the nucleus.^[92] This phenomenon is also conserved in three-dimensional collagen gels, where PDGF inhibits the response of SMCs to mechanical stimulation.^[57] It has been hypothesized that the decrease in contractile machinery is related to the focus of the cell on proliferation rather than maintenance of phenotype.^[93] However, it has been reported that PDGF is sufficient to induce SMC contractile protein expression in progenitor cells.^[73]

TGF- β is involved in mitogenesis and morphogenesis throughout the body in development and adult tissue remodeling. One of the main effects of TGF- β on vascular tissue is a decrease in proliferation. However, during angiogenesis, TGF- β appears to stimulate growth through overlapping signaling mechanisms related to the current cellular phenotype and ECM composition.^[94] Other effects of TGF- β in the vasculature are increases in matrix, matricellular protein, and integrin proteins to help maintain the vessel wall integrity.^[95] Taken together, the increase in matrix production and MMP expression seems to indicate a role for TGF- β in cell migration and remodeling. TGF- β can also have varying effects on the way the cells respond to other growth factors such as PDGF. For tissue engineering, TGF- β has shown increases in α -SMA and matrix production in collagen gels exposed to both static and dynamic environments.^[57] TGF- β also can induce differentiation of BMPCs through expression of α -SMA.^[93]

VEGF is one of the most studied and characterized vascular growth factors because of its importance

during fetal development, oncogenesis, lymphangiogenesis, and angiogenesis. VEGF is a specific mitogen for ECs and progenitor cells.^[86] Additionally, stimulation of CD34⁺ progenitor cells with VEGF alone has been shown to be sufficient for EC differentiation.^[96,97] This differentiation can be enhanced by utilizing several VEGF isoforms that have specific binding affinities for matrix proteins.^[98] VEGF also stimulates the production of NOS mRNA, ultimately leading to the production of more NO.^[99] In addition to the vasoprotective NO, VEGF also stimulates the production of prostaglandins, such as PGI₂, which can also act to maintain SMCs in a quiescent state, and may prevent such pathologies as intimal hyperplasia.^[100,101]

Although growth factors and biomechanical stimulation can independently alter the behavior of the cells constituting a TEVG, it is their constant interaction that provides the precise results for the maintenance of a healthy phenotype. In addition to these two signals, relative oxygen tension, and other biochemicals such as amino acids, vitamins, and minerals have an affect on cellular behavior and require tight control. Thus, a bioreactor is the ideal means to provide this type of control *in vitro*. The bioreactor, through its design, can impart strict biomechanical regimens by controlling fluid flow that imparts shear stress and radial distension through pressure, and alter the timing and concentration of growth factor delivery. It can also ensure that the proper oxygen tension, amino acids, vitamins, and minerals are present throughout the tissue by various mixing and mass transport processes.

The ability to perfuse multiple constructs in a single system is an attractive scale-up feature necessary for the mass production of engineered tissues in a controlled manner. One such system uses air to move a silicone membrane, displacing media in a pulsatile manner, and has been utilized to simultaneously perfuse four TEVG constructs.^[102] Williams and Wick^[103] have also designed a bioreactor with modular components that can be stacked to provide single or multiple construct development.

Although bioreactors cannot control every facet of TEVG development that would exist in an *in vivo* environment, they can help us bring the raw materials of biology together, refine them, and efficiently produce a tissue-engineered product that can withstand the rigors of the body and provide a key component to regenerative medicine.

IN VIVO REMODELING

One of the hallmarks of tissue engineering is the body's natural ability to restore and regenerate functional tissues over biological substitutes.^[31] In some tissue

engineering approaches, the body works as a “bioreactor” to complete the construction of the desired graft through remodeling. It is important to note that most of the tissue engineering approaches that have been successfully carried into the clinical field have utilized the *in vivo* remodeling as their main concept.^[104]

A key factor for successful *in vivo* remodeling is the proper ECM.^[29,30] The correct architecture of the ECM has been shown to induce changes in the cellular signaling process that yield arranged and functional tissue regeneration as opposed to scar tissue formation. In tissue engineering, biomaterials have been used to replicate the biologic and mechanical function of the native ECM found in tissues in the body.^[31] Several authors, particularly in the vascular field, have successfully utilized the *in vivo* remodeling concept.^[105,106] In one such study, the infrarenal aorta was replaced with an ECM graft in a dog model resulting in functional tissue remodeling and good patency rates after eight years.^[29,30] In another study, a segment of the carotid artery was replaced with a native ECM-based scaffold and was found to have similar histology as a saphenous vein graft.^[107]

Using a different approach, an *in vivo* model was used as a bioreactor for the complete construction of the TEVG by implanting a rod in the peritoneal cavity and retrieving a tubular conduit several weeks later.^[108] Although these approaches rely completely on *in vivo* remodeling, there are several other authors who have utilized an *in vivo* model only to complete the development of the grafts.^[16,18,31,109] Rather than trying to achieve a fully functional and morphological tissue *in vitro*, the aim of the *in vivo* approach is to provide initial mechanical support through a scaffold and stimulate tissue replacement through cell signaling by loading these scaffolds with the desired cell type or growth factors. It is not certain which components of the initial graft are more relevant to guide the proper remodeling. There is enough evidence that the architectural structure of the scaffold has a significant impact on the outcome. Porosity, fiber alignment, and nanostructure have shown relevant implications on cellular integration.^[21,28,110] It is also important to consider the role that the seeded cells play in the remodeling process. Some studies have shown that part of the seeded cells are integrated in the final vessel histology with the desired phenotype and those constructs had a better outcome than the acellular controls.^[109] BMPCs that were tracked using the carboxyfluorescein diacetate marker also expressed endothelial markers and were engrafted within a TEVG eight weeks after implantation. In a separate study, scaffolds seeded with BMPCs and implanted remained patent after eight weeks whereas nonseeded grafts occluded after two weeks.^[18] The specific

mechanisms by which the cells contribute to the remodeling remain unclear, despite years of research. A potential answer to that question may emerge from the studies utilizing cell therapy to restore functionality to damaged or diseased tissues and have already shown some clinical success.^[111]

CLINICAL APPLICATION

To be clinically viable, a TEVG must meet several requirements and successful preclinical testing is only one of them. Many successful studies in animal models require long-term cell culture and expansion preventing them from being available off-the-shelf.^[16,54,108] A long manufacturing process would create a large production cost from an industrial perspective and hamper widespread clinical use. Reproducibility is also important to be able to test and predict clinical outcomes in different patient populations. For that purpose, research should be focused on a manufacturing process where all the steps involved in the construction of the TEVG are user independent. This is a very important consideration when dealing with complex bioreactors that require a high degree of skill for implementation.^[103] If off-the-shelf availability is to be combined with an industrialized approach, it is likely that the successful TEVG will rely on a bioreactor being implemented inside the operating room where all nonsurgical events have to be maintained as simple as possible for safety purposes. Moreover, biological storage and transportation between the health care institution and the manufacturing company would need to address significant requirements for regulatory approval that would hinder commercial feasibility. The existence of so many different approaches to develop a TEVG suggests the difficulty in developing the right combination of the key factors summarized in this review.

Most specialists in the field agree that we are at least a decade away from a complete clinical application of these innovative technologies, but early-stage clinical trials are already being conducted with promising results. Shin'oka and coworkers^[112–114] have successfully implanted a porous P(CL/LA) scaffold reinforced with an external sleeve of nonwoven PGA seeded manually with BMPCs isolated at the same time of the procedure to repair single ventricle anomalies using the total cavopulmonary connection approach. They reported eight patients who were asymptomatic and with no need of reoperation at an average follow-up of 13.4 mo. These encouraging results provide evidence that although widespread clinical applications of vascular tissue engineering may be a long way off, clinical translation of this emerging science is clearly feasible.

CONCLUSIONS

Despite efforts to improve the current therapeutic modalities, available vascular grafts fall short in necessary quantity and quality. Vascular tissue engineering research has undergone great advancement in the last decade with numerous successful approaches in the preclinical setting and more recently with preliminary clinical applications. Cell source, scaffold type, seeding methods, and in vitro bioreactors are factors that are key to achieving a clinically viable TEVG. Future efforts should be focused on finding the right combination of these factors to obtain off-the-shelf availability, reproducibility, and scale-up possibilities to reach a widespread clinical benefit of this evolving technology.

INTRODUCTION

The urgent and growing need for improved methods of cryopreservation for viable tissue-engineered products has stimulated discussion and debate in the literature regarding the relative merits of traditional freezing methods versus approaches involving ice-free vitrification. Prevention of freezing by vitrification means that the water in a tissue remains liquid during cooling. Vitrification is the solidification of a liquid without crystallization. As cooling proceeds, however, the molecular motions in the liquid permeating the tissue decrease. Eventually, an arrested liquid state known as a glass is achieved. It is this conversion of a liquid into a glass that is called vitrification (derived from *vitri*, the Greek word for glass). A glass is a liquid that is too cold or viscous to flow. A vitrified liquid is essentially a liquid in molecular stasis. Vitrification does not have any of the biologically-damaging effects associated with freezing because no appreciable degradation occurs over time in living matter trapped within a vitreous matrix. Vitrification is potentially applicable to all biological systems.

Vitrification has been shown to provide effective preservation for a number of cells, including monocytes, ova and early embryos, and pancreatic islets.^[2-5] We review here some of the basic physicochemical and biophysics principles of vitrification and progress on the extension of vitrification from single cells and cell aggregates to more complex structured tissues. Cryopreservation by vitrification versus conventional freezing is illustrated using articular cartilage as a model. Despite decades of research, articular cartilage has proved refractory to satisfactory cryopreservation using conventional freezing methods. Therefore, cartilage was selected as an ideal model to test the hypothesis that vitreous cryopreservation, in which the formation of extracellular ice is inhibited or prevented, will result in significantly improved preservation.

Vitrification and freezing (water crystallization) are not mutually exclusive processes; the crystalline phase and vitreous phase often coexist within a system. In fact, during conventional cryopreservation involving

controlled freezing of cells, a part of the system vitrifies. This occurs because during freezing, the concentration of solutes in the unfrozen phase increases progressively until the point is reached when the residual solution is sufficiently concentrated to vitrify in the presence of ice. Conventional cryopreservation techniques are optimized by designing protocols that avoid intracellular freezing (Fig. 1). Under these cooling conditions the cell contents actually vitrify due to the combined processes of dehydration, cooling, and the promotion of vitrification by intracellular macromolecules. However, the term, vitrification, is generally used to refer to a process in which the objective is to attempt to vitrify the whole system from the outset such that any ice formation (intracellular and extracellular) is avoided.^[6-11]

PHYSICOCHEMICAL BASIS OF VITRIFICATION

During the low-temperature preservation of biological systems, events rarely take place under true equilibrium conditions. Many interdependent factors determine whether an aqueous system, such as a biological system, approaches the thermodynamic state of lowest free energy during cooling. Metastability is thus often unavoidable, especially in concentrated systems. Such nonequilibrium states are, however, sufficiently reproducible and permanent to have been described as pseudoequilibrium states, and conversion of such metastable thermodynamic states to more stable forms may be subject to large kinetic barriers. The prevalence of so-called unfreezable or bound water in the vicinity of macromolecules is a prime example, where the expected path of thermodynamic stabilization by way of crystallization is prevented by large kinetic restraints.^[12-14] A clear understanding of the occurrence and effects of metastable states during the cooling of compartmentalized living systems is complicated by the interaction of thermodynamic and kinetic factors. Some basic principles have been established with the aid of aqueous solutions of cryoprotective solutes and other macromolecules that interact with water by

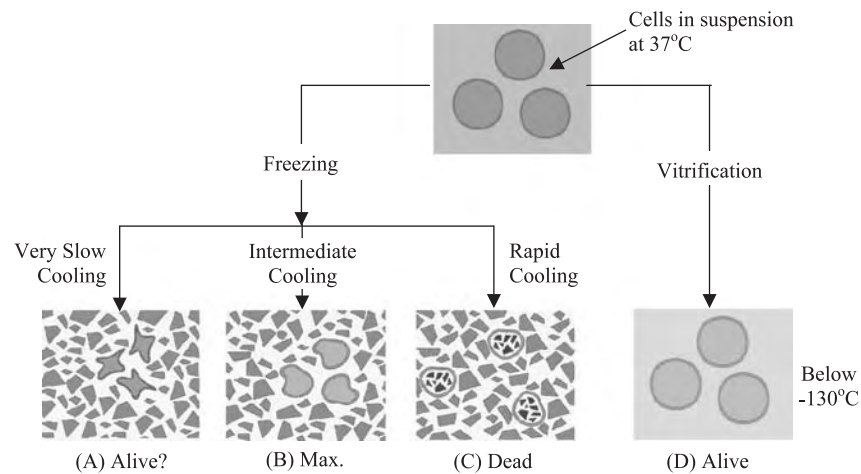

Fig. 1 Comparison of cryopreservation using vitrification or freezing strategies for cells in suspension. If the cells are cryopreserved by freezing (left side), ice forms initially in the extracellular environment and the cells undergo cooling rate-dependent shrinkage due to osmotic dehydration. The slower the cooling rate, the longer intracellular water has the opportunity to move out of the cell by osmosis due to the increasing osmolality of the extracellular environment as water is incorporated into ice crystals. The cells also become concentrated at slower cooling rates as they are pushed together by the forming ice (A,B). Maximum cell viability is usually achieved at an intermediate cooling rate (B) that balances osmotic dehydration and the risk of intracellular ice formation. Rapid cooling (C) permits intracellular ice formation and usually leads to cell death upon rewarming. Very slow cooling (A) may lead to excessive cell dehydration and cell death. In contrast, right side (D), cells cryopreserved by vitrification undergo neither ice formation nor shrinkage due to dehydration and most of the cells should be viable.^[1]

hydrogen bonding.^[15,16] Phase diagrams have proved to be a useful tool in understanding the physico-chemical relationship between temperature, concentration, and change of phase (Fig. 2). For a detailed discussion of the role and interpretation of solid-liquid state diagrams in relation to low-temperature biology, please refer to the review by Taylor.^[14] In particular, supplemented phase diagrams that combine nonequilibrium data on conventional equilibrium phase diagrams serve to depict the important transitions inherent in cooling and warming aqueous solutions of cryoprotective solutes (Fig. 2).

The equilibrium freezing curve, labeled T_m , is often described as the liquidus curve and represents points at which a solution having a particular concentration will freeze (or melt) under equilibrium conditions of temperature change. Hence, this curve represents the phase change boundary for the two-component solution as a function of temperature. Cooling a solution below the liquidus curve will result in ice formation if the conditions are favorable for nucleation, with the result that the remaining liquid phase becomes more concentrated in the solute as defined by the curve. In practice, freezing is rarely initiated at the liquidus point. Solutions tend to undercool to varying degrees before significant nucleation and ice crystal growth occur. Heterogeneous nucleation occurs in water at temperatures above -38.5°C , and it is usually catalyzed by the surfaces of particulate impurities that act

as seeds for crystal growth. Pure samples of water will self-nucleate at the homogeneous nucleation temperature (T_h), -38.5°C .^[14] Both heterogeneous and homogeneous nucleation temperatures decrease with increasing dissolved solute concentration (Fig. 2).

The phase diagram for propanediol (Fig. 2) shows that in the region of 0–35%, freezing will occur at some point 5–20°C below T_m , invariably by heterogeneous nucleation. At sufficiently high concentrations and low temperatures, the kinetics of the process become so slow that T_h is difficult to detect and any nucleated crystals that form in the region of T_h remain microscopic. As temperature is lowered further, molecular motion is slowed to the point where translational and rotational molecular motion is essentially halted and the system is trapped in a high-energy state that resembles a liquidlike configuration, or a vitreous glass.^[17] This glass transition (T_g) is associated with a marked change in physical properties such as specific heat and refractive index and certain mechanical properties such that T_g can be clearly identified. Determination of the transition temperatures that provide data for the construction of supplemented phase diagrams is usually derived from thermograms generated using differential scanning calorimetry (DSC) or the related technique, differential thermal analysis (DTA).^[14] A DSC-derived thermogram for a complex solution of cryoprotectants in water is presented in Fig. 3. The kinetic nature of these transitions

Fig. 2 Supplemented phase diagram for propanediol in water. Data are derived from differential scanning calorimetry thermograms showing the principal events and phase changes associated with cooling and heating. A supplemented phase diagram combines nonequilibrium data on a conventional equilibrium phase diagram and serves to depict the important transitions inherent in cooling and warming aqueous solutions of cryoprotective solutes. (T_m =equilibrium melting point curve, T_h =homogeneous nucleation curve, T_d =devitrification curve, T_g =glass transition curve). (Redrawn from the data of MacFarlane et al. (From Refs. [17,19,20].)

means that T_g has to be defined with reference to a particular set of experimental conditions.

Reference to Fig. 2 shows that in the region of 35–40% propanediol, it is possible to cool samples through the T_h curve without apparent freezing and form what have been referred to as doubly unstable glasses.^[18] This term reflects the high probability that

the vitreous system contains ice nuclei and if warming is not sufficiently rapid, further nucleation and crystallization will occur. This event is known as devitrification and is depicted on the supplemented phase diagram as T_d . Hence, during cooling the sample attains the glassy state, but it invariably contains ice nuclei, the growth of which is arrested along with all other molecular motions in the sample. However, upon rewarming, crystallization can be detected, either visibly or by an exothermic event in a thermogram (Fig. 3), reflecting the growth of ice by devitrification (transition of glassy to crystalline state) and recrystallization (growth of existing ice crystals).^[14] The phenomenon of crystallization on warming a glassy sample to temperatures in the vicinity of T_g is often referred to as devitrification of a doubly unstable glass since it is unstable with respect to both the liquid and solid states.^[18,19] Hence, the process by which a metastable glass, or supercooled liquid obtained by heating the glass above its glass transition temperature, forms the stable crystalline phase is generally referred to as devitrification.^[19]

In the higher concentration range of 41–50% for propanediol (Fig. 2), the T_h curve meets T_g and in this region, it is possible to slowly cool even bulk liquids directly to T_g without experiencing any detectable freezing events, and devitrification can be avoided by using moderate warming rates. Devitrification ceases to be detectable at concentrations above 50%, even at low warming rates, and the system can be regarded as stable (Fig. 2). The intersection of the melting curve and the glass transformation curve at T_g' indicates the minimum concentration of propanediol in aqueous solution that will vitrify irrespective of cooling rate. The concentration at which a glass transition occurs varies according to the nature of the solute. It appears

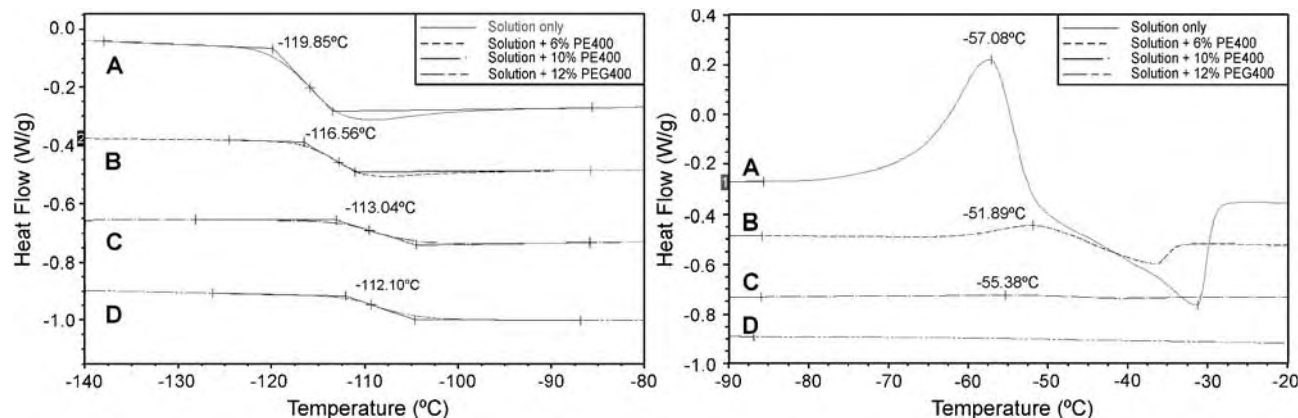

Fig. 3 Representative thermograms illustrating the influence of poly(ethylene glycol) 400 concentration on the glass transition (A) and peak devitrification (B) temperatures of EuroCollin's solution containing 3.0 M DMSO and 3.0 M propanediol. PEG400 elevated the glass transition temperature (A), reduced the energy associated with the transition (A), and reduced the risk of devitrification (B) in a concentration-dependent manner.

that those systems with the strongest solute–solvent hydrogen bonding provide the best suppression of ice nucleation and promote vitrification.^[17,20]

VITREOUS STABILITY

Stability of the vitreous state is critical for the retention of vitrified tissue integrity and viability. Comprehensive studies of vitreous stability for a variety of potentially important cryoprotective mixtures have been made.^[21] Glass stability of vitrified blood vessel samples stored in vapor phase liquid nitrogen storage with retention of smooth muscle function has been demonstrated up to four months of storage.^[22] The stability of the amorphous state has been defined empirically in terms of the critical heating rate, V_{cr} , above which there is insufficient time for a vitreous sample to crystallize before T_m is reached. The smaller the value of V_{cr} , the more stable the amorphous state. The dependence of T_d on the rate of warming can be measured and $T_m - T_d$ has been used to define the stability of the vitreous state.^[21,23] The warming rate for which $T_m - T_d$ is zero is defined as the V_{cr} for which the supercooled mixture neither devitrifies nor recrystallizes. Such studies have shown that stability of glasses formed from aqueous solutions of 1,2-propanediol are much greater, for the same water contents, than for all other solutions of commonly used cryoprotectants including glycerol, dimethyl sulfoxide (DMSO), and ethylene glycol. Unfortunately solutions of poly(alcoholic cryoprotectants) (CPAs) such as propanediol and butanediol, which show the most promise in terms of cooling rates and concentrations necessary for vitrification, also required unrealistically high heating rates to avoid devitrification. Moreover, due principally to isomeric impurities that form a hydrate at reduced temperatures, 2,3-butanediol has proved to have an unanticipated biological toxicity at concentrations below that necessary for vitrification.^[24–27]

Despite developments to devise solutions that would vitrify at practically attainable cooling rates for sizeable biological tissues, the corresponding critical warming rate necessary to avoid devitrification remains a critical challenge. Conceptually, elevated pressures,^[28] electromagnetic heating,^[29–31] the use of naturally occurring antifreeze molecules,^[32] and synthetic ice blockers^[33] have been proposed as means to tackle the problem.

TISSUE VITRIFICATION

Advances in biostabilization and low-temperature biology have produced high-viability preservation

technologies for cells and tissues in the areas of hypothermic storage, cryopreservation by freezing, and vitrification, as well as anhydrobiotic preservation.^[34] However, the development of preservation methods is not straightforward. Process development requires the optimization of chemical and thermal treatments to achieve maximal survival and stability. In a recent editorial,^[35] the need for ice-free cryopreservation methods was emphasized. The consensus opinion was that viable tissues such as blood vessels, corneas, and cartilage that have proven refractory to cryopreservation by conventional freezing methods, despite decades of intense research by many investigators, can only be successfully preserved if steps are taken to prevent or control the ice that forms during cooling and warming. Mathematical modeling may ultimately improve our ability to optimize freezing procedures for tissues,^[36] but has not yet contributed to significant advances. Our laboratory has developed a cryopreservation approach using vitrification, which thus far has demonstrated >80% preservation of smooth muscle cell viability and function in cardiovascular grafts^[37,38] (Table 1).

Avoidance of ice by vitrification can generally be achieved with one of two approaches or a combination of both. The first approach employs cooling highly concentrated solutions (typically >50% w/w) that become sufficiently viscous at low temperatures to suppress crystallization rates. Typically, a vitrified material is considered solid when the viscosity reaches 10^{15} poise^[12] Vitrification can also be achieved by selecting sufficiently high cooling rates to prevent ice crystallization in relatively dilute solutions (<50% w/w). This second approach generally produces a metastable state that is at risk of devitrification (recrystallization) during warming. Ice formation during warming is just as potentially injurious as during cooling.

The tissue vitrification technology described here employs >50% w/w cryoprotective agents. The formulation and method was licensed from the American Red Cross, where it was intended for organ preservation.^[39,40] However, even though rabbit kidneys were vitrified, they could not be rewarmed. Viability

Table 1 Vascular tissue functions after either frozen or vitrified cryopreservation and storage

Tissue type	Survival outcome	
	Frozen (%)	Vitrified (%)
Jugular vein ^[37,38]	6–22	84–87
Carotid artery ^[72]	<30	>80
Tissue-engineered blood vessels ^[73]	10.7	82.7

was lost due to ice formation upon rewarming by the aforementioned process. The rewarming of vitrified materials requires careful selection of heating rates sufficient to prevent significant thermal cracking, devitrification, and recrystallization during heating. The use of carefully designed warming protocols is necessary to maximize product viability and structural integrity. Vitrified materials, which may contain appreciable thermal stresses developed during cooling, may require an initial slow warming step to relieve residual thermal stresses. Dwell times in heating profiles above the glass transition should be brief to minimize the potential for devitrification and recrystallization phenomena. Rapid warming through these temperature regimes generally minimizes prominent effects of any ice crystal damage. It is presently not possible to rewarm organs rapidly enough due to their high volume relative to the volume of tissues. Development of optimum vitrification solutions requires selecting compounds with glass-forming tendencies and tolerable levels of toxicity at the levels required to achieve vitrification. Due to the high total solute concentration within the solution, stepwise protocols should be used at low temperatures for the addition and removal of cryoprotectants to limit excessive cell volume excursions and lower the risk of cytotoxicity. For a current comprehensive review of vitrification, see Taylor et al.^[33]

In addition to *in vitro* studies of cardiovascular tissues, transplant studies have been performed that demonstrate normal *in vivo* behavior of vitrified tissues.^[37,38,41] More recently, we have discovered that vitrification decreases the rate of calcification observed in subcutaneously implanted frozen rat heart valves,^[42] suggesting that vitrification may have other benefits for tissues in addition to increasing cell viability and tissue functions.

More recently, we have extended our vitrification studies to musculoskeletal tissues. Although fresh osteochondral allografts have proven to be effective and functional for transplantation, the limited availability of fresh allograft tissues necessitates the use of osteoarticular allograft banking for long-term storage.^[43–46] Conventional cryopreservation by means of freezing is currently a preferred method for storing tissue in general until needed; however, such protocols result in the death of 80–100% of the chondrocytes in articular cartilage plus extracellular matrix damage due to ice formation. These detrimental effects are major obstacles preventing successful clinical utilization of osteochondral allografts^[45,47,48] and commercial success of tissue-engineered cartilage constructs. Consequently, the search has continued for a better preservation method. The method we have employed for vitrification of articular cartilage is outlined subsequently as an example of a vitrification protocol.

Table 2 Cryopreservation methods

	Freezing	Vitrification
Cryoprotectants	1 M DMSO 2.5% Chondroitin Sulphate	3.1 M DMSO 2.2 M 1,2-propanediol 3.1 M Formamide
Cooling rate	−1°C/min to −80°C	−40°C/min to −100°C −3°C/min to −135°C
Storage	Vapor phase nitrogen	
Warming	Rapid	
Cryoprotectant removal	3 steps	6 steps

This method is contrasted with the method^[49] that we have employed for cryopreservation by freezing of cartilage in Fig. 1 and Table 2.

Example: Protocol for Cryopreservation of Cartilage by Vitrification

Osteochondral plugs (4.0 mm diameter) from New Zealand white rabbits' femurs were gradually infiltrated with an 8.4 M vitrification solution consisting of 3.10 M DMSO, 3.10 M formamide, and 2.21 M 1,2-propanediol in EuroCollins solution at 4°C.^[37,38] Precooled vitrification solution (4°C) was added in six sequential, 15-minute steps. After addition of the final vitrification solution, osteochondral plugs were placed in a glass scintillation vial (Dia. × H, 25 × 60 mm) containing 2 ml of the precooled vitrification solution. The top of the vitrification solution was then covered with 0.7 ml of 2-methylbutane (isopentane, freezing point: −160°C, density: 0.62) at 4°C to prevent direct air contact. A thermocouple was inserted into a separate dummy sample of the same vitrification solution and its output monitored via a digital thermometer throughout the cooling process. Samples were cooled rapidly (43°C/min) to −100°C, followed by slow cooling (3°C/min) to −135°C, and finally storage in a freezer at −135°C for a minimum of 24 hours. Vitrified plugs were rewarmed in two stages: first, slow warming to −100°C (30°C/min) and then rapid warmed to melting (225°C/min). After rewarming, the vitrification solution was removed in a stepwise manner.

CARTILAGE VITRIFICATION

Cryosubstitution studies of frozen and vitrified articular cartilage plugs revealed negligible ice in the vitrified specimens (Fig. 4), and extensive ice

Fig. 4 Light microscopic comparison of frozen and vitrified cartilage specimens that were cryosubstituted during low-temperature storage. The vitrified specimen (A) is free of ice. In contrast, the frozen specimen (B) demonstrates extensive ice in both the lacunae and the extracellular matrix. Cells on the outermost edge (top, right side) of the frozen cartilage specimen are free of ice. Cryosubstitution is a method for demonstrating the presence or absence of ice during cryopreserved storage.^[50] Cryosubstitution was performed using chilled (-90°C) 1% osmium tetroxide in 100% methanol in high-density polyethylene scintillation vials containing cryopreserved specimens at -90°C . The tissues were dehydrated by replacing the frozen or vitrified water with cryosubstitution medium over a period of several days at -90°C . The heat-sink and vials were then placed in a -20°C freezer overnight, followed by 4°C for one hour, and then finally brought to room temperature. This gradual warming of the tissue and cryosubstitution media ensures complete osmium tetroxide tissue fixation. Finally, these tissues were transferred to 100% acetone; infiltrated with araldite resin; and polymerized, sectioned, stained, and viewed by light microscopy.

formation, both in the extracellular matrix and deeper lacunae, in frozen specimens (Fig. 4). Some cell shrinkage was observed in the lacunae of vitrified specimens (Fig. 4), which is most likely related to high cryoprotectant concentrations. The presence and absence of ice are better appreciated in representative electron micrographs of frozen (Fig. 5) and vitrified, cryosubstituted (Fig. 5) cartilage samples.

Viability assessment of fresh and cryopreserved rabbit articular cartilage specimens demonstrated that oxidation–reduction in vitrified samples was approximately 85% of fresh samples (Fig. 6). Similar values have been obtained using live/dead stains for assessment of cell viability.^[51] Transplantation studies have also been performed in rabbits to compare the performance of fresh, frozen, and vitrified specimens. These studies demonstrated that vitrified cartilage performance was not significantly different to fresh, untreated cartilage. In contrast, frozen cartilage performance was significantly different when compared to either fresh or vitrified cartilage.^[74] These studies combine to demonstrate that the vitrification process results in ice-free preservation of rabbit articular cartilage plugs and that about 85% of cellular metabolic activity is retained following rewarming. Frozen tissues contained ice within the cells and the matrix, with the exception of the articular surface, where some viable cells were observed (Fig. 4).

GENERAL DISCUSSION

We believe that the experimental data presented here makes a strong case for cryopreservation of cartilage

by vitrification for osteochondral grafts. The baseline vitrification process, which has yet to be optimized, protected the cartilage from ice formation and demonstrated retention of cell metabolism and viability.^[51] These observations support the hypothesis that vitrification may be applicable to all biological systems.

Simple freezing of cells or tissues results in nonviable, nonfunctional materials. Little advance was made in the field of cryopreservation until Polge et al.^[52] discovered the cryoprotective properties of glycerol. Subsequently, Lovelock and Bishop^[53] discovered that DMSO could also be used as a cryoprotectant. Since the discovery of these cryoprotective agents, cryoprotection during freezing and thawing of biological materials has become established and many other cryoprotectants have been identified that may play a role in cryopreservation, either by freezing or vitrification methods (Table 3). Isolated chondrocytes in suspension, in common with many other cell types, can be preserved using conventional cryopreservation methods involving freezing. In such methods, the cells may be concentrated and vitrified in channels between regions of extracellular ice (Fig. 1); however, chondrocytes embedded in their natural matrix are extremely difficult to preserve by similar freezing methods, presumably because the cells cannot move away from forming extracellular ice.

Studies using a variety of animal articular cartilage models^[44,45,54,55] and human cartilage biopsies^[47] have revealed no more than 20% chondrocyte viability following conventional cryopreservation procedures employing either DMSO or glycerol as cryoprotectants. Ohlendorf et al.^[45] used a bovine articular cartilage, osteochondral plug model to develop a clinical

Fig. 5 Transmission and scanning microscopic comparison of frozen and vitrified cartilage specimens that were cryosubstituted during low-temperature storage. Both the transmission electron and scanning electron micrographs (A & C) illustrate the absence of cellular material in the articular cartilage lacunae. In contrast, the cells are still present in the lacunae of vitrified articular cartilage specimens (B & D). Specimens were cryosubstituted as indicated in the legend for Fig. 4. Tissue for transmission electron microscopy was dehydrated in acetone, gradually infiltrated with an araldite epoxy resin, embedded, and polymerized for 18 hours at 60°C. Sections (75 nm) were cut using a diamond knife with a Reichert OMU2 ultramicrotome. The sections were then double-stained using uranyl acetate followed by lead citrate. The sections were viewed in a JEM-1210 transmission electron microscope (JEOL USA Inc., Peabody, MA) at 80 kV accelerating voltage. For scanning electron microscopy, three changes of 10 ml Hexamethyldisilazane were used in the drying process. The tissue was then oriented on a specimen stub and coated with 20 nm of gold/palladium using an ion-sputter coater. The samples were viewed using a JSM 5410 scanning electron microscope (JEOL USA Inc., Peabody, MA) operated at 10 kV accelerating voltage.

cryopreservation protocol. This protocol employed slow-rate cooling and 8% DMSO as the cryoprotectant. They observed loss of viability in all chondrocytes except those in the most superficial layer at the articular surface. Muldrew et al.^[54] previously investigated chondrocyte survival in a similar sheep model. These researchers observed cells surviving postcryopreservation close to the articular surface and deep at the bone/cartilage interface. The middle layer was devoid of viable cells. More recently, Muldrew et al. demonstrated improved results using a step-cooling cryopreservation protocol, but cell survival posttransplantation was poor and again there was significant loss of cells in the midportion of the graft.^[56] The reason for lack of cell survival deeper than the superficial layers of articular cartilage is most likely multifactorial and related principally to heat and mass transfer considerations.^[57] Surface cells freeze and thaw more rapidly than cells located deep within

the matrix. This phenomenon could result in a greater opportunity for ice to form, both within cells and in the extracellular matrix, deeper within the articular cartilage. Furthermore, typically employed concentrations of DMSO (8–20%) may not penetrate adequately to limit intracellular ice formation. Recent data from Jomha et al.^[58] demonstrated that increasing DMSO concentrations to 6 M can result in higher overall cell survival (40%) after cryopreservation. These observations suggest that use of higher DMSO concentrations results in better penetration of the DMSO into the cartilage.

We are aware that other factors, in addition to ice formation, may have biological consequences during freezing procedures. Two of these factors are the inhibitory effects of low temperatures on chemical and physical processes, and, perhaps more importantly, the physiochemical effects of rising solute concentrations as the volume of liquid water decreases

Fig. 6 Metabolic comparison of frozen and vitrified specimens after rewarming under tissue culture conditions. The alamarBlue™ assay was employed as a noncell-specific viability assay. This assay utilizes a water-soluble fluorometric viability indicator based on the detection of metabolic activity, specifically, an oxidation-reduction (REDOX) indicator, which both fluoresces and changes color in response to chemical reduction of the cell culture medium caused by cell metabolism. Aliquots of medium from tissue samples were incubated with alamarBlue™ working solution in microtiter plate wells and read on a microtiter plate spectrofluorometer at 590 nm. The data are expressed as the mean \pm 1 standard error of the mean of 10 samples of articular cartilage assayed using alamarBlue™. Viability is expressed as relative fluorescence units (RFU) relative to the dry weight of each articular cartilage sample. (Reproduced with permission from Ref. [33].)

during crystallization. This latter process results in a decrease in cell volume and the risk of solute precipitation. Several hypotheses have been published on mechanisms of freezing-induced injury based upon such factors,^[57,59] but our own experiences with mammalian tissues concur with others that the principal disadvantage of conventional cryopreservation revolves primarily around ice formation.^[37,38,40,60–62]

Furthermore, cryopreservation by vitrification of tissues offers several important advantages compared with procedures that allow or require ice formation. First, complete vitrification eliminates concerns for the known damaging effects of intra- and extracellular ice crystallization. Second, tissues cryopreserved by vitrification are exposed to less concentrated solutions of cryoprotectants for shorter time periods. For example, Rall^[9] has calculated for embryos that during a typical cryopreservation protocol involving slow freezing to -40°C or -70°C , the cells are exposed to cryoprotectant concentrations of 21.5 and 37.6 osmolal, respectively. In contrast, cells dehydrated in vitrification solutions are exposed for much shorter periods to <18 osmolal solution, although the temperature of exposure is higher. Finally, unlike conventional cryopreservation procedures that employ freezing,

Table 3 Cryoprotective Agents

Small molecular compounds	Permeable (e.g., DMSO, glycerol, 1,2-propanediol) Nonpermeable (e.g., sucrose, polyvinylpyrrolidone)
Used in slow rate freezing and vitrification	
Protect cells via several mechanisms	Displacement of freezable water Suppression of high electrolyte concentration Used to control frozen fraction of water

vitrification does not require controlled cooling and warming at optimum rates. A principal benefit of vitrification is the elimination of requisite studies to determine optimal cooling rates for tissues with multiple cell types. Successful vitrification requires that the thermal processing be rapid enough to transition regions of maximal ice crystal nucleation and growth that occur above the glass transition temperature of the solution. Thus, it is only necessary to cool solutions at rates in which a negligible fraction of the solution forms ice (typically $<0.2\%$).^[63] Vitrified materials have a similar rate requirement during heating, when samples are rewarmed for subsequent use, to limit ice formation to negligible levels (typically $<0.5\%$).^[64] A major objective of our current research is the development of nontoxic vitrification formulations that have a minimal risk of ice formation during cooling and warming of bulk samples.

REMAINING HURDLES IN THE DEVELOPMENT OF VITRIFICATION METHODS FOR BIOLOGICAL SPECIMENS

There are a number of significant challenges for deployment of vitrification methods for tissue-engineered medical products. Vitrification approaches to preservation have some of the limitations associated with conventional freezing approaches. First, both approaches require low-temperature storage and transportation conditions. Neither can be stored above its glass transition temperature for long without significant risk of product damage due to inherent instabilities leading to ice formation and growth. Both approaches employ cryoprotectants with their attendant problems and require competent technical support during rewarming and cryoprotectant elution phases. The high concentrations of cryoprotectants necessary to facilitate vitrification are potentially toxic because

the cells may be exposed to these high concentrations at higher temperatures than in freezing methods of cryopreservation. Cryoprotectants can kill cells by direct chemical toxicity, or indirectly by osmotically-induced stresses during suboptimal addition or removal. Upon completion of warming, the cells should not be exposed to temperatures above 0°C for more than a few minutes before the glass-forming cryoprotectants are removed. It is possible to employ vitrified products in highly controlled environments, such as a commercial manufacturing facility or an operating theater, but not in a doctor's outpatient office, or in third world environments. Formamide, one of the components of the 55% (v/v) vitrification solution consisting of 3.10 M DMSO, 3.10 M formamide, and 2.21 M 1,2-propanediol in EuroCollins solution at 4°C^[37,38] (known as VS55), is a known mutagen. Alternatives to formamide with less safety risks and potentially easier clinical acceptance are being sought. However, the cytotoxicity of complex cryoprotectant formulations containing formamide is surprisingly much less than the cytotoxicity of single-component formulations at the same concentrations.

Heat transfer issues are the primary hurdle for scaling up the successes in tissues to larger organs. The limits of heat and mass transfer in bulky systems result in nonuniform cooling and contribute to stresses that may initiate cracking. In fact, the higher cooling rates that facilitate vitrification will typically lead to higher mechanical stresses. Macroscopic scale instability manifested as cracking or fractures was first reported during the vitrification of glycerol solutions.^[65] Fractures may also provide an interface for nucleation that can initiate devitrification.^[66] Very little information on the material properties of vitreous aqueous solutions exists. Material properties such as thermal conductivity and fracture strength of vitreous aqueous solutions have many similarities with their inorganic analogues that exist at normal temperatures, e.g., window glass and ceramics. Any material that is unrestrained will undergo a change in size (thermal strain) when subjected to a change in temperature. Materials in general, and tissues as they are cryopreserved in particular, shrink when they are brought from physiological temperature down to lower temperatures. Extensive testing is necessary to determine how the thermal strain (shrinkage) of a material depends on the temperature and possibly on the rate at which the temperature is changed. Under these unrestrained conditions when thermal expansion or contraction is free to occur, the stress remains zero, i.e., no forces act on the material. As tissues are cryopreserved, they are externally free to shrink. However, in practice, it is impossible to cool a tissue uniformly. The outer surface decreases in temperature more rapidly than the inside. The outside of the tissue

is forced to shrink less and the inside to shrink more. The stresses that arise to accommodate the differential shrinkage are dependent on the stiffness and relaxation of the material. If these stresses are too severe, fractures may occur.

Calculations of stress in frozen biological tissues have shown that thermal stress can easily reach the yield strength of the frozen tissue, resulting in plastic deformations or fractures.^[67-69] The driving mechanism of thermal stress is the constrained contraction of the frozen or vitrified tissue. It is commonly assumed that thermal expansion of frozen biological tissues is similar to that of pure water ice crystals,^[67,70] and Rabin et al.^[71] have confirmed this experimentally. Moreover, their studies provided some preliminary insight with regard to the effect of the presence of cryoprotectants on the thermal expansion. Results of pilot expansion tests of rabbit muscle permeated by the cryoprotectants DMSO and glycerol solutions, and pig liver perfused with DMSO solution indicated that the cryoprotectants dramatically reduced the thermal expansion at higher temperatures and created a maximum value of thermal expansion within the temperature range of -70 to -100°C. Rabin (personal communication) has preliminary data indicating that tissue thermal expansion decreases with increasing DMSO concentration that may be explained by a change in physical properties associated with a glass transition. The competing needs of vitrification and minimization of mechanical damage demand a greater understanding of both vitrification and stress development. Although mechanical stress has long been recognized as an important mechanism of tissue destruction, it has received very little attention in the context of cryobiology.

Another major hurdle for deployment of vitrification methods is the development of effective rapid warming techniques for larger specimens (greater than 10 ml volume) to prevent devitrification and ice growth by recrystallization. Microwave warming has been attempted, but has never been successful due to the uneven warming of specimens and problems with thermal runaway, which results in heat-denatured tissues. In 1990, Ruggera and Fahy^[31] reported success in warming test solutions at rates of up to about 200°C/min using a novel technology based on electromagnetic techniques (essentially microwave heating). Unfortunately, unpublished results indicate that this method is also problematic due to the uneven warming of specimens and problems associated with thermal runaway. Others have taken a systematic approach to develop a dielectric heating device to achieve uniform and high rates of temperature change.^[29,30] This has been achieved in some early model systems, but application of this technology to the survival of cells and tissues has yet to be reported.

INTRODUCTION

Over two million artificial hip and knee joints are implanted in patients every year. For many patients, these provide excellent clinical performance for 10 years or longer, with relief of pain and restoration of function. Clinical studies show survivorship of 90% for prosthetic components after 10 years implantation. In the longer term, failure rates start to increase. One major cause of medium- to long-term failure is bone loss or bone lysis (osteolysis) caused by adverse reactions to the wear particles generated by the artificial joints. Billions of micron and submicron size wear particles are generated every year by the articulating interfaces in the artificial joints. These particles accumulate in periprosthetic tissues and in interface tissues where adverse cellular reactions, predominantly mediated by macrophages, lead to bone resorption and eventually loosening and failure of the prostheses. The particle/cell-mediated biological pathways that lead to osteolysis are complex. Two independent processes predominate. For most prostheses, micron and submicron particles (such as those generated by the polyethylene bearing surfaces) are taken up by macrophages, which are stimulated to produce osteolytic cytokines such as TNF alpha, which act to cause bone resorption. For chemically stable particles such as polyethylene, these are not digested by the macrophages and persist to produce a chronic inflammatory response. Additionally, other wear particles that are chemically active, such as metal, release ions into the tissues. At high concentrations, these can affect cell viability (of macrophages, fibroblasts, osteocytes) causing local tissue necrosis.

These adverse reactions to wear particles are dependent on the concentration, size, morphology, and chemistry of the wear particles generated by the artificial joints, and directly determine the longevity of the prosthesis. Additionally, the accumulation of particles within the periprosthetic tissues is dependent on the transport processes within the body, which, in turn, are determined by particle size and morphology, as well as the structure and integrity of local tissue interfaces. Larger particles, one micron and above, as well as submicron (0.1 to 1 μm) size particles have been found

to remain and accumulate in the periprosthetic tissues. Smaller nanometer size particles (1 to 100 nm) have also been found to be distributed more widely and cause adverse systemic reactions. The longevity of the prostheses and its functional biocompatibility is critically determined by the wear volume and characteristics of the wear particles generated during articulation. Traditionally, the materials used in artificial joints have been primarily selected on the basis of volumetric wear rate, and while this remains important, it is now recognized that the characteristics and biological activity of the wear debris produced is also critical to the clinical performance of the artificial joints.

OVERVIEW

In this article, an holistic approach to wear debris generation in artificial joints is taken in which the tribological processes that generate the wear particles and the wear rates, the characteristics of the wear particles, and the biological reactions and functional biocompatibility of the wear particles are considered in an integrated manner.^[1,2]

In artificial hip joints, the traditional bearing materials have been a metal femoral head articulating against an ultrahigh molecular weight polyethylene socket. Concerns about polyethylene wear debris-induced osteolysis have led to the development of improved polyethylenes, the use of ceramic femoral heads, and the introduction of hard-on-hard bearing surfaces such as metal on metal and ceramic on ceramic. The introduction of modular prosthetic designs has led to additional interfaces in which wear particles can be generated, such as the head stem junction and the acetabular insert/acetabular cup interface, as well as fixation interfaces such as the stem cement interface. Although the volume of debris generated at these non-articulating interfaces is often much less than at the articulating surfaces, the debris can have direct access to local areas of periprosthetic tissues (such as through screw holes or through the cement mantle) and, hence, produce high localized concentrations and osteolysis.

In artificial knee joints, the predominant bearing materials currently used are metal and polyethylene. Clinical experience and follow-up in knees is generally shorter than in hips and the longer-term problem of osteolysis is only just emerging. Although few materials have been used in the knee, there are a greater number of design variables that influence wear particle generation.

In this article, wear particle generation in traditional metal-on-polyethylene hips is described along with the recently introduced improved polyethylenes. Wear particle generation in hard-on-hard bearings for hips is then discussed. In the knee, polyethylene wear particle generation is described with a particular emphasis on the effect of different prosthetic designs on particle generation.

HISTORICAL POLYETHYLENE ON METAL HIP PROSTHESES

Polyethylene-on-metal bearing couples for artificial hip joints were first introduced over 40 years ago by the late Sir John Charnley. Charnley also introduced the concept of bone cement fixation. Both these approaches remain the primary bearing surface and fixation methods used in hip prostheses today. In these prostheses, the primary source of wear debris is the articulating interface between the polished metallic spherical convex head and the concave hemispherical ultrahigh-molecular-weight polyethylene acetabular cup. As the polished head slides over the polymer cup during normal activities, the polyethylene wear particles are produced by microscopic asperity interactions, causing adhesive, abrasive, and micro fatigue wear mechanisms. The polyethylene particles have been found to be in the range 0.1 to 10 μm in size with the majority being submicron in dimensions. These very small particles mean that there are over 10 billion particles produced for every one cubic millimeter of wear volume. Clinical studies^[3] have revealed wear rates of approximately 60 mm^3 per year, with substantial patient variability. Total wear volumes of over 600 mm^3 at failure are equivalent to approximately 6000 billion polyethylene wear particles released into the periprosthetic tissue.

Laboratory wear studies of the historical polyethylene have shown wear rates of approximately 40 mm^3 per million cycles,^[4] with similar wear particle characteristics to those found in vivo.^[5] Laboratory wear studies have allowed the identification of factors that can increase the acceleration of wear debris generation in the historical polyethylenes and that may contribute to the patient-to-patient variation seen clinically. Increased patient activity (number of cycles) as well as a larger head size increases the wear rate due

to increased sliding distances.^[6] Damage to the polished metallic heads, often caused by hard third body particles, can accelerate wear by a factor of two to three times,^[7] and this has been also shown in clinical studies.^[3]

The majority of the historical ultrahigh molecular weight polyethylene had a molecular weight in the range of two to four million and was sterilized with gamma irradiation in the presence of oxygen. Irradiation produces chain scission of the polyethylene, generating both cross-links and free radicals. In the presence of oxygen, the latter cause degradation of the polyethylene, both while on the shelf and also once implanted in vivo.^[8] This degradation can accelerate the wear rate^[9] and, most importantly, also reduce the size of the wear particles.^[5] Serum proteins have been shown to be absorbed by polyethylene.^[10] Other factors, such as the nature of the lubricant, affect wear, with increased lipid concentration reducing wear.^[11] The nature of the gait cycle and the kinematics of the wear path can alter wear rates in polyethylene. Pooley and Tabor^[12] showed that with linear polymers, linear motion or sliding produced strain hardening and increased wear resistance. Wang^[13] showed that for conditions in the hip in which there is multidirectional sliding, the material is strain softened in the transverse direction, allowing cross shear frictional forces found in multidirectional sliding to accelerate wear. A clinical correlation between the aspect ratio of the wear track and the wear rate has been shown by Bennett et al.^[14] Low-aspect tracks with higher cross shear increased wear, while high-aspect, more linear wear tracks produced lower wear rates, confirming earlier simulator studies.^[4,13] The concentration, size, and morphology of the polyethylene wear particles have been found to be critical in determining the stimulation of macrophages and the release of osteolytic cytokines. Increased volumetric concentrations of wear particles increased the release of osteolytic cytokines.^[15] Polyethylene particles in the size range 0.1 to 1 μm were found to be six times more reactive than particles in the range 1 to 10 μm .^[16] Direct studies of bone resorption^[17] have confirmed higher levels of osteolysis with the smaller particles in the 0.1 to 1 μm size range. These findings of the osteolytic response being dependent on wear particle size have significant impact. For example, oxidative degradation, which produces smaller wear particles,^[5] will work synergistically with increased wear volume to accelerate osteolysis and loosening. A small increase in the molecular weight of polyethylene from two to four million to four to six million has also been shown to reduce the size of the wear particles and increase the levels of osteolytic cytokines produced.^[18] Laboratory models have now been developed that combine tribological and biological studies to directly predict the functional

osteolytic potential of polyethylene-bearing materials and designs in artificial hip joints.^[19] These can be applied to investigate reductions in osteolytic potential of new and improved polyethylenes that have been introduced into clinical practice in recent years.

NEW AND IMPROVED POLYETHYLENES FOR HIP PROSTHESES

The recognition that polyethylene wear particles are a major cause of osteolysis and failure in hip prostheses, and the understanding of the role of oxidation following gamma irradiation in air leading to degradation and increased wear rates has led to two new approaches for improvement of polyethylene. Stabilized polyethylenes have been produced either through alternative sterilization methods such as ethylene oxide or gas plasma or through irradiation in an inert atmosphere such as nitrogen, vacuum, or argon. The latter is thought to have an advantage as it also introduces a moderate level of cross-linking which can reduce wear rates. Moderate cross-linking of ultrahigh-molecular-weight polyethylene (molecular weight 2 to 4 MRad) has been shown to reduce the volumetric wear rate of ultrahigh molecular weight polyethylene by 30% in hip simulator studies^[20] (from 49 to 35 mm³ per million cycles). However, the moderate cross-linking also produced a greater percentage volume of the smaller particles in the 0.1 to 1 µm size range, with the net result of little difference in the functional osteolytic potential of the two stabilized materials. However, both of these stabilized materials have substantially reduced wear rates and osteolytic potential compared to historical gamma irradiated in air and aged polyethylene.^[21]

The reduction in wear volume found by moderately cross-linking polyethylene led to intentional cross-linking with higher levels (medium or high) of irradiation, either gamma irradiation in an inert atmosphere or electron beam irradiation, followed by heat treatment to recombine free radicals and produce additional cross-links. These increased levels of cross-linking increase the wear resistance of the ultrahigh molecular weight polyethylene, but also reduce its ductility and toughness. McKellop et al. have shown an 85% reduction in wear rate with 5 MRad gamma irradiation and heat treatment.^[22] While Muratoglu et al. have shown a greater reduction of over 90% with 10 MRad of electron beam irradiation,^[23] Kurtz et al. have also shown reduced wear rates with increased levels of cross-linking.^[24] In our wear simulator studies,^[25] the reduction in wear rate with increased cross-linking was significant, but not as great as reported in other studies (see Table 1).

Table 1 Relative wear rates with irradiation cross-linking of UHMWPE

Cross-linked polyethylene	Relative wear rate
0 MRad	100%
5 MRad	80%
10 MRad	25%

Analysis of the wear particles showed a trend toward smaller particles in the 0.1 to 1.0 micrometer size range with the higher levels of cross-linking. Cell culture studies also showed that a unit volume of wear debris from the cross-linked material produced higher levels of osteolytic cytokines.^[26] This has to be considered alongside the reduction in wear volume. Analysis of the volume of wear particles in the most biologically active size range (0.1 to 1 µm) showed a reduction with cross-linking (Table 2), and this was consistent with a predicted reduction in functional osteolytic potential with cross-linking of the higher molecular weight polyethylene.

These studies of cross-linked higher molecular weight polyethylene have to be considered with the separate studies, which showed that the lower molecular weight polyethylene wear debris in its non-cross-linked form also had a substantial reduction in osteolytic potential compared to this higher molecular weight material.^[18,26] Clinical studies are now under way with the new cross-linked polyethylenes. However, longer periods of time of follow-ups of 10 to 20 years will be necessary to determine the reduction in osteolytic potential clinically.

ALTERNATIVE HARD-ON-HARD BEARING COUPLES

Ceramic-on-ceramic^[27] and metal-on-metal bearing couples^[28] have been used in very limited numbers for over 30 years. It is only in the last five years, with concerns over polyethylene wear debris-induced osteolysis, that they have been used more extensively

Table 2 Relative total volume of wear particles in critical size range 0.1 to 1 µm for higher molecular weight polyethylene

Cross-linked polyethylene	Relative total volume of wear particles in size range 0.1 to 1 µm rate
0 MRad	100%
5 MRad	95%
10 MRad	35%

clinically. Both materials are substantially harder than polyethylene with the hardness of alumina ceramic (25,000 MPa) and cobalt chrome alloy (4000 MPa) being substantially greater than ultrahigh molecular weight polyethylene (less than 100 MPa). In classical wear terms, the wear rate is inversely proportional to hardness, giving lower wear rates for the harder materials. Additionally, the smooth surface finishes of the ceramic and metal bearings (surface roughness $\sim 0.01 \mu\text{m Ra}$), compared to $0.1 \mu\text{m Ra}$ for polyethylene, provide further potential for wear reduction through fluid film lubrication.

Clinically-recorded wear rates for these historical hard-on-hard bearings have been approximately 1 mm^3 per year for metal on metal^[28] and even less for alumina ceramic on ceramic couples.^[29] These values are 100 times less than those found for historical polyethylene, which is consistent with the differences in hardness of the materials. It is not surprising that there has been little evidence of wear debris-induced osteolysis in hard-on-hard bearings. However, historical wear rates and clinical performance have been variable, and geometrical factors such as radial clearance and sphericity, anatomical factors such as positioning, fixation stability, and soft tissue tension,^[30,31] as well as historical material quality^[27] have all influenced wear rates. Only recently has the wear of these hard-on-hard bearings been investigated systematically and the wear debris and subsequent cellular and tissue reactions studied.

There have been considerable improvements in the properties of alumina ceramics over the last 20 years with smaller grain sizes and more recently, hot isostatic pressing (HIPING) producing increased fracture toughness and hardness. Under standard walking cycle hip simulator conditions, the wear rates of alumina ceramic-on-ceramic bearings are extremely low, less than 0.1 mm^3 per million cycles^[32] with a small reduction in wear with HIPED material.^[33] The wear mechanism found was relief polishing,^[32,33] leaving an extremely smooth wear surface, $Ra < 0.01 \mu\text{m}$, and extremely small wear debris, 10 nm in size.^[34] However, these wear rates, scars, mechanisms, and debris did not fully represent clinical retrievals, in which relief polishing was found on all components. Additionally, on many retrievals, more severe stripe wear and intergranular fracture were found on femoral heads, cup rim damage was identified, and higher wear rates of up to 1 mm^3 per year were found.^[29,31] Furthermore, clinical wear debris was both nanometer in size with large micron-size debris associated with stripe wear, identified in periprosthetic tissue.^[35] More recently, this has been simulated in the laboratory by introducing joint laxity and contact of the head on the rim of the acetabular cup,^[30] which produced higher wear rates up to 1 mm^3 per million cycles. The nanometer

and micrometer ceramic wear particles and the characteristic stripe wear on the head and cup rim damage^[36] were also generated. Hence, it has been found that this head cup rim contact is necessary to replicate clinical wear rates, mechanisms, and debris generated in alumina ceramic-on-ceramic bearings.^[34]

Alumina ceramic has been used extensively, as in its bulk it is a bioinert biomaterial.^[27] However, as we have seen with polyethylene, the biological response to particles has been found to be very different to that of the bulk. Recent studies have directly cultured macrophages with clinically relevant alumina ceramic wear debris and have found that at very high volumetric concentrations, it will stimulate macrophages to produce osteolytic cytokines such as $\text{TNF}\alpha$.^[37] However, for a given volumetric concentration, ceramic debris is less reactive than the more widely used polyethylene debris. Most importantly, at functional concentrations, which are much lower for alumina ceramic, the osteolytic potential wear debris of alumina ceramic bearings is much less than polyethylene bearings.^[38]

The clinical wear rates of historical cobalt chrome alloy were reviewed by Amstutz et al.^[28] and although found to be highly variable, they were found to be substantially lower than polyethylene, approximately 1 mm^3 per year. Doorn et al. studied the characteristics of cobalt chrome debris in surrounding periprosthetic tissues and generally found it to be very small in size (10 to 100 nm) with only a few particles larger than 100 nm in size.^[39] Again, the harder historical bearing was found to produce lower wear rates and have smaller particles and a smoother wear surface than polyethylene. There have been clinical concerns about the chemical activity of small cobalt chrome wear particles, and release of cobalt chrome ions into the periprosthetic tissues and systemically in the body. There is anecdotal evidence of widespread distribution of smaller metallic particles throughout the body.^[40]

The recent development and clinical introduction of second generation metal-on-metal hip prostheses has led to more widespread simulator studies and better understanding of the variables that control the generation of wear debris in cobalt chrome metal on metal hip prostheses. The carbon content of the cobalt chrome alloy has been found to be an important determinant of wear, with combinations of high carbon cobalt chrome alloys producing lower wear rates than low carbon cobalt chrome alloys.^[41,42] In both cases, nanometer size wear particles in the range 10 to 100 nm were identified. Metal-on-metal hip prostheses appear to be very sensitive to the tribological conditions of the simulator with kinematics and loading conditions changing the wear rates from 0.1 mm^3 /million cycles to 1.5 mm^3 /million cycles for the same prostheses.^[43] Chan et al. found stop start motion to

increase wear^[44] and more recently, it has been shown that both elevation of the swing phase load from 100N to 270N and also increased joint laxity can increase wear rates from 0.1 to over 1 mm³/million cycles.^[45] This is indicative that metal-on-metal hips are sensitive to the contact conditions and resulting lubricating film thicknesses.^[46] This is then supportive of findings that larger diameter metal-on-metal hips will reduce wear by improved lubrication.^[46] However, there are concerns about these arguments as the reduction of wear by lubrication is dependent on many factors such as contact conditions, loading conditions (including swing phase load), and the need for continuous motion and activity. If the fluid film breaks down, boundary lubrication will occur, friction and wear will increase, and under these conditions, the greater sliding distance of the larger diameter head will increase wear rates. Although the wear rates of metal on metal under these conditions of 1 to 2 mm³/million cycles remain low compared to polyethylene, it is the nature of the wear debris and its biochemical activity that remain a concern. Recent cell culture studies with clinically relevant nanometer-size cobalt chrome wear debris showed substantial reductions in cell viability at low concentration levels of 5 (μm)³/cell.^[47] It is interesting to compare this with the concentration of 30 to 100 (μm)³/cell of polyethylene particles that are needed to stimulate significant amounts of osteolytic cytokines.^[15,16] At the lower levels of concentration 5 (μm)³/cell, neither polyethylene nor ceramic debris has any effect on cell viability. The small cobalt chrome wear particles have a very large surface area for release of both cobalt and chromium ions, which influences cell and tissue viability at low concentration levels. Clinical evidence of local tissue necrosis (metallosis) has been found when metallic ion release has been high.^[28,34] The more recent introduction of large diameter metal-on-metal surface replacement hip prostheses has further highlighted these concerns.

ARTIFICIAL KNEE PROSTHESES

The predominant bearing surfaces in knee prostheses have been ultrahigh-molecular-weight polyethylene (UHMWPE) articulating against polished cobalt chrome femoral components. Whereas the articulating surfaces are the primary source of wear debris, other interfaces such as the backside wear with the metal tibial tray can generate debris, which may directly access the periprosthetic interfaces through screwholes. UHMWPE wear debris is the predominant concern in the knee with the potential for osteolysis as found in the hip.

Historically, as in the hip, UHMWPE has been irradiated in the presence of air. Oxidative degradation,^[8] which results in reduced toughness, ductility,

and fatigue strength has led to failures of knees by delamination fatigue^[48,49] or delamination wear. This type of wear is predominantly associated with designs that have high contact stress, by excessive gliding of femoral components over tibial trays, by misalignment, or poor surgical technique.^[50] The introduction of oxidative resistant polyethylenes and stabilized materials has been shown to substantially reduce or eliminate this type of delamination failure in laboratory tests.^[51,52]

Although methods of reducing or eliminating delamination failures in knees have been identified, concerns about surface wear and the generation of micron and submicron-size polyethylene wear particles, which can cause osteolysis, remain.^[53] Whereas excellent clinical results at 10 years in the knee have been found,^[54] with over 90% success rates, as in the hip, concerns about longer-term wear debris-induced osteolysis remain.^[53] Howling et al. have identified micron and submicron-size polyethylene wear particles in the knee from early retrievals and predict the increase and accumulation with time to produce osteolysis and late failure, as in the hip.^[55]

In the last five years, there have been several studies of the wear of polyethylene in knee prostheses in knee joint simulators. Initial studies reported low wear rates of less than 5 mm³/million cycles, which is much less than found in the hip.^[56–58] This may have been due to the application of force control to tibial tray motions, which did not realize physiological displacements^[56,57] or the absence of a critical tibial motion such as internal–external rotation^[58] in the simulation. More recent studies using displacement controlled knee simulators, which directly control the tibial tray motions to clinically relevant displacement conditions, have shown much higher wear rates of the order of 5 to 40 mm³/million cycles.^[55,59,60] These studies have also revealed a predominance of submicron and micron-size wear particles as found in the surface wear mechanisms in the hip. Wear rates have been found to be greater in gamma irradiated in air polyethylene^[61] than in more recently developed stabilized polyethylene irradiated in a vacuum.^[62] The wear rate has also been found to be critically dependent on the displacement inputs to the tibial tray. An increase in internal–external rotation and anterior–posterior displacements by a factor of two revealed a sevenfold increase in wear rate.^[59,61] The increased tibial rotation provides additional cross shear frictional forces in the transverse direction, which has been strain softened,^[13] so substantially increasing wear. This dependency of wear on kinematics is similar to that found in the hip.^[4,12–14] In the knee, the development of rotating platform mobile bearing designs, which allows rotation at the tibial platform interface, as well as articulation at the femoral condylar, produces, effectively, linear motion at both

interfaces and a substantial reduction in wear volume.^[59,62] This more unidirectional motion has the additional advantage of generating a lower percentage number of the most biologically active submicron polyethylene wear particles.^[63] Studies of different types of polyethylene materials have shown that they appear to have less influence on wear than the different kinematic conditions or the influence of design.^[59] As increasing numbers of knee replacements are being implanted in younger, more active patients, the incidence of polyethylene wear debris-induced osteolysis and long-term failure may well increase.

CONCLUSIONS

Artificial joints are implanted to provide interfaces for both load carriage and articulation. Wear and the generation of wear debris is an inevitable consequence of restoration of function. The release of wear debris and its accumulation in periprosthetic tissues can lead to adverse tissue reactions, loosening, and failure. These adverse biological reactions are dependent on the volumetric concentration, physical characteristics, size, morphology, and chemistry of the wear particles. This has led to the concept of functional biocompatibility of wear debris^[19] generated in artificial joints, which is dependent on the materials, design, tribological conditions, and surgical approach as well as individual patient specific responses.

Historical polyethylenes that have been gamma irradiated in the presence of air, degrade due to oxidation both in vitro and in vivo, leading to increased wear and increased volumes of smaller and more biologically active wear particles. This has led to osteolysis, loosening, and failure in the hip and the knee. Polyethylene wear particles in the size range 100 nm to 1 μ m have been found to be the most biologically active. Stabilized polyethylenes that do not degrade oxidatively produce lower wear volumes and debris that is less biologically active. In contrast, the use of higher-molecular-weight polyethylene produces debris that is more reactive. Increased levels of cross-linking further reduce the volumetric wear rate, but some of the advantage is lost as the debris itself is smaller and more biologically active. For all polyethylenes, variables such as femoral head damage, increased femoral head size, low aspect ratio (more circular) wear paths, and gait will accelerate wear or debris generation.

Hard-on-hard bearings produce smaller volumes of wear debris than polyethylene bearings in the hip. Additionally, alumina ceramic debris has been found to be both nanometer as well as submicron in size and produces lower levels of biological activity, resulting in substantially reduced osteolytic potential

than polyethylene bearings. Whereas metal-on-metal bearings do give rise to smaller wear volumes, the small nanometer-size particles are chemically active, releasing cobalt and chromium ions, which, even at low volume concentrations, can reduce cell viability. Designs or tribological conditions that accelerate metal-on-metal wear above the low levels of 1 mm³ per year may lead to adverse local tissue reactions and necrosis, as well as elevated systemic metal ion levels. For all the different types of wear debris, there are substantial variations in the levels of individual responses seen in different patients, and further work is needed to understand these patient-specific reactions to wear debris.

The generation of wear debris, which can lead to failure of joint replacement, is a result of complex and interactive mechanical and biological processes. Development and evaluation of new and improved materials and designs, which lead to improved functional biocompatibility and reduced osteolytic potential, need to involve an holistic, multidisciplinary biological engineering approach.

New York, U.S.A*

INTRODUCTION

Although total joint replacement is one of the most successful procedures in modern medicine, many patients will suffer from aseptic loosening of their implants. This complication is a result of periprosthetic osteolysis, which has been documented in up to 20% of patients at ten years.^[1] The osteolysis in aseptic loosening is caused by both biomechanical and biological factors.^[2,3] Motion at the bearing surfaces of the prosthetic joint results in the generation of sub-micrometer particles composed of polyethylene and metallic debris. These implant wear particles from the artificial joint accumulate in the synovium and activate cells in the periprosthetic membrane surrounding the joint. A variety of cell responses triggered by these particles results in the activation and survival of osteoclasts and leads to bone resorption. Thus, the process is initiated and propagated by wear debris particles.

PROINFLAMMATORY CELLULAR RESPONSE TO WEAR DEBRIS

Macrophage and Foreign Body Reaction

As the first line of the innate immune defense, macrophages act as a housekeeper to get rid of any abnormal or non-self entities encountered in the body. Suggested by their name, these cells take advantage of their specific function called phagocytosis, which is the engulfment of foreign particles that can be as large as 10 micrometers in diameter. Phagocytosis of inert particles leads to a foreign body reaction, which is generally regarded as a secondary response following the unsuccessful attempt of macrophages to remove the extracellular materials. The foreign body reaction is characterized by the formation of giant cells, encapsulation of the implant, and chronic inflammation. Foreign body giant cells are formed from the fusion of many individual macrophages when a large object such as an artificial joint implant is encountered. They can secrete degradative agents such as superoxides and free

radicals, causing damage to implants, while at the same time inducing the infiltration of inflammatory cells. In periprosthetic osteolysis, macrophages and foreign body giant cells tend to remain at the interfacial membrane around the implant and form granulation tissue. Initial studies in this field focused on tissues retrieved from patients with revision implant surgery and demonstrated the correlation of the increasing number of macrophages with the deteriorated clinical grade of loosening and osteolysis, suggesting the important roles of macrophages.^[4] The next line of investigation focused on the proinflammatory molecules produced by macrophages following the phagocytosis of wear debris particles. In vitro studies using peripheral blood mononuclear cells (PBMC) and different macrophages cell lines demonstrated a series of cell responses, including the production of: interleukin-1 (IL-1), prostaglandin E2 (PGE2), tumor necrosis factor- α (TNF- α), interleukin-6 (IL-6), lysosomal enzymes, nitric oxide synthase, cyclooxygenase-2 (COX-2), monocyte chemoattractant protein-1, monocyte inflammatory protein-1 α , and RANTES.^[4-9] These osteoclastogenic factors will participate in the inflammatory processes leading into bone resorption, as discussed below. The direct interaction of particles with macrophages was also examined by electron microscopy, revealing that in vitro macrophages tend to surround and attach to the surface of the larger particles and phagocytose the smaller particles within 2 hr.^[10]

In addition to the production of proinflammatory factors that induce osteolysis, a direct role in bone resorption by macrophages has also been suggested from in vitro organ (calvaria) culture studies that demonstrated the bone-resorbing ability of activated macrophages by wear particles.^[11,12] As such, the macrophage has been considered not only an initiator of inflammation mediated osteolysis, but also an important executor of bone digestion.

Tumor Necrosis Factor and Interleukins

Tumor necrosis factor- α is an important agent in human diseases.^[13] The fact that TNF- α has potent

W

and diversified biological effects on cells including apoptosis, host defense, inflammation, and development rendered it a critical factor in both physiology and pathology. The function of TNF- α depends on the interaction of this soluble ligand with its cognate cellular receptors (TNFR1 and TNFR2), activating intracellular signaling events that lead to various biological consequences depending on the circumstances.

One of the first factors investigated in the pro-inflammatory response to wear debris was TNF- α .^[8,9] First, these studies demonstrated that it is an abundant cytokine released by wear debris-activated macrophages/monocytes. Histology studies on periprosthetic membranes indicated increased TNF- α expression in patients with implant loosening with osteolysis vs. patients without osteolysis.^[14] Moreover, the importance of TNF- α in wear debris-induced osteolysis was unambiguously supported by *in vivo* experiments in the mouse calvaria model.^[15] These studies indicated that mice genetically designed to overproduce TNF- α (human TNF- α transgenic mice) demonstrated an exaggerated response, whereas mice defective in TNF- α signaling (TNF-receptor I knockout mice) had significantly less inflammation and bone resorption in response to wear debris. Further investigation using the soluble TNF- α inhibitor etanercept (Enbrel) also demonstrated that blockade of TNF- α function *in vivo* not only prevented the osteolysis induced by wear particles, but also ameliorated the established osteolysis.^[16] All together, this evidence indicates a critical role for TNF- α in aseptic loosening.

Another class of cytokines believed to be critically involved in wear debris-induced osteolysis is the interleukins. Interleukins are hormone-like proteins that mainly regulate the immune system. Normally secreted by lymphocytes, interleukins can activate receptors on cells to influence a variety of inflammation-associated cell behaviors including cell proliferation, cell-cell contact, lymphocyte activation, cell differentiation, T-cell attraction, and other cytokine production. Interleukins also play fundamental roles in many other aspects of homeostasis.^[17] Not surprisingly, interleukins are among the cytokines associated with prosthetic osteolysis reported in patients with aseptic loosening.

IL-1 was first reported in macrophages located in periprosthetic membranes obtained from patients during revised joint replacement.^[5] Subsequently, it was demonstrated that IL-1 is released from macrophages following stimulation with wear debris and mediates increased bone resorption activity *in vitro*.^[11] Similarly, a remarkable level of IL-6 was observed in synovial fluid from failed total joint replacement patients. In a canine model of aseptic loosening, IL-6 was reported in the implant interface following the addition of particles.^[18] Moreover, IL-6 was reported

in many cells challenged with particles *in vitro*,^[8,9] including macrophages, osteoblasts, and fibroblasts, suggesting a broad range of activity. Interestingly, cocultures of macrophages with fibroblasts together significantly increase the production of IL-6, particularly compared with particle-activated macrophages alone, indicating a synergistic effect in the inflammatory response from macrophage-fibroblast interaction in the periprosthetic membrane. The anti-inflammatory mediator IL-10 was also investigated in human PBMC activated by particles. IL-10 can block the production of TNF- α and IL-6 and potentially down-regulate the cytokine response to wear debris. In therapeutic animal models, the viral gene delivery of either IL-1 inhibitor (human IL-1 receptor antagonist) or IL-10 can directly reduce the local inflammation elicited by particles, indicating pivotal roles played by interleukins in the pathology of aseptic loosening.^[19]

In summary, during the foreign body reaction around orthopedic implants, phagocytosis of wear particles by macrophages can release a series of cytokines, including TNF- α , IL-1, and IL-6, to promote an inflammatory network around the implant. By activating other cells in the vicinity and attracting immune cells including T cells, this proinflammation phase can become chronic, leading to a sustained bone resorption phase and aseptic loosening.

OSTEOCLASTOGENESIS INDUCED BY WEAR DEBRIS

Osteoclasts and Rank Ligand

In adult life, bone is continuously turned over, or remodeled, by bone-forming cells (osteoblasts) and bone-resorbing cells (osteoclasts).^[20,21] An imbalance in remodeling often leads to bone defects. Osteoporosis occurs when resorption exceeds formation, whereas osteopetrosis is caused by a lack of bone resorption. In both cases, the number and activity of osteoclasts are usually the key features of the level of bone resorption and therefore are central to the pathogenesis of bone disease. Osteoclasts are derived from the monocyte-macrophage lineage of the hematopoietic stem cell. Osteoclasts form via cell fusion of mononuclear pre-osteoclasts to become multinuclear giant cells and then form specialized structures (i.e., sealing zone, ruffle border) that allow them to firmly attach to bone and secrete acid and degradative enzymes to dissolve the mineralized bone matrix.^[20,21] Osteoclast formation normally requires cell contact from stromal cells or osteoblasts *in vivo*. Macrophage clonal stimulating factor (M-CSF) and receptor activator of nuclear factor- κ B ligand (RANKL) are two main factors that drive the differentiation of osteoclasts. Whereas

M-CSF works as a growth factor for permissive proliferation of osteoclast precursors (OCP), RANKL serves as a differentiation factor specific for osteoclast formation.^[22]

RANKL is a member of the TNF/TNR receptor (TNFR) superfamily and is present primarily as a membrane protein produced by osteoblasts/stromal cells. Its receptor, receptor activator of nuclear factor- κ B (RANK), is located on macrophage/osteoclast precursors and, upon activation by RANKL, stimulates the expression of genes required for osteoclast differentiation. In order to downregulate bone resorption, stromal cells and osteoblast also produce a soluble decoy receptor of RANKL called OPG (osteoprotegerin), which specifically blocks RANK/RANKL signaling.^[20–22] Both gain- and loss-of-function experiments using genetically altered mice established RANKL/RANK as essential determinants for osteoclast formation. The absence of RANKL or overproduction of OPG in mice results in severe osteopetrosis and loss of osteoclasts, whereas the overexpression of RANKL or deletion of OPG induces osteoporosis by excessive osteoclast formation.

Various stromal cell populations express RANKL. RANKL is induced in osteoblasts by many systemic regulators such as parathyroid hormone, vitamin D₃, and the IL-6 family of cytokines and is inhibited by transforming growth factor- β (TGF- β). RANKL expression is associated with many inflammation-associated joint diseases, including rheumatoid arthritis. Synovial fibroblasts cultured from rheumatoid arthritis patients expressed RANKL in response to vitamin D₃. The fact that high levels of RANKL are present in rheumatoid synovial tissue indicates that the inflammatory cell reaction in synovial tissue is essential in the pathogenesis of bone resorption, which likely involves RANKL expression.^[23]

Overwhelming bone resorption is the key feature in the pathogenesis of aseptic loosening, indicating the pivotal role played by osteoclastogenesis. Thus, RANKL is considered an essential regulator in osteolysis induced by wear debris particles. Experiments revealed that either bone marrow cell culture or synovial fibroblasts can increase RANKL expression in response to wear particles *in vitro*^[24] and the enhancement of both RANKL expression and osteoclastogenesis is associated with peri-implant tissue of patients in whom the dramatic osteolytic region is observed.

The importance of RANKL and osteoclasts for aseptic loosening is further indicated by the results of animal experiments in which osteolysis was evaluated in mice lacking RANK/RANKL signaling.^[25–27] First, in a gene therapy model, particles stimulated a sixfold increase in osteoclastogenesis compared with controls without particles, which was efficiently prevented by

the exogenous OPG.^[25,27] Second, RANK^{-/-} mice and mice treated with RANK:Fc are completely resistant to wear debris-induced osteolysis because they have no osteoclasts.^[26] Finally, the same suppression is demonstrated in mice deficient in intracellular downstream effector of RANK (NF- κ B1 knockout mice).^[15]

Thus, preclinical studies formally demonstrated that osteoclastogenesis is a therapeutic target for the prevention of osteolysis in aseptic loosening. For example, the osteoclast inhibitor alendronate controlled the implant failure induced by osteolysis.^[28] Similarly, drugs that inhibit RANKL are also strong candidates for therapeutic interventions in aseptic loosening.

Cytokines and Osteoclast

For a long time, IL-1 and TNF- α have been considered important regulators of osteoclast formation, as well as proinflammation.^[20] Both cytokines can induce bone resorption and osteoclast-like cell formation in murine and human marrow cultures indirectly by inducing RANKL in effector cells and directly stimulating osteoclast differentiation. IL-1 can induce hypercalcemia (a symptom with high calcium release from bone indicating more bone loss) and enhance the growth and differentiation of early osteoclast precursors. IL-1 also increases the number of more committed OCP and stimulates their maturation to bone-resorbing osteoclasts.^[20] Similarly, TNF- α affects the activity of mature osteoclasts and markedly stimulates the induction of OCP in which CD11b is highly expressed.^[29] In addition, TNF- α potentiates the effects of IL-1 on osteoclast formation.^[20] IL-6 can stimulate *in vitro* bone resorption in fetal mouse calvaria and plays roles in systemic osteoclast recruitment and RANKL regulation.^[20,30] Although IL-6-deficient mice do not develop obvious bone abnormality, they are protected from bone loss after estrogen depletion, indicating that IL-6 might be involved in postmenopausal osteoporosis.^[31] As described previously, all of these cytokines are observed in the proinflammation phase of the cell response to wear particles and are implicated in the pathogenesis of aseptic loosening. Thus, it was hypothesized that this synergistic inflammatory microenvironment around bone is associated with osteoclast activation, followed by increasing bone resorption.

TGF- α is a potent inhibitory cytokine for osteoclastic bone resorption.^[20] TGF- β is released and activated during osteoclastic bone resorption, suggesting that TGF- β may be an important coupling factor that induces subsequently new bone formation after inhibiting excess osteoclast formation.^[20] The decrease in total TGF- β observed in the particle-exposed animal group therefore might indicate another mechanism

involving both increasing bone resorption and the suppression of bone formation.^[32]

Cyclooxygenase-2 and Prostaglandin E2

Among factors observed in periprosthetic membranes retrieved from patients with loose, non-septic failed hip replacements, prostaglandins represent another predominant player involved in osteolysis. PGE2 is a primary product of arachidonic acid metabolism in many cells. The COX enzymes mediate a critical step in prostaglandin biosynthesis and include two major isoforms,^[33] COX-1, which is constitutive, and COX-2, which is inducible. Non-steroidal anti-inflammatory drugs, which block both COX-1 and COX-2, have been used successfully to reduce inflammatory responses to a variety of different stimuli. More recently, specific inhibitors for COX-2 have been introduced that have the ability to selectively inhibit the COX-2 isoform and avoid potential complications associated with the blockade of COX-1-mediated events.^[33] There are also four different types of protein membrane receptors for PGE2, named EP1–4.^[34] All of them are members of the G-protein-coupled receptor family. Different species of G proteins are associated with different EP receptors, linking them with the respective downstream gene regulation.^[34] Such differences in the intracellular signaling pathway and downstream targets result in complex PGE2-induced signals in different cell types *in vivo*.

In addition to its role as a proinflammatory mediator, PGE2 is also important in bone regulation. In terms of osteoclastogenesis, PGE2 is normally thought of as a strong activator, although its mechanism of action is not fully understood and contradictory evidence exists.^[20] Analysis of periprosthetic membranes revealed that synovial-like lining cells synthesized a large amount of PGE2, which was consistent with their rheumatoid synovial tissue-like phenotype.^[6] Similarly, analyses of retrieval tissue from revision arthroplasty cases demonstrated that loose components, whether cemented or not, have statistically higher PGE2 levels in the surrounding membrane compared with the non-loose group.^[7] These all suggest that PGE2 may be associated with the bone lysis associated with prosthesis loosening.

Previous work performed in animals also implicated the importance of PGE2 in wear debris-induced osteolysis. In COX-2^{-/-} mice or in mice treated with COX-2 inhibitors, bone resorption was significantly reduced compared with wild type or COX-1^{-/-} mice, indicating that PGE2 induced by wear debris particles through COX-2 may play an essential role leading to local osteolysis.^[35] PGE2 can be produced by macrophages and fibroblasts of synovial tissue in

inflammatory joint diseases and in cells exposed to wear particles *in vitro*.^[24]

Compared to the strong evidence for the pivotal role of COX-2 in wear debris-induced osteolysis, the mechanism and function of PGE2 is poorly understood. Using various EP receptor knockout mice, it is possible to examine the physiologic role of PGE2 mediated by each receptor. EP2 and EP4 receptors mediate the bone resorption activity of PGE2, because studies reported that osteoclast formation is impaired in cells cultured from EP2- or EP4-deficient mice.^[36,37] Moreover, PGE2 can also induce RANKL expression in osteoblast and stromal cells.^[37] In aseptic loosening, synovial fibroblasts may be another cell target for PGE2 because the evidence indicated that wear particles can induce synovial fibroblasts to express RANKL in a COX-2-dependent manner.^[24]

PGE2 can also induce bone formation by driving osteoblast differentiation. The exogenous addition of PGE2 or receptor agonist can directly induce bone formation both in organ cultures and in the mouse model.^[38,39] Thus, it seems that PGE2 has opposite effects on the regulation of bone turnover. Given the fact that different prostaglandin metabolites could be synthesized through COX-2 and the controversial roles of PGE2 through different downstream receptors, the significance of PGE2 and the underlying mechanisms in osteolysis induced by wear debris must be further clarified.

In summary, following inflammation stimulated by particles, a bone resorption phase is gradually developed, involving the enhancement of osteoclastogenesis. Many factors are involved in this process including RANKL, cytokines, and COX-2. By increasing OCP numbers and promoting their proliferation, differentiation, and activation to bone-resorbing cells, these factors increase the number and activity of the osteoclasts surrounding the prosthesis to mediate osteolysis and aseptic loosening.

Animal Models of Wear Debris-Induced Osteolysis

Central to the investigation of the etiology of human disease is the development of animal models that recapitulate *in vivo* pathology. Because the cellular response to wear debris particles is believed to be the basis for the commencement and development of aseptic loosening, a variety of *in vivo* bone resorption models using dogs, rabbits, rats, and mice has been developed.^[15,16,18,19,25–28,32,35,40–54] Combined with *in vitro* studies and clinical observations, these animal models can facilitate our research to further the understanding of wear debris-induced osteolysis and evaluate novel therapeutic interventions. Here we

discuss several of these animal models and describe their advantages and disadvantages.

Animal models of aseptic loosening are divided into two groups. The first comprises larger, long-term models that contained a joint implant designed to closely resemble the clinical situation.^[18,32,40–43] These dogs suffer acute inflammation and bone resorption within 24 hr of surgery and a classic inflammatory reaction that includes macrophage infiltration and the elevation of PGE2 and IL-1 is observed. Furthermore, Shanbhag et al. were able to demonstrate the efficacy of oral bisphosphonate therapy (alendronate) to successfully inhibit wear debris-mediated bone resorption in this model.^[40]

These implant models have also been useful toward understanding other aspects of total joint replacement. For instance, a comparison between non-cemented smooth and porous implant surfaces was made^[41] and femoral–acetabular component interactions were reported.^[42] Also, an implant coated with hydroxyapatite prevented the migration of particles along the interface and demonstrated significant benefits in a canine total hip arthroplasty (THA) model.^[43] Others used a rabbit model as an alternative for the long-term effects of wear debris-mediated bone resorption.^[44,45] In this model, particles can be directly introduced through a drill hole into the proximal tibia of rabbits, or submicrometer particles of UHMWPE are placed around pressfit tibial hemiarthroplasties in rabbits to determine the biological reaction.^[45]

Unfortunately, the ultimate goal of these large animal models, to recapitulate aseptic loosening, has yet to be demonstrated. The results of these studies indicate that the >5 year postop period required for clinical manifestation of aseptic loosening appears to be a requisite for these models as well, because accelerated aseptic loosening of a well-fixed implant has yet to be demonstrated in any *in vivo* model. For example, in a canine total hip arthroplasty model in which synovial membrane biopsies were harvested after surgery, no signs of loosening were reported after 2 years.^[40] Even in a rat model in which the investigators utilized a running wheel in an attempt to accelerate the biomechanical effects, the prostheses were mechanically stable after 6 months, with no evidence of loosening.^[46] Our interpretation of these results is that the host bone healing response to injury in healthy animals is very robust, and attempts to induce loosening of an osteointegrated implant by any acute insult are doomed to failure. However, if an implant model could be devised with roughened components that would be a source of chronic wear debris, this might lead to a model of aseptic loosening.

Thus, it is easy to focus mainly on the biology of osteolysis induced by wear debris in animal

models despite the other critical mechanical and biomechanical components of aseptic loosening. Based on this, other non-implant models were developed, and the particular biology of osteolysis stimulated by wear particles was analyzed. In a rat model with a non-weight-bearing plug inserted at the distal part of the femur, injections of particles into the knee joint elicited bone resorption at this stable interface.^[47] A bone chamber model in the rabbit was also developed.^[44] A bone-harvest chamber with a transverse channel for tissue ingrowth was introduced into the proximal part of the tibia. After a 6-week period of initial incorporation, the contents of the channel were harvested for assay repeatedly. The addition of particles such as polyethylene or cobalt-chromium stimulated a chronic inflammation with the reduction of bone formation and enhancement of bone resorption.^[45] The mitigating effect by local delivery of fibroblast growth factor-2, which can increase bone growth, was also suggested in this model.

Although these large animal models are used successfully, their more general application is significantly limited by their major disadvantages, including the inconvenience of experimental handling (time consuming and complex surgery), their cost, and the scarcity of tools for the system (much less information for dog or rabbit compared with mouse, e.g., a database of genome and transgene animals). For these reasons, two models were developed in the mouse to facilitate research and incorporate a variety of exquisite molecular reagents and genetically defined animal strains. Together with highly quantitative outcome measurements of osteoclast formation and bone resorption, these mouse models can be used in delicate biological studies to pinpoint the major factors involved in wear debris-induced osteolysis.

The mouse calvaria model is perhaps the most widely used animal model in the field.^[28] Because there is only a little soft tissue around the skull bones that contains a large number of osteoclast and osteoblast precursor cells, calvaria are useful for many *in vitro* and *in vivo* studies to evaluate the biological responses of bone. For example, in a study on wear particles, an *in vitro* experiment using neonatal calvaria organ culture has been frequently used to demonstrate the ability of particles to induce bone resorption.^[11,12] In the *in vivo* mouse model, a fixed amount of Ti, polymethylmethacrylate (PMMA), or PE particles are surgically implanted, which initiates inflammatory bone loss after a short period of time (3–7 days). In this manner, the *in vivo* mechanisms responsible for wear debris-induced osteolysis can be readily elucidated. Another advantage of this model is that it can be utilized for drug screening, which often requires a large number of animals to define the effective dose and regimen.

To date, several factors associated with wear particles have been identified using the murine calvaria model. In particular, the roles of RANKL, TNF- α , and NF κ B signaling have been extensively studied in this animal model using knockout mice.^[15,16,25,26] Similarly, the importance of COX-2 and PGE2 has been suggested.^[35] A comparison between PE and Ti particles was performed, indicating that bone resorption response to particles in other materials could also be examined in this model.^[48] For clinical relevance, some drug trials such as those using pentoxifylline or alendronate can significantly reduce inflammatory osteolysis in particle implantation in mice, providing a good example for potential drug development.^[28] Moreover, the efficiency of gene therapy was further tested in this model, suggesting an alternative treatment for the disease.^[25]

The air pouch model is another useful murine model for the evaluation of inflammatory response to wear debris particles in vivo.^[49] Filtered air is injected subcutaneously into the back of mice and a section of femur or calvaria bone is surgically introduced into the established air pouch from a syngenic mouse donor in the presence of debris particles. This model was generally used to assess the cellular and cytokine effects in inflammation processes. Shown as a relevant tissue response to orthopedic materials, a series of resembled reactions including cellular infiltration and production of inflammatory mediators can be observed in the air pouch model compared with the peri-implant tissue. The analysis on harvested air pouch tissue containing wear particles may reveal the basics in the pathogenesis of peri-implant osteolysis.

In this setting of wear-induced inflammation and bone resorption, the involvement of a variety of factors is implicated. Particles in different materials (UHMWPE, PMMA, cobalt-chrome and titanium alloy) and different shapes (elongated or globular) were examined.^[50] Additionally, the gene expression profile was investigated in pouch tissue.^[51] Higher RANKL/RANK ratio, IL-1, and TNF- α were associated with tissue inflammation status and osteoclast-like cell accumulation. The protective effects of anti-inflammation cytokines (IL-10 and IL-1 receptor antagonists and soluble receptor of TNF- α) and the negative regulator for bone resorption (OPG) by gene delivery were also evaluated.^[19,27,52] On the other hand, the locations of wear debris in these models are different from that of joint replacement. Such discrepancy in the adjacent cell population and micro-environment for osteoclast function might result in significant impacts in the interpretation of data.

Apart from these established animal models, more studies and new designs for improvement and refinement are being performed.^[53,54] For example, a novel xenograft-based model was recently used in which

human periprosthetic tissues obtained from patients during revision arthroplasty were transplanted into immune competent mice [severe combined immunodeficiency (SCID) mouse].^[54] Provided that animal experimental models have been successfully used to further understanding of the pathology and developing novel therapies, we hope that animal studies will ultimately lead to an effective intervention for aseptic loosening.

CONCLUSION

Above all, wear debris-induced osteolysis is associated with complex cellular responses that involve many biological factors. These factors likely interact to form a network that strongly promotes local bone loss by enhancing osteoclast formation and activity. Because the inevitable result of wear debris-induced osteolysis is implant failure, which remains one of the major problems in orthopedics, understanding the mechanisms responsible is important. As demonstrated by the evidence from both in vitro and in vivo experiments discussed here, osteolysis induced by wear debris is derived from a chronic inflammatory process followed by an increase in osteoclast formation. TNF- α , interleukins, RANKL, and prostaglandin are the main effector molecules that have been described, and other novel mediators continue to be identified. However, the answers to several important questions remain elusive, including the identity of the initiator messenger following exposure to wear debris. It has been postulated that osteolysis is initiated by the uptake of particles by cells, although the detailed mechanisms that govern this process are not fully clear, and many new factors are being described, such as particle-associated endotoxin or reactive oxygen species as a result of cell damage. Another key question relates to the function of cytokines in the disease. An exact explanation of the role of cytokines is still needed. Researchers must continue to seek these answers from in vitro studies and experiments with animal models.

Wear Debris from Joint Arthroplasties, Biological Effects Of

Ting Ma

Stuart B. Goodman

Department of Orthopedic Surgery, Stanford Medical Center, Stanford, California, U.S.A.

INTRODUCTION

Total joint replacement (TJR) is currently one of the most successful operations performed in orthopedic surgery. For the hip and knee, these operations consistently yield excellent clinical results, with 15–20 yr survivorship of 90% or more, using contemporary prostheses and techniques.^[1] These results have prompted the use of joint replacement in younger patients, who frequently lead more active lifestyles than the sedentary, elderly population for which TJR was originally designed. Furthermore, the general population is aging, and the elderly are becoming more physically active. These facts have led to increased expectations by patients undergoing TJR, and increased demands on the prosthesis construct. Although some technical advances have been associated with an increasing success rate of specific prostheses, the number of cases requiring surgical revision is still increasing. According to a recent report, a 10-year survival rate could be observed in 90% of patients older than 70, and only 72% of patients younger than 50.^[2]

Wear of TJRs and the biological effects of wear debris currently remain the most important problems in arthroplasty surgery. The wear between the primary bearing surfaces is generally a silent process with no clinical symptoms or signs in the early stages. However, when debris-associated chronic synovitis and osteolysis become more advanced, revision surgery is indicated, including thorough debridement and replacement of worn and damaged components.

In this article, the characteristics of the tissue at the bone–implant interface are reviewed, and the biological effects of wear debris from TJRs are summarized.

THE TISSUE AT THE BONE–IMPLANT INTERFACE IN HUMANS

Characteristics of Wear Debris Retrieved from Surgery or Autopsy

Any prosthesis used for total hip replacement (THR) can generate biologically responsive particles.^[3] The observation of tissue surrounding loose prostheses

provided us the firsthand information about implant wear and has substantially enhanced our understanding of the nature of the wear debris generated from the prosthesis.

Histological observations of the retrieved periprosthetic membrane first suggested that the generation of wear particles and the process of loosening were related.^[4,5] Numerous particles of bone cement, polyethylene, and metallic debris were observed in the retrieved periprosthetic tissue. The nature of the particles is different depending on the materials used for the prosthesis.^[5–7] It is believed that cementless prostheses are associated with more particles than cemented ones.^[3] McKellop et al.^[8] predicted that using a metal-on-polyethylene joint prosthesis, several hundreds of thousands of polyethylene particles can be expected during a single gait cycle. When metal-on-metal wear is involved, black metal particles can be easily found in the retrieved membrane. In cases in which massive amounts of metallic particles have been generated, the tissues may be grey or black on gross examination. Perhaps these particles are the easiest, but often the smallest, ones to identify. The size of the particles ranges from several microns in diameter to the submicron range. Many of them are located in the interstitium and within macrophages.^[3,9–14] It is believed that these metal particles are usually associated with less overall inflammatory reaction.^[15]

Particles of polymethylmethacrylate (PMMA) are often found to be surrounded by a florid foreign-body response in a fibrous stroma. Smaller particles of PMMA, and particles of the radiopaque marker in bone cement (barium sulfate or zirconium), less than approximately 10 μm are phagocytosed by macrophages; larger particles up to approximately 30 μm are found within multinucleated foreign-body giant cells. Still larger agglomerates of large and small particles are surrounded by a foreign-body granulomatous reaction.^[16,17]

Polyethylene particles are perhaps the most difficult to identify histologically in retrieved tissues.^[18] However, it is now widely accepted that ultrahigh-molecular-weight polyethylene (UHMWPE) is probably one of the dominant wear debris contributing to particle-associated osteolysis.^[19,20] Irregularly shaped polyethylene particles with the size ranging from 0.2 to 7 μm are especially bioactive, and provoke greater

inflammatory responses than other particles.^[21] Using laser diffraction wear particle analysis, Elfick et al.^[18] reported that the majority of the UHMWPE particles in periprosthetic tissue of THR are submicron in size, with the median particle diameter being 0.69 μm . No UHMWPE smaller than 0.113 μm were found. The number of particles associated with the chronic foreign-body reaction in tissue was higher than 10^9 particles per gram tissue, and can interact with cells that are then induced to release bone-resorbing mediators.^[20,22,23]

Till date, particles generated from all biomaterials clinically in use for THR are bioactive, that is, able to promote inflammatory responses, formation of foreign-body granulomas, and eventually the destruction of bone structure.^[3] Osteolysis refers to the destruction of bone seen radiographically as localized or more widespread, large radiolucent areas. Particles generated from the wearing of prosthesis have been shown to elicit a florid foreign-body reaction, eventually leading to bone destruction.^[16,24–28] The prostheses do not have to be mechanically loose to demonstrate this reaction. Cemented femoral prostheses made of titanium alloy, especially those with a titanium alloy femoral head, may be associated with higher than expected wear rates, loosening, and osteolysis.^[29–32] Ceramic-on-ceramic prosthesis may yield a relatively low number of particles, although foreign-body response and periprosthetic osteolysis are present with ceramic-bearing surfaces.^[33]

Biochemistry

Current research efforts have identified factors in the retrieved membrane that regulate inflammatory processes, bone formation, and osteolysis following THR.

The presence of proinflammatory cytokines including interleukin-1 (IL-1), interleukin-6 (IL-6), and tumor necrosis factor alpha (TNF-alpha) have been well documented.^[34,35] Interleukin-1 and TNF-alpha are potent osteoclastogenic cytokines produced by activated monocytes/macrophages. Their important role in particle-induced osteolysis has therefore received much attention.^[6] Other cytokines such as IL-8^[36] and IL-11^[37] are also identified in the membrane. Their potential role in the periprosthetic osteolysis is yet to be determined.

In addition to the cytokines, prostaglandin E₂ (PGE₂),^[38] metalloproteinases, collagenase,^[39] superoxide anions such as peroxynitrite,^[40] receptor activator of nuclear factor kappa B (NF-kappaB) ligand (RANKL),^[41] macrophage colony-stimulating factor (M-CSF),^[42] and vascular endothelial growth factor (VEGF)^[43] are released by cells associated with wear particles.^[44]

PGE₂ plays an important role in regulating osteoclastic bone resorption.^[45,46] Enzymes such as collagenase promote bone resorption by digesting the extracellular matrix to expose bone mineral for osteoclastic activities.^[47] RANKL, together with M-CSF, function as potent factors for osteoclastogenesis. Their presence in fibroblast and macrophage lineage cells in the retrieved membrane suggests the in situ involvement of RANKL in osteoclastic bone resorption occurring during the process of prosthetic osteolysis.^[48] The VEGF was detected in the synovial fluid and in the periprosthetic membrane.^[43] In association with other preangiogenic mediators present in the membrane such as TNF-alpha,^[37,49,50] granulocyte-macrophage colony-stimulating factor,^[51,52] basic fibroblast growth factor,^[53] and transforming growth factor-beta 1 and 2,^[54] endothelial leukocyte adhesion molecule-1, and vascular cell adhesion molecule-1,^[55] the process of angiogenesis has been implicated in osteolysis.

Biochemical studies of harvested tissue have added another dimension to our understanding of the events at the bone-implant interface of orthopedic prostheses. Further studies are necessary to document and fully understand the plethora of substances produced at the prosthetic interface and their role in loosening and resorption of bone.

Cellular Profiles

The retrieved periprosthetic membrane surrounding the implant contains various types of cells including macrophages, fibroblasts, and lymphocytes.^[6,38,56] In cases of loosening without osteolysis, fibroblast-like mesenchymal cells are predominant; in cases of aggressive granulomatosis, mono- and multinucleated histiocytes are common, and activated fibroblasts are more scarce.^[57,58] As to the involvement of lymphocytes in aseptic loosening of THR, research results have been contradictory. Farber et al.^[59] detected large numbers of antigen-presenting cells expressing B7-1 or B7-2, two well-characterized ligands of the costimulatory signal, and T cells using monoclonal antibodies. Although there were no statistically significant differences in expression of proteins in the B7-CD28 costimulatory pathway between the osteolytic and nonosteolytic groups, they postulated the involvement of activated immune response in process of aseptic loosening owing to the magnitude of positive staining. In a study by Li et al.^[60] the number of T cells in the membrane-like tissue was low, and none of the T cells was activated as shown by the absence of interleukin-2 receptor immunoreactivity. Sandhu et al.^[61] reported that T cells constitute approximately 10% of the total cell population and likely play an important role in modulating the foreign body and chronic

inflammatory reaction in response to wear particles by a nonspecific immune mechanism.

BIOLOGICAL EFFECTS OF PARTICLES IN VIVO AND IN VITRO

Particulate wear debris can alter the function of a variety of cell types including macrophages, fibroblasts, osteoblasts, and osteoclasts by means of phagocytosis or surface activation.^[3,21,62-64] At present, monocyte/macrophages are thought to be the most predominant cells associated with the inflammatory and foreign-body cascade.^[44]

Macrophages

Wear particles less than approximately 10 μm can be engulfed by macrophages,^[65] thus activating a cascade of events resulting in upregulation of proinflammatory mediators. These mediators in turn perpetuate the inflammation by means of autocrine and paracrine mechanisms, resulting in the differentiation and activation of more macrophages.^[43,44] To date, almost all the particles generated from wearing of prostheses, including metal particles, UHMWPE, PMMA, ceramics, and hydroxyapatite, have been shown to activate macrophages.^[28,66-70] Following the initial uptake of particles, the materials may be subsequently exposed to macrophage-derived enzymes with the potential for material degradation. To examine the impact of polymeric surface characteristics on the production of macrophage biodegradative enzymes, Santerre and coworkers^[71] cultured human peripheral blood monocytes on biomaterials with different surface characters. They found that the material surface itself is a potent activator of macrophages, and the activities of degradative enzymes they assayed showed different patterns depending on the materials added.

Activation of macrophages following particle exposure may not require phagocytosis.^[62] Particles can be associated with specific serum proteins to form a particle-protein complex. This complex interacts with cell surface receptors on macrophages and activates these cells.^[6,72] The surface characters of particles can also have a marked effect on the material's ability to elicit cellular responses in this respect.^[73,74]

The potential role of adherent endotoxin in the process of macrophage activation and cytokine production remains unclear. Greenfield and coworkers^[75] demonstrated that removal of adherent endotoxin significantly inhibited the response of murine marrow cells and human peripheral blood monocytes to titanium particles. Addition of lipopolysaccharide (LPS)

to the endotoxin-free particles restored the inflammatory cytokine release of macrophages. However, this result was challenged by the study of Clohisy et al.^[76] that showed the PMMA-induced activation of NF-kappaB, a crucial transcription factor mediating TNF signaling necessary for osteoclastogenesis, is independent of LPS because the level of NF-kappaB activation is no different between wild type mice and LPS-hyporesponsive mice.

Because of the predominant presence of macrophages at the bone-implant interface, some believe that macrophages themselves are capable of direct bone resorption.^[77,78] The enzymes capable of direct bone degradation were detected within macrophages by immunohistochemistry.^[79] The report by Quinn et al.^[80] that macrophages containing PMMA particles could directly erode bone supports the direct role of macrophages in osteolysis.

Osteoclasts

The differentiation, migration, and activation of osteoclasts has been implicated as the key step accelerating the degradation of bone.^[6] Most inflammatory mediators present at the bone-implant interface, including PGE₂, TNF-alpha, IL-1beta, and M-CSF are potent stimulators of osteoclastogenesis.^[81-83] Recent studies suggested that the essential signaling mechanism involved in osteoclastogenesis is the interaction of RANKL and RANK. Osteoprotegerin (OPG), a decoy receptor of RANKL, blocks the RANKL-RANK coupling, thus, inhibiting the osteoclastic activity. Baumann et al.^[84] studied the effect of polyethylene and TiAlV wear particles on expression of RANK, RANKL, and OPG using a human monocytic leukemic cell line. They showed that TiAlV and polyethylene particles induced upregulation of RANK mRNA expression; OPG mRNA expression was transiently upregulated, and RANKL mRNA was not detectable.^[84] This study may not completely represent the *in vivo* situation of human cells given the fact that cell lines behave differently from primary cells in many aspects. In fact, Kim et al.^[85] demonstrated that the OPG levels in the joint fluid from failed total hip arthroplasty patients were much lower than that collected from patients with osteoarthritis. RANK-RANKL coupling is required for other well-observed events of osteoclastic bone resorption. For example, it has been proved that both TNF-alpha and IL-1 signaling on osteoclastogenesis depend on RANK-RANKL interactions. In the presence of permissive levels of RANKL, TNF-alpha potentiates osteoclastogenesis.^[81] IL-1 prolongs the survival and actin ring formation (a functional marker of osteoclasts) of

osteoclasts in the presence of RANKL, and appears to act independent of TNF-alpha.^[82,86]

Osteoblasts

Osteoblasts are mainly responsible for the process of bone formation. Therefore, inhibition of osteoblast activity may be another mechanism accelerating periprosthetic bone loss. We have observed reduced new bone formation in the presence of particles using an in vivo rabbit model.^[17,87] Furthermore, osteoblasts are able to phagocytose particles in culture, which implicates the active involvement of these bone-forming cells in periprosthetic osteolysis.^[64] Vermes et al.^[63,64] treated MG-63 osteoblast-like cells with metal particles or polymeric particles. They found that a maximum of 40–60 particles can be phagocytosed by one cell, and those particles suppress the synthesis of type I collagen and increase the secretion of IL-6 and PGE₂ by activating osteoblasts.^[88] It is therefore likely that, in human patients, while the ability for new bone formation had been impaired by particulate wear debris, the process of bone resorption continues to be potentiated by factors released from osteoblasts. In addition, it has been reported that metallic particles alter osteoblast adhesion behavior, proliferation, viability, and gene expression.^[49,89–91]

Mesenchymal Stem Cells

Submicron-sized metallic wear particles have been identified in bone marrow surrounding the femoral stem and in more remote sites such as the iliac crest when implant fixation is relatively poor.^[92] Thus the behavior of bone marrow cells is continuously challenged by wear debris. Wang et al.^[93] reported that the exposure to wear particles could compromise the viability of human mesenchymal stem cells (MSCs) by direct and indirect induction of apoptosis. They also found that the osteogenic differentiation of human marrow stroma-derived MSCs was suppressed by titanium particles. These findings suggest that prolonged exposure of bone marrow cells to implant-derived particles may significantly decrease the number of viable stem cells. With the diminished number of the stem cell population and the compromised stem cell function, the process of osseointegration and prosthesis fixation can be severely jeopardized.^[94]

CONCLUSIONS

The biological response to wear debris in patients with a joint arthroplasty is a complicated process. In vitro and in vivo studies using multiple investigative

techniques, including histology, cell biology, and molecular biology have provided insightful information to our current understanding of these biological processes. Wear debris generated from implants, in particulate form, stimulates a foreign body and chronic inflammatory response that is capable of inducing the resorption of bone by osteoclasts and macrophages. The particles disrupt the formation of bone by negatively impacting the normal behavior of osteoblasts and MSC differentiation. The degree to which this reaction occurs is dependent on the location of the implantation, the specific experimental model, the characteristics of the particles, and the particle load. Because of possible adverse reactions to particles, it behooves surgeons, material scientists, and biologists to develop new strategies to prevent the generation of particulate debris from orthopedic implants and modulate the process of osteolysis at an early stage.

Wheeled Mobility: Wheelchairs and Personal Transportation

Jon L. Pearlman

Rory A. Cooper

Rehabilitation Science and Technology, School of Health and Rehabilitation Sciences, University of Pittsburgh, and Human Engineering Research Laboratories, VA Pittsburgh Healthcare System, Pittsburgh, Pennsylvania, U.S.A.

INTRODUCTION

There are an estimated 600 million people with disabilities (PWD) worldwide. In the U.S.A. alone, there are over two million full-time wheelchair users, roughly 150,000 of them user electric powered wheelchairs (EPWs).^[1,2] The population of part-time wheelchair (WC) users is much larger, and another subset of the population uses scooters to facilitate community and home mobility (approximately 142,000^[1,2]). These mobility devices fall into the family of devices named assistive technologies (AT), which are governed by regulations that can simultaneously ensure the products are of high quality (protecting consumers), but also restrict the types of technological innovations that are eligible for reimbursement from public and private insurance companies (the most typical payer of these devices). Like most technology, significant advancements have been made in AT quality and function over the last several decades. This has significantly impacted on the lives of PWD, as more complex disabilities can be accommodated with these advanced AT, allowing a larger population to utilize these technologies. Unfortunately, this technological advancement is slow, especially with manual WCs and EPWs. The overarching reason for this is that a large portion of society still sees WC users as unable to fully participate in society (regardless of the AT provided). There is a stigma associated with WC users, which stems from what is termed a “medical” model of disability—where PWD are judged on whether they can be “cured.” Progressive thinkers realize that a “social” model of disability is more appropriate—where technology minimizes the consequence of impairment and maximizes the opportunity for PWD to integrate and participate in society; this maximizes the likelihood that PWD will lead more fulfilling lives by integrating socially and having careers (and thus contributing to rather than being supported by society). The cascade of the “medical” model thinking has prioritized WCs under other AT, such as prosthesis, which affects both technological advancement (as WC research and development funds are not high priorities), and also reimbursement mechanisms (as insurers encourage the

lowest-cost WCs). While the medical model misconceptions are still prevalent, they are fading, which is met with advances in WC technology.

Advances in manual WCs are largely focused on setup, injury prevention, and weight—much of this progress has been driven by research showing correlations between secondary injuries (such as carpal tunnel syndrome), propulsion style (related to WC setup), and the weight of the WC and user. EPWs have become more complex; with active–passive suspension to minimize potentially injurious road vibrations, seats that can be adjusted in several degrees of freedom to both minimize the incidence of pressure ulcers (another commonly deadly secondary injury) and allow the user to reposition to maximize their interaction with the world (reach high cabinets, cook, maneuver under desks, etc.). The most advanced EPWs are mobile robots, constantly evaluating the users input (desired direction) and the physical world to maximize the safety and maneuverability of the device in all physical environments.

Electric powered scooters are similarly mobility devices for PWD, but are most suited for people who need part-time mobility accommodation. These devices are commonly used by individuals who tire or fatigue quickly or are in pain when ambulating long distances. Furthermore, they are commonly used outdoors, and can be critical to allow social integration of PWD. While PWD in Western countries have, in many cases, benefited from the advances in mobility devices, PWD in developing countries still lag far behind. Many countries have laws similar to the US Rehab Act of 1973 and the American with Disabilities Act (India, for example), but they have neither the medical reimbursement nor the regulations in place to ensure PWD have access to appropriate AT and full access to public buildings and job opportunities.

DEMOGRAPHICS OF WC USERS

The number of WC and scooter users has nearly sextupled between 1970 and 2000, and expansion is

expected to continue at a significant rate.^[2] This expansion stems from several sources. First, until after World War II, people with spinal injuries or traumatic brain injuries had short life expectancies. As medical technology advanced, so did the life expectancy, which necessitated AT that could be functional (for younger individuals) and that could last longer. Much of the technology, recreational devices and activities, and occupational rehabilitation stem from the military's response to the surviving wounded soldiers. Second, and similar to above, medical technology has increased the life expectancy of the populous as a whole. Because there is a strong positive correlation between age and disability, the population of PWD naturally increases, expanding the need for WCs and other mobility devices. Third, the quality and function of AT itself has had a dramatic impact on the number of people who can use that technology. Because of advances in EPWs, people who were previously confined to their bed can be more independent and mobile; thus, as AT improves, more people can utilize it, effectively expanding the market. Finally, stigmas that have made people hesitant to use wheeled mobility are being broken down. As the devices become more socially acceptable, they are more acceptable to potential users. For instance, individuals who have been using crutches their entire life to help them ambulate (at the cost of shoulder injuries) are switching to WCs and EPWs, which allow them to be more mobile and involved in society. Notably, the electric powered scooter is a common choice for PWD interested in socially acceptable devices. Scooters do not have the same stigma attached to them as WCs. It is common in our clinic (Center for Assistive Technology, University of Pittsburgh Medical Center) to encounter PWD who are candidates for EPW (to facilitate in-the-home mobility) to choose to order a scooter because they consider it to be more "socially acceptable," regardless of whether it is the most appropriate device.

MANUAL WCs

Surprisingly, the most common WC manufactured today is of nearly the same design as the Everest and Jennings (E&J) design of the 1950s (Fig. 1). These "depot" WCs are designed and manufactured for institutional use (hospitals, airports, etc.), but were (and unfortunately still are in many cases) accepted as the standard WC for some users. Today, these low-quality WCs are mostly manufactured in China and Taiwan and are the standard of care for developing countries. As discussed above, injured soldiers who

Fig. 1 E&J style WC.

were young and wanted to be mobile drove the advances in manual WCs. While the original E&J weigh roughly 80 lb, current titanium and carbon-fiber WCs can weigh less than 15 lb. Weight has a significant impact on maneuverability and portability, allowing WC users to accelerate and decelerate very quickly and independently load the WC into their automobile.

Research has shown that weight is an important factor in secondary injuries, including median nerve conduction, carpal tunnel syndrome, and impingement of tissue in the shoulder.^[3] A heavy WC can have a cascading negative affect on the health of the upper extremity musculoskeletal system. To accelerate heavier WCs, users must apply more push-rim force (based on purely physical arguments). These higher force requirements put increased loading on the joints, increasing the risk for musculoskeletal injury.^[3] Practical observations and engineering arguments^[4] suggest that WC fitting is an important issue in WC prescription. The E&J had a fixed axle position, and the seat was set in a 90° (seat-to-back angle) configuration. Axle position adjustment allows the users or technician to shift the weight distribution of the user with respect to the wheels. Shifting the weight can allow individuals to balance on the back tires (allowing them to go up and down curbs and maneuver through rough terrain) and reduce their rolling resistance, and also allows users to optimize their propulsion efficiency (by positioning the wheels so they can take long strokes).^[4-6] Adjusting the seat setup has allowed users to minimize the risk of deadly pressure ulcers, maximize stability, and accommodate postural deformities—all providing more safe and functional mobility for the MWC user. While adjustability is always encouraged (to allow

customized setup of the MWC to the user), once a user has found their optimal axle and seat configuration, they may choose to have a custom, non-adjustable WC built to these specifications; these customized WCs are lighter than their adjustable counterparts, because they shed the weight of the fasteners needed for the adjustable components.

Manual WC frames vary widely, but most fall into two categories—either folding or rigid. Folding WCs commonly have a cross-brace that allows them to collapse laterally and fit into a narrow cabinet. Rigid frame WCs are non-collapsible, but may have a folding backrest. When the wheels are removed and the backrest is folded down on a rigid WC frame, the WC can be easily transported. The benefits of the rigid frame are that they are lighter, and the increased stiffness of the frame tends to make them more efficient, comfortable, and maneuverable.

Other specialized manual WCs exist for both adult and pediatric applications. Adult variations typically include specialized seating systems to accommodate people with postural deformities or reduced neuromuscular function. Both adult and pediatric WCs can be highly specialized, allowing manual tilt and recline functions and specialized postural support devices. Specialized WCs to accommodate people with complex disabilities tend to be highly adjustable, and many accessories can be added so to meet the needs of the user.

EPWs

The first EPWs were developed in the early 1900s and were based on manual WC structural designs.^[6] The manual WC wheels were driven by motors retrofitted to the WC. The power and drive systems were coopted automobile parts, using the 12-V liquid-acid batteries for power, and the starter motors as the drive motors. Early controllers used solenoid or relay devices that performed simple on/off switching for each direction (rather than proportional control), making the devices hard to maneuver.^[7] Major advances in EPW did not occur until the 1960s and 1970s, when battery, controller, and structural components improved, making the EPW a viable mobility aid for PWD.

STRUCTURAL COMPONENTS

As noted above, original EPWs frames were identical to manual WCs, where the seat is integrated into the main structure of the WC (Fig. 2). These traditional designs still exist; although in most cases, they have been strengthened to support the added weight of the batteries, motors, and controller. A more recent

Fig. 2 Conventional EPW based on manual WC frame (Alero shown).

development is the power base design, where the main structural and drive components are integrated into the base unit, and the seating system is added to the base via a post or other substructure (Fig. 3). The power base design is novel, because it allows for different seating systems to be used on the same power base. Also, it allows the base to be optimized by engineers, without affecting the seating systems that can vary based on the clients needs.

POWER AND CONTROL SYSTEMS

As discussed above, the first power and control systems were coopted parts from automobiles. These systems have made steady advancement over the last decades and now allow EPW and scooter users to maneuver their WCs or scooters accurately and safely with a number of different input devices (joysticks, switches, etc.) over different terrains and for substantial distances before they need to be recharged. Original 12 V DC designs have been upgraded to 24 V DC systems (in most cases, although higher voltages are sometimes used), which increases the efficiency of the motors. Motors are typically permanent magnet with worm- or spur-gear reduction. Worm drives are most common, because the motor axle and drive axle are perpendicular, allowing the motor to be easily bolted to

Fig. 3 Power base style EPW.

the frame or suspension system. Spur-gear motors are more efficient, but can be noisier and are more difficult to design into the structural system, given the motor is oriented in-line with the drive axle. Typically, motors have solenoid deactivated magnetic fail-safe brakes fixed to the end of the motor arbor. A voltage is applied across the solenoid by the controller to release the brakes before current passes through the motors. Thus, if there is a controller or power-system malfunction, the brakes turn on to stop the device.

While the motors operate off of 24 V, the controllers are 12 V, and use an amplifier and a metal-oxide semiconductor field-effect transistor (MOSFET) H-bridge in lieu of relays. Thus, the motor speed is varied using a pulse width-modulated oscillating square-wave. The higher duty cycle, the more effective current passes through the motor, increasing the speed. Proportional control of the MOSFET circuitry is typically provided by an X-Y joystick that users manipulate.

While the joystick is most prevalent, and can be moved to be manipulated by the foot, head, or mouth, many other input devices are available to take advantage of the user's functional abilities. Examples of these

input devices include a steering wheel type input (for use with the foot or hand), a sip-and-puff device to be used by blowing or sucking on a straw-like device, or a single or multiswitch selection type of input. Individuals with severely limited sensory-motor function, who have only one reliable body movement can drive via a single switch. For these situations, a controller can be programmed to automatically scan through the different possible directions, and the user presses the switch to select the desired direction. More advanced input devices are being developed, including variable compliance joysticks, which can be tailored to read kinematic motion (like a typical joystick) combined with force production.^[8] Some individuals can produce force in certain direction, but have limited range of motion (owing to contractures, for example); this joystick could be tuned to read this input, allowing the individual to safely maneuver the EPW.^[8] Head position input devices are also being developed to derive input information from the kinematic motion of the head relative to the headrest.^[9] While head-controlled joysticks have been in use for many years, they are only effective for individuals with the appropriate range of neck motion. The new head position monitor based on kinematic tracking of magnets worn on a hat or headband will allow more individuals to safely maneuver an EPW. The forefront of input devices are those directly reading brain inputs either inter- or extracranially.^[10] For individuals with the most disabling impairments, advances in reading and filtering volitional brain signals may be the only means for them to independently and safely maneuver an EPW.^[10]

Related to the advancing input devices is the prospect of being able to tune the input device to the individual through software. The latest EPW controllers are microprocessor based, but still rely on simple control algorithms that only have approximate models or no model of the EPW and the user (the system). Programmable controllers are included on most EPWs, allowing parameters such as maximum and minimum speed and acceleration and directional sensitivity (forward/reverse) of the joystick to be changed. Furthermore, some controllers integrate feedback information from the motors and/or seating functions to adjust or limit the speed to make maneuvering more safe. While currently available controller technology has come a long way over the past decades, innovations are still be made in controller technology. For example, controllers are being developed to integrate more feedback information from sensors attached to the EPW, which can detect nearby obstacles or the inclination of the WC and adjust the controller to maximize the safety of the device.^[7] Similarly, controllers are being augmented to allow for more advanced programming of the input device. This can be useful, for example, if a user has a complex

impairment limiting their functional range of hand motion in one direction (e.g., anterior/posterior) but not in another (e.g., medial/lateral). Current advanced controllers can scale the sensitivity symmetrically (forward/reverse and/or left/right), but advancements are being made to allow complex mapping between user input and controller output (to the motors).^[11] In practice, the required mapping function would be determined by allowing the prospective EPW user to interface with a joystick attached to a “virtual” EPW driving task (much like a computer or video game). By performing computer-guided driving tasks, an optimal mapping function would be developed and loaded into the controller.^[11]

SEATING

Seating systems, especially those used in the power base style EPWs, can vary widely both in their postural support and in their functionality. Low-tech seating systems may allow for good postural support and are minimal or non-adjustable. Higher-tech seating systems can include adjustable postural supports and custom-formed cushions. Still higher-tech seating systems integrate functions that can be controlled by either the user or their assistant. Furthermore, these functions can be manually operated or powered by actuators that are integrated into the original power and control system of the WC. These seating systems can include all of the following functions: recline of the backrest, tilting of the seat, elevation of the seat, extension of the footrests, standing mechanism, and lateral tilting of the seat.

The importance of these seating functions cannot be overstated, for both clinical reasons, and to allow the individual to be more independent and integrate into society. Clinically, changing the seated posture helps to relieve high stresses transferred between the seat and the user's soft tissue, helping to reduce the incidence of pressure ulcers. Furthermore, postural changes are required to lower the risk of long-term postural deformities. While upright sitting (with the back at 90° to the horizontal) may be functional and required for some tasks (such as eating or working), it is an inherently unstable position for individuals with neuromuscular impairment. Gravitational forces acting on the torso tend to initiate and/or accelerate postural deformities (such as a kyphosis), when the spine is in a vertical position (Fig. 4). A slight posterior tilt of the seat and back will stabilize the spine by distributing gravitational forces acting on the body through the backrest, rather than vertically through the spine, stabilizing the torso.

Seating functions have a pivotal role in promoting functional independence for EPW users, in all contexts

Fig. 4 Sagittal (A) and coronal (B) views of the effects of gravity on the vertical spine. When the spine is vertical, and the torso is not confined with postural devices, there is a tendency for the spine to deform either laterally or anteriorly. This can be avoided with slight posterior recline or tilt.

of their life—in the home, community, and work. For example, in the home, a power seat elevation system can allow independent and safe meal preparation (reaching the stove, into cabinets, etc.). Seat elevators can also be essential for independent transfers: By adjusting the PWC seat level, user can take advantage of gravitational forces by always transferring to a lower seat height (bed, couch, toilet, etc.). By allowing independent transfers and meal preparation [along with other activities of daily living (ADLs)], the seat elevator can decrease or eliminate the need for an assistant. However, they are almost universally denied by public and private health insurance as *not medically necessary*.

Besides providing pressure relief functions, power tilt and recline seating functions allow the user to position themselves into a comfortable posture. This improves the user's quality of life, and will also minimize the need for transfers; if a user is comfortable in their EPW for a longer period of time, then they are less likely to want to move to a more comfortable chair or couch. Importantly, we discuss the tilt and recline functions together in this entry. This is because in only very few cases should recline be used independently from tilt. Recline alone allows for improved pressure distribution when the seat back is reclined slightly. But as the seatback is moved into to an upright position after it has been reclined, the user is shifted forward in the seat, and shear stresses increase on the user's buttocks. Mechanically, this is because the pivot point of the seatback is not at the point of hip rotation. Clinically, these shear stresses can accelerate the formation of pressure ulcers, possibly negating the affect of the beneficial pressure distribution provided by the recline

function. Only users with intact sensory systems in their buttocks and the motor ability to reposition should be candidates for recline-only PWC seating systems, as they would be aware of the shear stresses on their buttocks and can then reposition to relieve these stresses.

Occupational tasks may require a person maneuvering under a desk, or reposition in a standing posture to teach a group of students. Seat elevators and standing functions on a PWC can allow for this repositioning. Changing to a standing posture may also help the user clinically. A survey study suggests that standing may be associated with increased circulation, increased range of motion of the legs (helping to avoid contractures), improved bladder function, and increased bone mass.^[12] Furthermore, because force is relieved off the buttocks, standing can help lower the risk of pressure ulcers.

SCOOTERS

Scooter technology has changed only slightly over the past decades. Structurally, these devices are typically three wheeled (although some are made with four wheels) and have a tiller-type steering system (Fig. 5). Thus, a fairly intact range of motion of the upper extremities is necessary to safely drive the scooter. The power system is 24 V DC, and scooters typically use a single permanent magnet motor that is attached to a small differential, which drives the rear wheels. Like in an automobile, the differential allows each wheel to rotate at a different speed when the scooter is turning. Because of the single motor, and the fact that the turning mechanism is mechanical, the controllers for

Fig. 5 Scooter (Rascal shown).

scooters are much simpler than those for EPWs. The control system has an H-Bridge MOSFET circuit, but it takes only forward/backward information from the input device on the tiller. The input device is typically a small lever that operates a rheostat and can be depressed either by the left or right thumb. In most cases, pressing the lever with the right thumb is the forward direction, and pressing the lever with the left thumb is reverse.

Scooters tend to be laterally unstable because of the user's high center of mass, narrow rear wheelbase, and relatively high top speed. Design changes have been made to try to minimize this instability. Four-wheel scooters have been developed, which increase lateral stability. Also, small antitipper wheels have been placed near the front wheel to help prevent the scooter from tipping completely on its side if it does begin to tip. Like power and manual WCs, scooters are subjected to the American National Standards Institute/Rehabilitation Engineering and Assistive Technology Society of North America (ANSI/RESNA) standards. Unfortunately, the static stability tests, where scooters sometimes perform quite poorly, are not pass/fail; instead, they just report the angle where stability is lost.

Scooters tend to be the best for individuals who need a part-time mobility aid because they tire easily or have joint pain. The reasons for this are several fold, including the lateral stability issues described above, the mechanical tiller, and the fact that maneuverability of the scooter is relatively poor. For example, a user would likely find maneuvering around their house difficult in a scooter because of its large turning radius owing to its long front-to-back wheelbase. An EPW is generally a much better choice for individuals who need mobility in their home. However, there are mid-wheel drive scooters designed for use in the home, which may be appropriate for some clients.

Regardless that there are drawbacks of scooters, they are widely used, and their numbers are likely to increase. One of the reasons for their current popularity is that they cost around half of the price of an EPW. Furthermore, the largest population of scooter users is that of older generations; as people age, they tend to be less able to walk long distances because of fatigue or pain. Because there is a growing population of older individuals in U.S.A. (as well as other countries), there will likely be an increased need for scooters. The prevalence of scooters in society has removed much of the stigma associated with them. Thus, scooters have been a good example of how AT can be accepted into society, which has not fully occurred with manual WCs and EPWs. On the other hand, because of their social acceptance, many individuals who may be better served with a manual WC or EPW would rather have a scooter. This poses a challenge for clinicians providing the devices, who want to provide

the device that is in the best interest of the user (both functionally and socially). Until manual and EPWs have less of a stigma associated with them, clinicians may struggle to advise their client on the technology that is best for them.

ADVANCED MOBILITY DEVICES: HYBRID DEVICES AND MOBILE ROBOTS

Aside from the advancing power and manual WCs, new, novel AT have emerged. Pushrim-activated power assist WC (PAPAW) wheels are an example of this technology.(Fig. 6).^[1] Rather than having a purely manually propelled WC, these devices incorporate a motor into the hub of a manual WC wheel, and are actuated by the push-rim. Thus, these WCs are propelled like manual WCs, but have a power assist. These devices can be used as a transition between manual and powered mobility, and are especially useful for manual WC users who cannot propel their WCs for long distances because of upper extremity pain or fatigue.

Another example of these advanced devices are termed “mobile robots.” These devices are significantly more advanced than power chairs, incorporating advanced mobility and sensor functions. One example of these mobile robots is the IBOT 3000 mobility device, from Johnson & Johnson (Fig. 7). Using redundant computers, gyroscopes, and a number of sensors, the device constantly evaluates its environment and adjusts based both on the users commands and on the sensor information. This allows the device to expand the basic functions of a manual WC by

Fig. 6 PAPAW. Quickie extender shown.

Fig. 7 IBOT 3000 mobility device from Johnson & Johnson.

allowing it to balance on two wheels and climb stairs, significantly expanding the function of the EPW.

Other mobile robots are being developed and are based on EPW and PAPAW designs. The overall goal of these devices is to use sensor information to provide feedback into the controller unit on the device.^[7] This essentially makes the device more informed about the environment and/or the user. This feedback can be used to alter how the user input is read into the controller. For example, for users with vision impairments, who are typically unable to use power mobility for safety reasons, PAPAWs are being designed with sensors to detect obstacles.^[13] Thus, user’s command to maneuver forward would be augmented to avoid an obstacle. This makes using these mobility devices more safe, allowing a broader population of PWD to use them, and ultimately affording them more independence.

Efforts are also being made to integrate more sensors into EPWs to give feedback of the position and the orientation of the device.^[14] Approximately, 70,000 WC accidents are reported per year in U.S.A. with 70% of them attributed to tips and falls.^[15] More extensive user training may be one way to reduce the incidence of these accidents, but another possibly more reliable way is to program the EPW controller to

respond to the physical environment.^[16] Thus, if the user is on a slope, the WC controller would reduce the maximum speed to lower the risk of tipping. Furthermore, there is increasing evidence that vibrations endured when driving an EPW may cause neck and back injuries.^[17] Accelerometers giving feedback to active suspension systems could be dynamically tuned to ensure that the risk of injury was minimized.

WC STANDARDS

Formal development of WC quality assurance standards did not begin until 1979, and was funded by the Department of Veterans Affairs (VA) Rehabilitation Research and Development, and the US Department of Education through the National Institutes of Disability and Rehabilitation Research (NIDRR) Rehabilitation Engineering Research Center (RERC).^[6] Formal US standards have been developed and are titled ANSI/RESNA WC Standard Volumes I and II.^[18,19] International versions of these standards are under the auspices of the International Standards Institute (ISO) and are numbered 7176.^[20] These standards have been important in improving WC quality in U.S.A. and throughout the world, and have important components that are relevant to consumers, WC designers and manufactures, service delivery providers, governmental regulatory departments, and insurance providers.

These standards are broken up into 20 sections, and additional tests are performed on powered devices (WCs and scooters) to ensure electrical safety. Sections include information disclosure; static and dynamic stability analysis; speed, acceleration, and retardation analysis; static and fatigue strength analysis; and environmental testing such as hot, cold, and wet weather and storage testing. Electric powered devices also undergo short-circuiting (of the power and charging system), battery overcharging tests, and energy consumption tests. Recently in 2000, the ANSI/RESNA^[21] and^[22,23] WC standards have been broadened to include standards, ensuring that WCs and tie-down mechanisms are appropriate for use in both public and private transportation (busses, automobiles, etc.)

Data resulting from applying the standards to select WCs has been published^[24-28] and provides comparison data for consumers and clinicians who provide these devices to select WCs. These studies have highlighted the more hazardous and less durable products that the consumer should avoid. WC standards also provide a basic guideline and a set of minimum requirements for WC designers, allowing them to avoid financially costly design iterations. These standards have also been useful as a regulatory tool, allowing governmental organizations (such as the US

Food and Drug Administration) to require that all products available to consumers meet the ANSI/RESNA standards. Similarly, third-party payers for these devices such as Medicare and other insurance companies also use the ANSI/RESNA standards both as a minimum requirement for the devices that they will reimburse for, and also as a way to distinguish between higher- and lower-rated devices that it will pay varying amounts for.^[1,6]

DISTRIBUTION AND PAYMENT METHODS

The most common purchaser of mobility devices are third-party payers and not the consumers. In U.S.A., Medicare, Medicaid, and the Department of VA pay for many of the WCs and scooters provided. In 2003, Medicare alone paid for over 230,000 EPWs, 830,000 light-weight (K0004) WCs, and 2.2 million depot WCs.^[29] In developing countries, charitable organizations typically pay for the majority of the mobility aids consumed. India and China both have AT reimbursement programs targeted toward the low-wage earners, but the low reimbursement amount (\$150 in India^[30] and \$50 in China^[31]) restricts the types of AT that can be provided to very low cost. The consequence of the third-party paying system is that it is difficult for the consumers to advocate for better technology. In a typical market system, competition and users' demands drive product development and quality. In the case of AT, third-party payers fundamentally play the pivotal role in demanding technological advances and higher quality devices; because these payers are commonly for profit (such as private insurance companies), their primary interest may be in increased profit, which typically does not translate into more advanced (and thus more costly) technology that may be in the best interest of the consumer. Thus, the role of regulatory agencies such as the FDA is important to require insurance companies to provide high-quality devices that comply with the ANSI/RESNA standards. Consumer advocacy groups such as the Paralyzed Veterans of America and United Spinal Association also can successfully lobby governmental organizations to regulate the devices and clinical care provided to PWD.

CONCLUSIONS

Mobility devices are essential to hundreds of millions of people worldwide, to allow them to participate in society, to work, and to have a more fulfilling life. As the average age of the population increases (as it is in U.S.A. and Japan, along with other countries), more mobility devices will be required. Furthermore, the more appropriate the devices are for the prospective

users, the more socially integrated and self-sufficient they will be.

We have described many of the aspects of personal mobility, highlighting the technology, the payment systems, and, in some cases, the social implications of providing more appropriate technology. While these AT are advancing, they still, in many cases, fail to optimally meet the needs of the users; this is especially true in developing countries, but is commonplace in developed countries where either the technology does not exist or the insurance system will not cover the costs of the necessary technology. Because of these issues, there is much work to be done not only advancing the state of AT, but also advocating for people to be provided technology that will optimally meet their needs.

INTRODUCTION

Among a number of medical advances at the beginning of the twentieth century was the vascular anastomosis, the connecting of the cut ends of blood vessels. First performed in 1896, this technique would launch the field of organ transplantation, which now offers the preferred means of treating chronic failure of the heart, lungs, kidney, liver, pancreas, and, most recently, small intestine. Although a medical triumph, transplantation is equally a source of frustration, as the number of organs needed far exceeds those available. The shortage of organs has spurred investigation of alternative means to treat organ failure. Among these means, the most widely studied and perhaps nearest to clinical practice is xenotransplantation, the use of living cells, tissues, and organs from a nonhuman animal source for human transplantation, implantation, or ex-vivo perfusion. The potential benefits of xenotransplantation extend beyond addressing the shortage of human organs for transplantation. For example, xenotransplantation might be a preferred way to treat certain diseases that afflict human but not animal organs (i.e., HIV and hepatitis). Xenotransplantation could also offer a way of dealing with acute organ failure owing, for example, to new epidemics of myocarditis, viral pneumonia, or nephritis. In addition, xenotransplantation could provide an opportunity for manipulation of the donor organ instead of the host to promote organ acceptance. Manipulation of this type might include expression of genes by production of transgenic animals that promote acceptance of the organ or impact new functions. Finally, xenotransplantation might be used to enable the growth of human stem cells into organs in a surrogate animal.

With the potential uses for xenotransplantation, there are equivalent hurdles to clinical application. The first hurdle is the immune reaction of the host against the graft. Significant progress has been made in understanding this reaction and in devising strategies to overcome it. The second hurdle is physiological incompatibility between the xenograft and the recipient.

The third hurdle is the transfer of zoonotic agents from the graft to the recipient and potentially to other members of society. The following section describes the historical context in which xenotransplantation arose, the potential applications and the hurdles to application, approaches to overcoming these hurdles, and a projection for clinical application.

HISTORICAL PERSPECTIVE

Xenotransplantation has a long history. Some would place its inception more than two hundred years ago with blood transfusion from animals to humans. The first serious attempts at xenotransplantation were made in the early years of the 20th century when Jaboulay^[1] and Ullman^[2] each tried to connect animal kidneys to human blood vessels. The subjects suffered kidney failure and in neither case did the xenograft kidney exhibit more than momentary function. Several other failed attempts discouraged further studies in the field of xenotransplantation until the early 1960s with the advent of immunosuppression. In 1963, Reemtsma transplanted chimpanzee kidneys into thirteen patients. One patient survived for nearly nine months after receiving the organ, before dying from an electrolyte imbalance (the xenograft appeared normal).^[3] This relative success triggered a resurgence of interest in xenotransplantation and led to the conducting of fourteen kidney transplants, eight heart transplants, and eleven liver transplants at various centers. Unfortunately, these attempts were less successful, with approximate survival averaging 15 days (Table 1).^[4]

Due to the limited clinical success of xenotransplantation and the attendant risk of transmitting infectious viruses from the animal to the recipient patient, the U.S. Food and Drug Administration has suggested that solid-organ xenotransplantation not enter clinical trials until there is a “reasonable expectation for success.”^[5] In an effort to improve clinical outcome, extensive benchtop and preclinical studies have been initiated over the past three decades

Table 1 History of whole-organ xenotransplantation

Year	Recipients (surgeon)	Xenotransplant	Survival
1910	1 (Unger)	Monkey kidney	<2 days
1913	1 (Schonstadt)		
1963/64	13 (Reemtsma)	Chimpanzee (12), monkey (1) kidneys	1 case 9 months
1964	3 (Traeger)	Chimpanzee kidney	<49 days
1964	1 (Hume)	Chimpanzee kidney	1 day
1964	6 (Starzl)	Baboon kidney	<60 days
1964	1 (Hitchcock)	Baboon kidney	5 days
1964	1 (Hardy)	Chimpanzee heart	2 hours
1965	2 (Goldsmith)	Chimpanzee kidney	4 months
1966	1 (Starzl)	Chimpanzee liver	<1 day
1966	1 (Cortesini)	Chimpanzee kidney	31 days
1969	2 (Starzl)	Chimpanzee liver	<9 days, <2 days
1969	1 (Bertoye)	Baboon liver	<1 day
1969	1 (Marion)	Chimpanzee heart	4 hours
1970	1 (Leger)	Baboon liver	3 days
1970	1 (Marion)	Baboon liver	<1 day
1971	1 (Poyet)	Baboon liver	<1 day
1971	1 (Motin)	Baboon liver	3 days
1974	1 (Starzl)	Chimpanzee liver	14 days
1977	1 (Barnard)	Baboon heart	5 hours
1977	1 (Barnard)	Chimpanzee heart	4 days
1984	1 (Bailey)	Baboon heart	20 days
1992	1 (Starzl)	Baboon liver	70 days
1993	1 (Starzl)	Baboon liver	26 days

to understand the molecular and biochemical mechanisms responsible for xenograft rejection. Such efforts are discussed in great detail below.

THE SOURCE OF XENOGRAFTS

Clearly, the organs of nonhuman primates would stand the greatest chance of survival in a human recipient, as nonhuman primates are quite similar to humans with respect to genetic composition, anatomy, physiology, immune components, hormones, and enzymes. However, relatedness also extends to receptor molecules for infectious microorganisms including filoviruses (e.g., Ebola virus and Marburg disease) and herpesviruses (e.g., B virus), thus increasing the likelihood of disease transfer from nonhuman primate to human. In addition, because monkeys and apes have long gestation periods and few offspring, they would not supply enough organs to meet the need. One possible exception may be the baboon; however, these animals are smaller than humans, and hence their usefulness to adults might be limited.

Because of the limitations to the use of nonhuman primates as a source of xenografts, many now focus on lower animals such as pigs. Pigs have several advantages over other nonprimate species for xenotransplantation. First, porcine organs are very similar to human organs in size and structure. Second, pigs have large litters and a relatively short gestation period of 114 days; thus, large numbers of organs could become available in a short time. Third, the large litter size and short gestation make housing in specific pathogen-free facilities economically feasible.

Pathogen-free facilities will reduce the risk of transferring exogenous viruses, but the question of endogenous viral transfer remains unclear. All mammalian species harbor endogenous retroviruses. These viruses enter an oocyte or sperm cells at random evolutionary time points and are passed on to progeny like normal genes. Pigs harbor at least one family of retroviruses termed porcine endogenous retroviruses (PERV). It is unclear whether PERVs are able to infect humans *in vivo* and whether they are pathogenic (see the section titled "zoonosis"). This aside, pigs offer a final advantage in that their organs may be genetically

modified to promote organ acceptance by the human host (see the following sections on rejection therapies).

PHYSIOLOGICAL CONCERNS

In using pigs for xenotransplantation, the question of whether physiological compatibility exists between pig organs and the human host must be addressed. In the case of the heart, cardiac outputs and action potentials are quite similar between pigs and humans.^[6] Nevertheless, the innervation and overall morphology of the atrioventricular node in pigs is quite different from that of humans. Such differences could alter heart rate and contractility, thereby increasing the potential for arrhythmias. In the transplantation setting, this difference has not been significantly detrimental, as porcine hearts exhibit excellent cardiac output in immunosuppressed baboons.^[7] Normal sinus rhythm without electrocardiographic ST-segment elevation was also observed and serological parameters indicated little myocardial injury. Unfortunately, early immune rejection has made long-term physiological assessment impossible.

Porcine and human kidneys are also physiologically similar. Kidneys from these two species are of similar size and structure and maintain similar maximal concentration ability (1080 mosmol/liter) and glomerular filtration rate (126–175 ml/h).^[6] Porcine kidney xenografts in primates maintain creatinine (glomerular filtration), urea, sodium, and potassium within the range of normal.^[8] The only insufficiency found relates to porcine erythropoietin. In all cases tested, primates with porcine kidney xenografts experienced severe anemia despite production of porcine erythropoietin.^[9] Primates received species-specific erythropoietin to stimulate primate red blood cell production.

The porcine lung exhibits adequate hemodynamics and gas exchange in baboons.^[10] Liver tissue also seems to function adequately in the short life of the graft, though the electrophoretic motility of the proteins change from that of the primate to that of the pig.^[11] Many of the porcine proteins and enzymes secreted may prove incompatible with a primate host. In addition, xenogeneic proteins may disturb normal metabolic and physiological functions of the recipient. For example, a transplanted liver may secrete prothrombotic or proinflammatory products into the blood of the recipient. There are a great number of proteins that may fail to be cross-species compatible and many more that may disturb normal recipient functions. The critical question is which of these defects can be overcome by the recipient and which must be repaired by pharmaceutical or genetic therapies. Only with extended xenograft survival will the answers to these questions and others related to physiological deficiencies become apparent.

IMMUNOLOGICAL CONCERNS

All xenografts elicit an immune response; however, the impact of the immune response is dictated by the manner in which a xenograft is connected to the recipient. In the case of whole-organ transplants, anastomoses of large blood vessels connect donor to recipient (Fig. 1b). Hence, the blood vessels of organ xenografts are in direct contact with recipient blood and the components of the immune system contained therein. It is primarily the interaction of these immune components with donor blood vessel endothelium that leads to the distinct types of vascular disease associated with xenogeneic organ rejection. The progression of vascular disease in this setting is depicted in Fig. 1 and will be described in detail later in this article. In contrast, cell and tissue xenografts receive blood supply by ingrowth of blood vessels of the recipient. In this setting, the blood vessels of the graft provide a barrier between immune reactants of the transplanted tissue (Fig. 1a). In the following sections we describe the types of rejection seen in whole-organ vs. cellular/tissue xenografts and approaches taken to prevent xenograft rejection.

Whole Organ Xenotransplantation

Hyperacute rejection

Hyperacute rejection is the first immunological hurdle to xenogeneic organ success. Hyperacute rejection is characterized by bleeding into the transplant and formation of platelet microthrombi, which in concert lead to graft destruction within several minutes to a few hours. Hyperacute rejection is initiated by the binding of xenoreactive natural antibodies to the endothelial lining of donor blood vessels. The main antigen recognized by xenoreactive antibodies is a saccharide consisting of terminal Gal α 1-3Gal residues.^[12] The binding of xenoreactive antibodies to this sugar activates the complement system of the recipient. Activation of complement in the xenografts is amplified because complement regulatory proteins are species-specific and, thus, relatively ineffective at controlling complement of foreign species.^[13] The result is rapid insertion of terminal complement complexes into the cell membrane of donor luminal endothelial cells and eventual severe organ injury.

Hyperacute rejection therapies

Hyperacute rejection can be averted in several ways. Hyperacute rejection can be averted by depleting recipient plasma of xenoreactive antibodies using immunoabsorption columns.^[14] This therapy must be

Fig. 1 Biological responses to transplantation depend on the means by which a xenograft receives its vascular supply. a) Cell and tissue xenografts are vascularized, for the most part, by recipient blood vessels. These grafts are subject to failure of engraftment (primary nonfunction) or cellular rejection, but not to vascular rejection. b) Organ xenografts are vascularized by donor blood vessels. The grafts are subject to a series of vascular responses beginning with hyperacute rejection (minutes to hours), acute vascular rejection (days to weeks), cellular rejection, and chronic rejection. (Reprinted and adapted from Ref. [39] with permission.)

used in conjunction with immunosuppressive agents such as cyclophosphamide, mycophenolate, leflunomide, or similar new agents, to prevent rapid antibody resynthesis. These agents alone, despite good success in human allotransplantation, cannot prevent hyperacute rejection. Another way of preventing hyperacute rejection is to inhibit complement. Systemic inhibitors of complement, such as cobra venom factor, soluble complement receptor Type 1 (SCR1), and antibodies against complement component C5 and γ globulin have been used with relative efficacy.^[15] However, inhibition of complement deprives the treated individual of a vital defense against extracellular pathogens and, hence, the treated individual is susceptible to severe infection.

Genetic engineering affords an opportunity to inhibit complement without abridging the defense of the transplant recipient. Specifically, lines of animals that are transgenic for human complement regulatory proteins have been proposed. Organs from these animals would presumably be able to control activation of complement in the xenograft. Organs from transgenic

pigs carrying and expressing human complement regulatory proteins CD55, CD46 (membrane cofactor protein), and CD59 (protectin), either singly or in combination, do not undergo hyperacute rejection after transplantation into nonhuman primates.^[8,16] This result underscores the importance of genetic engineering as a means of improving the outcome of xenografts.

Another way to preclude hyperacute rejection may be to modify expression of antigens recognized by xenoreactive natural antibodies. Transgenic model systems have been developed to accomplish that end. One approach has involved overexpressing an alternate glycosyltransferase (H transferase), which would compete with α 1,3 galactosyltransferase, placing H-antigen residues at the terminus of some sugar chains instead of Gal α 1-3Gal.^[17] To date, these endeavors have shown an ex-vivo decrease in complement-mediated lysis of isolated porcine cells with increased H-transferase, but complete elimination of hyperacute rejection is still uncertain.

Cloning has also been used to modify expression of antigens recognized by xenoreactive natural antibodies. Recent reports describe the successful double knockout in pigs of both alleles of the gene $\alpha 1,3$ -galactosyltransferase. Targeted disruption of one allele was accomplished by homologous recombination in vitro followed by nuclear transfer of the modified cells to generate cloned pigs with the mutant $\alpha 1,3$ -galactosyltransferase allele.^[18] A selection procedure based on a bacterial toxin was used to select for cells in which the second allele of the $\alpha 1,3$ -galactosyltransferase gene was knocked out. Sequencing analysis demonstrated that knockout of the second allele was caused by a T-to-G single point mutation at the second base of exon 9, resulting in inactivation of the $\alpha 1,3$ -galactosyltransferase protein.^[19] Three consecutive rounds of cloning produced the $\alpha 1,3$ -galactosyltransferase double-knockout piglets. The piglets have yet to be extensively tested for expression of the Gal $\alpha 1$ -3Gal antigen. In the interim, homozygous (–/–) fetal-pig fibroblast cells have been produced from heterozygous embryos using a novel selection method. These cells express low (~1%) but detectable levels of the Gal $\alpha 1$ -3Gal antigen.^[20] Whether cells expressing low-level antigen are as susceptible to hyperacute rejection as their wild-type counterparts remains to be seen. As cloning technology continues to advance, it is possible that much simpler and less expensive technology will be developed.

Acute vascular rejection

When hyperacute rejection is prevented, a xenogeneic organ is subject to acute vascular rejection, sometimes known as acute humoral or delayed xenograft rejection. The pathology of acute vascular rejection is characterized by focal ischemia, intravascular fibrin deposition, and thrombosis. Acute vascular rejection may begin within 24 hours of transplantation with graft failure ensuing over a period of days to weeks, or it may begin later and exhibit a more indolent course. Acute vascular rejection has been thought to lead inexorably to destruction of the graft and is, therefore, the main barrier to clinical xenotransplantation.

Acute vascular rejection appears to be initiated by the binding of xenoreactive antibodies to the xenograft, causing activation of endothelium in the graft by three potential mechanisms. First, endothelial cell activation might be induced by the binding of antibodies to cell surface antigens, such as integrins, which can transduce signals.^[21] Second, xenoreactive antibodies could activate complement in small amounts, leading to activation of endothelial cells.^[22] And finally, xenoreactive antibodies could serve as targets for F_c-bearing cells, which may in turn activate endothelium.^[23] Activated

Fig. 2 Pathogenesis of acute vascular rejection. The endothelial lining of blood vessels can be activated by xenoreactive antibodies (Ab), complement (C), platelets, and perhaps inflammatory cells (natural killer (NK) cells and macrophages). Endothelial cell activation leads to expression of new pathophysiological properties. These new properties include synthesis of tissue factor and plasminogen activator inhibitor type 1 (procoagulation) and E selectin and other cytokines (proinflammation). These changes in turn cause thrombosis, ischemia, and endothelial injury, the characteristic features of acute vascular rejection. (Reprinted and adapted from Ref. [40] with permission.)

endothelial cells express procoagulant molecules such as tissue factor and proinflammatory molecules such as E-selectin and cytokines. The pathogenesis of acute vascular rejection is summarized in Fig. 2.

Developing therapies to prevent acute vascular rejection has been more challenging than developing therapies to prevent hyperacute rejection. Part of the challenge is that acute vascular rejection is triggered by low levels of antibody binding. The antibodies that initiate acute vascular rejection include anti-Gal $\alpha 1$ -3Gal antibodies but may also include other antidonor antibodies.^[24] Hence, eradication of one antigen or depletion of antibodies that recognize it may be insufficient to prevent acute vascular rejection. Nevertheless, much effort is underway to generate animals deficient in Gal $\alpha 1$ -3Gal and donor pigs transgenic for complement regulatory proteins, as discussed for hyperacute rejection, to help avert acute vascular rejection.^[8,16]

Acute vascular rejection may also be promoted by NK cells and macrophages. Infiltration of these inflammatory cells leads to synthesis of tissue factor and plasminogen activator inhibitor type 1. Tissue factor and plasminogen activator inhibitor type 1 promote coagulation and synthesis of E-selectin and cytokines, which promotes inflammation. In this manner, the injury triggered by xenoreactive antibodies is further exacerbated.^[25]

Acute vascular rejection therapies

Acute vascular rejection poses a more difficult challenge than hyperacute rejection, owing to the many immunological players involved and to the need for

Table 2 Therapeutic strategies for acute vascular xenograft rejection

Therapeutic approach	Manipulation of recipient	Manipulation of donor
Induction of immune tolerance	Pretransplant infusion with donor bone marrow or genetically engineered Gal α 1-3Gal ⁺ bone marrow	
Induction of accommodation	Transient depletion of xenoreactive antibodies	
Inhibition of endothelial cell activation	Administration of antiinflammatory agents	Suppression of procoagulant or proinflammatory genes
Reduction/elimination of xenograft antigen expression	Specific depletion of xenoreactive antibodies	Breeding pigs with inherently low levels of antigen
	Prevention of xenoreactive antibody synthesis (e.g., cyclophosphamide, leflunomide)	Generating transgenic pigs with low levels of antigen
		Cloning pigs without antigen (i.e., α 1,3 GT knockout and possibly other gene knockouts)

ongoing therapy. Therefore, a multifaceted approach might be envisioned for treating acute vascular rejection (Table 2). One approach involves induction of immunological tolerance. Tolerance in xenotransplantation implies cessation of the synthesis of xenoreactive antibodies. Such a condition might be achieved by transplantation of donor bone marrow, or genetically manipulated bone marrow, to bring about the expression of relevant donor antigens and, subsequently, the deletion or suppression of B-cells of the recipient that secrete antidonor antibodies. Bracy et al. used the latter approach by expressing α 1,3 galactosyltransferase in bone marrow cells by gene transfer. Administration of the Gal α 1-3Gal⁺ bone marrow cells in α 1,3-galactosyltransferase knockout mice decreased production of anti-Gal α 1-3Gal antibodies. One possible limitation to the induction of tolerance is that the antibodies directed against Gal α 1-3Gal are produced independently of T cells. Hence, if anti-Gal α 1-3Gal antibodies are important in causing xenograft rejection, approaches focused on T cells, such as inhibition of costimulation, may not be as effective in inducing tolerance in the xenograft setting.

Another approach to avoiding acute vascular rejection is to bring about accommodation of the graft. Accommodation is an acquired resistance to humoral injury. Accommodation was first observed in the successful transplantation of ABO-incompatible renal allografts.^[26] For this purpose, anti-blood group antibodies were depleted from the recipient before placement of an incompatible allograft. The grafts survived in spite of the return of anti-blood group antibodies. Others found that accommodation can occur in pig-to-primate xenografts, in that organ transplants from pigs can survive in primates for even one month without evidence of acute vascular rejection.^[27] The biological

mechanisms underlying accommodation are still incompletely understood, and thus although it is known that initial depletion of donor antibodies is necessary, depletion duration is unclear. Some have suggested that accommodation might be initiated via expression of antiapoptotic genes such as hemoxygenase 1, A 20 and bcl2,^[28] changes in functional properties of xenoreactive antibodies, changes in antigens, or changes in the graft that render it less susceptible to humoral injury. Careful studies to elucidate the full nature of accommodation are needed, however.

A third approach to avoiding acute vascular rejection is to decrease xenograft antigen expression (as discussed previously for hyperacute rejection). Although decreased antigen expression was initially conceived for prevention of hyperacute rejection, the main application will likely be for prevention of acute vascular rejection. There is evidence to suggest that the level of antibody binding needed to initiate acute vascular rejection is lower than the level needed to initiate hyperacute rejection. Accordingly, the antigen expression on the cells of xenogeneic organs may have to be reduced significantly to achieve therapeutic benefit for acute vascular rejection. Thus, the α 1,3-galactosyltransferase knockout animals (as discussed previously) may offer the greatest therapeutic potential. In addition to lowering or eliminating antigen expression, it is likely that expression of human complement regulatory proteins will be helpful in preventing acute vascular rejection. Cozzi and associates^[9] achieved prolonged survival of xenografts, presumably by preventing acute vascular rejection, by using transgenic pigs expressing high levels of decay-accelerating factor and cynomolgus monkeys treated with very high doses of cyclophosphamide. The immunosuppression may have precluded antidonor antibody synthesis.

Cell-mediated rejection

If hyperacute rejection and acute vascular rejection can be circumvented, a xenograft would be subject to cellular rejection. It is unclear whether and to what extent cellular immunity to xenografts differs from cellular immunity to allotransplants. Here we discuss the potential differences and similarities in cell-mediated rejection of xenografts vs. allografts.

There are four critical issues that likely bear on cell-mediated immune responses to xenotransplantation. The first is the interaction of recipient T cells with donor T cells. There is evidence to suggest that human T cells can recognize pig major histocompatibility antigens as they are expressed in pig cells, just as T cells can recognize major histocompatibility complexes of other human cells of an allograft.^[29] But is recognition of pig cells enough to elicit full T cell activation of human cells? Complete activation between species may be hindered if, for example, incompatibilities of cell adhesion or cell signaling molecules exist. The second important issue is that while in allotransplantation, the polymorphism giving rise to rejection is largely restricted to major histocompatibility complex antigens. In xenotransplantation, almost any porcine protein can give rise to immunogenic peptides. Therefore, the number of different T cell clones directed against xenogenic antigens is likely to be very large. The importance of this diversity of peptide antigens is unknown, but it may prove a great challenge to those interested in applying tolerance to the prevention of cell-mediated xenograft rejection. The third important factor relates to the role of humoral immunity. Allotransplant rejection is more likely if the recipient of an allotransplant has antibodies directed against the donor. Because virtually all xenotransplant recipients will have antibodies directed against the donor, cellular rejection of xenotransplants may be much worse. The final issue relates to the function of immunoregulatory T cells. Defects in T-cell recognition of xenogenic cells may affect the ability of regulatory T cells to control cell-mediated immunity.

Cell-mediated rejection therapies

A variety of immunosuppressive agents and immunomodulatory regimens are currently under investigation to combat cell-mediated rejection. These regimens are based on those used for allograft and include cyclosporin A, tacrolimus (FK506), azathioprin, and/or prednisolone. Because cell-mediated immune responses to xenografts may be more severe than in allografts, it is possible that currently used immunosuppressive agents will not suffice to prevent cellular rejection. On the other hand, a recent study on transplantation of

xenogenic hepatocytes suggests that disparate cells might be transplanted using even less immunosuppression than is used for allografts in humans.^[30] In addition, pharmaceutical therapies for xenotransplantation can be planned in advance (instead of the few hours available when using cadaveric organs). The extra time may allow pretreatment of the xenograft recipient in an effort to lessen the cell-mediated or humoral response. Such pretreatment may extend into the application of immunological tolerance, making certain regimens feasible for xenotransplantation that could not be considered for allotransplantation.

Aside from pharmaceutical regimens, immunological tolerance and/or limiting cell-mediated immunity may also be promoted by genetic engineering. Certainly, efforts to control the natural immune barriers to xenotransplantation may contribute to limiting the elicited cell-mediated response. Given the recognition of donor cells by recipient T cells, the xenogenic donor might be engineered to downregulate expression of corecognition molecules (i.e., CD4 and CD8) or costimulatory molecules (i.e., CD28). Alternatively, or in addition, molecules that inhibit T-cell interactions such as CD59 or Fas ligand might be overexpressed in the donor cells. Expression of inhibitory molecules is currently under investigation for allotransplantation but may prove more effective in xenotransplantation since the inhibitory genes can be introduced as transgenes and, therefore, expressed only in relevant cells in the graft.

Chronic rejection

Chronic rejection in the context of xenotransplantation is rarely discussed, given the short survival of xenografts. It is assumed that chronic rejection akin to that observed for allografts is likely in the xenotransplantation setting. Though the mechanisms of chronic rejection are not fully understood, potential triggers may include repeated acute rejection crises or ischemic injuries of the grafted tissue. Whatever the trigger, the results are ongoing inflammatory reactions and diffuse intimal proliferation in the arterial vessels eventually leading to graft arteriosclerosis. Current immunosuppression therapies are unable to combat chronic rejection in the allotransplant setting and will likely be insufficient for xenotransplants as well. However, unlike the current circumstances in the case of human transplantation, xenografts undergoing chronic rejection could be replaced.

Cellular and Tissue Xenografts

Cell and tissue transplants are of increasing interest as potential means of treating disease and regenerating

diseased organs. Transplantation of isolated islets of Langerhans has been pursued as a treatment for diabetes mellitus, transplantation of hepatocytes for genetic disease of the liver, transplantation of myoblasts for treatment of cardiac failure, and transplantation of neurons for treatment of neurological defects.^[31] Another potential application of cell and tissue transplants is as a means of gene delivery. Although in some cases it is possible to use cells from the affected individual, for some purposes, autologous cells cannot be used, and the main limitation to transplanting human cells and tissues is availability of donors. For this reason, there has been interest in the potential use of animal cells and tissues for transplantation.

Cell and tissue transplants are less susceptible than organ transplants to humoral immunity because the cell and tissue transplants are fed by recipient blood vessels and, therefore, the blood vessels are not subject to attack by xenoreactive antibodies (Fig. 1a). Cell and tissue xenografts that are in contact with recipient blood such as xenogeneic bone marrow cells injected into the systemic circulation or xenogeneic islets injected in the portal vein are subject to injury by xenoreactive antibodies, complement, and other inflammatory mediators.^[32] Cell and tissue transplants are also subject to immediate failure, called primary nonfunction. The mechanistic details of primary nonfunction are not fully understood, but it may be caused by one or more of three factors: 1) the inability of growth factors of the recipient to support newly implanted cells and/or failure of graft factors to support host angiogenesis; 2) the action of natural killer cells or recently activated T cells on the newly implanted graft; and 3) the action of complement on xenogeneic cells and tissues introduced into the blood.

Therapeutic strategies for cellular and tissue xenografts are likely to require little more than presently available immunosuppressive agents. Those cellular/tissue xenografts in contact with recipient blood will require therapies similar to those under investigation for organ transplants (as discussed previously). Another approach to promote cellular xenograft survival may be microencapsulation of the graft with a biocompatible membrane. Microcapsules could protect the xenograft from immune attack while enabling the exchange of nutrients and hormones.^[33] This approach may be particularly useful in the context of pancreatic islet and parathyroid transplantation. It may even prove useful for prevention of endogenous viral transfer.

ZOONOSIS

Recent progress in clinical application of cellular xenotransplantation has brought to the fore concerns

about the possibility of the transfer of infectious agents from the xenograft to the recipient and concern that these agents might spread more broadly in the population. Most pathogens known to cross the species barrier can be readily detected and eliminated from the xenograft source. An exception to this may be the porcine endogenous retroviruses (PERVs), which are present in the germ line of all pigs. Some would argue that since humans have existed in close proximity to pigs for years without known episodes of infection, PERV transfer is unlikely in the transplantation setting. However, PERV can infect cultured human cell lines^[34] and has been shown to infect human cells transferred to SCID mice.^[35] In a multitude of long-term clinical studies with patients exposed to porcine cells (islets and hepatocytes), however, no evidence of retroviral infection has been detected.^[36]

If a given organism such as PERV were to prove a significant hazard, novel therapeutics of various sorts could be applied. For example, introduction of genes encoding retroviral decoys might succeed in preventing or decreasing the production of infectious virus. This type of strategy has proven unsuccessful for the treatment of human retroviruses because the genes could not be delivered to stem cells. This limitation would not apply in animals where the gene of interest could be introduced into the germ line.

In addition to endogenous retroviral transmission, there is the possibility that the recipient will be subject to infections of the xenograft to which humans are not ordinarily susceptible. Thus, it may be useful to investigate the efficacy of animal-specific antimicrobial agents in humans and the efficacy of human-specific antimicrobial agents against animal microorganisms.

ETHICAL CONSIDERATIONS

Experimentation conducted in humans is subject to certain ethical principles (as outlined in the Belmont Report^[37]), including respect for persons, beneficence, and justice. Ethical consideration of xenotransplantation in humans is distinct from this principle because the risks may extend beyond the patient to society as a whole. Therefore, the Institute of Medicine and the Food and Drug Administration^[38] have endeavored to establish guidelines for clinical trials that take into account the potential impact of xenotransplantation on society. The ethical issues under scrutiny by these bodies include granting consent (when potential harm extends beyond an individual to public health), monitoring potential zoonotic infections, assessing psychological effects of receiving an

animal organ, and ensuring appropriate care and use of animal donors.

CLINICAL PROJECTIONS

Although scientific progress in the field of xenotransplantation is significant, substantial difficulties remain, particularly with respect to the immune response of the recipient against the xenograft. There is no reason to doubt that cellular xenotransplantation from pig to human could and in fact has been undertaken^[31] through the use of presently available immunosuppressive agents. However, xenogeneic organ transplantation is a different matter. Hyperacute rejection has been overcome, but the barriers to acute vascular rejection remain intact. And, in fact, the barriers seem insurmountable in light of the possibility that antibodies against antigens other than Gal α 1-3Gal might exist. Still, pharmaceutical progress in overcoming the humoral barrier to allotransplantation and the possibility of genetic engineering provides some encouragement that acute vascular rejection may be prevented or at least suppressed in some individuals. Even so, chronic rejection has yet to be addressed. Chronic rejection is the major cause for allograft loss and if, as some research suggests, chronic rejection is caused by antidonor antibodies, it is likely to be exponentially worse for xenografts. Nevertheless, one redeeming aspect of xenotransplantation validates pursuance of clinical application. If a clinical xenograft were to fail, it might be easily replaced—an option not routinely afforded when a clinical allograft fails. And, in fact, the next step to further xenotransplantation may be bridge or temporary organ transplants to be followed either by an allograft or subsequent xenograft. Bridge transplants will help address the problem of the human organ shortage and will provide opportunity for incisive analysis to overcome the remaining immunological hurdles barring whole-organ xenotransplantation. As a final note, tandem investigation of PERV and other zoonotic agents must be furthered if xenograft safety and eventual FDA clearance is to be attained.

Zirconia Ceramics

Mariano A. Polack

Gainesville, Virginia, U.S.A.

INTRODUCTION

High-performance ceramic materials are increasingly used in a variety of engineering and biomechanical applications. Some significant examples include all-ceramic dental crowns to replace dental enamel, total hip replacement prostheses, and thermal barrier coatings in jet turbine and diesel engines. These ceramics are particularly appealing because of their high hardness, strength, and modulus that provide them with increased resistance to fracture and deformation under long-term cyclic conditions, among other properties. Zirconia is an example of this group of materials and is an attractive candidate for the above-mentioned applications. This chapter will identify the composition and main properties of zirconia, describe its dental applications, and discuss ways of improving its clinical behavior through an understanding of current research.

COMPOSITION AND PROPERTIES

General

Zirconia, or zirconium dioxide (ZrO_2), is a ceramic that can exist in three major phases: monoclinic, tetragonal, and cubic.^[1,2] The monoclinic phase is the low-temperature, stable phase. Pure zirconia is monoclinic at room temperature, and this phase is stable up to $1170^\circ C$ ^[3] but its structure can transition to tetragonal and cubic with increasing temperatures. Upon cooling, the phase transformation from cubic to tetragonal to monoclinic is accompanied by a 1–5% volume expansion that induces large stresses in the material. This causes cracks in pure zirconia, decimating its mechanical properties and making it useless for any of the applications mentioned previously.

Partially Stabilized Zirconia

In order to stabilize ZrO_2 , different oxides that dissolve in its crystal structure can be added. These typically include yttrium oxide (Y_2O_3), calcium oxide (CaO), and magnesium oxide (MgO). The exact mechanisms that strengthen and toughen tetragonal zirconia are beyond the scope of this chapter but, in general, they depend on

the type and amount of stabilizing agent, the grain size, and the thermal history of the ceramic. This generates two different partially stabilized zirconias (PSZ) known as TTZ (tetragonally toughened zirconia) and TZP (tetragonal-zirconia polycrystal). The former is a MgO partially stabilized zirconia, a common commercial material also known as MgPSZ or MgTTZ. The latter requires the addition of 3% Y_2O_3 (or more rarely, ceria) to ZrO_2 as a stabilizing agent and produces a material known as yttrium-tetragonal zirconia polycrystal (YTZP).^[1] This very fine grain ceramic has outstanding toughness and hardness that can be challenging to produce.

Transformation Toughening

When a stress is applied to YTZP and a crack tries to propagate through it, the stress concentration at the leading edge of the crack can induce the YTZP to transform from its tetragonal to a monoclinic configuration.^[4] The monoclinic phase is 3–5% larger than the tetragonal crystal, and therefore the phase change generates a volume expansion at the tip of the crack that places it in compression, preventing its propagation. This process, called transformation toughening, increases the fracture toughness of the ceramic (the material's ability to resist crack propagation)^[5] and makes it appealing for cutting, wear-resistant, and dental applications (e.g., replacing the tooth structure subject to load).^[4] However, the value of this mechanism for the latter application is being questioned.^[6]

Thermal and Electrical Behavior

All toughened zirconias suffer degradation of their properties with increasing temperatures,^[2] limiting their applications to below $800^\circ C$. At room temperature, zirconia is highly resistant but its conductivity increases at high temperatures, and it becomes a very good conductor above $2000^\circ C$.

The addition of sufficient CaO oxide amounts allows the cubic structure of zirconia to be maintained at room temperature, which in turns allows it to be used as a refractory material. Stabilized zirconia, because of its high ionic and low electronic conductivity, is also an important electroceramic. Some other applications for

zirconia include high-density ball and pebble mill-grinding media, rollers and guides for metal tube forming, thread and wire guides, oxygen sensors, and fuel cell membranes.

DENTAL APPLICATIONS

Where severe destruction of the tooth structure has occurred, a dental crown may be needed to replace the loss of enamel or dentin to restore anatomy, function, and esthetics. In the past, dental crowns were exclusively fabricated with a metallic core that was veneered with feldspathic porcelain to provide the esthetic component. These were known as porcelain fused to metal crowns (Fig. 1). The search for a more esthetic, biocompatible, and inert option^[7] has led, in the past few years, to a surge of all-ceramic systems that are rapidly becoming the material of choice for dental crowns.^[8]

The initial attempts at developing such systems started with a monolithic approach (i.e., a single-layer ceramic such as Dicor[®], Dentsply/Caulk, Milford, DE; or IPS Empress[®], Ivoclar, Schaan, Lichtenstein) but presented failure rates between 3% and 6% per year,^[9–11] significantly higher than the 2–3% failure estimate at 10 years of their porcelain fused to metal counterparts.^[12] In consequence, a bilayer design was utilized with an alumina core that was either glass-infiltrated (InCeram[®], Vident, Brea, CA)^[13] or densely sintered (Procera[®], Nobel Biocare, Yorba Linda, CA)^[14] to support the veneering porcelain applied for esthetic reasons. Clinical studies demonstrated a lower failure rate for the alumina systems when used for single crowns,^[15,16] but results have not been encouraging when used for replacing a missing tooth with a single all-ceramic structure (i.e., fixed-partial denture (FPD) or dental bridge) in the posterior intraoral

regions,^[17,18] where forces of mastication are greater. In fact, failure rates in some cases were up to 24% for molars.^[17]

YTZP cores were developed based on a need to improve the clinical performance of all-ceramic systems through stronger substructures with improved physical properties^[7,19] and can be used for anterior or posterior crowns and bridges (Lava[™], 3M ESPE, Minneapolis, MN; DCS Smart-Fit, Austenal, Chicago, IL; Cercon Smart Ceramics, Dentsply Ceramco, Burlington, NJ; Procera[®] AllZirkon, Nobel Biocare, Yorba Linda, CA; Vita YZ, Vident, Brea, CA).^[20,21] Fracture toughness of 9–19 MPa^[22] and a flexural strength between 900 and 1200 MPa^[22] are some of the properties that make YTZP appealing as a core material.

Core Manufacturing

The manufacturing of zirconia cores (for single crowns) or frameworks (for multiple teeth replacement with one structure) will depend on the system utilized. Frameworks for fixed-partial dentures are traditionally fabricated by machining techniques that require conventional waxing first and then scanning or a computer-aided design/computer-assisted manufacturing (CAD/CAM) protocol.^[23] Lava (3M ESPE) is an example of the latter. In order to fabricate a zirconia core or framework with this system, four main steps are needed: a) scanning of the prepared areas; b) computer-assisted design of the framework; c) CAM milling of the partially sintered zirconia block; and d) sintering. After this step, compatible feldspathic porcelain is used to veneer the framework to obtain full anatomic contour and appropriate esthetics (Figs. 2 and 3). During the fabrication process, the substructures are expanded by 20% through a computer to compensate for the sintering shrinkage that takes place for 6–8 h in a

Fig. 1 Lateral and intaglio surface of a porcelain fused to metal crown.

Fig. 2 Intaglio surface of a YTZP fixed partial denture fabricated with the Lava system that will replace the maxillary left central incisor.

Z

high-temperature oven. A clinical study of posterior three-unit FPDs (i.e., replacing one tooth) fabricated with the Lava system demonstrated a success rate of 100% after a mean follow-up of 31.2 months.^[6] In this study, all assessed parameters of the restorations were rated “alpha” except for minor chipping of the veneering porcelain detected in five FPDs (“bravo” for clinical fracture resistance) and the marginal integrity of one restoration that was rated bravo at 36 months.

The DCS Smart-Fit system (Austenal) is a CAD/CAM system that mills the cores and frameworks from fully sintered blocks under hot isostatic pressure. This results in an extremely hard and dense ceramic,^[1] although milling fully sintered zirconia blocks can introduce microcracks and damage its microstructure.^[24]

Single copings and FPD frameworks fabricated with the Vita InCeram YZ blocks (Vident) and the Cercon Smart Ceramics system (Dentsply Ceramco) also undergo an enlarging and sintering process. The former system employs presintered YTZP blocks^[25] that are milled in the CEREC inLab unit (Sirona, Charlotte, NC), a specific CAD/CAM machine. The substructures are then sintered in a special furnace for 2 h at 1530°C to permit shrinkage to full density.^[26] The Cercon system utilizes partially sintered YTZP with no CAD stage. Instead, the substructure is waxed by a laboratory technician using traditional techniques that are analog to the “lost-wax” fabrication method of a metal coping for a porcelain fused to metal crown. The wax pattern is then optically scanned into a computer and virtually enlarged before the automatic milling (CAM stage) and sintering of the ceramic blocks take place. Veneering of the substructures with compatible feldspathic porcelain follows.

Procera Zirconia (Nobel Biocare) is also a CAD/CAM system that utilizes this ceramic as an option for the fabrication of single^[27] and multiple-unit restorations.^[25] In this system, the master cast is scanned and the information transferred through a modem to a

production unit. Then the dies or frameworks are virtually enlarged to balance the sintering shrinkage and milled out of a solid piece of high-purity zirconium oxide, which is then sintered. The resulting substructures are sent back to a laboratory where they are veneered for esthetics.

One other system (InCeram Zirconia, Vident) employs a glass-infiltrated 35% zirconia/65% alumina material for the fabrication of posterior crowns and FPDs,^[28] which can be slip cast or milled from presintered blocks. Its flexural strength is about 620 MPa,^[29] which is lower than that reported for densely sintered zirconia, the ceramic used in the other systems mentioned above.^[22,30] A 3-year clinical study of posterior FPDs fabricated with InCeram Zirconia demonstrated a success rate of approximately 94.5%.^[31]

Implant Abutments

YTZP also has applications in implant dentistry. When a missing tooth is replaced with a dental implant, an abutment is connected to the implant to support the crown that will be placed over it. In the past, abutments were fabricated in metal (Fig. 4) but with the introduction of high-strength ceramics, alumina and YTZP have been utilized for these purposes whenever the esthetic requirements are high (Fig. 5).^[32] Most recently, there seems to be increased interest in the development of a zirconia implant (versus the traditional ones made of titanium or titanium alloy).^[33]

BEHAVIOR AND CLINICAL CONSIDERATIONS FOR YTZP CROWNS

Radial Cracking

In clinical practice, the most reported cause of failure for all-ceramic crowns is bulk fracture.^[34] Contrary to

Fig. 4 Metal abutments connected to osseointegrated implants (implants not seen) that will support porcelain fused to metal crowns.

Fig. 5 Zirconia abutment connected to osseointegrated implant (implant not seen) that will support an all-ceramic crown.

intuition, this type of failure does not arise from the weaker occlusal (top) surface but from radial cracks located at the cementation interface (i.e., between the tooth and the ceramic core) generated by a high enough load (critical load).^[35] These radial cracks produced by flexure induced by loads at the top surface have been identified as the most harmful for prosthesis survival.^[19]

Lawn et al. demonstrated that once formed, radial cracks will travel and spread laterally outward as the load increases but will tend to close up, without healing, as the load diminishes.^[19] When this occurs, radial cracks become difficult to detect by top-surface inspection, making them particularly dangerous: A sufficient high load can make the existing cracks penetrate the entire thickness of the core and lead to the catastrophic failure of the restoration.

Radial cracking is highly dependent on the thickness of the ceramic layer (the combined total thickness of the core and the feldspathic porcelain veneer applied over it). This has a direct effect on crown design, where the feldspathic veneer requires a certain thickness for esthetics (approximately 1.5 mm) but reaching this thickness at the expense of the core can increase the chances of radial cracking. Therefore, sufficient reduction of tooth structure must be done when one of these all-ceramic crowns will be utilized, so that the core and the veneering porcelain will have the appropriate dimensions.

Cyclic Fatigue

It has been also questioned whether YTZP will sustain its performance when exposed to mechanical damages, as in prosthesis handling (for crowns) or insertion procedures (for total hip replacements). There have

been numerous reports of fatigue for YTZP stemming from some combination of slow crack growth and mechanical degradation.^[36] Research indicates that cyclic loading causes substantial loss of strength for YTZP, pointing to a mechanical degradation process by slow crack growth. In addition, YTZP can suffer degradation from thermal events that might be encountered during sterilization, for example. This could weaken the material by inducing transformations leading to microcracking.^[37]

In summary, YTZP seems to have some mechanical and thermodynamic instability, requiring strict control during manufacturing and handling to protect it from inadvertent, excessive degradation.^[36] This supports the application of YTZP as a core material in dental crowns, where its surface is somewhat shielded from external influences by the veneering feldspathic porcelain. However, it is worth noting that critical loads for the initiation of radial cracks tend to diminish with time from intrusion of moisture into starting flaws at the cementation interface.

Role of Moisture

There is a potentially dangerous top-surface damage mode called inner-cone crack that appears mostly under cyclic loading in water.^[38] In ceramics such as YTZP, these cone cracks can appear before radial cracks and lead to failure in bilayer structures by entering the brittle coating layer (dentin in the case of dental crowns) and causing delamination.^[39] The mechanical driving force for this phenomenon appears to be hydraulic pumping: as confined water enters and exits the crack interface under pressure during cyclic loading, it forces entrapped liquid toward the crack tip, opening surface flaws and driving the cracks deep into the sublayer.^[40] With more cycles, more water enters the crack interfaces turning into a continuous, deep driving force for the cracks. This demonstrates the deleterious role that the oral environment, and specifically saliva, can have on the longevity of zirconia restorations under these loading circumstances.

Sharp Occlusal Contacts

In addition to the above, YTZP is highly sensitive to fatigue from sharp-indenter damage (micrometer scale indentations) in cyclic flexural stressing.^[40] This means that small indentations below which radial cracking occur can generate significant strength loss in YTZP. For instance, a sharp contact with a load of 0.1 N is as damaging as a 1.98-mm-radius blunt surface contact at 300 N. Therefore, under these conditions, YTZP must be considered a somewhat brittle ceramic that must be

handled with care during fabrication and handling to avoid deleterious strength damage.

In short, sharp contacts will concentrate stress on a small number of microcracks, although much more strongly than blunt contacts. As the load increases, radial cracks develop and slow crack growth becomes the dominant fatigue mechanism.^[41] One clinical procedure that could prove beneficial to neutralize the effect of sharp contacts would be rounding off sharp cusps in the dentition opposing YTZP crowns.

Curved Surfaces

Research on all-ceramic crowns performed on flat surfaces can provide important information about the behavior of these materials. However, teeth are curved, and this could change the results obtained. The influence of surface curvature on the conditions to set off and propagate radial cracks has been studied and, in general, higher loads are needed to initiate these cracks in curved surfaces.^[42] This early inhibition of the initiation of radial cracks by curved surfaces is followed by an acceleration of the propagation of cracks toward the support base, particularly on convex surfaces. At the same time, the load needed to propagate radial cracks to the support base (failure load) diminishes as convexity increases. This study also demonstrated that tests performed on flat surfaces^[43] can provide accurate approximations of the loads needed to initiate radial cracking in more convoluted surfaces. The clinical implication is to avoid sharp convex curvatures during the construction of YTZP crowns.

Sandblasting

Sandblasting the interior surface of an all-ceramic crown is a common procedure when cementing these restorations.^[44] Sandblasting produces a roughened surface that enhances the mechanical bond with dental cements. On the other hand, sandblasting introduces defects that could affect the strength of the crown. Research indicates that under dynamic and cyclic loading, slow crack growth will degrade the strength of YTZP by a factor of 2–4.^[45] Sandblasting YTZP crowns before cementation could further reduce strength levels under certain loading conditions,^[46] outweighing its possible benefits. The recommendations from the literature indicate that the best cementation for YTZP restorations is achieved with an adhesive phosphate monomer containing resin luting cement.^[47]

CONCLUSIONS

The use of high-strength ceramics is increasing at a rapid pace. In this respect, the introduction of zirconia

for biomechanical applications has been interesting because of its enhanced mechanical properties, esthetics, and biocompatibility. The utilization of a strong and stiff core material such as YTZP in dental crowns may offer some protection against strength degradation from cyclic loading and moisture-induced cone cracks compared with other ceramics. However, to improve the life expectancy of replacement structures fabricated with zirconia, a better understanding of its behavior is needed.

Extensive research has been done in this respect, and some design strategies for dental crowns can be applied to maximize their performance, such as providing adequate crown thickness to avoid radial cracks. Additionally, eliminating sharp opposing contacts and extremely convex surfaces during crown construction can enhance the lifetime of YTZP restorations. Finally, a phosphate monomer containing resin–cement should be used for the cementation of zirconia crowns, whereas sandblasting should be avoided to prevent introducing flaws in the core structure that could reduce its strength.

magnetic nanoparticles, 1709–1710
overview, 1695
scale-up and economic issues, 1702
- Cell sheets, tissue engineering, esophagus, 2721
- Cell signaling
articular cartilage, tissue engineering, 2697
interfacial transport, biomaterials
basic principles, 2347–2348
current applications, 2348–2349
electrolyte concentration and permeability, 2352–2353
future research issues, 2354–2355
gold-palladium alloy coatings, 2354
membrane transport, 2349–2358
molecular mass
artificial membranes, 2350–2351
permeability and, 2354
pH effects, 2351–2352
overview and history, 2346
pore size and permeability, 2353–2354
water/wastewater treatment applications, 2349
- surfactants
biomaterials applications, 2340–2343
cationic materials, 2342–2343
future research issues, 2344
hydrophilicity/hydrophobicity, 2341–2342
intracellular/extracellular mechanisms, 2339–2340
natural materials, 2337–2338
overview, 2337
pH and LDH activity, 2341–2343
semipermeable membrane transport, 2343
- Cell sources, tissue engineering
fat tissue, 2727–2728
intestinal system, 2753–2754
vascular system, 3036–3039
- Cell structures
biofilm formation, detachment and dissolution mechanisms, 212–213
bioreactors and differentiation, 310–311
cell culture assays, proliferation mechanisms, 564
confocal microscopy analysis, 711
connective tissue healing and proliferation, 1251–1252
cryopreservation
cold shock injury, below-freezing water temperatures, 767
future research, 768
mechanisms, 767–768
osmotic and potential toxic effects on, 766–767
overview, 762–765
slow freezing, 765–766
storage period, 766
vitrification, 766
warming process, 766
ligaments, 2761
magnetic resonance imaging, 1726
magnetic resonance microscopy, 1744–1747
mass transfer and tissue function, 1751
mathematical modeling, cardiovascular system, 1898
mechano-transduction, 1789–1790
mimics of components, 294–298
peripheral nerve injury, 2118–2120
tissue engineering
bladder, cell transplants, 2637
fat tissue, 2726–2727
topographical surface analysis
chemistry vs., 2552
classification, 2551–2556
discontinuous substratum, 2555
fibers, 2553
microfabrication, 2552
nanotopography vs. microtopography, 2556
overview, 2551
pits/holes, 2553
repeating grooved substrata, 2553
roughened surfaces, 2555–2556
single steps, 2552–2553
substratum influences, 2556–2558
tunnels/tubes, 2555
in vivo applications, 2558–2560
xenografts, 3099–3100
- Cellular solids. *See* Foams, polymer foams
- Cellulosic dialysis membranes, 1583–1584
- Cemented implants, total hip arthroplasty, 1379–1380
- Cementless implants
bone-implant interface, 427–428
total hip arthroplasty, 1379–1380
total knee replacement, 1612
- Center-of-mass modeling, gait analysis, 1138
- Central difference interrogation (CDI), microparticle image velocimetry, 1875–1876
- Central nervous system (CNS). *See also* Peripheral nerves
disorders, controlled-release drug delivery systems, 888
electrical stimulation
basic principles, 1009–1012
brain tissue stimulation, 1017
electrochemistry, 1015–1017
membrane-electric field interaction, 1012–1015
overview, 1009
nanoscale neurosurgery and, 1903–1906
tissue engineering, gene-activated matrix regeneration, 1147–1148
- Centrifugal blood pumps
clinical applications, 581–583
components, 575–580
continuous flow ventricular assist device, 473–474
overview, 574–575
performance evaluation, 580–581
purging vs. nonpurging systems, 576–577
- Centrifugation techniques, bone cements, 409–410
- Ceramics. *See also* Bioactive materials; Glasses and glass ceramics
alumina, 17–18
biocomposites, resorbable vs. nonresorbable components, 183–184
biomimetics, 590–591
biphasic calcium phosphate
bioactive, osteoconductive, and osteoinductive properties, 364–365
biodegradation/biodissolution, 363–364
cell interactions, 362
crystal properties, 361
dissolution properties, 361
future research, 365
hydroxyapatite/tribasic composition, 360

 powder-based fabrication, 147
 processing, 585–586
 shape memory metal coatings, 2423
 sol-gel fabrication, 147–148
 tissue engineering
 bone, 2655
 glass-ceramics, 144–150
 total hip arthroplasty, 1472, 1474
 transparent ceramics
 alkaline phosphatase activity staining, 2918
 calcium staining, 2918
 cell culture, 2917–2918
 mineralized matrix, 2918
 osteogenic differentiation, 2919–2920
 surface characterization, 2917–2919
 tissue engineering applications, 2916–2923
 wear debris, 3058–3063
 zirconia ceramics
 composition and properties, 3104–3105
 dental applications, 3105–3106
 YTZP crowns, 3106–3108
- Ceramics process, glass dental ceramics, 598
- Ceratitis[®] biphasic ceramic, 464
- Cervical spine plates, anterior cervical spine plate, failure analysis, 1832–1834
- Chain-growth polymerization, poly(lactic acid), 2250–2251
- Chain polymerization, poly(lactide-co-glycolide) synthesis, 2260–2261
- Characterization techniques, multilayer assemblies, polyelectrolytes, 2221–2222
- Charge-coupled device (CCD)
 endoscopic techniques, 987–993
 optical mapping, 2020–2021
 small-angle light scattering, soft tissue analysis, 2452
 wireless capsule endoscopy, 992–993
- Charge-duration curve, electrical stimulation waveform, 1015
- Chemical fiber optic biosensors, 1068–1069
- Chemical fixation techniques
 allografts, 8–9
 microscale tissue engineering, 2782
- Chemical shift, nuclear magnetic resonance, 1962
- Chemical vapor deposition (CVD), pyrolytic carbon, 2371
- Chemiluminescence, biosensors and, 339–343
- Chemokines, immune response, major histocompatibility complex, 266–267
- Chemotaxis, electrical cell impedance sensing, 913
- Chemotherapy
 angiogenesis inhibitors *vs.*, 30–31
 controlled-release drug delivery systems, 887–888
- Children. *See also* Neonatology; Pediatric cardiology
 orthognathic surgery, bioabsorbable plates and screws, 436–437
 radiofrequency electromagnetic field/radiation effects in, 257–258
 ventricular assist devices, positive displacement pumps, 97–100
- Chiral separation, multilayer assemblies, polyelectrolytes, 2223
- Chitosans
 applications, 604
 azide chitosan lactose, 1192
 chitosan/glycerol phosphate gels, applications, 605
 drug delivery systems, 604–609
 first-generation bioadhesives, 152
 food technology, 613–614
 gene therapy, 607–611
 hydrogels, 1446–1447
 inherently conductive polymer composites, 699
 orthopedic devices, 2069
 overview, 604
 tissue engineering, 611–613, 2291
- Chloramphenicol acetyltransferase (CAT)
 expression, chitosan nanoparticles, 609–610
- Chondrocytes
 articular cartilage, 558–559
 tissue engineering
 composition, 2694–2695
 differentiated chondrocytes, 2701–2702
 function, 2696–2697

- Convection dialysis membranes, 1587–1588 mass transfer and tissue function, 1761 microcirculatory oxygen transport, 1844–1845
- Cooling rates, bioactive glass, 133–134
- Copolymers biodegradable compounds, 196–199 natural materials, 199–200 hemocompatibility, inert materials, 1346 hydrogels, 1445–1446 interpenetrating polymer networks, 1552–1554 orthopedic devices, 2064 piezoelectric materials, 2168–2169 poly(lactide-co-glycolide) basic properties, 2259 biocompatibility and tissue reactions, 2265–2267 biomedical applications, 2267 crystallinity, 2262 degradation, 2263–2265 future research issues, 2267 mechanical properties, 2262–2263 performance characteristics, 2261–2267 solubility, 2261–2262 synthesis, 2259–2261 thermal stability, 2262 polyurethane biomaterials, 2304 tissue engineering applications, 2293–2294
- Copper ions, as antimicrobial biomaterials, 66–67
- Coprecipitation, magnetic nanoparticles, 1706–1707
- Copy milling, dental ceramics, 601
- Copyright law, 1545–1546
- Corline[®] Heparin Surface (CHS), heparin biocompatibility, 1371
- Corneal implants. *See also* Keratoprostheses; Ocular implants alumina ceramics, 23 fibrin sealant applications, 1086 future research issues, 751 glossary of terms, 747–748 intracorneal implants, 1974–1975 keratoprosthesis, 750–751

- Corneal implants (*cont.*)
 overview, 747
 phosphorylcholine technology, 2145–2146
 refractive keratoplasty, 748–750
 tissue engineering
 cell sources, 2707–2710
 clinical applications, 2715–2716
 collagen gels, 2710–2711
 collagen sponges, 2711
 endothelial cells, 2710
 epithelial cells, 2708–2710
 experimental applications, 2715
 extracellular matrix expression, 2714
 fibrin gel cell cultures, 2710
 future challenges, 2714–2716
 integrin expression and wound healing, 2713–2714
 keratocytes, 2710
 reconstructive technology, 2707–2708
 self-assembly techniques, 2711–2712
 wound healing, 2712–2714
- Corneal reflection, eye movement research and, 1029–1031
- Corona discharge
 plasma biomaterials modification, 2175
 wettability gradient surfaces, 1213
- Coronary angiography, catheterization techniques, 492–493
- Coronary artery bypass graft (CABG)
 cardiac catheterization, 501–503
 tissue-engineered blood vessels, 2643–2644
- Coronary artery disease (CAD)
 stent implants, *in vivo* animal models, 1571
 two-dimensional strain imaging, 506–512
- Correction factor, cardiac output measurement, 520
- Correlation function, microparticle image velocimetry, 1881–1882
- Corrosion
 electrochemical reactions, 754–757
 electrolyte chemical analysis, 759–760
 endovascular stent-grafts, 2486–2487
 metal surface analysis, 758–759
 nickel alloys, 1943–1947
 overview, 754
 shape memory metal surfaces, 2421–2422
 total hip arthroplasty implants, 1479–1480
- Cortical bone, elasticity properties, 1237–1241
- Cortical remapping, tinnitus device design, 2617
- Cortical screws, fracture fixation, 415, 2075
- Corticosteroids, reservoir ocular implants, 1989–1990
- CORx™ artificial lung system, 1679–1680
- Counter-current distribution technology, cell separation, 1695
- Counterion polarization, biological materials, 836–837
- Covalent attachment, cell-adhesive polymers, 218–220
- Covalent chemistry, hemocompatibility assessment, 1352–1353
- Crack propagation
 orthopedic device failure analysis, 1832–1833
 pyrolytic carbon, 2377–2380
 zirconia ceramics, 3106–3108
- Craniofacial trauma fixation, reconstructive biomaterials, 2399–2400
- Cranio-maxillofacial (CMF) skeleton,
 orthognathic surgery, bioabsorbable plates and screws, 434–435
- Creep
 articular cartilage biomechanics, 87
 ligament and tendon viscoelasticity, 2596

Versamid[®], 2190–2191
- Polyamidoamine (PAMAM) dendrimer, drug delivery systems, 789–794
- Poly(amino acids)
polyamides, 2186–2187
tissue engineering applications, 2288
- Polyanhydrides
orthopedic devices, 2065
tissue engineering applications, 2287–2288
- Poly(β -malic acid) (PMA), biodegradable compounds, 200
- Polycaprolactone (PCL)
biocomposites, 183
biodegradable polymers, 196–199
bone/cartilage interface, 2203
bone grafts, 2203
cartilage repair, 2202–2203
composite materials, 2200–2201
degradation, 2198–2200
drug delivery systems, 2201–2202
elastomers, 897–900
gene therapy, 2204
heart tissue, 2203–2204
liver repair, 2203
nerve grafts, 2202
orthopedic devices, 2064–2065
skin grafts, 2202
synthesis and structure, 2197–2198
tissue engineering, 2202
tissue engineering applications, 2287
- Polycarbonates, structure/property relationships, 2278–2279
- Poly(carbonate)urethanes
basic properties, 2208–2209
biocompatibility testing, 2211–2212
biodegradability testing, 2209–2211
melt processing, 2212–2213
regulatory status, 2213–2214
- Polycarboxylate adhesives, basic properties, 2
- Polycations, multilayer assemblies, polyelectrolytes, 2219–2221
- Polycondensation, poly(lactide-co-glycolide), 2259–2261
- Poly(dimethylsiloxane) (PDMS)
bio-artificial liver systems, 1654–1655
hydrogel contact lenses, 716–727
silicone structure, 2427
tissue engineering, microvascular networks, 2796
- Polydioxanones
biodegradability, 197–198
orthopedic devices, 2065
- Polyelectrolytes, multilayer assemblies
biomolecules, cell adhesion/encapsulation, 2223–2226
characterization, 2221–2222
deposition techniques, 2219–2221
formation mechanisms, 2218–2219
light emitting diodes, 2222–2223
materials, 2219
microfluidics flow control, 2226
overview, 2217
separations, 2223
structural properties, 2217–2218
- Polyepoxy compounds
antiadhesive membranes, 2237–2238
blood vessel prostheses, 2236
collagen tissue fixation, 645
cross-linking mechanisms
artificial organs, 2231
biomaterials, 2231–2232
collagen molecules, 2232
glutaraldehyde vs., 2232–2235
growable vascular prosthesis, 2236–2237
heart valve applications, 2235–2236
hemostat applications, 2237
- Poly(ester amide)s (PEAs), biodegradable compounds, 200–201
- Polyesters
biodegradable elastomers, 897–901
biodegradation mechanisms, 900–901
cross-linked synthesis, 898
linear synthesis, 898–899
mechanical properties, 900
endovascular stent grafts, 2483
natural origins, tissue engineering applications, 2292–2293
structure/property relationships, 2278–2279
- Poly(ethylene glycol) monomethacrylate (PEGMA), self-regulated insulin delivery, 1168–1170
- Polyethylene glycol (PEG)
adsorption resistance of, 278
bioadhesive properties, 4–5
cell-adhesive properties, 219–220
chitosan, tissue engineering, 611–613
dendrimer-base drug delivery, unimolecular dendritic micelles, 790–793
glue materials, 1191
diacrylate, 1192
hemocompatibility, 1346
NHS-PEG compounds, 1191
protein-based drug delivery systems, hydrogels, 2363–2364
self-regulated insulin delivery, glucose hydrogels, 1165–1170
tissue engineering applications, 2289
- Polyethyleneimine (PEI)
gradient surface preparation, 1215
heparin biocompatibility, Carmedia Bioactive Surface (CBAS), 1371
nitric oxides, 222
- Poly(ethylene oxide) (PEO)
biodegradability, 199
gradient surfaces, 1215
tissue engineering applications, 2289
- Polyethylene (PE). *See also* Ultra-high molecular weight polyethylene (UHMWPE)
cardiac catheters, 496
structure/property relationships, 2276–2278
wear debris, prosthetic devices, 3058–3063
- Poly(ethylene terephthalate) (PET)
structure/property relationships, 2278–2279
vascular grafts, 2987–2988
- Polyfumarates, tissue engineering applications, 2288

- Poly(glycerol sebacate) (PGS)
 applications, 333
 biocompatibility, 331–333
 characterization, 328–329
 degradation, 329–331
 design criteria, 327–328
 overview, 327
 synthesis, 328
- Poly(glycolic acid)/poly(glycolide) (PGA)
 applications, 2244–2245
 articular cartilage repair, 556
 basic properties, 2241
 biocomposites, 183
 biodegradable polymers, 196–199, 779–780
 elastomers, 897–900
 nonporous polymer-ceramic composites, 784–785
 characterization, 2242
 degradation, 2242–2244
 orthopedic devices, 2064
 regulatory issues, 2245–2246
 structure/property relationships, 2278–2279
 synthesis, 2241–2242
 tissue engineering
 clinical applications, 2285–2287
 small intestine scaffold materials, 2865–2866
 vascular grafts, development strategies, 2999
 in vivo tissue response, 2246–2247
- Polyhydroxyalkanoates (PHAs)
 elastomers, biodegradability, 899
 tissue engineering applications, 2292–2293
- Poly(hydroxybutyrate) (PHB), tissue engineering applications, 2292–2293
- Poly(lactic acid)/poly(lactide) (PLA)
 articular cartilage repair, 556
 biocomposites, 183
 biodegradable compounds, 779–780
 elastomers, 897–900
 nonporous polymer-ceramics, 784–785
 biomedical applications, 2254–2255
 characterization, 2252
 degradation, 2252–2253
 in vivo characteristics, 2253–2254
 foreign body response, 1115–1116
 formation mechanisms, 2250–2251
 orthopedic devices, 2064
 overview, 2249
 synthesis, 2249–2250
 tissue engineering, applications, 2285–2287
- Polylactideglycolic acid (PLAGA), fabric scaffolds, 1056–1059
- Poly(lactic/lactide-co-glycolide/glycolic acid) (PLGA)
 basic properties, 2259
 biocompatibility and tissue reactions, 2265–2267
 biocomposites, 183
 fabrication techniques, 186–189
 biomedical applications, 2267
 crystallinity, 2262
 degradation, 2263–2265
 future research issues, 2267
 mechanical properties, 2262–2263
 performance characteristics, 2261–2267
 reconstructive biomaterials, 2396–2397
 solubility, 2261–2262
 structure/property relationships, 2278–2279
 synthesis, 2259–2261
 thermal stability, 2262
 tissue engineering, small intestine scaffold materials, 2866
- Poly(L/DL) lactide (PLDLA), bioabsorbable plates and screws, 433–437
- Poly(L-glutamic acid) (PLGA), gelatin-based glues, 1190–1191
- Poly(L-lactic acid/poly-L-lactide) (PLLA)
 bioabsorbable plates and screws, 433–437
 biodegradability, 198–199
 free radical reactions, 203–204
 tissue engineering, small intestine scaffold materials, 2866
- Poly(L-lactide-co-D,L-lactide) (PDLLA)
 biodegradability, free radical reactions, 203–204
 facial skeletal fixation, 2996–2997
- Polymer foams
 bioactive scaffold fabrication, 149–150
 burn dressings, 458–459
 microporous materials, 1887
- Polymerization, inherently conductive polymers, 697–699
- Polymers. *See also* Elastomers;
 Photopolymerization; specific polymer compounds
 antimicrobial/antibiotic materials, 61–62
 articular cartilage repair
 natural materials, 555–556
 synthetic polymers, 557
 artificial liver systems, 1654–1655
 artificial lung systems
 extracorporeal membrane oxygenation, 1669–1670
 membrane permeance, 1663–1665
 artificial pancreas, 2803–2805
 bioadhesive properties, 4–5, 154
 formulation factors, 156–157
 biodegradable polymers
 basic properties, 195–196
 degradation properties, 201–204
 free radicals, 203–204
 glycolide, lactide, and caprolactone-based compounds, 196–199
 linear aliphatic polymers, 196
 natural materials, 199–200
 poly(ester amide)s, 200–201
 bifunctional applications, 218
 ECM-mimetic materials, 218–221
 pharmacologically active materials, 220–222
 biomimetic materials, 295–296
 biorubbers, 327–333
 blood-material interactions, 374–376
 bone cement, 404–406
 bone matrices, 2047
 osteoclasts and regeneration, 2096
 cardiac catheters, 494–498
 cardiac pacing leads, 535
 cell-material interactions, 568–572
 coatings, 2531–2532
 collagen
 polyepoxy compounds, 645
 scaffold fixation strategies, 643–644
 composites
 degradable compounds, 779–785
 clinical applications and limitations, 782–783
 nonporous polymer-ceramics, 784–785
 scaffold materials, 784
 resorbable vs. nonresorbable components, 182–184
 controlled-release drug delivery systems, 741–742
 fabrication and encapsulation technologies, 881–883
 films and rods, 882
 formulations, 881

 Proton-electron double-resonance imaging (PEDRI), magnetic resonance imaging, 1720

- Proton magnetic resonance spectroscopy
brain imaging, 1969–1970
proton density, 1716–1718
- Proton resonance frequency shift (PRFS)
clinical applications, 1733–1734
temperature measurement, 1731–1733
- Prototype development, biocomposite
fabrication, 190–192
- Pseudo-diffusion coefficient, magnetic
resonance imaging, 1719
- Pseudoelasticity
blood vessel mechanics, 396
nickel-titanium alloys, 1945–1947
- Pseudophakia, defined, 748
- Psoas syndrome, overuse injuries, 1395–1396
- Public/private cooperation, intellectual
property rights, 1546
- Pull-out measurement, dental implants,
815–816
- Pulmonary circulation, vascular fluid
dynamics, 2982–2983
- Pulmonary function
cardiac output measurement, Fick method,
517–518
oxygen transport, 1843–1844
toxicity testing, animal surrogate systems,
54
- Pulmonary vasodilation, nitric oxide,
1952–1953
- Pulsatile flow properties
circulatory support systems, 1781–1782
macrocirculatory hemodynamics,
1361–1364
transmyocardial laser revascularization,
1635–1636
ventricular assist devices, 472–474
- Pulsed electric field, sterilization of medical
devices, 2507–2508
- Pulsed Fourier transform spectroscopy,
nuclear magnetic resonance, 1963–1964
- Pulsed laser radiation/ablation
diamond/diamond-like carbons, 824
laser-tissue interactions, 1626–1628
- Pulsed wave (PW) Doppler ultrasound, basic
principles, 2944
- Pulse generators, cardiac pacemakers,
535–536
- Pulse modulation, radiofrequency
electromagnetic field/radiation effects,
255
- Pulse sequence, magnetic resonance imaging,
1716
- Pumping systems
artificial heart fluid dynamics, 95–105
circulatory support systems, 1776
controlled release drug delivery, 739–741
HeartMate implantable pump, 1777–1778
insulin delivery, 1518, 2366
- Pure tone average (PTA), hearing loss and,
1265
- Purification requirements, blood composition
and structure
hemodialysis, 378–384
hemofiltration, 384
overview, 378
plasmapheresis, 384–391
- Purity requirements, silicones, 2435–2438
distillation/stripping, 2437
filtration, 2437
in-process purification, 2437
packaging materials, 2437–2438
processing environment, 2436–2437
raw material purity control, 2436
- Purkinje image eye tracker, eye movement
research, 1030–1031
- Push-out test, dental implants, 815–816
- Pushrim-activated power assist wheelchairs
(PAWPAW), 3089–3090
- P wave, electrocardiography, 938
- Pyrolysis, magnetic nanoparticles, 1708
- Pyrolytic carbon (PyC)
biocompatibility, 2375
design criteria, 2375–2381
development and applications,
2371–2374
examples of, 2379–2380
fatigue testing, 2377
fracture mechanics, 2377
future research issues, 2379
long-term implants, 2376
mechanical heart valves
durability, 1329–1330
fatigue analysis, 1330–1331
microcrack propagation/non-propagation,
2377–2378
orthopedic applications, 2374–2375
overview and history, 2370
physical and mechanical properties,
2375–2376
structural analysis, 2378–2379
- Pyrrrole-imidazole polyamides, 2191–2192
- ## Q
- QRS waves
biomedical signal acquisition and
processing, 851–852
cardiac pacemakers, 536–538
electrocardiography, 533, 938–939
- Quadratic time-frequency representations,
digital biomedical signal acquisition
and processing, 858–861
- Quantification
electromyography data, 964–965
functional magnetic resonance imaging,
1126
positron emission tomography, 2318
- Quantitative functional magnetic resonance
imaging, 1126
- Quantitative structure-activity relationships
(QSARs), toxicity testing, animal
surrogate systems, 51–52
- Quantization techniques, digital signal
acquisition and processing, 845
- Quantum mechanics, protein adsorption
modeling, 2330
- Quantum theory, biomedical optics, 2030
- Quasilinear viscoelastic theory (QLV),
ligament and tendon viscoelasticity,
2596–2597
- Quasistatic formulation, electrical
stimulation, 1010
- Quenching, melt spinning, polymer fibers,
1817–1818
- Quick response hydrogel, soft contact lenses,
1443
- Quorum sensing, biofilm formation, 209–211
- ## R
- Race and ethnicity, stress fractures and,
2512
- Radial sector scanning, endoscopic
techniques, 991
- Radiant exposure, light-tissue interactions,
1625
- Radiation
biomedical optics, 2030
sterilization of medical devices, 2505–2506
surface modification methods, 2540–2543
ion beam techniques, 2540–2541
laser, ultraviolet, and gamma radiation,
2541–2543
ultrasound systems, 2935
- Radiative transfer optical techniques, cancer
diagnosis and therapy, 2009–2010
- Radiative transport equation, light
propagation in tissue, 2033
- Radioactive coatings
diamond/diamond-like carbons, 829
stents, 2496–2497
- Radiofrequency electromagnetic field/
radiation (RFR)
basic properties, 254
exposure frequency and duration, 256
frequency, intensity and energy absorption
patterns, 254–255
future research issues, 258
research issues, 257–258
thermal/nonthermal effects, 256–257
- Radiofrequency plasma-activated chemical
vapor deposition, diamond/diamond-
like carbons, 826
- Radiofrequency plasma discharge, gradient
surfaces, 1212–1213
- Radiofrequency (RF) signals
implantable cardioverter-defibrillators,
776
magnetic resonance imaging, 1715
plasma discharge techniques, 2174–2175
speech processors, cochlear implants,
1509–1510
- Radiography, stress fracture diagnosis, 2514
- Radiopacity, coating materials, 2532
- Raman spectroscopy
biomedical optics, 2035
optical detection of cancer, 2015
- Raoult's law, cryopreservation of cells,
764–765
- Rapid acquisition with relaxation
enhancement (RARE), magnetic
resonance imaging, 1717
- Rapid expansion of supercritical solutions
(RESS), 2523
- Rapid prototyping (RP)
basic principles, 2382–2383
bioactive material fabrication, 148–149
fused deposition modeling, 2387–2388
future research issues, 2388–2389
microporous materials, 1887
selective laser sintering, 2384–2386
stereolithography, 2383–2388
three-dimensional printing, 2386–2387
tissue engineering scaffolds, 2833–2834
- Rapid-scanning all-reflective phase delay
(RSAD), optical coherence
tomography, 2000–2001
- Rapid-scanning optical phase delay (RSOD),
optical coherence tomography,
2000–2001
- Ras homology protein (RHO), integrin
postadhesion, 1529–1530
- Ras-related c3 botulinum toxin substrate
(RAC), integrin postadhesion,
1529–1530
- Rate-controlling membranes, transdermal
drug delivery, 2896
- Rayleigh's rectangular array, composite
micromechanics, 666–667
- Reaching tasks
mechanics of, 731–732
neuroprostheses, 1927–1928
- Reaction kinetics, mass transfer and tissue
function, diffusion, 1760–1761
- Reading, eye movements during, 1034–1035
- Real-time telemedicine systems, components
of, 2580–2581
- Real-time tomographic reflection (RTTR)
augmented reality and head-mounted
displays, 2391
calibration
affine transform, 2393
geometric transform, 2392–2393
current and future applications, 2393–2394
image overlay, 2391–2392
overview, 2391
techniques and procedures, 2392–2393

- Reaming techniques, total hip arthroplasty, 1377–1379
- “Receding horizon” strategy, insulin delivery, 1521
- Receiver-stimulator systems, cochlear implants, 1510–1511
- Receptor activator of NF- κ B ligand (RANKL)/receptor activator of NF- κ B (RANK)
- osteoclasts
 - basic properties, 2081
 - bone remodeling, 2088
 - differentiation and activation signaling, 2084–2085
 - wear debris, osteoclasts and, 3068–3069
- Receptor for HA-Mediated Mobility (RHAMM), structure and properties, 1422
- Receptor function
- integrins, 1526–1527
 - positron emission tomography imaging, 2320
- Recombinant DNA technology, biocatalysis and, 162
- Recombinant proteins, artificial silk design and synthesis, 2446–2447
- Recommended weight limit (RWL), ergonomics guidelines, 1002–1003
- Reconstructive biomaterials

Biomedical Engineering

"...The volumes are well organized and each section consistently present[s] **the most important concepts of each topic...**
A very good first reference for researchers and students."

—*Pharmaceutical Research*

"...The encyclopedia is up-to-date and covers topics in depth...**Recommended.**"

—*Choice*

"...This work will be **of considerable value** to scientists, clinicians, and others needing a conceptual framework, data, and suggested approaches to research problems and product development."

—*Dr. Frederick J. Schoen, Professor and Executive Vice Chairman, Department of Pathology, Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts, USA*

"...Comprehensive coverage of the field...Authors include **world-renowned clinicians, engineers and biomedical scientists from all relevant disciplines...**"

—*Dr. Harvey S. Borovetz, Professor and Chair, Department of Bioengineering, University of Pittsburgh, Pennsylvania, USA*

about the book...

Written by more than 400 subject experts representing diverse academic and applied domains, this multidisciplinary resource surveys the vanguard of biomaterials and biomedical engineering technologies utilizing biomaterials that lead to quality-of-life improvements. Building on traditional engineering principles, it serves to bridge advances in materials science, life sciences, nanotechnology, and cell biology to innovations in solving medical problems with applications in tissue engineering, prosthetics, drug delivery, biosensors, and medical devices.

In nearly 300 entries, this four-volume ***Encyclopedia of Biomaterials and Biomedical Engineering, Second Edition***, covers:

- essential topics integral to tissue engineering research: bioreactors, scaffolding materials and fabrication, tissue mechanics, cellular interaction, and development of major tissues and organs being attempted by researchers worldwide
- artificial lungs and muscles, bio-artificial livers, and corneal, dental, inner ear, and total hip implants
- tissue engineering of blood vessels, heart valves, ligaments, microvascular networks, skeletal muscle, and skin
- bone remodeling, bone cement, and bioabsorbable bone plates and screws
- controlled drug delivery, insulin delivery, and transdermal and ocular implant-based drug delivery
- endovascular stent grafts, vascular grafts, and xenografts
- 3-D medical imaging, electrical impedance imaging, and intravascular ultrasound
- biomedical, protein adsorption, and *in vivo* cardiovascular modeling
- polymer foams, biofunctional and conductive polymers, and electroactive polymeric materials
- blood–material interactions, the bone–implant interface, host reactions, and foreign body responses
- and much more

about the editors...

GARY E. WNEK is the Joseph F. Toot, Jr. Professor of Engineering, Professor and Chair of the Department of Macromolecular Science and Engineering, and Faculty Director of The Institute for Management and Engineering, Case Western Reserve University, Cleveland, Ohio. He is the author or coauthor of over 130 journal articles and 19 patents, and the coeditor of four books, including the *Handbook of Pharmaceutical Controlled Release Technology*, *Photonic Polymer Systems*, and *Electrical and Optical Polymer Systems* (Informa Press). His research interests include the development of polymeric materials for applications in medicine, microfluidics, and energy conversion and storage. A member of the American Chemical Society, the Materials Research Society, and the American Institute of Chemical Engineers, Dr. Wnek received the B.S. degree in chemical engineering from Worcester Polytechnic Institute, Massachusetts, and the Ph.D. degree in polymer science and engineering from the University of Massachusetts, Amherst.

GARY L. BOWLIN is an Associate Professor and the Louis and Ruth Harris Exceptional Scholar Professorship of Biomedical Engineering at Virginia Commonwealth University, Richmond, Virginia. He has extensive experience in cardiovascular materials and the field of tissue engineering. As a researcher, he has authored or coauthored over 50 journal articles in the areas of vascular tissue engineering and biopolymer processing for tissue engineering scaffolds. He also holds five U.S. patents and is a Co-Founding inventor of NanoMatrix, Inc., based on electrospinning tissue engineering scaffold technology and TraumaCure, Inc., regarding the development of hemostatic products. Dr. Bowlin is a member of the Biomedical Engineering Society, American Institute of Chemical Engineers, Society for Biomaterials, Tissue Engineering and Regenerative Medicine International Society, and the International Society of Applied Cardiovascular Biology. Dr. Bowlin received the B.S. in chemical engineering from Youngstown State University, Ohio, the M.S. in chemical engineering from the University of New Hampshire, Durham, and the Ph.D. degree in biomedical engineering from The University of Akron, Ohio.
