where, $\alpha^2 = R^2 \omega \rho / \mu$. α is an important nondimensional parameter in pulsatile flow and is now known as the

Womersley parameter. Similar to the Re , it represents the ratio of transient inertial forces to viscous forces and is also referred to as the unsteady Re or unsteadiness parameter. For small values of α , the inertial forces are negligible and the viscous forces predominate. As α increases, the inertial forces are dominant, which implies that most of the fluid can be regarded as inviscid, and the velocity profile across the tube will be blunt except for the regions near the wall, which will have a steep velocity gradient. Some values of α in the circulation are: 21 in the ascending aorta, 12 in the abdominal aorta, 4 in the femoral artery, 17 in the inferior vena cava, and 20 in the main pulmonary artery^[1] under resting conditions. It may be mentioned in passing that in fluid dynamics experiments, scaled models are frequently employed, because they are either easier to work with or allow measurements with higher resolution. The correspondence of the flow in these scaled models is validated by matching up the nondimensional parameters (called dynamic similarity). For pulsatile flow studies of blood flow, both the Re and Womersley number, as well as the shape of the pulsatile waveform, must be matched.

Given boundary conditions from axisymmetry and no-slip at the wall, Eq. (13) can be solved for the axial velocity component.

$$v_z = \frac{PR^2}{i\mu\alpha^2} \left\{ 1 - \frac{J_0(i^{3/2}\alpha\hat{r})}{J_0(i^{3/2}\alpha)} \right\} \quad (14)$$

The instantaneous flow rate Q at any given cross section can then be obtained by integrating this expression

$$Q = 2\pi R^2 \int_0^1 w\hat{r}d\hat{r} \\ = \frac{\pi R^2 P}{i\omega\rho} \left\{ 1 - \frac{2J_1(i^{3/2}\alpha)}{i^{3/2}\alpha J_0(i^{3/2}\alpha)} \right\} e^{i\omega t} \quad (15)$$

where, J_0 and J_1 are Bessel functions of order zero and one, respectively. Bessel functions are standard solutions to certain forms of differential equations [such as Eq. (13)] that define many problems involving cylindrical or spherical coordinates such as heat conduction in a cylindrical object or modes of vibration of a thin circular membrane.

The advantage of assuming a sinusoidal pressure gradient during the derivation is that any pressure gradient curve can be expressed as a summation of sinusoidal components (Fourier series expansion). Then, velocity profiles and instantaneous flow rates can be obtained for each term in the Fourier series expansion (harmonics) from Eq. (14) [Eq. (15) for flow], and these can be added up to give the complete axial velocity profile across the tube, or the

instantaneous flow rate at any cross section. Fig. 3A compares the instantaneous flow rate calculated using this model to that measured in a canine femoral artery, by following the motion of a gas bubble in the artery

Fig. 3 Flow and velocity computations from mathematical models of pulsatile flow. (A) Measured flow rates in a canine femoral artery compared to the values calculated from Womersley's initial model. The bottom graph is the pressure gradient curve derived from measurements of pressure. (B) Axial velocity profiles in a canine descending aorta computed by nonlinear theory from measurements of pressure difference signals. The radial distance (r) was normalized by the inside radius [$R(\tau)$], where τ was the normalized time (t/T). T represents the time period of flow and w_m was the maximum centerline velocity measured with hot-film anemometry. The axial velocity w was normalized by w_m . Backflow can be noticed at $\tau = 0.37$ and 0.57 . [Pane (A) from Ref. [2]. Pane (B) from Ling, S.C.; Atabek, H.B.; Letzing, W.G.; Patel, D.J. Nonlinear analysis of aortic flow in living dogs. *Circ. Res.* 1973, 33 (2), 198–212.]

by means of high-speed cinematography. The pressure gradient that was used in the solution was calculated from measurements of pressure.^[2] As can be noted, the two graphs are in good agreement.

If the walls were assumed to be distensible, i.e., if elastic or viscoelastic wall material is assumed, then the governing equations of motion for the wall must be developed, and they must be solved in concert with the equations of fluid motion. Such models allow the analysis of pulse waves, which will be discussed in the next section. Theories where the nonlinear components of the Navier–Stokes equations are included in the problem definition have also been developed,^[4] although oscillatory flow components calculated from such models have been found to differ only slightly from linear models.^[1] The linear models, however, overestimate the steady flow term.^[1] Axial velocity profiles calculated by a nonlinear model based on measurements of pressure gradient (pressure difference over a finite length) in a canine descending aorta are shown in Fig. 3B.

Arterial Pulse Waves

The ventricle ejects approximately 85 ml of blood during each systole^[1] into the proximal aorta, which distends that portion of the vessel. During diastole, the elastic recoil of the aorta pushes the blood into the next distal section, which in turns distends and recoils, and thus a pressure wave travels down the arterial tree. The observation by Hales that this process is similar to a compression chamber (“Windkessel” in German), and the subsequent mathematical expression of this observation led to the development of the Windkessel theory.^[1] This theory considers the arterial tree as an elastic storage chamber into which ventricular outflow enters, and the outflow of this chamber faces a resistance and pressure gradient derived from Poiseuille flow. Equating the net rate of flow into the chamber with the rate of storage, an expression of pressure within the chamber and the ventricular stroke volume can be calculated. Although the Windkessel theory is useful for calculations of stroke volume, its validity in determining pressure pulse curves is generally not accepted today, primarily because the theory assumes instantaneous transmission of the pulse. In reality, the pressure pulse travels with a finite speed through the arterial wall, with the speed of transmission being dependent on the vessel wall properties and the interaction between the vessel wall and the flow of blood within.^[3]

Pulse wave propagation in a conduit carrying inviscid fluid was investigated by Thomas Young in about 1808, and was given relevant mathematical expression by Moens and Korteweg in 1878. The

expression for the velocity of propagation (also called wave velocity) in a long, thin-walled, elastic tube in which an incompressible, inviscid fluid is flowing is now called the Moens–Korteweg relationship.

$$c_0 = \sqrt{\frac{hE}{2R\rho}} \quad (16)$$

where, c_0 is the wave velocity, ρ is fluid density, R is the tube radius, h is the thickness of the wall ($h \ll R$), and E is the incremental circumferential elastic modulus.

Womersley^[7] derived a complex expression for the wave velocity, considering the effect of fluid viscosity in a freely moving elastic tube.

$$\frac{c}{c_0} = \sqrt{2(1 - \Phi)} \left[1 + k/2 - \Phi(k/2 + \sigma - 1/4) \right. \\ \left. \pm \sqrt{\left\{ 1 + k/2 - \Phi(k/2 + \sigma - 1/4) \right\}^2 + (1 - \sigma^2)(\Phi^2 - (1 - 2k)\Phi - 2k)} \right]^{-1/2} \quad (17)$$

where, $\Phi = \frac{2J_1(\alpha i^{3/2})}{\alpha i^{3/2} J_0(\alpha i^{3/2})}$, and $k = \frac{h\rho}{R\rho_0}$.

Here, c_0 is the wave velocity for inviscid flow [Eq. (16)], h is the wall thickness, R is the vessel radius, ρ is the density of the wall material, ρ_0 is the fluid density, and α is the Womersley parameter. The complex wave velocity c describes both speed of propagation (pulse velocity) and attenuation.^[1] The estimates for pressure wave velocity in the human vasculature are 5 m/sec in the ascending aorta, 8 m/sec in the femoral artery, 12 m/sec in the popliteal artery, and 7.5 m/sec in the carotid.^[1] Pulse waves are attenuated as they travel down a vessel wall and Womersley described this attenuation as

$$e^{2\pi(z/\lambda)(\text{imag}(c_0/c)/\text{real}(c_0/c))} \quad (18)$$

where, $\lambda = 2\pi c/\omega$ is the wave length. The attenuation in terms of the transmission per wavelength is therefore

$$e^{2\pi(\text{imag}(c_0/c)/\text{real}(c_0/c))} \quad (19)$$

A wave is thus attenuated by this amount, after traveling a distance of one wavelength.

Expressions for resistance and impedance of the vascular system can be written by electrical analogy. For steady flow,

$$\Omega = \frac{\Delta P}{Q} \quad (20)$$

where, Ω is the vascular resistance, ΔP is the mean pressure gradient, and Q is the mean flow. The vascular

resistance provides a measure of the extent by which the system resists flowing under the applied pressure gradient.^[1] By similar reasoning, for pulsatile flow,^[8]

$$Z_n = \frac{\bar{P}_n}{\bar{Q}_n} = \frac{|P_n|e^{i(\omega_n t + \phi_n)}}{|Q_n|e^{i(\omega_n t + \varphi_n)}} \quad (21)$$

where, Z_n represents vascular impedance that is dependent on frequency, and the subscript n refers to the n th harmonic of the corresponding waveform. The n th harmonic of the vascular impedance is then

$$Z_n = |Z_n|e^{i\theta_n} \quad (22)$$

where, the magnitude of the impedance $|Z_n| = \frac{|P_n|}{|Q_n|}$, and the phase lag $\theta_n = \phi_n - \varphi_n$

Three kinds of vascular impedance are relevant in physiologic flow: a) characteristic impedance is the ratio of oscillatory pressure to oscillatory flow, when there are no reflected waves present in the vessel segment being considered; b) longitudinal impedance is the ratio of oscillatory pressure gradient to oscillatory flow; and c) input impedance of a region of the circulation is represented by the ratio of one harmonic of the pressure at the input to the region divided by the corresponding harmonic of flow [Eq. (21)]. The input impedance of the femoral artery, for example, is the impedance of the entire vasculature supplied by it. The characteristic impedance of the human aorta is of the order of 50 dyn sec/cm⁵, and that of the femoral artery is 7000 dyn sec/cm⁵.^[1]

If pressure waves at various distances along the arterial tree are measured, it is found that the amplitude of the pressure wave actually increases down the arterial length (Fig. 4). This is owing to wave reflections that occur at branching points, or essentially, at any point on a vessel where there is a change in the impedance. It can also be noted from the figure that the amplitude of the flow velocity pulse decays, eventually terminating in steady flow in the finer vessels.

If the vascular network has the same impedance at each point (impedance matching), then there will be no wave reflections, and the wave energy will be transmitted efficiently.^[9] If we consider a wave traveling down an artery that ends in a bifurcation, a part of this wave will be reflected back upon reaching the bifurcation point. The other part of this wave energy will be transmitted into the two daughter branches. If the parent tube has a characteristic impedance of Z_0 , and the daughter branches have impedances Z_1 and Z_2 , then perfect impedance matching requires

$$\frac{1}{Z_0} = \frac{1}{Z_1} + \frac{1}{Z_2} \quad (23)$$

As was mentioned earlier, perfect impedance matching is not achieved in the circulation and wave

Fig. 4 A series of pressure and flow velocity pulse waves recorded along the arterial tree. The change in shape that occurs can be noted. The oscillatory pressure starts to decrease after the saphenous artery, which is represented by the dotted lines. The corresponding dotted lines in the flow pulses represent the continued decrease to steady flow in the microcirculation. (From Ref. [2].)

reflections occur. The reflection coefficient is given as

$$\mathfrak{R} = \frac{Z_0^{-1} - (Z_1^{-1} + Z_2^{-1})}{Z_0^{-1} + (Z_1^{-1} + Z_2^{-1})} \quad (24)$$

The pressure (or flow) wave recorded at any point in the network can be regarded as the sum of a forward traveling (antegrade) wave and a backward traveling (retrograde) wave. It is possible to mathematically extract the antegrade and retrograde components from such measurements.^[8] It should be noted that although the mode of wave propagation that is usually considered (axially traveling waves of radial distension) is the most physiologically relevant, other modes do exist. These include: a) longitudinal mode, where the vessel wall compresses and elongates in the longitudinal direction as the wave propagates; b) torsional mode, involving twisting motions of the vessel wall; and c) flexural mode, where the wave propagates by lateral displacements of the tube.^[1]

Venous Hemodynamics

The reason that the veins are considered storage reservoirs and capacitance vessels can be appreciated from Table 1 as they contain approximately 70% of the systemic blood volume. During blood loss, it is

H

venous blood volume and not arterial blood volume that decreases to maintain adequate arterial perfusion pressure.^[8] The pressure in a vein is considerably lower than the pressure in an artery at the same location, and venous pressures rarely exceed approximately 15 mmHg. In general, the flow through a vessel is considered a unique function of the pressure gradient across the tube. The pressure outside the vessels in our body is approximately atmospheric, except possibly for the vessels in the chest. The difference between the inner pressure and outer pressure is approximately 3 mmHg at the exit of the vena cavae.^[5] If we then consider veins above the heart, or the veins in an arm raised up, this pressure difference may become negative, thus collapsing the vein. This situation does not arise in arteries, because the arterial system is highly pressurized and the pressure difference stays positive, keeping arteries patent. It thus becomes important to consider transmural pressures (difference between the internal and external pressures) when considering pressure–flow relationships in veins. The collapse of venous walls is studied by observing pressure–radius relationships, as shown in Fig. 5A. This relationship in the excised segment of canine vena cava shows that collapse can occur to extremely small cross-sectional areas under negative transmural pressure, thereby dramatically affecting the flow. Two other factors effectively reduce the transmural pressure in veins: the “skeletal muscle pump,” where voluntary contraction of skeletal muscles outside the veins can push blood toward the heart, and the presence of valves in the mid-sized veins that serve to prevent backflow and bear the weight of columns of venous blood.^[1,6]

The Starling resistor (Fig. 5B) is possibly the most popular experimental device to study flow through collapsible tubes. It consists of a segment of collapsible tube whose ends are connected to rigid tubes. The segment itself is contained within a chamber whose pressure (p_e) can be varied. The chamber pressure represents the external pressure, and with this device, the variations in flow through the collapsible tube because of alterations in pressure-differences (e.g., $p_1 - p_2$ or $p_1 - p_e$) can be studied. One interesting outcome of such experiments is that for certain pressure differences, when $p_1 > p_e > p_2$, the flow through the tube might be completely independent of the outlet pressure p_2 , varying only with $p_1 - p_e$. This is called the Starling resistor phenomenon, sluicing, flow limitation, or waterfall effect. This effect has been reported in venous blood flow from extrathoracic to intrathoracic veins in dogs.^[4]

Pressure and flow pulses have also been studied in veins. The pressure in the right atrium of man is about 2 mmHg and the amplitude of pressure fluctuations is about 5 mmHg, whereas the pressure in the venules is about 18 mmHg with the amplitude of fluctuations being around 0.3 mmHg.^[6] The velocity waves in

Fig. 5 (A) Transmural pressure (p_{tm}) as a function of area (A) normalized by the area at zero transmural pressure (A_0) of an excised segment of canine abdominal vena cava. The curve for a latex tube is also shown for comparison. (B) Sketch of a Starling resistor. R , p , and Q represent resistance, pressure, and flow, respectively. [Pane (A) from Moreno, A.H.; Katz, A.I.; Gold, L.D.; Reddy, R.V. *Mechanics of distension of dog veins and other very thin-walled tubular structures*. *Circ. Res.* **1970**, 27 (6), 1069–1080. Pane (B) from Ref. [5].]

human vena cava show two main oscillations that are out of phase with the pressure oscillations in the right atrium.^[6] In an experiment conducted by applying pressure waves to venous segments to study their propagation, it was found that the wave speed at any given transmural pressure was independent of the frequency of oscillation, implying that venous wave propagation is essentially nondispersive. The attenuation per wavelength was estimated to be in the range of about 65–90%.^[6]

PATHOLOGY

Abdominal aortic aneurysms are abnormal dilations of the abdominal aorta that carry a serious risk of rupture. Discrete parts of the arterial tree are predisposed to gathering atherosclerotic fatty deposits, thereby constricting these vessels. Blood flow through such sudden dilations or constrictions can be understood by a simple model of steady flow of an inviscid, incompressible fluid, called Bernoulli's theorem. This is

based on the principle of conservation of energy. The total energy per unit volume at any point may be given as the sum of the pressure energy, kinetic energy, and the gravitational energy. If we consider the cross section of the normal vessel wall as station 1, having mean velocity v_1 and area A_1 , and the cross section immediately after a sudden enlargement as station 2, having velocity v_2 and area A_2 , then the flow of blood (Q) must be the same at both these stations, according to the principle of conservation of mass. Therefore,

$$A_1 v_1 = Q = A_2 v_2 \quad (25)$$

As A_2 is larger than A_1 , it follows that v_2 is smaller than v_1 . Conservation of energy states that the total energies at these two stations must also be equal.

$$P_1 + 1/2\rho v_1^2 + \rho g h_1 = P_2 + 1/2\rho v_2^2 + \rho g h_2 \quad (26)$$

where, P represents the pressure and ρ , the density of the fluid; the second term represents the kinetic energy, and the third term is the hydrostatic energy. If both stations are at the same height, and as v_2 is less than v_1 , it follows that P_2 is greater than P_1 . In other words, the kinetic energy at station 1 is converted to pressure energy at station 2, and the flow velocity reduces. Owing to this pressure rise, the fluid decelerates, and being unable to follow the wall at the dilatation, the flow separates resulting in recirculating eddies. This recirculation region has biochemical implications as blood is essentially a suspension of formed elements in plasma, and the blood particles keep circulating in one place for a longer period of time (increased residence time), possibly causing adverse biochemical reactions there. The same conditions may apply at the exit of a stenosis, while the converse happens as flow enters a stenosis. The pressure energy is traded for kinetic energy and the flow velocity increases as it goes through the stenosed section.

The carotid sinus is a frequent site of atherosclerosis, and it is now thought that low and oscillating wall shear stresses that are produced at this location owing to complex flow patterns are an atherogenic factor. Hemodynamics has also been implicated in the growth and rupture of intracranial aneurysms, which are sacular abnormalities found mostly at the bifurcations of vessels in the brain. These are just a few of the examples that signify the importance of understanding the normal and abnormal states of hemodynamic values and flow patterns in various parts of the circulation.

CONCLUSIONS

Hemodynamic factors have been implicated in a variety of vascular diseases, and many models, both theoretical and experimental, have been developed by researchers to glean the complex flow variations that occur in

physiologic flow. Some of these steady and pulsatile flow models have been discussed here along with their results. Representative dimensions of the vasculature and the rheology of blood and the vessel wall have been mentioned. Arterial pulse waves and flow in collapsible veins have been briefly reviewed.

Although this article covers the fundamental theoretical concepts of hemodynamics, computational fluid dynamics and medical imaging have rapidly advanced our ability to calculate detailed 3-D flows in anatomically accurate, patient-specific geometries of the vasculature. Numerical computing has thus become sufficiently complex to be regarded as a separate field in itself. Any degree of accuracy in determining flow fields does not, however, mitigate the fact that the vascular system is biochemical in nature. Biochemical interactions have not yet been adequately incorporated into hemodynamic models, and this is the subject of current research. Needless to say, the description of hemodynamic concepts presented here is a very brief account of the present state of knowledge in the science, and the interested reader is directed to the references for further depth.

Heparin-Binding to Improve Biocompatibility

Rolf Larsson

Department of Oncology, Radiology and Clinical Immunology, University Hospital, Uppsala, Sweden

INTRODUCTION

Heparin is one of the most negatively charged biomolecules known to be present in the body. It is always bound to tissues, most abundantly to mast cells, as a proteoglycan in which heparin molecules are covalently linked to a protein core. Despite the fact that soluble heparin, detached from the protein core, has been used as an efficient anticoagulant for more than five decades, the true physiological role of heparin is still not fully clarified.^[1-4] In the mid-1970s, it was discovered that the anticoagulant mechanism of heparin involves a catalytic interaction with antithrombin.^[5]

The concept of binding heparin to an artificial surface emerged by serendipity in the early 1960s.^[6] A carbon surface that was sterilized by immersion in benzalkonium chloride was subsequently soaked in a heparin/saline solution as a measure of surgical precaution, and a benzalkonium-heparin complex was inadvertently deposited. This discovery led to a number of different heparin surfaces with major emphasis on easiness of preparation, production costs, and related technical aspects but without considering the biological mechanisms of heparin (examples given in the following text). Concomitantly with the unravelling of the biological mechanisms of the interaction between heparin and antithrombin, a new method for covalent immobilization of heparin was developed involving partial depolymerization of heparin to introduce terminal aldehyde groups to avoid compromising the antithrombin binding capacity.^[7] This approach formed the basis for the heparin surface now known as Carmeda Bioactive Surface (CBAS), which is widely published.^[8] Another permanent heparin surface built on a macromolecular conjugate of unfractionated heparin allowing the antithrombin binding capacity to be adjusted, incidentally also developed in Sweden, is known as Corline Heparin Surface, CHS.^[9-12,68] This article covers a brief overview of some important and relevant biological interactions of heparin with emphasis on immobilized heparin, which is followed by a catalogue of the most prominent heparin surfaces describing their chemical constitution and the rationale for their use. Finally, some clinical applications are exemplified.

THE CATALYTIC ROLE OF HEPARIN

Heparin exerts its anticoagulant effect via a unique pentasaccharide sequence normally present in one-third of a commercial preparation of heparin.^[13-15] This high affinity fraction holds a high specific anticoagulant activity (typically, 250 IU/mg), whereas the residual low affinity fraction displays very low activity (typically, 10–20 IU/mg). The pentasaccharide sequence in heparin, which may also be present in heparan sulphate, binds to antithrombin whereby a structural reorientation is induced to the effect that the binding site of antithrombin for a number of serine proteases (e.g., thrombin) is more readily accessible.^[16] Binding of heparin to antithrombin thus accomplishes a thousandfold increase of the inhibition rate without altering the stoichiometry.^[16] Once an antithrombin-protease complex has been formed, heparin acquires a lower binding affinity and heparin can depart from the complex to find a new antithrombin molecule to bind to.^[17,18] This explains the catalytic role of heparin, which may occur both with soluble heparin and with heparin adequately immobilized to a solid surface. Due to their strong anionic character, heparin and related sulphated glucosaminoglycans exert a number of additional biological interactions.^[1-4]

ANTICOAGULANT ACTIVITY OF THE VASCULAR ENDOTHELIUM

The endothelial lining on the natural vascular wall exposes specific antithrombin binding sites linked to the presence of heparan sulfate.^[20] The density differs among different types of vessels, such that capillaries expose 10–12 pmol/cm², whereas the corresponding figure for aortic tissue is much lower, typically 2–3 pmol/cm².^[21] Experiments on fresh vessel segments with intact endothelium, as well as with vessels in which the endothelial cell layer had been experimentally detached, have revealed that factor XIIa, the initiator of the contact activation system, is bound to both types of vascular linings, but is immediately inhibited only if the endothelium is intact.^[21] The sub-endothelial structures also readily attract and activate platelets^[22] and white blood cells (Fig. 1).^[23]

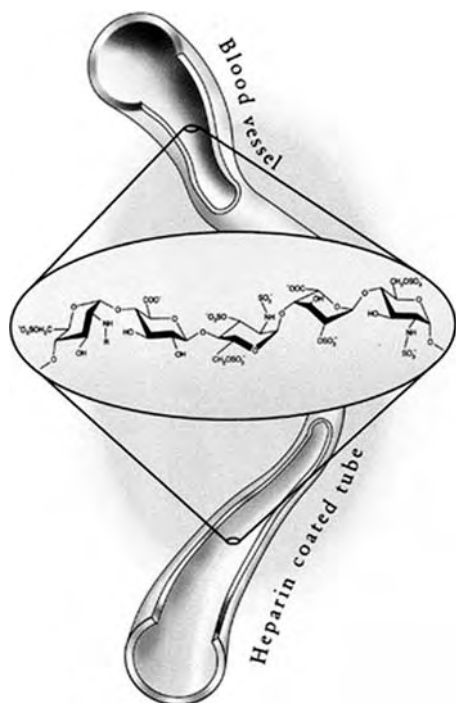

Fig. 1 An artist's view of a common denominator of the vascular endothelium and a heparin-modified surface: the antithrombin binding sequence.

BIOLOGICAL EFFECTS OF IMMOBILIZED HEPARIN

From a principal point of view, it is important to distinguish between effects induced by slow release of heparin from a surface and effects related to interactions with immobilized heparin. The former situation may merely be viewed as a rather complicated way of administering heparin locally for short-term use, whereas immobilized heparin may act as a catalyst over an extended period of time. The following discussion of biological effects related to heparin surfaces will emphasize interactions with immobilized heparin, confined to the interface between blood and a modified surface, rather than discussing possible effects that are likely to occur in the bulk phase of blood due to release of heparin. It is, however, difficult to compare the vast literature on the effects of heparin surfaces, due to the fact that the chemical nature and characteristics of the various heparin surfaces are often poorly described. The characteristics related to performance may differ quite extensively depending on the chemical constitution of the modified heparin surfaces.

Platelet Adhesion and Activation

Early investigations have established that platelet adhesion is dramatically reduced and virtually

eliminated at a heparin-coated surface,^[24,25] which has been verified in a number of later studies.^[9,12,26–30] It was demonstrated that fibrinogen did not adsorb to a heparin surface exposed to plasma, but if fibrinogen was adsorbed to the heparin surface from a pure fibrinogen solution prior to contact with blood, platelet adhesion promptly occurred.^[25] In a recent study, it was shown that activation of platelets, as indicated by release of β -thromboglobulin, decreased with increasing capacity of the heparin surface to bind antithrombin.^[12] Numerous reports have verified by, e.g., scanning electron spectroscopy that heparin surfaces are conspicuously free from deposits including platelets (Fig. 2). If platelet adhesion is not affected by surface modification with heparin, as reported in one study,^[31] the most likely explanation would be that the particular method used did not result in a coherent coating.

White Blood Cell Adhesion and Activation

Microscopic investigations, as illustrated in Fig. 2, imply that not only platelet adhesion but also adhesion of WBC is greatly reduced, which has been confirmed in several studies.^[28,32–34] In a clinical study of coronary bypass, oxygenators that were either unmodified or modified with the Corline Heparin Surface were investigated with respect to attachment of cells. The number of platelets, granulocytes, and monocytes retrieved in the eluates from the two different types of oxygenators were significantly reduced in the group with heparin-coated surfaces.^[11] Experimental and clinical studies have demonstrated less activation of WBC as indicated by reduced levels of markers for activation of WBC as, e.g., myeloperoxidase,^[10,35] lactoferrin,^[35] and the integrin CD11b.^[10]

Fig. 2 Unmodified (left), and CHS-modified (right) Stent Graft after exposure to fresh human blood for one hour at 37°C. The specimens were gently rinsed with saline, fixed with glutaraldehyde and subsequently dried at CO₂ critical point, covered with gold, and finally examined by scanning electron microscopy (magnification $\times 50$).

H

Interaction with the Enzymatic Coagulation System

Early studies with an ionic heparin surface stabilized with glutaraldehyde demonstrated that immobilized heparin is able to bind and inhibit thrombin,^[36] but a sulphated surface devoid of the anticoagulant effect of heparin proved to be thrombogenic due to the fact that thrombin would still be bound but protected from inhibition.^[25,36] In the first report on the method of covalent end-point binding of heparin, it was reported that ordinary heparin could be irreversibly attached by ionic binding under certain conditions, resulting in firmly bound heparin, which, however, proved to be thrombogenic due to binding of thrombin in a form that could not be inhibited.^[7] These findings demonstrate that certain requirements have to be met in order to obtain the desired capacity for inhibition of thrombin. A number of studies have been published to show that the heparin surface prepared by end-point attachment of partially degraded heparin inhibits thrombin, coagulation factor Xa, and factor XIIIa (for review, see Ref. [37]). Also the heparin surface based on a macromolecular heparin conjugate has proved to reduce coagulation activation *in vitro* effectively based on tests with fresh human blood,^[9,12] and to prevent contact activation.^[38] In a clinical study on coronary bypass patients, it was demonstrated that activation of coagulation, which normally occurs during bypass despite systemic administration of heparin, could be reduced by applying the Corline Heparin Surface to the complete bypass system.^[10,11]

Contact Activation

The contact activating system is generally considered to be activated by negatively charged surfaces primarily by adsorption of factor XII, which will then be converted to the active enzyme FXIIa. The two other proenzymes of the contact activation system, factor XI and prokallekrein, together with the cofactor high molecular mass kininogen may then become activated leading to activation of coagulation and inflammatory reactions. Several studies have shown that FXII binds to a heparin surface, most likely due to its negative charge, but that any FXIIa that is formed is immediately inhibited, provided that the heparin surface displays adequate antithrombin binding capacity.^[39,40] If, however, the surface is devoid of antithrombin binding capacity, as was demonstrated by preparing a heparin surface with low affinity heparin,^[40] the adsorbed FXIIa could not be effectively inhibited. Again, we see an example of a surface that does contain heparin but does not qualify as a nonthrombogenic surface. As

pointed out previously, FXII is adsorbed to the vascular endothelium but FXIIa is rapidly inhibited as long as the endothelium remains intact. Any damage to the endothelium will render the surface incapable of inhibiting FXIIa, which implies that the whole contact activation system may be activated.^[21] There seems to be a close link between contact activation and activation of platelets as described in a recent study. Selective inhibition of contact activation induced reduced activation of platelets and also caused less thrombin generation. The latter effect could also be achieved by blocking the platelet receptor GPIIb/IIIa.^[41]

Complement and Inflammatory Response

The effects exerted by surface-attached heparin on complement and inflammatory response have been broadly investigated. The vast majority of studies are related to coronary bypass surgery. In general, heparin surfaces reduce complement activation^[35,42-46] and also minimize activation of granulocytes as evidenced by less release of lactoferrin and myeloperoxidase.^[35] In this context, it is interesting to note that selective blockade of complement results in considerable reduction of adhesion of granulocytes to foreign surfaces.^[47] In a recent publication, a link between chemical constitution of a heparin surface and complement activation was established. Activation of complement was shown to decrease as the antithrombin binding capacity increased.^[12]

Protein Interactions

Due to the strong anionic character and the presence of specific binding domains, heparin binds and interacts with a large number of peptides, proteins, lipids, etc., both in a specific and nonspecific manner.^[48] Antithrombin, a natural inhibitor of several serine proteases in the coagulation system, binds to a specific pentasaccharide domain in heparin, whereby the rate of inhibition is greatly accelerated.^[16] Surfaces modified with heparin using selective coupling methods have been shown to bind antithrombin, which is clearly related to functional integrity.^[12,40] Using plasmon resonance, it could be demonstrated that the binding of several proteins including antithrombin was strongly affected by the method used to immobilize heparin.^[49] A few, nonlimiting examples of additional peptides and proteins that bind to heparin are a variety of growth factors,^[50] vitronectin,^[51,52] laminin,^[53] lipoprotein lipase,^[54-56] complement factors,^[57-59] protamine,^[60] kininogens,^[61] coagulation factor XII,^[62] and tissue factor pathway inhibitor.^[63]

TYPES OF HEPARIN SURFACES

Carmeda Bioactive Surface (CBAS™)

In the first publication on this heparin surface based on single end-point covalent attachment of heparin, the priming layer onto which heparin was attached was composed of polyethyleneimine (PEI) irreversibly adsorbed to a sulphated polyethylene surface.^[7] Interestingly, two quite different priming layers could be accomplished simply by changing the pH of the PEI solution used during surface adsorption of PEI. At an acidic pH, the PEI layer proved to bind unmodified heparin only by electrostatic interaction firmly enough so that heparin could not be eluted from the surface layer. However, this particular heparin surface was found to be thrombogenic due to the fact that thrombin that was adsorbed to the surface appeared to be protected against inhibition. When the pH of the PEI solution was adjusted to 9, the ionic interaction with heparin was very weak and unmodified heparin was readily eluted from the surface. By using heparin that had been partially depolymerized by mild treatment with nitrous acid, thereby introducing terminal 2,5-anhydromannose residues exposing a reactive aldehyde, heparin could be covalently immobilized while retaining adequate mobility to avoid compromising the antithrombin binding sequence of heparin.^[7] Thrombin adsorbed to this surface with upright heparin proved to be effectively inhibited in the presence of antithrombin in sharp contrast to the surface with laying heparin (PEI at pH 4 followed by unmodified heparin). This discovery laid the foundation for what later came to be known as CBAS™. A priming layer based on sulphated polyethylene is, however, not very useful for practical and commercial purposes. Hence, the CBAS™ involves a different priming layer composed of a sandwich ending with PEI. The underlying layers are composed of alternating layers of PEI treated with glutaraldehyde and dextran sulphate, respectively.

Pharmacia HSM Intraocular Lens

Intraocular lenses (IOLs) made of poly(methyl methacrylate) are available with a covalent heparin coating (Heparin Surfaced Modified, HSM). This coating is a modification of the CBAS™ basically to improve the stability towards mechanical abrasion. Heparin is covalently linked to PEI, being irreversibly adsorbed to PMMA after prior treatment with ammonium persulphate. To achieve adequate thickness, the sequence of PEI and heparin is repeated. The HSM surface has proved to be stable, as demonstrated by the fact that there was no detectable loss of heparin

following two years implantation in the anterior eye chamber of rabbits,^[64] and to reduce inflammatory response.^[65,66]

Corline® Heparin Surface (CHS)

The most conspicuous component of this rather new heparin surface is a macromolecular conjugate composed of a carrier chain to which a large number of heparin molecules (typically seventy) have been covalently linked.^[9–12,67,68] The heparin conjugate is then irreversibly bound, basically by multiple ionic interaction, to surfaces that have been primed by a polymeric amine compound (PAV, proprietary substance supplied by Corline Systems AB, Uppsala, Sweden).

Trillium™ Biopassive Surface

This coating is commercialized by Medtronic on their line of Affinity oxygenators under a license from Biointeractions Ltd., Reading, U.K. The Trillium coating is composed of a priming layer (unknown composition) to which polyethylene oxide (PEO) chains have been attached. Heparin molecules are covalently bound to the PEO chains and in order to increase the negative charge sulphate/sulfonate groups have been introduced in addition to the negative charges provided by heparin.^[69–72] According to information put forward by Biointeractions Ltd., the sulphate/sulfonate groups should be expected to improve the nonthrombogenic character by increased binding of antithrombin.^[73] There are, however, no data available on the antithrombin binding capacity of the Trillium™ surface. With reference to reports showing that negatively charged surfaces that are not based on properly bound heparin induce coagulation,^[7,25,36] and to the detailed information of the molecular mechanisms responsible for heparin-antithrombin binding (c.f. previous text), caution should be exercised in anticipating increased antithrombin binding due to nonspecific sulfate/sulfonate groups.

Duraflo II

This coating, developed by Baxter,^[74] has been widely used in connection with products for extracorporeal circulation. The concept is based on the same approach used for preparing a surface with benzalkonium-heparin complex,^[75] but Duraflo II takes advantage of a branched surfactant carrying quarternary ammonium groups^[76] instead of benzalkonium chlorid as a way to decrease the rate of decomposition of the heparin-surfactant complex in contact with blood. Basically, a heparin-surfactant complex is precipitated

from an aqueous solution, and the precipitate is dried and then dissolved in an organic solvent. The products to be modified are then subjected to a dip-dry process. These types of heparin surface have not been designed to bind antithrombin, and there are no reports to show that antithrombin effectively interacts with a Duraflo II surface. Due to the fact that these types of ionically bound heparin surfaces are not stable in contact with blood, they are confined to short-term use.

Bioline Coating™

According to the manufacturer (Jostra AG, Hechingen, Germany) this heparin coating takes advantage of both ionic and covalent bonding of heparin to natural polypeptides,^[77] but there are no scientific reports that describe the chemical constitution or molecular structure of this approach. The main application in which Bioline is used is bypass systems intended for short-term use.^[78] To the best of our knowledge, the Bioline Coating™ does not bind any appreciable amounts of antithrombin.

T-NCVC Coating

This recent development carried out jointly by Toyobo Corporation and National Cardiovascular Center in Japan employs an ionic complex of heparin and aliphatic coupling reagent composed of several long-chain dialkyl groups.^[79] The coating is applied by a dip-dry process. No information is available on the antithrombin binding capacity of this surface. Encouraging results indicating long term stability at extracorporeal circulation in goats have been presented.^[79]

Hepaface (Terumo Co., Tokyo, Japan)

Heparin is N-desulphated using sulfuric acid to generate primary amine groups. Heparin is then linked by glutaraldehyde to PEI adsorbed to the substrate surface after treatment with ozone gas.^[80,81] Already from this description, it can be deduced that this surface should not be expected to interact favorably with antithrombin due to the fact that the aminosulfate groups of heparin are essential for its anticoagulant activity via binding to antithrombin.

CLINICAL APPLICATIONS OF HEPARIN-MODIFIED SURFACES

A heparin surface does not exist as a specific product but needs to be carried along by some sort of

medical device. This implies that very few, if any, products have been developed based on a specification that a heparin surface should be included to improve blood compatibility. The use of heparin surface modification has rather emerged by a recognized need to improve blood compatibility of existing devices that have been developed relying on available construction materials, such as polymers and metals.

The most wide-spread use of heparin surfaces is to be found in the area of extracorporeal circulation as applied in open-heart surgery. There are numerous reports from clinical studies that confirm favorable performance with less inflammatory and procoagulant response of bypass systems being modified with a heparin surface,^[11,12,35,45,82] but there are also other reports in which the investigators failed to demonstrate any improvements with respect to less formation of thrombin by adding the heparin surface.^[83,84] As pointed out above, it is important to realize that a number of different heparin surfaces have been involved in these studies and that it is impossible to draw any general conclusion that would be valid for all types of heparin surfaces.

ECMO, extracorporeal membrane oxygenation, is an example of a bypass procedure that is supposed to operate over a more extended period of time, typically several weeks. The patients undergoing this treatment are often susceptible to bleeding and would be better helped if systemic use of heparin could be reduced to a minimum. There are reports that have demonstrated that ECMO can indeed be maintained over a prolonged period of time with very little or no heparin given to the patient, provided that the blood-contacting surfaces have been modified with permanently bound heparin.^[85]

Following encouraging preclinical reports of implanting intraocular lenses made of polymethyl (methacrylate) surface modified with heparin,^[28,64,65] such IOLs are now commercially available. Clinical studies have confirmed less incidence of inflammatory adverse reactions following implantation of heparin-surface-modified IOLs.^[66] Heparin coating of stainless steel stents has been demonstrated to reduce thrombogenicity *in vitro*^[9,27,86] and *in vivo*.^[29,87] Clinical studies have confirmed less incidence of subacute thrombosis and there seems to be a trend toward reduced rate of restenosis but the evidence regarding the latter aspect is less convincing.^[88-91] Further aspects on this topic can be found in the following reviews: Refs. [67] and [92].

Additional examples of medical devices that have been modified with immobilized heparin are vascular grafts,^[93,94] indwelling catheters including decreased incidence of bacterial contamination,^[95,96] and intravascular sensors.^[97,98]

CONCLUSIONS

Heparin-binding to improve biocompatibility is a long story with many facets, which has been condensed into some major aspects in this article. Due to the catalytic mode of action, heparin offers unique opportunities for use as an immobilized substance, and it is indeed gratifying to know that this mode of action is involved in regulating the hemostatic balance of the circulating blood continuously in contact with the immense endothelial surface of the blood vessels. It follows that it is important to identify the nature and chemical constitution of surfaces designed and promoted as heparin surfaces. Adequate interaction between immobilized heparin and antithrombin is an essential prerequisite for any surface that qualifies to be considered as a heparin surface.

THE NORMAL HIP, ARTHRITIS, AND THE ARTIFICIAL HIP

The hip is an essential component to human locomotion whose mechanical unit function can be explained by the law of mechanics. The hip joint is composed of the femur (ball) and acetabulum (socket). Although neither are perfect spheres or congruent, they usually function as an effective ball and socket joint. The three bones of the pelvis form the acetabulum: the ilium (wing), the ischium, and the pubis (Fig. 1).

Numerous ligaments and tendons traverse the healthy hip and thus it is the most difficult joint in the body to dislocate.^[1] When a person stands symmetrically on both legs, the hips support 62% of the body weight. In a static equilibrium position, little muscular force is needed to maintain equilibrium, and thus each hip supports 31% of the body weight.^[2] When a person stands on one leg, the hip supports the upper body as well as the other leg, or 81% of the total body weight (K). However, Maquet^[2] formulates that the joint reaction force in the hip is a little more than three times the body weight owing to abductor muscles (M) counterbalancing the eccentric forces of gravity (Fig. 2). So the resultant force inside the hip joint (R) is the vector sum of the (K) and (M):

$$R = \sqrt{K^2 + M^2 + 2KM \cos(\widehat{KM})} \quad (1)$$

During gait, kinematics is computed by tracking markers on the body. Once the body is in motion the inertia forces change the dynamics of the pelvis/leg joint forces. Using Newton's and Euler's equations the inverse dynamic problem results in the evaluation of those reaction forces at the hip. The forces at the hip joint during gait were estimated by Maquet to vary between 138% body weight during the middle of the leg swing, and can reach 433% at the time of impact during heel strike.

In the late 1980s, a group of engineers and surgeons at Case Western led by Davy implanted a total hip with a load cell, battery, and transmitter built into the neck of an artificial hip.^[4] One month after surgery, they recorded joint forces different than those previously calculated. During single leg stance, the hip force was 1.0 times body weight, more than three times that calculated by Maquet. During single leg stance, 2.1 times the body weight was recorded, 30% less than Maquet (Table 1).

For this study, we assumed that the maximum force exerted to the hip during gait is approximately three times the body weight or 1500 N.

SURGICAL TECHNIQUE FOR TOTAL HIP REPLACEMENT

Cementless total hip arthroplasty (THA) is coated with a porous surface (200–400 μm pore size) that allows bone ingrowth providing long-term integration and fixation of the prosthesis. To ensure ingrowth into the prosthesis there must be: 1) minimal motion between the bone and prosthesis and 2) close apposition between the prosthesis and the bone. A 3- to 10-in. incision is made parallel to the femur, through the skin and the musculature of the hip. The hip can be dislocated anteriorly or posteriorly.^[5] The femoral neck is cut, the head removed, and the canal reamed with cylindrical reamers. The proximal femur is then shaped with broaches to accept the femoral component. The prosthesis must be placed in tight apposition to permit ingrowth, but care must be taken not to oversize the prosthesis and fracture the bone.^[6]

Reaming of the acetabulum must be precise to guarantee a tight interference fit of the cup into the bone. Bone will not ingrow into a cup exhibiting gross motion. The acetabular reamer looks like a spherical cheese grater with a handle that attaches to a reamer (Fig. 3).

Fig. 1 An illustration of the human pelvis with a healthy hip joint on the right and an artificial hip joint on the left. The pubis, ischium, ilium, and acetabulum form the healthy pelvis. The shell and insert make up the acetabular component of the total hip. The ball, neck, and stem make up the femoral component.

Reaming is performed with reamers of increasingly larger diameters to remove all cartilage and attain the proper depth. Then the surgeon aligns the reamer to a position correlating to 45° of abduction from the horizontal and approximately 25° of anteversion.^[7] Research suggests that the spherical cut has diametric errors averaging 2.1%.^[8] This leads to a limited contact of the bone with the cup that some estimate to be as low as 20% to 60% of the total surface area of the acetabulum.^[9] After reaming is complete, the surgeon implants the cup with an impactor. An alignment guide is used to achieve 45° of inclination and 0° to 30° of anteversion. If the cup is placed in too much anteversion, the risk of posterior impingement increases, and too little

Fig. 2 Person standing with weight supported symmetrically on both legs. The center of gravity of the head, trunk, and upper limbs is denoted by S_4 . R denotes the force exerted on the hip.

Table 1 Calculated and measured peak hip forces during different activities

Activity	Hip forces calculated by Maquet	Hip forces measured by Davy
Dual leg stance	31% BW	100% BW
Single leg stance	300% BW	210% BW
Gait cycle	433% BW	
Walking with crutch		280% BW
Walking with parallel bars		240% BW
Climbing stairs		260% BW

anteversion runs a risk of anterior impingement.^[9] Impingement of the femoral neck on the acetabular component produces a shear on the bone prosthesis interface that is detrimental to its stability (Fig. 4).

The reaming can be performed 2 mm less in diameter than the diameter of the cup (under-reaming) to improve the interference fit. Under-reaming in very osteoporotic bone can cause an acetabular fracture and is to be avoided. After implantation of the acetabular cup, the polyethylene acetabular liner is inserted.

A femoral trial is now placed into the femur and a trial femoral head is used to judge the stability of the implant. The neck length of and offset of the femoral head can now be used to adjust stability of the prosthesis and leg length. The appropriate femoral component is now inserted into the femur. The modular head of appropriate length is locked onto the Morse taper of the femoral trunion. The prosthesis is reduced and the joint closed in layers.

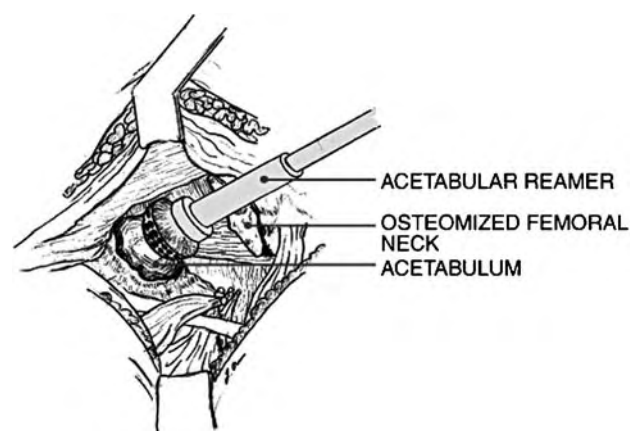

Fig. 3 Reaming of the acetabulum. The acetabular reamer is placed inside a drill, and the bone is reamed using successively larger reamers until the desired diameter is reached.

Fig. 4 An illustration of a femoral stem impinging on an acetabular cup.

IMPLANT FIXATION

Modern implant fixation is generally fostered by cementation with methylmethacrylate and by cementless fixation. Various implant designs rely on different design elements to achieve fixation. These designs can be generally categorized as follows.

1. **Cemented**—Implants rely on polymethylmethacrylate cement that mechanically interlocks with both the metallic implant and the bone. Cement pressurization during the surgery helps the cement to interdigitate with the trabecular bone.
2. **Cementless**—Implants rely on bony ingrowth into a porous coated metallic implant (pore size 200–400 μm). This is most commonly done by sintering titanium or cobalt chromium bead or fiber mesh onto the implant.
3. **Hybrid**—A cementless cup is implanted with a cemented stem.

An abundance of clinical studies show excellent performance of both cemented and uncemented femoral components. Cemented femoral stems are technique intensive and long-term survival of the prosthesis is dependent on an adequate cement mantle (2–3 mm) surrounding the prosthesis. Cemented stems are immediately stable and are preferred by some surgeons in older patients where osteoporosis may limit stability and ingrowth into a cementless prosthesis.

There have been several studies showing progressive loosening of cemented acetabular components, compelling a majority of surgeons in the U.S.A. to prefer cementless fixation for the acetabular cup. In older patients, some surgeons prefer a cemented stem with a cementless cup termed “hybrid fixation.” Most

successful implants rely on a porous material that is conducive for bony ingrowth and a geometry that enables the surgeon to attain initial press fit. Popular acetabular designs include a simple hemisphere cup, a tri-spike design, and a cup that includes holes for adjunctive screw fixation.

Adjunctive screws are commonly used to enhance the initial stability of a hip cup. However, adjunctive screws have three potential failure modes. One, the screw holes are direct pathways for polyethylene wear particles to enter the bone–prosthesis interface. Two, the screw itself is another wear surface, scratching the polyethylene liner and the metal shell, contributing to the number of wear particles in the joint space. Three, the use of screw fixation leads to an uneven load distribution, and often an uneven bone remodeling. In scenarios where bone prosthesis contact is deficient or bone is severely osteoporotic, adjunctive screws may be necessary to achieve implant stability.

Biomaterial

The chief mode of failure of the modern THA is aseptic loosening.^[10] The hip articulation is relatively concentric producing fine submicron polyethylene wear particles. Wear debris is opsonized by macrophages, initiating an inflammatory cascade that creates osteolysis. Osteolysis degrades both the bone–prosthesis interface and the bone–cement interface producing loosening. Improvements in prosthesis design and surgical technique have led to reduction in wear. Improvements in polyethylene manufacture, such as cross-linking, and the introduction of alternate bearing surfaces such as metal-on-metal and ceramic-on-ceramic may further improve total hip longevity in the future.

Material selection is an important factor in the development of wear particles. Titanium is commonly used to fabricate femoral stems and cups because of high strength, low stiffness, and osteophilic properties. Titanium alloys however, are not used for femoral head fabrication because of poor wear characteristics.^[11] A polished cobalt chrome head articulating on an ultra-high molecular weight polyethylene (UHMWPE) liner has improved wear characteristics. The UHMWPE is an inert and nontoxic material. In its bulk form it is harmless to the body. In particle form it is an initiator of osteolysis. It is estimated that one million UHMWPE wear particles are produced from a total hip in a single step.^[12] It is also estimated that the average individual takes one million steps a year. The volume of wear produced is relatively small, but the large number of submicron particles appear to be the primary cause of osteolysis and the eventual loosening of a previously well-fixed prosthesis.

In 1977, Willert was among the first to hypothesize that local macrophage response to wear particles

contributes to aseptic loosening.^[13] Goldring, in 1983, showed that cells within the periprosthetic membrane produces large amounts of “bone resorbing” factors around loose implants.^[14] In 1992, Quinn and others demonstrated that wear particle-induced giant cells are capable of absorbing bone in vitro. More recent studies have documented the exact biochemical pathways of bone resorption and its relationship to UHMWPE particles.^[15]

One way to reduce the effects of osteolysis on the success of a total hip is to limit the exposure of the bone to wear particles. Femoral stems designed with circumferential coating have a better survival than partially coated stems because complete ingrowth around the fully coated stems precludes the passage of wear particles into the bone–prosthesis interface. Acetabular cups with no screw holes or with screw-in plugs for the holes to limit the egress of particulate matter into the bone–cup interface have been developed.

Implant Design

The femoral component has two essential components: the ball and the stem. The ball is typically a highly polished cobalt chromium sphere, which provides an excellent articulating surface. The stem provides the fixation interface between the femur and the prosthesis.

The acetabular component is typically composed of a metal shell and a UHMWPE insert. The UHMWPE insert is an essential component to the success of the joint. Excessive wear of the polyethylene component and subsequent aseptic loosening is the leading cause of implant failure. Therefore researchers have concentrated on reducing wear by decreasing contact stresses, evenly distributing contact stresses, and improving the wear characteristics of the polyethylene liner. Work has also been done to diminish the effects of wear particles by manipulating the size of the particle produced and preventing the particles from entering the bone–prosthesis interface by removing screw holes and sealing the insertion hole.

It was once believed that a low-friction hip joint applied very little torque to the hip cup. Research more recently suggests that impingement (Fig. 4) of the femoral stem on the rim of the acetabular cup produces a torque on the cup.^[16] Also, radiographic evidence exists that the femoral component commonly subluxes when a patient sits and then recenters during stance initiation.^[17] During recentering, the cup is eccentrically loaded and thus a torque is produced (Fig. 5). Newer cup designs incorporate rigid locking mechanism designs of the liner in the outer metal cup to counteract rotational and torsional forces.

Fig. 5 An illustration of a femoral that has been subluxed from the cup and is recentering, applying a torque to the cup.

THE RELATIONSHIP BETWEEN HIP CUP STABILITY, MICROMOTION, FIXATION, AND OSTEOLYSIS

If initial stability is not achieved, the normal physiological movements of the patient will produce excessive micromotion between the bone and the prosthesis, preventing bony ingrowth. Without bony ingrowth, loosening of the hip cup will lead to early failure.^[18] The obvious and most common solution is to add adjunctive screw fixation to the acetabular component. While adjunctive screws do decrease micromotion by 20% to 30%,^[19] they may indirectly lead to the increase of osteolysis.^[20]

THE RELATIONSHIP BETWEEN PELVIC OSTEOLYSIS AND ADJUNCTIVE SCREWS

A recent study involving 132 primary cementless hip arthroplasties at Tulane University reported an acetabular revision rate of 5% at five to eight years owing to acetabular osteolysis (Fig. 6).^[20] “Abrasion of the screw head against the back-side of the polyethylene liner was seen in all retrieved cases and may have contributed to the development of the lytic lesions seen.” The materials used in the uncemented THA implant selected for this study can be divided in two groups, metallic

Fig. 6 Well-fixed THA with osteolytic lesion of the superior acetabulum as a result of polyethylene wear.

biomaterials (femoral head, femur stem, and acetabular cup) and polymeric biomaterial (liner). Table 2 shows the material properties of biomaterials involved in the present study.

Implant design has been shown to have an adverse effect on polyethylene wear. With certain designs, a gap may be found between the polyethylene liner and the metal cup component. Implants are manufactured with exact dimensions drawn from computer aided design (CAD) drawings under some tolerance conditions. In the manufacturing process, reproduction of the exact dimensions of the proposed design is not always achieved. The actual implant may be slightly smaller or larger than the design specifications, and a gap clearance would occur between the liner and the metal cup. Therefore, the liner would be unsupported over the weight-bearing dome location of the gap of the prosthesis and would then transfer high stresses to the rim. In some designs of liner, the polyethylene thickness at the rim may be smaller than in the dome surface; therefore, greater stresses are generated in the thinner

parts of the liner. When the polyethylene yield stress is exceeded as might be the case in other designs, a failure in the liner rim may occur with eventual fracture and penetration of the femoral head against the acetabular cup.

Dislocation after THA

After aseptic loosening, dislocation of the femoral head within the acetabular liner is the most significant complication that occurs after THA.^[21–23] The incidence of dislocation after THA varies from study to study, but in general it is in the range of 1% to 10% of the THA patients (Fig 7). It is important to highlight that the incidence of dislocation after THA revision is significantly greater. The most significant preoperative risk factor for dislocation after THA is previous hip surgery. Other factors include operative technique (leg length and component position), gender (greater dislocation cases in females over males), mental disorders, neuromuscular disease, alcoholism, and patient noncompliance.

Femoral Head Subluxation

During THA many supporting structures for the retention of the femoral head within the acetabulum are removed. Previous studies have determined that this lack of supporting structures may lead to separation of the femoral head within the polyethylene liner.^[24,25] Subluxation of the femoral head can be defined as the separation of the femoral head within the liner during abduction/adduction activities. While total dislocation after THA does not necessarily imply a relocation of the femoral head just following the dislocation, subluxation is always followed by the relocation of the femoral head within the liner.

In previous studies using fluoroscopy techniques, separation between the femoral head and the liner during subluxation were computed.^[25] In this study 20 subjects were analyzed. Five subjects had a normal hip, 10 subjects were implanted with an unconstrained THA, and five subjects were implanted with a THA using a constrained acetabular component. All THA

Table 2 Selected properties of biomaterials

Material	Young's modulus, E (GPa)	Tensile strength (MPa)	Poisson's ratio, ν (unitless)	Density, ρ (g/cm ³)
Stainless steel	190	586–1351	0.33	8.8
Cobalt-chromium	210–253	655–1896	0.28	7.8
Titanium alloy	110	760	0.34	4.5
UHMWPE	0.975	≥ 35	0.46	0.94

Fig. 7 Patient with bilateral THA. The prosthesis on the right of the picture is reduced concentrically and the prosthesis on the left of the picture is dislocated posteriorly.

subjects were implanted by the same surgeon; none of them reported any signs of hip instability and none had suffered a total dislocation postoperatively.

To measure the separation distances between the femoral head and the liner socket, THA subjects were analyzed using fluoroscopy imaging and posterior three-dimensional (3-D) fitting. Based on the 3-D model fitting, axial separation of the femoral head was measured. Additionally, during subluxation, the femoral head appeared to remain in contact with and pivot on the polyethylene liner, potentially creating excessive loads in the region of contact. The average separation detected in the subjects analyzed by Dennis et al. was 3.3 mm (range 1.9–5.2 mm).

The first objective of this investigation was to evaluate the stability of the acetabular liner within the acetabular shell when subjected to physiological cycling loads. The second objective of the experiment was to validate a finite element (FE) model of the cementless modular acetabular component that is going to be described in following sections.

To perform the experiment presented in this study, a complete setup was designed. To satisfy the design requirements of the experiment, both commercially available and custom-made testing instruments were used.

Linear variable differential transducers (LVDT) were used to measure the micromotion and deformation that occurred in the liner when subjected to load. Six LVDT sensors were positioned in contact with the liner at specific locations. Three of the sensors touch the liner perpendicularly to the outer flat surface, while the other three are in contact with the liner perpendicularly from the side, as shown in Fig. 8. To avoid interferences

Fig. 8 Relative orientation of the LVDT sensors with respect to the liner.

of the loader with the LVDT sensors, the positioning plate was rotated 30° with respect to the loader.

A custom-made loader was designed to transfer load from the load unit to the acetabular liner in a manner that resembled the way loads are applied in the actual components. A commercially available femoral head (DePuy, Inc., Warsaw, Indiana) was press fitted in a metal rod, which was connected to the testing machine load cell.

Experiment Setup

The following commercially available (DePuy, Inc., Warsaw, Indiana) cementless modular acetabular implant components were tested:

- Seven UHMWPE liners, 28 mm inner diameter and 54 mm outer diameter
- Two acetabular cups, 66 mm outer diameter
- One femoral head, 28 mm outer diameter

The experimental procedure was as follows. Upon positioning the acetabular liner into the acetabular shell using the specific tool designed for such purpose, the latter is screwed to the holding/positioning jig from its bottom. The positioning jig was designed to hold the acetabular shell at a constant angle of 45° with respect to the horizontal, simulating a 45° inclination angle. For this experiment the anteversion angle was 0°. Two acetabular shells (66 mm) were used during the experiments. The first had only a polar fenestration and the second had polar fenestration and three screw holes. At this point, the sensor positioning plate containing six calibrated LVDT sensors was attached to the positioning jig. The positioning plate must be screwed tightly to minimize motion. The metal tip of each

LVDT sensor was calibrated at zero position when it came in contact with the liner.

The femoral head was inserted into the liner socket and adjusted until a perfect conformity was achieved; this was done without applying significant load on the liner to eliminate initial micromotion and deformations of the liner.

FE Model and Validation

A 3-D 3300-element FE model of the femoral head, liner, and acetabular cup was developed based on the CAD previously created in Pro-E (DePuy, Johnson and Johnson; PINNACLE) using ANSYS/LS-DYNA (Fig. 9) shows, respectively, the FE models for the acetabular cup, liner, and femoral head used in the FE explicit analysis. The three components were put in contact and an assembly was created. The diameter of the articulating surface femoral head/liner measured 28 mm while the liner back-side diameter measured 54 mm; a 12 mm diameter polar fenestration was considered in the metal acetabular cup. The acetabular cup was positioned with 45° inclination and 25° anteversion with respect to the reference coordinate system.^[26]

The FE mesh of the acetabular cup, liner, and femoral head consisted of eight-node hexahedron solid elements. Owing to the hemispherical shape of the contacting areas between all the components, two main types of mapped mesh can be performed, polar and nonpolar mesh. A polar mesh design was selected to be the one that better solves the nodal “penetration” problem. The pattern of mesh is the same in all the contacting areas (outer surface of the femoral head/liner front side and liner back-side and acetabular cup) so that the nodes placed in the contacting surfaces do not interfere in the target area. When meshing 3-D solids, the elements of the mesh that cannot be seen

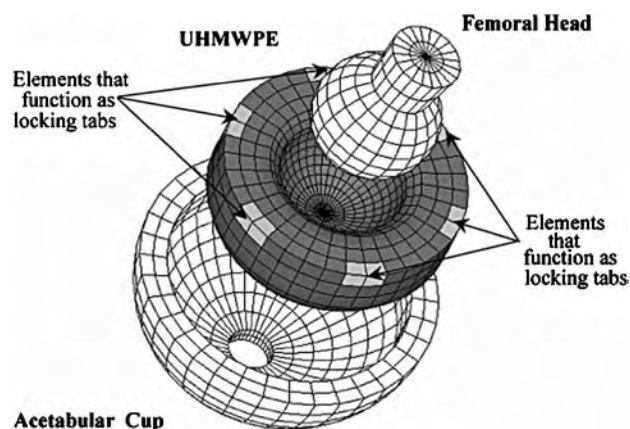

Fig. 9 FE element models of the femoral head, liner, and acetabular cup. The model shows the nodes that were constrained to simulate the liner-locking tabs.

from the outside may have irregular shapes. Owing to the axial symmetry of the liner, acetabular cup, and femoral head, a cross section of those was first meshed. Planar elements were then used (shell 163), having perfect control of the shape of the elements. The major problem of polar mesh design occurs in the change of shape of the elements placed in the poles, where the hexahedron elements are converted to tetrahedron elements.^[27] Singularities occur in tetrahedron elements when the angle between adjacent facets is smaller than a certain angle. In this case, a singularity nonconvergence problem may occur. Material properties of the liner were based on the information obtained in the available literature, Young's modulus = 975 MPa, Poisson's ratio = 0.46.^[28]

It is important to note that the definition of contacts in an explicit analysis differs from the way they are usually defined in an implicit analysis. In the latter analyses, contact is represented by specific contact elements. For explicit analyses there are no contact elements. The definition of the contact is done defining the contact surfaces instead. Also, the type of contact between surfaces and some other parameters related with the contact type must be defined.

To adequately describe the interaction between the implant components, an automatic surface-to-surface contact was selected. This type of contact is established when a surface of one body penetrates the surface of another body (such as the case of the femoral head impacting against the liner). Also, this type of contact is the most effective when dealing with bodies of arbitrary geometry.

The frictional coefficient used for contact (μ_c) is determined from the static friction coefficient, the dynamic friction coefficient, and the exponential decay coefficient. The frictional coefficient is assumed to be dependent on the relative velocity of the surfaces in contact (V_{rel}). Different values for the friction coefficient between the metal and UHMWPE components were studied. The values ranged from 0.083 to 0.2. The friction coefficient data was based on the information obtained through two ways: published literature in the field of biomechanics of human prosthesis,^[28] and general literature regarding the material properties of UHMWPE^[29] when subjected to friction experiments against different materials and contacting shape surfaces. The minimum value found in the published literature^[30] was $\mu = 0.083$ and a maximum value of $\mu = 0.2$.

$$\mu_c = FD + (FS - FD)e^{-DC \times V_{rel}} \quad (2)$$

A similar loading profile to the one used in the experiment setup was created in ANSYS/LS-DYNA to validate the experimental results in terms of stability/micromotions of the liner. The maximum force applied

over the liner during the experiment was 10,000 N. Because there is no evidence that this force can actually be achieved in the human body (even during worst case scenarios such as falling situations), it did not seem necessary to reach that force to validate the FE. At the center of gravity of the femoral head, a dynamic load was applied, ranging from 0 to 1775 N, applied linearly. Based on previous studies of the gait model describing the hip forces and orientations,^[3,30] the value of 1775 seemed perfectly reasonable to be reached in most cases during normal activities.

To reproduce the experimental conditions as closely as possible, both the orientation of the applied load (vertical) and the position of the acetabular component (45° anteversion) were the same in the FE model as well as in the experiment setup. The values ranged from 0.083 to 0.2. Taking the minimum value as a reference, comparisons of the results obtained in the FE model and the experiment, in terms of micromotions, stresses, and deformations of the liner were performed. The friction coefficient value that better fitted both results was selected.

The main steps are as follows:

- *Apply loads and obtain the solution.* Unlike implicit analyses, all loads in an explicit analysis must be time dependent in nature. For this reason, all loads are applied using a pair of array parameters, one corresponding to the time and the other one corresponding to the loading condition.
 - *Review the results.* To review the results obtained in LS-DYNA the postprocessor available in ANSYS was used. Reviewing the results implies getting the deformation, stresses, strains, etc. of nodes and elements. Two different explicit loading profiles were applied to the prosthesis and the consequences over the liner were analyzed. Micromotions, maximum stresses, and deformations were measured.
1. *Gait Loading Profile.* To compute the behavior of the liner when subjected to full gait cycle, a gait loading profile was created and applied to the FE model described and validated. Perfect conformity between the liner and the femoral head was assumed. Gait model data was based on the published literature of hip muscle forces during gait.^[2,31,43] A time–force array was created based on the force data and input in the FE model. The liner-locking mechanism as well as the conformity between contacting surfaces follow the same pattern as described in the FE model (Fig. 10). The resultant forces applied at the center mass of the femoral head are shown in Fig. 11. The analysis was performed using LS-DYNA.
 2. *Impact Loading Profile (Subluxation).* Subluxation occurring in patients with THA has been

Fig. 10 Relative positions of the liner-locking tabs and the nodes that represent contacting points of the LVDT sensors.

studied *in vivo* using fluoroscopy techniques.^[25] Subluxation is studied in terms of the separation of the femoral head and the liner during abduction/adduction activities. The separation values ranged from $\Delta y = 0$ to 5.3 mm.

Most of the data provided highlight the axial separation (Δy , Fig. 12). Therefore, the values for the radial separation (Δx , Fig. 12) were calculated based on the condition that a portion of the femoral head always remains in contact with the liner. Δx values were calculated using simple trigonometric equations, ranging from $\Delta x = 0$ to 1.1 mm. The different subluxation cases with the corresponding values of Δx and Δy separation are shown in Table 3.

As depicted by Dennis et al.^[25] the average axial separation detected over all the studied patients was $\Delta y = 3.3$ mm. For this value, a radial separation of $\Delta x = 0.3$ mm was calculated. To create a pattern of study, 12 subluxation cases were considered with a displacement increment of 0.5 mm. An extrapolation was made to get results for the average separation case.

A loading profile was developed to simulate the effect of the relocation of the femoral head within the liner after subluxation occurred. For all subluxation cases, according to Mow et al. a maximum peak force of 2132 N was applied at an angle of 23.4° lateral and 5.7° posterior.^[32–35] The load was applied at the center of the dislocated femoral head. In all subluxation cases the time interval considered for the duration of the load was $\Delta t = 0.1$ sec. The magnitude and orientation of the input force were assumed constant during the analysis, owing to the small duration of the impact.

Certain conditions must be given as an input while performing a dynamic analysis, such as the initial

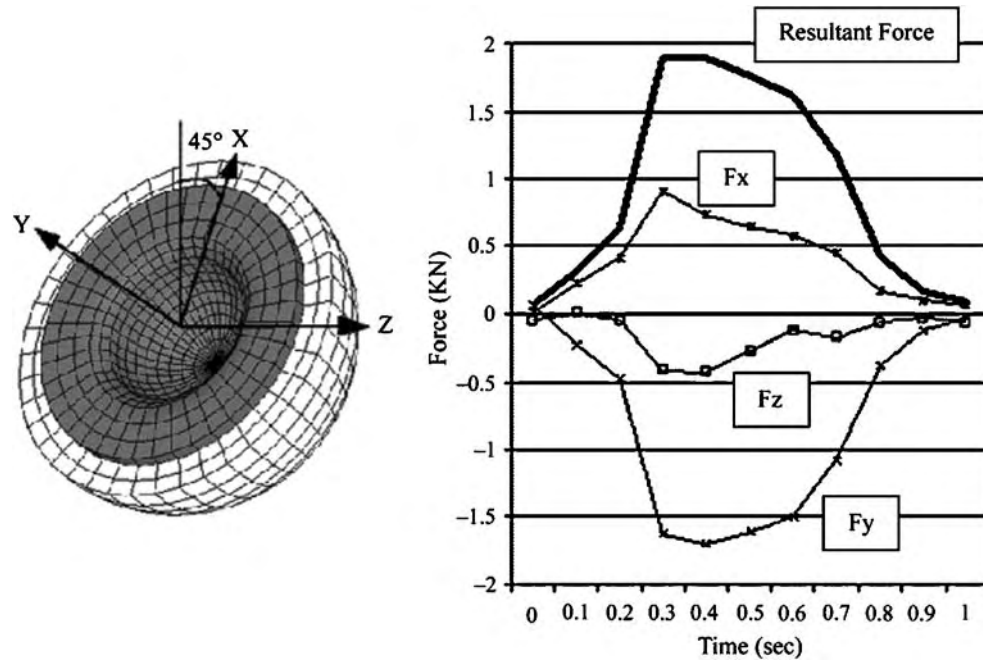

Fig. 11 Gait loading profile applied to the femoral head for the gait analysis.

velocity and acceleration of all the bodies involved in the problem. The analysis time Δt starts when the femoral head is moving backwards to relocate its position within the liner. Therefore, the initial velocity and acceleration was considered to be negligible. The same constrain conditions as described in the FE model were applied for this loading profile.

Experiment Results: Liner Micromotion and FE Model Validation

The maximum physiological loads experienced in the hip are within a range of 1700 to 2200 N. As described before in this study, the maximum load applied to each liner specimen during the validation experiment was 10,000 N, which is beyond the attainable force in the body. The objective of applying such load profiles was to determine the local deformation as well as the range

Fig. 12 Separation of the femoral head occurred during subluxation. Δx represents the radial separation and Δy represents the axial separation.

Fig. 13 Average micromotion values of the seven liner specimens analyzed for each LVDT sensor. The maximum micromotion values for the validation load range are S1 = 75.85 μm , S2 = 38.41 μm , S3 = 42.65 μm , S4 = 67.32 μm , S5 = 31.94 μm , and S6 = 77.02 μm .

at which there will be a jump in the deformation curve corresponding to permanent deformation.

The average results in terms of micromotions for the seven liners analyzed are shown in Fig. 13. To perform the FE model, validation loads were applied in the same fashion as it was done in the experiment. The force values applied in the FE model was restricted only to the force range from 0 to 1775 N. According to the experimental setup, the micromotion results corresponded to six specific points, where the sensors' tips came in contact with the liner. Those micromotion values did not depict the rigid body motion of the liner, but they serve as a reference when compared with the results obtained from the FE model. Those six points were identified in the FE model.

Because the LVDT sensors only measure displacements along their longitudinal axes, those directions were identified with simple trigonometric calculation in the FE model through superposition of the experimental axes. The micromotions (displacements) were computed in the FE model of the nodes positioned at the reference points, along the calculated direction. The micromotion results obtained in the FE analysis for the two different friction coefficients analyzed are shown in Fig. 14.

Gait Loading Results

During gait the liner is subjected to certain loading conditions that can lead to relative motion of the liner

within the acetabular cup (micromotion of the liner's back-side surface) and relative motion of the femoral head within the liner (micromotion of the liner's front side surface). The maximum micromotions occurring during a full gait cycle were computed for the front- and back-side surfaces of the liner at each of the time steps of the cycle. Table 4 shows those results.

To determine the areas where such micromotion occurred, a vector representation of the micromotion tracks at each step time is shown in Fig. 15, for back-side surfaces of the liner. In this figure, the micromotion tracks are represented as a series of drawings of the liner at each step time, accompanied with a general drawing of the FE model of the acetabular component to understand the spatial position of the liner with respect to the applied load. The arrows that appear in each liner represent the micromotion tracks at each element centroid.

Subluxation Loading Results

Twelve different subluxation cases were studied. Each subluxation case was defined by a certain separation of the femoral head with respect to the liner. The maximum stresses and micromotions occurred in the liner when the femoral head relocations within the liner (impact situation) were computed.

The period of time (Δt) for the application of the relocating load used in all subluxation cases was

Fig. 14 Micromotion results obtained in the FE model for two different friction coefficients.

viewed to be reasonable to capture the complete effects of impact. The average subluxation case ($\Delta y = 3.3$ mm, $\Delta x = 0.3$ mm) achieved a maximum stress of 44 MPa. In addition, the average stress results achieved for the average dislocation case was 17.5 MPa at $t = 0.015$ sec.

Fig. 16 represents the maximum stresses that occurred in the liner during the relocation process for the average subluxation case (total time $t = 0.1$ sec). The stresses occurred in the liner at three different time intervals of the average subluxation case. The first time step ($t = 0.015$ sec) represents the stresses in the instant the femoral head first impacts with the liner. The second time step ($t = 0.02$ sec) represents the bouncing of

the femoral head after the first impact. The third time ($t = 0.03$ sec) interval represents the second impact of the femoral head with the liner.

Computing the displacement of the nodes in the back-side surface of the liner, with respect to the nodes of the inner surface of the acetabular cup, allowed us to obtain the micromotion values and the wear vectors during impact relocation. The wear vector orientation are based on the micromotion tracks. The maximum micromotion achieved in the average subluxation case was 0.324 mm.

Similar to the gait loading case, it is important to consider the areas where the maximum micromotion

Table 4 Maximum micromotions occurred in the front- and back-side surface of the liner during gait loading profile

Load step	Time (sec)	Front-side micromotion (μm)	Back-side micromotion (μm)
1	0	31.2	12.1
2	0.1	33.0	23.7
3	0.2	39.0	34.2
4	0.3	82.4	81.7
5	0.4	108.72	92.2
6	0.5	138.78	97.1
7	0.6	154.8	102.8
8	0.7	169.38	117.58
9	0.8	180.45	121.22
10	0.9	178.11	107.92
11	1	175.95	101.22

occurred during the relocation process of the femoral head after subluxation. The way to observe graphically those areas is through the use of tracks (vectors) that represent the micromotion magnitude and orientation for each time step. Liner micromotion corresponds to the fourth subluxation case ($\Delta x = 0.081$ mm and $\Delta y = 1.5$ mm) at time $t = 0.02$ sec, moment at which the femoral head strikes the polyethylene liner for the first time. To have a better idea of the different solicitations to which the liner is subjected after subluxation, a comparison between the micromotion tracks in the subluxation analysis and the micromotion tracks in the gait analysis were also made. Fig. 14 shows an example of the micromotion tracks in the back-side of the liner's surfaces during gait ($t = 0.4$ sec).

During relocation, the micromotion tracks follow a steady path, while during gait it can be observed that at the points where the micromotion are higher, the micromotion tracks do not follow any specific path as evident as during relocation. The main reason for this behavior may be that during the relocation of the femoral head with the liner the impact force is much higher than the contacting forces that occur afterwards. Also, the orientation of the impact force is almost constant during the entire relocation process; therefore micromotion during relocation is mainly owing to one resultant force, which is constant in magnitude and orientation. During gait, the resultant force involved in the contact of the femoral head and the liner varies in magnitude and orientation. Therefore, there is not a main contributing load (in terms of magnitude and orientation) responsible for such micromotion tracks, creating an unsteady micromotion tracks distribution over the liner's surfaces.

FURTHER DISCUSSION OF THE RESULTS

Based on the micromotion values obtained experimentally for each liner specimen (Fig. 12), it can be observed that the sensors positioned perpendicularly to the outer flat surface of the liner (as shown in Fig. 16) recorded the most significant micromotion. The latter makes sense, because this is the direction along which the liner is less constrained.

The three sensors positioned perpendicularly to the side of the liner (Fig. 16) recorded very little micromotion. These micromotions were produced because of local deformations from the bulging effect of the polyethylene when subjected to compressive loads. In most of the cases the result obtained in the FE model, for both friction coefficients, are between the maximum and minimum values obtained in the experiment. Considering the average values for the experiment results (based on the maximum and minimum micromotion values), we can conclude that the FE model friction coefficient that better fit with those values is $\mu = 0.083$. The latter was the friction coefficient used for the remaining FE analysis in which contact was involved.

$$\begin{aligned}
 & \begin{bmatrix} S2_{T_{i+1}} & 0 & S6_{T_{i+1}} \\ 0 & S4_{T_{i+1}} & 0 \\ S1_{T_{i+1}} & S3_{T_{i+1}} & S5_{T_{i+1}} \\ 1 & 1 & 1 \end{bmatrix} \\
 & = \begin{bmatrix} \cos \theta_y & 0 & \sin \theta_y & T_x \\ \sin \theta_x \cos \theta_y & \cos \theta_x & -\sin \theta_x \cos \theta_y & T_y \\ -\cos \theta_x \sin \theta_y & \sin \theta_x & \cos \theta_x \sin \theta_y & T_z \\ 0 & 0 & 0 & 1 \end{bmatrix} \\
 & \times \begin{bmatrix} S2_{T_i} & 0 & S6_{T_i} \\ 0 & S4_{T_i} & 0 \\ S1_{T_i} & S3_{T_i} & S5_{T_i} \\ 1 & 1 & 1 \end{bmatrix} \quad (3)
 \end{aligned}$$

$$e = \cos \left[\frac{1}{2} (\theta_x + \theta_z) \right] \cos \left(\frac{1}{2} \theta_y \right) \quad (4)$$

Using the transformation matrix shown in Eq. (3) (T_i represents the position of the LVDT sensor tips at time i , and T_{i+1} represent the position of the LVDT sensor tips at time $i+1$), the rigid solid movements of the liner within the acetabular cup were computed (three rotations θ_x , θ_y , and θ_z and three translations T_x ,

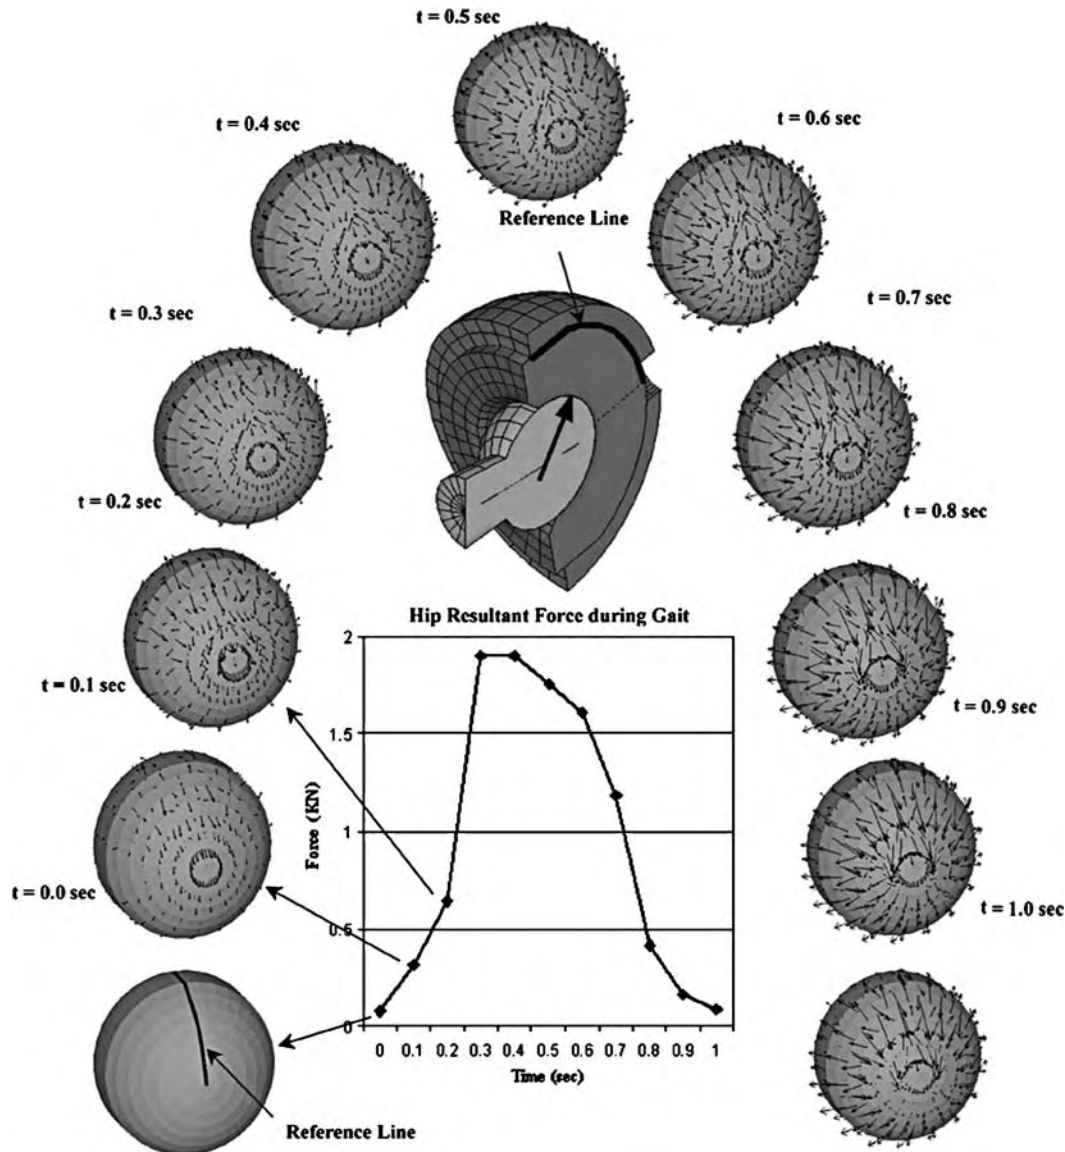

Fig. 15 Back-side liner micromotions vectors when subjected to gait loading profile. The graph represents the resultant force applied to the femoral head during gait. Reference line represents a reference on the liner position with respect to the resultant force.

T_y , and T_z). Using this transformation, Euler angles [Eq. (4)] and the vertical displacement of the liner were computed. Table 5 shows the Euler angle value, averaged for the seven-liner specimen, for the load range used in the validation process (0–1750 N). Table 5 also shows the displacement of the outer flat surface of the liner, which was computed based on the values given by Eq. (3).

From Table 5 it can be observed that the maximum rotation angle of the liner within the acetabular cup induced by the applied load is in every case lesser than 0.1° . Furthermore, the maximum vertical displacement of the outer surface of the liner is smaller than $30\ \mu\text{m}$. Both results demonstrate that the liner remains stable for the load range studied.

The maximum micromotion and stresses obtained during the relocation of the femoral head after subluxation appeared to be much higher than the ones obtained for the gait analysis. The maximum load applied in the subluxation case is a 12% larger than the maximum load applied during gait. However, the maximum micromotion during subluxation is almost three times larger than the one obtained during gait. Similarly, the maximum stress value during subluxation is almost seven times the stress value obtained during a full cycle of gait. Therefore, it can be speculated based on the results obtained, that during gait, the femoral head and the liner remain in contact at all times. However, during the relocation of the femoral head after subluxation, peak forces are achieved owing to the impacting conditions.

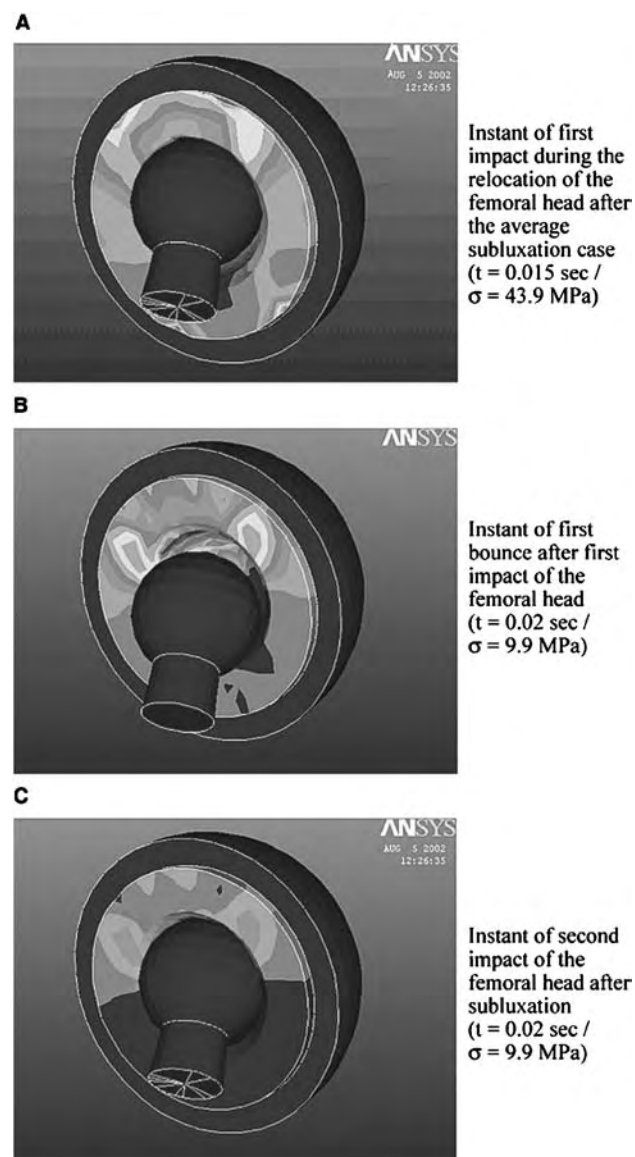

Fig. 16 Stresses occurred in the liner at three different time intervals of the average subluxation case. The first time step ($t = 0.015 \text{ sec}$) represents the stresses in the instant the femoral head first impacts with the liner. The second time step ($t = 0.02 \text{ sec}$) represents the bouncing of the femoral head after the first impact. The third time ($t = 0.03 \text{ sec}$) interval represents the second impact of the femoral head with the liner.

Past studies have described the loads applied to the hip joint in different activities such as gait, stair climbing, falling, and running. There is very little information on the loads generated in the relocation of the femoral head after subluxation. As previously described, the loading condition used for the subluxation cases correspond to a peak force of 2132 N. This is the force achieved in the hip joint at the moment when the leg strikes the ground during walking.

Table 5 Average rotation angle and vertical displacement of the liner within the acetabular cup

Load (N)	Euler angle ($^{\circ}$)	Rotational displacement (μm)	Vertical displacement (μm)
250	0.0141	8.11	1.02
350	0.0151	8.69	2.35

CONCLUSIONS

This article provided an overview into the biomechanics of the hip, focusing on the THA and the engineering and clinical problems associated with such a procedure. The clinical issues such as implant loosening, wear, impingement, and dislocation are described and illustrations are provided for each case.

This article also provides the modeling of the liner/cup interface and bone interface using the FE method and shows how such a tool can be used and validated with experimental data.

ACKNOWLEDGMENTS

The partial support of DePuy Orthopaedic is greatly appreciated. We also extend our gratitude and thanks to Francisco Romero at Biomechanics Research Laboratory (BRL) at UIC. We also like to thank Ivan Zivkovic for his technical assistance and the reviewers for their comments and valuable support.

Hip Joint: Overuse Injuries

Marko Pećina
Ivan Bojanić
Alan Ivković

Department of Orthopaedic Surgery, School of Medicine, University of Zagreb, Zagreb, Croatia

INTRODUCTION

Painful syndrome in the hip joint area is generally considered the most frequent overuse syndrome in some athletic activities, e.g., soccer. When considering the area and anatomic structures affected by overuse in the hip joint region, together with the locations and characteristics of pain, the location might be precise, but it could also be a case of diffuse vague pain in the groin region, small pelvis, and upper leg regions. The term syndrome is fully justified; indeed, the symptoms are numerous and so are the causes of pain in the locations mentioned. To understand the painful overuse syndromes in the hip joint area, one should bear in mind all the muscles that insert or originate in the hip region. These muscles are the abdominal group of muscles, adductors muscles, hamstring muscles, hip external rotator muscles, iliopsoas muscle, rectus femoris muscle, and others (sartorius, pyramidalis, cremaster muscles). In this entry we will describe the most important and the most frequent overuse syndromes in the hip joint area.

GROIN PAIN SYNDROME

The modern medical literature abounds with terms defining pain in the groin region: necrotic osteitis pubis, anterior pelvic joint syndrome, traumatic pubic osteitis, Pierson syndrome, gracilis muscle syndrome, pubic stress symphysis, pubic symphysis osteoarthropathy, symphysis, pubic chondritis, and post-traumatic necrosis of the pubic bone.^[1,2] These terms and expressions have commonly been used to describe adductor tendinitis, rectus abdominis tendinitis, avulsion injuries of the adductor tendons, postoperative changes without infection in the symphysis region, and a number of arthrotic changes. All of the above-mentioned terms clearly show that the painful groin syndrome cannot be attributed solely to one particular anatomic structure in the region but, rather, that the approach to the syndrome, in prevention, diagnosis, or treatment, should be based on the idea of multiple causative factors contributing to development of the

syndrome. It is precisely the approach we have assumed, although we distinguish between painful groin syndrome in a narrow sense and painful groin syndrome in a wider sense, for which “pain in the groin” seems to be a more appropriate term because the pain may arise from different pathological condition in and around the groin region. Painful groin syndrome in a narrow sense primarily implies tendinitis of the adductor muscles—the long adductor muscle and the gracilis muscle in the first instance, as well as the abdominal muscles, especially the rectus abdominis and pyramidalis muscles (see Fig. 1). Long-lasting tendinitis of these muscles may evolve into a general and vague picture of diffuse pain in the pubic bones and the symphysis region.

Groin Strain

This is the painful groin syndrome in a narrow sense. The cause of the painful groin strain lies in the disproportion between the strength of the abdominal wall muscles and the strength of the lower extremity muscles, as well as in an uneven load on all attachments in the symphysis and groin region. Groin strain is an injury or, more precisely, a lesion characteristically occurring in soccer players because the symphysis region is the point of attachment and the point of origin for groups of muscles with different functions, which are especially active during soccer playing. In addition to soccer players, these injuries have also been reported in ice hockey, water polo, handball players, fencers, high jumpers, bowlers, skaters, hurdlers, swimmers, and triathletes. Painful groin syndrome is characterized by pain in the inguinal and lower abdominal region. Often the pain develops gradually, and the athlete is unaware of its connection with any injury. As time goes by, the pain becomes more severe and irradiates into the upper leg adductor zone, the pubic region, and the perineum, spreading toward the hips and the anterior abdominal wall. The pain restricts certain motions during training and the game, especially reducing the speed of the player. Furthermore, the motion performed when entering or exiting a car may cause pain.

Fig. 1 Test for straight abdominal muscles: lift legs from the surface to form a 45° angle.

Similar to other overuse syndromes, painful groin syndrome is also characterized by specific developmental stages. In the most developed stage coughing, sneezing, defecation, urination, and sexual activity also cause pain in the groin. Clinical examination reveals pain during palpation of the pubic bone occurring above the gracilis and adductor longus muscle attachments. When testing adductors, the patient lies on his or her back with slightly abducted lower extremities so that the fist may be inserted between the knees (see Fig. 2).

The patient is then asked to hold the fist tightly by contracting the adductor muscles of the upper leg. The motion causes pain in the typical site of the upper leg adductor muscles attachment on the pubic bone. In tendinitis of the rectus abdominis muscles, pain following palpation appears in the region of the attachment to the ramus superior pubis. In a great number of patients, inspection of the abdominal wall reveals weakness of the oblique abdominal muscle. The so-called sausage and spindle-like prominences above the iliac crest and the inguinal ligament (in the literature commonly referred to as Malgaigne's sign) appearing during contraction of the abdominal muscles are also signs of abdominal wall weakness. Radiographic images of the pelvis, showing pubic bones, symphysis, and both hips, are necessary. These enable the physician to rule out arthrotic changes in the hip, stress fractures of the pubis ramus and pubic symphysis, pelvic avulsion injuries, and femoral stress fractures as causes of pain; it also enables rough analysis of the sacroiliac joints and the caudal segment of the lumbosacral spine (discogenic pain, spondylolysis). Radiologically identified changes in the symphysis and pubic bone may be classified into four stages that correspond to the developmental stages of the painful groin syndrome's clinical picture. Scintigraphy has proved highly valuable in the diagnosis. It helps to identify

stress fractures and avulsions in the pubic branch region. Ultrasound diagnostics are very useful in differential diagnosis of acute trauma from overuse injuries. If inguinal hernia is suspected as a cause of pain, herniography should be performed. Magnetic resonance imaging (MRI) is a valuable method for evaluating discrete and ambiguous pelvic pain in athletes.^[3] Treatment of the groin strain is as complex as the cause of its development. In our opinion, treatment should always commence with nonoperative procedures; only when these fail should strictly selective surgery be contemplated, i.e., depending on the cause of the syndrome. The following are some common principles of nonoperative treatment of painful groin syndrome regardless of its cause: alleviate pain and control inflammation in the myotendinous apparatus; hasten healing of the myotendinous apparatus, and control further activities. We emphasize that it is of utmost importance to commence treatment as early as possible, i.e., when the first symptoms occur. Not paying attention to initial symptoms and continuation with athletic activity of the same intensity are the most common mistakes. Nonoperative treatment consists of local cryotherapy, anti-inflammatory nonsteroidal medications, stretching and strengthening exercises,

Fig. 2 Test for determining tenderness of the adductor muscles.

and some authors recommend local corticosteroid injections. Athletes with weak abdominal muscles should work on strengthening the muscles. Generally speaking, the purpose of rehabilitation is to preserve the strength, elasticity, and contractual abilities of the tissues along with the improvement of mechanical and structural characteristics of the tissues. At the stage when isometric training may be performed without pain, dynamic strength training may be introduced. Isokinetic training is actually the best, although it requires special equipment (Cybex). At the end of rehabilitation athletes may return to their specific training. The common error is that many tend to resume full athletic engagement too soon, which may necessitate repeating the treatment. Operative treatment of painful groin syndrome, to a certain extent, depends on the attitude in approaching this complex problem. Authors who consider tendinitis the most important feature of the syndrome recommend operative treatment in terms of desinsertion, i.e., cutting (tenotomy) of the adductors, gracilis, rectus abdominis, pyramidalis, and other muscles. Authors who believe that painful groin syndrome is primarily caused by disproportion in strength between the abdominal wall muscles and the upper leg muscles, especially emphasizing weak abdominal muscles (oblique and transverse abdominal muscles in particular) recommend surgical strengthening of the anterior abdominal wall by the old or new methods applied for inguinal hernia. We agree with the opinion: "It is fairer to enrich the poor than to impoverish the rich," meaning that it is better to strengthen or support the abdominal muscles than to weaken the adductor muscles by tenotomy. Nevertheless, on the basis of our experiences, we have realized that sometimes the muscular balance may be achieved only by a combination of "enriching the poor and impoverishing the rich." It should be pointed out that when discussing treatment of painful groin syndrome, whether nonoperative or operative, the approach should always be individualized. In this regard, it should be emphasized that procedures may and should be combined and there is no unique scheme for painful groin treatment. Prevention is of utmost importance, especially in young athletes.

Osteitis Pubis

The term osteitis pubis indicates that inflammatory changes are taking place, although in the majority of cases, no causative agent has been isolated. A number of different terms have been used in the past with the purpose of avoiding the connotation of inflammation (e.g., osteitis necroticans pubis, syndroma rectus-adductor, traumatic inguino-leg syndrome, anterior

pelvic joint syndrome, groin pain in athletes, osteoarthropathy of the pubic symphysis, traumatic pubic osteitis, etc.). Osteitis pubis was first reported in an athlete (fencer) in 1932 by Spinelli, and after that it has been reported in soccer players, football players, long distance runners, and long distance walkers.^[4,5] Osteitis pubis is seen particularly in those sports requiring sprinting and sudden changes of direction. The patients complain of pain in the lower abdomen and in the groin, but cannot link it to any known injury. At a later stage, the pain spreads in a fan-like manner into the adductor region. The principal characteristics of the pain are that its onset is linked to the athletic activity, then it diminishes and gradually disappears upon resting. The pain may also occur or become more intense when coughing, sneezing, or laughing. Palpations during clinical examination cause pain along the pubic bone and the symphysis itself. Radiography of the pelvis shows no changes in the initial phase of the disorder, but later on, the alterations are visible in the symphyseal region (fraying and sclerosis).^[6] Scintigraphic scan shows increased bilateral accumulation of radionuclides around the pubic bone even in the initial stage of the disease. Scintigraphy helps in differential diagnosis, because in the case of avulsion or stress fracture in the pubic branch region, the accumulation of radionuclides is unilateral. In the case of a negative scintigraphic scan and positive clinical signs, adductor longus and rectus muscle tendinitis is usually in question. The increased signal intensity seen on MRI is due to pubic bone marrow edema, such that an association exists between the clinical features of osteitis pubis and the MRI finding of pubic bone marrow edema. The treatment recommended is reduced athletic activity or complete rest if the pain is too severe. Some authors recommend symphyseal corticosteroid injections as a useful technique for treatment of osteitis pubis in athletes.^[7,8] Prospects for recovery in athletes with osteitis pubis are very good. When athletic activities are avoided, the disease subsides spontaneously. However, the duration of the recovery process may be variable. Mulhall et al. reported an outcome with symphyseal curettage in cases refractory to conservative management of osteitis pubis in professional soccer players.^[9] Williams, Thomas, and Downes treated operatively rugby players with osteitis pubis and vertical instability at the pubic symphysis.^[10] Operative treatment consisted of arthrodesis of the pubic symphysis by bone grafting supplemented by a compression plate.

ILIOPSOAS TENDINITIS AND BURSITIS (PSOAS SYNDROME)

Iliopsoas muscle tendinitis is caused by frequent repetitive flexions in the hip joint. It is the cause of

anterior hip pain and anterior snapping hip in weight lifters, skiers, oarsmen, football players, long and high jumpers, and hurdlers. Bursitis of the iliopsoas is more common in gymnasts, wrestlers, and uphill runners.^[11,12] The principal clinical sign is pain in the groin region on the anterior aspect of the hip joint, in the small pelvis, and sometimes in the back as well; this is accounted for by the fact that tendinitis and bursitis of the iliopsoas develop as a result of hypertonic muscle and prolonged strain as a consequence of disturbed biomechanical relations in the lumbar spine and in the hip joint. Initially, the pain is mild in intensity, but the repetitive strain makes the pain increasingly intense to the degree that athletic activity becomes impossible. Often the athlete cannot find the link between the pain and injury. Palpation of the tendinous attachment to the small trochanter causes pain. During flexion of the upper leg in the hip joint against resistance, pain occurs at the point of the muscle attachment (see Fig. 3). The motion should be attempted in a sitting position because then the iliopsoas muscle is the chief and only flexor of the upper leg in the hip joint. Between the iliopsoas tendon and the anterior aspect of the hip joint articular capsule, there is a nut-sized synovial sac (bursa); when irritated, it produces a clinical picture of a typical bursitis with pain during and after the athletic

Fig. 3 Test for iliopsoas muscle function.

activity. In differential diagnosis of the iliopsoas tendinitis and bursitis should be considered: tendinitis of the adductor longus muscle and rectus femoris muscle; rupture and avulsion of the iliopsoas muscle, rectus femoris muscle, and adductor longus muscle; and labrum lesion of the hip joint. In addition to clinical diagnosis, radiographs and ultrasound should be taken and MRI especially in patients with clinical suspicion of labral lesion of the hip joint.^[13] Tendinitis and bursitis of the iliopsoas muscle are treated nonoperatively. The conservative treatment depends of the stage of the disorder. During the initial stage training should not be completely discontinued but only reduced in intensity, but at the later stage, a rest period of 3–4 weeks is necessary. During this time, the athlete may engage in substitute activities (swimming, bicycling). The anti-inflammatory nonsteroidal drugs are administered orally and Renstrom and Peterson recommend an additional local infiltration of corticosteroids followed by a 2-week rest.^[14] The stretching and strengthening exercises may be introduced, although care should be taken that the patient feels no pain.

TENDINITIS OF THE RECTUS FEMORIS MUSCLE

Tendinitis of the rectus femoris muscle usually occurs as a result of prolonged, repetitive, and a sudden increase in strengthening exercise training or intensive goal-shooting training, e.g., in soccer. The athlete feels pain in the region above the hip joint at the point where the rectus femoris muscle attaches anteriorly and inferiorly to the iliac spine. Pain appears on palpation of rectus femoris muscle tendon attachment and can be also provoked by resisting upper leg flexion and lower leg extension. In differential diagnosis, the following should be taken into consideration: rupture or avulsion of the rectus femoris muscle or iliopsoas muscle, tendinitis of the iliopsoas muscle or adductor longus muscle, stress fracture of the femoral neck, changes in the hip joint such as arthrosis, osteochondritis dissecans, loose body in a joint, or bursitis.^[14,15] Calcific tendinitis at the site of origin of the rectus femoris muscle is a rare lesion.^[16] Pain in the groin region may develop as a consequence of the rupture at the attachment point or in the proximal third of the rectus femoris muscle. At the moment of injury, the pain is so severe that the athlete is compelled to discontinue activity, while in tendinitis of the rectus femoris muscle the athlete is unable to associate the onset of pain with an injury. Ultrasound will confirm the diagnosis and enable evaluation of the severity of injury (see Fig. 4). Radiographs should also be taken to rule out bone avulsion. Complete rupture, especially if in combination with avulsion fracture, is treated

Fig. 4 Sonogram showing rupture with hematoma (black arrow) of rectus femoris muscle during contraction.

operatively.^[17] Partial rupture is treated non-operatively: RICE (rest, immobilization, compression, elevation) and nonsteroidal anti-inflammatory medication are prescribed. Rehabilitation in terms of strengthening the muscles may begin when pain and swelling disappear. Treatment of rectus femoris muscle tendinitis is very similar to treatment of tendinitis of the iliopsoas muscle.

HIP EXTERNAL ROTATOR SYNDROME

The external hip rotator syndrome is rare, but a complicated problem, with regard to both diagnosis and treatment.^[18] It is most frequently found in hurdlers and ballet dancers where the symptoms consist of a vague pain in the buttocks and the greater trochanter area. The inflexibility of the hip external rotators, primarily the piriformis, gemellus superior, and gemellus inferior muscles, together with the internal rotation contracture of the hip, is thought to lead to chronic overuse of these muscles. Tendinitis of the quadratus femoris muscle is described as a separate entity.^[19] To locate the exact area of the pain, the upper leg is maximally and externally rotated during physical examination; pressure is applied to the greater trochanter area (fossa trochanterica), producing intense pain. Differential diagnosis must take into account the possibility of piriformis muscle syndrome and trochanteric bursitis, which can be confirmed by ultrasound. Piriformis muscle syndrome is based on the anatomical relationships of the muscle and the sciatic nerve; direct and indirect trauma, muscular hypertrophy or anatomical nerve variations, inflammation, and local ischemia probably combine to induce the piriformis muscle syndrome.^[20-22] Frequently,

diagnosis of piriformis syndrome requires eliminating the other causes of sciatic pain. Nonoperative treatment of short external hip rotator syndrome is based on stretching exercises for the afflicted muscle groups and neighboring muscles, with the aim of increasing their flexibility and concurrently the flexibility of the whole hip. Other nonoperative measures include rest, ice, and nonsteroidal anti-inflammatory drugs. Steroid injections can also be administered.

GLUTEUS MEDIUS SYNDROME

Gluteus medius syndrome is caused by overuse and inflammation of the gluteus medius muscle or of the sciatic nerve, which is immediately adjacent. The pain involves the buttock, lateral hip, groin, or the sacroiliac joint. The patient may also report dysesthesia and numbness in the buttock or posterior aspect of the thigh. Prolonged sitting may exacerbate pain. Activities with high hip abductor demand have been associated with gluteus medius syndrome, especially martial arts, cycling, aerobics, and dancing. During physical examination, hip abductor strength should be compared with the contralateral extremity. A full neurological exam is essential to rule out neurological causes. Palpation in the buttock region and over the gluteus medius muscle can discover trigger points or tenderness to palpation on or around the muscle.^[23] Other physical findings in gluteus medius syndrome may include limited stretch range of muscle, presence of a taut, palpable band in muscle, and referred pain produced by direct palpation of trigger points. Magnetic resonance is the imaging technique of choice in differentiating the cause of hip pain in athletes. Differential diagnosis of the gluteus medius syndrome includes sciatica, radiculopathy, greater trochanteric bursitis, iliotibial band syndrome, quadratus femoris tendinitis, sacroiliac joint dysfunction, and especially piriformis syndrome, but also pelvic compartment syndrome.^[19] Stretching exercises of the gluteus medius, gluteus maximus, and gluteus minimus and the piriformis muscle are recommended in conservative treatment of the gluteus medius syndrome. Physical therapy program includes cold packs, ultrasound, and other modalities. Injection with anesthetics and corticosteroids has been diagnostic as well as therapeutic. In rare cases, surgical debridement of a chronic tendinosis is an available option.

SNAPPING HIP SYNDROME

Snapping hip syndrome is a symptom complex characterized by an audible snapping sensation, which is usually, but not necessarily, associated with pain

Table 1 Different snapping hip syndromes

Localization	Etiology
Medial (internal)	Iliopsoas tendon over iliopectineal eminence
	Iliofemoral ligament over femoral head
	Iliopsoas tendon over the anterior-inferior iliac spine
	Iliopsoas tendon over the bony bridge on the lesser trochanter
Lateral (external)	Iliotibial band over the greater trochanter
Posterior	Tendinous origin of the long head of the biceps femoris muscle

during certain movements of the hip joint. A number of different etiologies, both intra-articular and extra-articular, have been described.^[24] Intra-articular causes for the snapping hip include loose bodies, osteocartilaginous exostosis, osteochondromatosis, and subluxation of the hip. The most frequent extra-articular cause of the snapping hip is the snapping of the iliotibial band over the greater trochanter. There are other extra-articular etiologies of the snapping hip. These include the snapping of the iliopsoas tendon over the iliopectineal eminence of the pelvis, the iliofemoral ligaments, the femoral head, and the tendinous of the origin of the long head of the biceps femoris muscle over the ischial tuberosity. Taking into account the localization of the cause for snapping hip, we recognize three different snapping hip syndromes: medial (internal), lateral (external), and posterior (see Table 1).^[1]

Medial snapping hip syndrome is frequently found in ballet-dancers.^[25] The snapping of the iliopsoas tendon occurs when the hip is extended from a flexed, abducted, and externally rotated position. In addition to an audible snapping sound, this movement is also, in some cases, accompanied by a painful sensation in the frontal hip area. Differential diagnosis includes consideration of psoas muscle syndrome, which consists of psoas bursitis, enthesitis, and tenosynovitis of the iliopsoas muscle. Nonoperative treatment of medial snapping hip syndrome consists of reduction or temporary cessation of painful activities and movements, nonsteroidal anti-inflammatory medication, and stretching exercises.^[26] Surgical treatment is very rare and consists of resection of the lesser trochanter bony prominence and/or partial or total release of the iliopsoas tendon. Lateral snapping hip syndrome is the most frequent and the best known. It is caused by the slipping of the iliotibial band over the posterior part of the greater trochanter and is frequent in runners, dancers, and basketball players.^[26] It can be asymptomatic or accompanied by pain, which is especially intense in those cases that develop trochanteric bursitis. In addition to the audible snapping phenomenon, the symptomatic form is characterized by pain in the region of the greater trochanter, which sometimes radiates to the buttock and/or lateral thigh. The

snapping can be best observed by placing the palm of one's hand on the greater trochanter area of the patient during walking. Another maneuver that will consistently reproduce the patient's symptoms is to have the patient stand on the healthy leg and imitate running motions on the affected side. The most common cause of the slipping of the iliotibial band over the greater trochanter is its excessive tightness (shortening), which can result from leg length discrepancies, pelvic tilt, or certain activities such as habitual running on the side of the road. Tightness of the iliotibial band is diagnosed using Ober's test (see Fig. 5).

Excessive tightness of the iliotibial band causes greater friction between the band, the greater trochanter, and the bursa that is normally located there; this in turn leads to chronic trochanteric bursitis. Characteristic symptoms of this bursitis include intense pain in the greater trochanter area and limping. Conventional sonographic studies can identify signs of tendinitis, bursitis, or synovitis. Dynamic sonographic studies reveal the cause of snapping hip in most patients.^[21] Nonoperative treatment of lateral (external) snapping hip syndrome consists of rest, avoidance of painful movements, iliotibial band stretching exercises, strengthening of the hip flexors, buttocks, hamstrings,

**Fig. 5** Ober's test for assessing the flexibility of the iliotibial band.

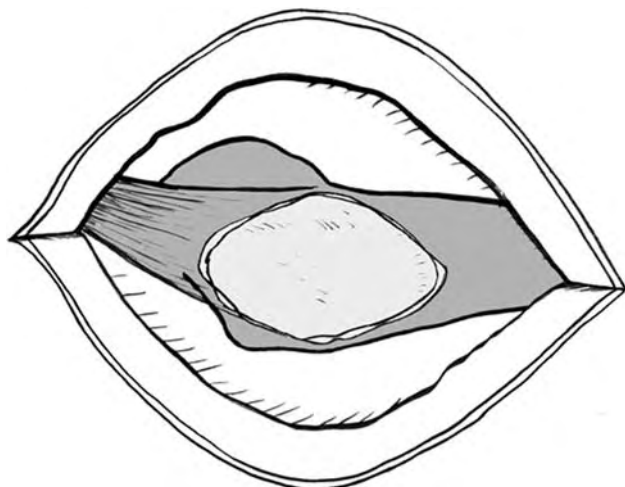

Fig. 6 Elipsoid excision of the iliotibial band overlying the greater trochanter.

hip rotation muscles, and quadriceps, nonsteroidal anti-inflammatory medication, and correction of the disturbed biomechanical relationships of the lower extremities (arch supports, adequate shoes, etc.). Injection of local anesthetics and soluble corticosteroids is also sometimes effective.^[27] In refractory cases surgical treatment is indicated. Numerous operative procedures have been described. We have successfully used the operative procedure described by Zoltan, Clancy, and Keene in our patients.^[28] We have termed this procedure fenestration of the iliotibial band (see Fig. 6).^[24]

Posterior snapping hip syndrome is caused by snapping of the tendinous origin of the long head of the biceps femoris muscle over the proximal part of the ischial tuberosity. Rask has described cases in which the subluxation of this tendon was accompanied by an audible snapping sound, a condition that he termed snapping bottom.^[29] Differential diagnosis must include consideration of developed bursitis in this area and enthesitis of the tendon, which we classify as part of the hamstring syndrome. Treatment is usually nonoperative.

HAMSTRING SYNDROME

Hamstring syndrome is a condition that affects muscles of the posterior thigh, primarily biceps femoris, semimembranosus and semitendinosus muscles. It is frequent in sprinters, hurdlers, and both long and high jumpers, but can also be found in other athletes, especially those who engage in rapid acceleration and short, intense sprinting, such as baseball players, football players, tennis players, water-skiers, dancers, and others.^[30-32] Hamstring syndrome is caused either by the overuse of the muscles at their insertion on the

ischial tuberosity or by the partial or total rupture of an individual muscle. The biceps femoris is the most commonly injured hamstring muscle and the semitendinosus is the second most commonly injured. Although hamstring injuries often involve one muscle injured proximally, multiple muscles were involved in 33% of athletes and the injuries were distal in 40% of athletes. All intramuscular injuries occurred at the musculotendinous junction, either in the ends of the muscle or within the muscle belly.^[33] Hamstring syndrome is a very common sports injury and numerous studies have been devoted to determining the causative factors and possible preventive measures of this typical self-induced injury. One of the reasons for this attention is the well-documented propensity of this syndrome to recur (as epitomized by the old saying “once a strain, always a strain”). Most authors today agree that the basic cause for the development of hamstring syndrome is muscle strength imbalance between the hamstring muscle group and the quadriceps femoris muscle. Hamstring syndrome will develop, in various forms, when there is relative weakness of the hamstring muscle group in relationship to the quadriceps femoris muscle. Studies have indicated that the hamstring muscles should have at least 60% of the strength of the quadriceps in athletes. Hamstring syndrome can also develop as a result of strength deficit between the right and left hamstring muscle groups. A 10% or greater muscle strength deficit between the two sides is also thought to be a predisposition for hamstring strain. In addition to the relative or absolute weakness of the hamstring muscles, another and fairly frequent cause of hamstring syndrome is decreased flexibility of these muscles. The flexibility of the hamstring muscles is determined by a number of individual characteristics, including sex, age, type and duration of athletic activity, and the specific type of training programs (during the season and off-season).

Flexibility of the hamstring muscles is commonly measured by Well’s “sit-and-reach” test (see Fig. 7). A more appropriate test for the flexibility of the hamstring muscle group has been described by Wallace (see Fig. 8). Aided by various types of testing equipment, of which the Cybex II is the most commonly used, the strength of the hamstring muscle and the hamstring-to-quadriceps muscle strength ratio are isokinetically determined. This test also allows evaluation of the muscle strength torque curve, which typically decreased in size.

Clinical features of hamstring syndrome that have resulted from overuse of the hamstring muscles at the point of their insertion at the ischial tuberosity include constant pain in the lower gluteal area, which radiates down the posterior thigh to the popliteal area. The pain typically increases during the performance of forcible or sudden movements, which stretch the

Fig. 7 Sit and reach test.

hamstring muscles. Another characteristic complaint is pain felt while sitting, e.g., while driving a car or sitting during lectures. The pain is often relentless, causing the patient to change position or stand up for relief. During physical examination, the pain can be reproduced by applying pressure to the ischial tuberosity area. Various clinical tests that cause the stretching of the hamstring muscles also induce pain at the site of the ischial tuberosity (Well's and Wallace's tests). Pećina and Bojanić use the more exact "shoe wiping" test, which consists of having the patient imitate movements typically used when wiping shoes on a doormat.^[1] The hip and knee are in a position of maximal extension while the hamstring muscles are in retroflexion in the hip. While performing these movements, the hamstring muscles are stretched and, at the same time, in motion, which gives an additional value to this test; this enables the patient to score positive even when scoring negative on other tests. A positive score is indicated by pain in the ischial tuberosity area or along one of the hamstring muscles. Any diagnosis of hamstring syndrome should include a neurological examination because differential diagnosis includes ruling out the possibility of spinal sciatica. Radiological, electrodiagnostic, CT, and MRI examinations can be used to achieve this. Piriformis syndrome presents a special problem in differential diagnosis.^[34] Magnetic resonance imaging is very helpful in detecting the site, extent, and characteristics of the injury, and can also predict the time period an athlete will be disabled and help decide the best treatment planning.^[33] Treatment of the hamstring syndrome can best be summarized with the old saying "the best treatment

is prevention." Treatment of hamstring syndrome that has developed as a result of overuse injury is usually nonoperative. It consists of a rehabilitation program of stretching exercises and strengthening of the hamstring muscles. Physical procedures commonly applied to

Fig. 8 Wallace's sign.

all chronic overuse syndromes are also applicable. Surgical treatment as recommended by Puranen and Orava consists of cutting and dividing the tendinous tissue near the site of origin of the hamstring muscles without loosening the muscles from the ischial tuberosity.^[32] After division, the tendon ends should be completely separated from each other. The sciatic nerve must also be freed from any tendinous parts of the hamstring muscle. According to Kujala, Orava, and Jarvinen after first aid with rest, compression, cold, and elevation, the treatment of hamstring muscle injury must be tailored to the grade of injury (slight, moderate, severe).^[35] Urgent surgical treatment is recommended in cases with total or nearly total soft tissue hamstring muscle insertion rupture.^[36]

CONCLUSIONS

In sports traumatology the hip joint pathology is not as abundant as it is in the rest of the orthopedic surgery. Nevertheless, the presence of numerous structures such as muscles, tendons, or synovial bursas in the pelvic region and hips, along with great dynamic and static forces exerted during physical activity, makes it prone to numerous athletic injuries. In contrast to the knee joint, which is known for acute injuries, the hip joint is particularly prone to overuse injuries and syndromes. Painful syndromes belonging to the overuse group are generally considered the most frequent in some athletic activities, e.g., soccer; however, neither the site nor the pain are precisely defined. Because of this these injuries are easily overlooked or not treated correctly. Therefore, it is of utmost importance to be familiar with the principles of epidemiology, etiology, pathophysiology, and diagnostics principles to treat the patients successfully and without recidives, which are not uncommon. The main treatment for hip overuse injuries is rest from the offending athletic activity, a concept known as “relative rest.” In the rare occasions when conservative treatment fails, surgical treatment is advised.

Histogenesis

Julie Glowacki

Department of Orthopedic Surgery, Brigham and Women's Hospital, Harvard Medical School, and Harvard School of Dental Medicine, Boston, Massachusetts, U.S.A.

INTRODUCTION

Histogenesis, or the formation of tissue, is accomplished by cells in various normal and pathological settings. Attempts to use new ideas of regenerative medicine and bioengineering to replace missing or lost parts rely on information gathered from different sources. Research in developmental biology shows that many species use the same genes to regulate the complex steps involved in tissue formation. Cell–cell interactions and cell–matrix interactions play critical roles in tissue formation both in embryogenesis and in wound healing. One of the best approaches to designing tissue replacements is to understand the processes of histogenesis during embryogenesis. Progress has been made by identifying factors that account for derangements of embryogenesis in mutant and recombinant mice and in clinical malformations. In-vitro models of histogenesis have used adult somatic cells and putative stem cells to identify the key elements in growing and maintaining tissues.

Tissue engineering offers the potential for consistent and practical management of patients in need of replacement tissues. Tissue engineering includes both cell-free and cell-based approaches. With cell-free therapies, agents or materials are introduced to stimulate the body to recapitulate the process of controlled tissue growth and maintenance. With cell-based therapies, manipulation of autogenous cells with signals provided by a scaffold or accompanying factors may require an intermediate in-vitro phase or proceed directly to reconstruct the missing volume in vivo. One challenge is to apply the growing body of information about normal and pathological processes for controlled therapeutic applications. The goal is to apply first principles from multidisciplinary approaches into rational design solutions. The translation of basic science knowledge to regenerative medicine is in its infancy and is likely to encounter many shifts as innovative ideas for modifiers of histogenesis are discovered and integrated into therapeutic possibilities.

TERMINOLOGY

The term histogenesis is derived from the Greek roots *histon*, meaning web or tissue, and *genesis*, meaning

generation or production. Its literal definition is given as “the formation and differentiation of tissues.” It may be more useful to separate the two processes into histodifferentiation and histogenesis. Thus, histodifferentiation refers to the process in which apparently indifferent, or unspecialized, groups of cells attain the distinctive features of adult form and function. Early stages of embryonic development are often characterized by the morphological appearance of recognizable tissue types, i.e., histomorphogenesis. Once the first signs of a specialized tissue type appear, further increase in the mass and form of the tissue is possible by its hypertrophy, or growth. Thus, histogenesis would indicate the accrual of more tissue mass of the specific differentiated type. The distinction between these two terms becomes especially useful in discussing the mechanisms and regulation of tissue repair processes. Histonomy, incorporating the Greek root *nomos* for law, consolidates the two processes into the laws that govern development and structure of tissues.

Histology deals with the microscopic structure of plant and animal parts and morphological evidence of their functions. It is usually restricted to light microscopic methods. Various techniques are used to gain information about tissue functions, including histochemical, histoenzymatic, and immunohistologic localization of specific molecular components. Histophysiology is the science that integrates the microscopic features of tissues in relation to tissue function. Histopathology is the science of disease states as they evidence themselves in tissues. New methods, such as in situ hybridization, offer powerful means to identify cellular markers. Gene transcripts that are not plentiful can be amplified and detected by RT-PCT/in situ hybridization. Alternatively, laser capture microdissection, or manual collection of specific cells with micromanipulators, can be used for identification of DNA or messenger RNA molecules within tissue sections or to compare cells or regions in tissues.

HIERARCHY

A histioblast is the generic term for a cell capable of forming a tissue. Classical usage reserves the term histiocyte for fixed or wandering macrophages within tissues and the term histoblast for certain epithelial

cells in insect larvae. Specialized histioblasts produce the characteristic tissue, for example, fibroblasts, osteoblasts, angioblasts, hepatoblasts, and neuroblasts. The suffix *-cyte* is often restricted to the mature cell that appears to be terminally differentiated and involved in the tissue function, but without conspicuous activity in synthesizing more tissue. One notable exception to this distinction between *-blast* and *-cyte* is the term *fibroblast*, which is used for both the cells producing fibrous tissue as well as the stromal cell residing in mature connective tissue; *fibrocyte* is rarely used. Another notable conventional usage is the term *chondrocyte*, which is used for both the cell producing cartilage tissue and the cell residing in cartilage; *chondroblast* is rarely encountered. There is no logic for these exceptions.

A tissue is an aggregate of cells that are specialized to perform a certain function. Tissue types can be organized on the basis of their primary functions (Table 1). There is some overlap in functions, but an extreme case is found with bone tissue.^[1] As a tissue, bone furnishes important mechanical properties to the skeleton. The mechanical roles of the skeleton are to provide support of the organism, locomotion, and protection of vital organs, such as the brain and heart. These mechanical demands require stiffness to resist large forces. The mechanical character is exquisitely achieved by the biphasic nature of the extracellular matrix, containing an organic component, largely collagen, and inorganic calcium phosphate mineral in the form of poorly crystalline carbonatohydroxyapatite. The metabolic role of bone is its contribution to calcium homeostasis. The extracellular mineral can be mobilized when calcium needed for vital bodily functions such as clotting of body fluids, neuromuscular irritability, growth and regeneration, maintenance of mucous coverings, intercellular contacts, and ameboid and ciliary motion. Bone's role in calcium metabolism is accomplished by the integrated activities of its three cell types: the osteoblast, osteocyte, and osteoclast, each directly or indirectly regulated by the three major calcitropic hormones: parathyroid hormone, 1,25-dihydroxyvitamin D, and calcitonin. Of note, the mechanical function can be sacrificed, to the devastating extent of risk for fracture, in situations of

Table 1 Types of tissue functions

Function	Examples
Structural	Connective tissue, muscle, bone, cartilage, epidermis, dermis
Metabolic	Pulmonary, hepatic, renal, pancreatic, gastrointestinal, blood, marrow, bone
Circulatory	Myocardium, vascular
Sensory	Neural, ocular

calcium deprivation, such as rickets, osteomalacia, osteoporosis, and aging. Processes are designed to ensure that calcium homeostasis is maintained as stored calcium is removed, without a failsafe limit, by resorption of bone matrix and reduction of new bone formation.

A simple tissue may be made of a single cell type, for example, cartilage. Cartilage comprises cells called chondrocytes and an extracellular matrix of fibrillar collagen type II, highly charged molecules of aggrecan, and water. It is avascular and has no nerves. Cartilage tissues function as a lubricating surface in joints and as a temporary (and readily resorbed) scaffold for bone formation.

Epithelial tissue may be simple or complex, but is usually bounded by basement membrane. Most tissues, however, consist of several cell types. Connective tissues, for example, include blood vessels, nerves, and specialized tissue cells, such as osteocytes, myocytes, or tenocytes. Connective tissues often have a large amount of extracellular matrix whereas other tissue types often have a high cell-to-matrix ratio. Thus, tissues constitute the level of organization between that of cells and organs.

An organ is a structure comprised of two or more tissues that are organized to carry out a specific function, e.g., kidneys, lungs. Development of organs involves the integrated activities of different cell and tissue types. Patterning is far more complex in organogenesis than in histogenesis. Skin can be considered either an organ or a tissue depending on the context. Likewise, bone can be discussed as a tissue or as a specific organ, e.g., femur, mandible. Authors generally attempt to avoid confusion in readers by specifying which level is intended.

TISSUE COMPLEXITY AND VARIABILITY

In unicellular organisms, specialized functions occur in different compartments. Mitochondria, for example, efficiently organize energy metabolism. Development of multicellular organisms directs the expression of specific phenotypes for different cells and patterning for histogenesis and organogenesis. The generation of cellular diversity is called differentiation.

It is insufficient to characterize a tissue type on the basis of generalized constituents and organization. A tissue type can display an array of arrangements in order to realize distinct properties. For example, skeletal muscle tissue anatomy is variable and highly dependent upon the energy requirements of the specific musculotendinous organ. The basic motor unit includes a peripheral nerve, the myoneuronal junction, and the muscle fibers innervated by that nerve cell. Each muscle fiber is a multinucleated syncytium

formed by the fusion of myoblasts during development. Histologically, groups of muscle fibers are enclosed by a fibrous epimysium and packed with endomysium through which neurovascular bundles course. Different types of sensory fibers serve as receptors of the stretch reflex, proprioception, vibration, and pain. Red and white skeletal muscle fiber types demonstrate an extreme range of function, the former with relatively slow contraction, but slower to fatigue. Examples of the red type are the intercostal muscles, masticatory musculature, and muscle of the eyeball. The red are thinner than the white fibers and more richly vascularized. White fibers compose the muscles of the extremities. Thus, it is evident that discussions of muscle tissue and its design requirements need to specify the precise function needed.

Another example of the wide variety of tissue arrangement is presented by bone tissue. Bone displays a variety of gross and histological patterns. At the macroscopic level, it can be compact, as in the cortical tubes in the midshafts of long bones, or more porous, as in the cancellous, often marrow-containing, inner portion of vertebrae, flat bones, and ends of long bones. Microscopically, human cortical bone shows a complicated pattern of osteons, or units, with a central vascular canal and radiating capillaries within concentric rings of matrix and network of intercommunicating osteocytes. This contrasts with the thin trabecular arrangement of cancellous bone. These arrangements result in different mechanical properties^[2] and metabolic^[3] consequences. Strength and stiffness differ in cortical bone depending on the direction of measurement. This is termed mechanical anisotropy. Whereas the bone is required to provide strength, it needs to be remodeled and renewed for rejuvenation of both its mineral and organic components.^[4] This is achieved by focal tunneling and refilling, or remodeling, within the tissue. Remodeling is visible histologically as cutting cones with osteoclasts at the advancing tip and a layer of osteoblasts and a capillary in the process of laying down concentric lamellae in new osteons. In contrast, the thin trabeculae (approximately 200 micrometers thick) in cancellous bone show morphological evidence of osteoclastic resorption and refilling of lacunae on their surfaces. The trabecular tissue is lighter due to its porosity and provides a greater surface for resorption. These histological features are a static image of the dynamic nature of bone, as it adapts to an acute or chronic mechanical or physiological stimulus.^[5,6]

EMBRYONIC HISTOGENESIS

Embryonic tissues are organized either as epithelia, in which cells are held together in layers, or as

mesenchyme, in which cells are enmeshed in an extracellular matrix. That pattern is also followed in compound structures. The ectodermal lineage gives rise to the outer epithelium of the body, to brain and neural structures, and parts of the tooth, adrenal gland, and skull and branchial cartilages. The endodermal lineage gives rise to gastrointestinal, urinary, and pharyngeal tissues and derivatives of the pharyngeal pouches, such as the thymus and parathyroids. The mesoderm give rise to musculoskeletal and connective tissue structures and components of viscera, hemangioblastic tissues, cardiac tissues, and adrenal cortex. The germ line cells that give rise to gametes are considered a unique lineage from primordial germ cells. In the avian and mammalian embryo, basal laminae first appear beneath the ectoderm and endoderm during the formation of the primitive streak. Mesenchymal cells migrate from the streak between ectoderm and endoderm, filling the space between and forming the third germ layer, the mesoderm.

Cells and tissues proceed along pathways of differentiation once they are determined, or committed to the lineage. That status can be demonstrated by transfer to another region of the embryo. A cell or tissue is said to be specified when, even if it does not appear to express its characteristic features, its lineage is imprinted and can be revealed *in vitro*. Current interest in the ability of adult cells to develop into different lineages widens the prospect of reparative medicine with so-called stem cell therapy.

Elegant studies in chick embryos by Saunders illustrate the process of formation of complex tissues and the phenomenon of inductive specificity.^[7] A striking lesson is learned from transfer and recombination experiments. Different parts of the chick's skin have different cutaneous structures: wide feathers, narrow feathers, scales, and claws. Saunders' experiments showed that the mesoderm instructs the ectoderm which structures to produce. When immature mesoderm from the foot is combined with ectoderm from the wing, the skin develops scales and claws. Thus, the mesenchyme regulates different genes in the responding cells of the ectoderm. Inductive interactions can occur in three ways: by diffusion from one cell toward another, by contact between cells, or by mediators in extracellular matrix. One approach to tissue engineering is to mimic the information provided by the embryonic mesenchyme by delivery of the signal either in soluble form or in a scaffold.

The dominant paradigm of morphogenesis involves differential cell affinities, either for the surfaces of other cells or for the molecules of the extracellular matrix. Cell adhesion molecules (CAMs) comprise two major classes: calcium-dependent glycoproteins called cadherins and calcium-independent immunoglobulin CAMs. Cell receptors for extracellular matrix

molecules constitute a family of integrins that integrate the extracellular and intracellular scaffolds.

Extracellular matrix molecules play important roles in organizing histogenesis. The basal laminae are made of collagen type IV and provide a structure to which the epithelial and mesenchymal cells can adhere. Collagen type II, a fibrillar collagen, first appears around the notochord and not only provides support, but also contributes to inductive effects of the notochord on growth and differentiation. Thin fibrils of collagen type I provide both structural and informational roles. Other extracellular proteins present in the early embryo are fibronectin, laminin, and tenascin. More information is available on the importance of extracellular hyaluronan and other proteoglycans on morphogenesis and differentiation. Both in-vivo and in-vitro studies provide evidence for cell–matrix interactions through specific binding receptors, such as CD44 for hyaluronan. Hyaluronan has excellent biochemical properties for tissue expansion. Accumulation of hyaluronan increases swelling pressure because of its hydrophilic nature and, conversely, its degradation leads to reduced swelling pressure, allowing recondensation. The embryonic cornea is an excellent example of this process. Heparin and other related compounds have been shown to inhibit cell proliferation and heparin-binding growth factors can modulate proliferation as matrix is remodeled. Branching morphogenesis is common in the development of many structures (mammary gland, lung, salivary gland, and renal tissue) and classical studies showed that digestion with hyaluronidase blocks branching. Toole's studies on limb development indicate the importance of changes in hyaluronan and of its organizing the pericellular matrix during mesoderm condensation and chondrogenesis.^[8]

Although much attention is paid to molecular regulators of pattern formation, signals involved in embryonic histogenesis are often mechanical in nature. The effect of motion on joint cavitation and of shear on blood vessels are examples of mechanical regulation in vivo. In addition, alteration of cell–matrix interactions have been shown to involve tension-dependent changes in cell shape and cytoskeletal mediators of cell function.^[9]

Three-dimensional, if not four-dimensional, development has been studied in models of dorsal/ventral and right/left axes in various species. There has been remarkable evolutionary conservation of gene organization and transcriptional expression. Examination of distribution of gene expression in very early embryos shows that neural crest cells, for example, are already committed to form structures specific to their location well before they begin to migrate. Gene knockout experiments offer the means to identify the patterning genes that regulate these events. Deletion of one of the

Hox genes, for example, by gene targeting gives rise to a mouse with lumbar vertebra that look like thoracic vertebrae with a rib.^[10] Experiments of nature, i.e., malformations, and studies with teratological agents have given us additional insights into patterns of development as well as coordination of development of different organs that are linked in congenital abnormalities. Rapid progress has been made in identifying different genes that control tissue and organ development, and mutations in many have been identified in congenital malformations. A remarkable illustration is a missense mutation in *MSX1* in all affected members of a family with absent second premolars and third molars.^[11]

As important as are embryonic cell differentiation and activity for histogenesis, programmed cell death, or apoptosis (from the Greek *apo*, off, and *ptosis*, falling or dropping), occurs as tissues remodel into functional units. Apoptosis is a way to change temporary structures or parts of structures, but has yet to be exploited in tissue engineering.

POSTNATAL HISTOGENESIS

Histodifferentiation is generally regarded as the process in embryonic development by which a tissue develops into its mature form. There are many examples, however, in which dramatic changes occur in tissues and organs after embryogenesis. In amphibian metamorphosis, explosive changes occur not only in visible signs (loss of gills and tail, gain of limbs and mucus glands), but in liver enzymes and hemoglobin. Also under hormonal direction, mammalian puberty is heralded by development of secondary sexual structures and by spurts of growth. There are dramatic changes in tissues of the womb during pregnancy and following parturition. Some cancers and diseases such as psoriasis are also characterized by continuous growth and histogenesis.

Postnatal histogenesis is usually thought of as that occurring in normal adult wound repair and regeneration. Repair is the process of response to an injury, usually as a scar, while regeneration is the restoration of the injured parts with characteristics indistinguishable from the original material. Postnatal skin is not capable of regeneration, but repairs quickly by scar formation. Scar is a poorly organized tissue that can be regarded as the quick way to seal the skin and avoid risk of invasion and infection. Experimental studies indicate that wound healing in fetal animals is fundamentally distinct from postnatal responses.^[12] Cutaneous wounds made in the midgestational period heal with true regeneration of epithelium and dermis, exactly like the surrounding tissues. Current thinking attributes the differences between fetal regeneration

and postnatal repair to environmental and cellular factors. Evidence implicates Transforming Growth Factor- β (TGF- β) as mediating fibrosis in the adult pattern.^[13] Full understanding of fetal regenerative mechanisms is likely to result in novel approaches to clinical management of wounds without scarring and adhesions.

Soft tissue wound healing begins with an acute inflammatory response to the injury. In general, the degree of the acute response is proportional to the extent of the injury, with complex reactions noted in cases of polytrauma. The cascade of responses includes immediate vasoconstriction, followed by vasodilation, leukocytic diapedesis, gathering of polymorphonuclear neutrophils, and predominance of mononuclear leukocytes. The clinical signs associated with this process are redness, swelling, warmth, and tenderness. Cell-derived factors and proteolytic enzymes mediate and amplify the cellular reactions, culminating with the beginning of repair, usually visible within three days after injury. Epithelial cells at the wound margin begin to proliferate and migrate. As necrotic tissue and clot (and bacteria, if present) are removed by granulocytes and macrophages, fibroblastic cells invade along fibrin fibers, accompanied by new capillary sprouts. Granulation tissue is characterized as rich in delicate small vessels. The name derives from the granular appearance of this tissue when it is incised. In the fibroblastic phase of matrix formation, capillaries regress and collagen synthesis diminishes with loss of fibroblasts. Changing patterns of cytokines control the initiation and mitigation of each phase. The matrix is modified by myofibroblasts and wound contraction.^[14] Intense lytic activity results in tissue compaction and continuous accumulation of fibrillar collagen gives rise to a gradual increase in tensile strength to nearly 70% as in intact skin. If scar formation is viewed as a rapid response of skin intended to seal openings against invading organisms, its efficiency for doing so clearly outweighs its lack of fidelity to the original structure.

Angiogenesis or neovascularization is a critical element in wound healing. Poorly vascularized tissues, like cartilage, cornea, and the white zone of the meniscus, are usually not able to repair large defects. In the case of penetrating wounds of the cornea, vascularization can occur, but is associated with formation of scar with disordered collagen fibers of random size that are opaque and cause varying degrees of disability. Clinicians have noted especially robust bone regeneration in sites with a modest degree of infection. This has been attributed to local inflammatory reaction to infection. Whether novel osteogenic regulators or combinations mediate this occurrence and whether the phenomenon can be harnessed is unknown.

Research on the factors that mediate the phases of wound healing of soft, hard, or visceral tissues has led

to trials to promote responses to injury, especially in compromised settings. Some of the tested agents are platelet-derived growth factor (PDGF), TGF- β , epidermal growth factors (EGFs), fibroblast growth factors (FGFs), insulin-like growth factors (IGFs), and morphogenic factors, such as the bone morphogenic proteins (BMPs). Although each may show promise in experimental model systems and small, controlled trials, therapeutic potential and optimal delivery remain to be realized. There may be a theoretical shortcoming to this strategy. Evidence suggests that addition of a single factor may enhance a phase of healing, but may disrupt the required downregulation of its action required for subsequent coordinated events. Negative feedback normally serves to progress from one stage of healing to the next and may be disorganized by application of a single agent. Several factors appear to act together and in tandem during progress from one phase to another. Another simple strategy that appears to be gaining popularity is the use of platelet-rich plasma (PRP), concentrated from autologous blood with cell separators at the time of surgery.^[15] Simply put, PRP is intended to amplify and accelerate the effects of growth factors (known and unidentified) found in platelets and normally involved as initiators of all wound healing. There is little risk of toxicity or immunoreactions with these preparations, and improvements in the technology advance quickly toward achieving greater concentrations with greater speed.

Tissue specificity is achieved in postnatal histogenesis by the available chemical mediators and cells. Sources of new cells capable of neohistogenesis are required, as are sources of neovascularization. These points are highlighted by the failure of repair and regeneration in postirradiation tissue. Irradiated tissue may be among the great challenges for tissue engineering. Periodontal tissue regeneration is an example of corrections needed in several tissue types, i.e., the periodontal ligament, cementum, and alveolar bone. In-vitro studies show that a combination of two growth factors, PDGF and IGF-I, is chemotactic for both periodontal ligament cells and osteoblasts and is a stimulus for both cell types.^[16]

ENGINEERED HISTOGENESIS

Defining the constituents of a tissue type and its three-dimensional organization is a starting point for understanding the elements needed for specific biological functions. It is incomplete and flawed, however, when reflecting on how to engineer dynamic tissue substitutes. One intellectual paradigm is to examine the ways that body parts operate in different species, to identify their character and limitations, and to design

substitutes. Synthetic materials have achieved some clinical success. For example, dental implants replace lost dental roots and can support prosthetic teeth. Long-term success of dental implants is due in part to their immediate mechanical stability and in part to osteointegration as the jaw bone remodels around them and incorporates them, indifferent to the fact that they are, in fact, foreign bodies. This is possible because of the development of biocompatible materials and attentive design used to manufacture them. Use of large metallic prostheses, for example, the long components inserted well into the proximal femur, seem like an extraordinary measure for replacing the function of the thin shell of articular cartilage that has eroded due to osteoarthritis. Current approaches attempt to activate the body's inherent regenerative capacity.

Different models exist for promoting histogenesis clinically (Fig. 1). For some applications, implantation of biocompatible scaffolds can act as a support for directing and containing tissue growth. There are many natural and synthetic resorbable materials with good biocompatibility and tissue compatibility that can be modified to have the porosity and mechanical properties needed for specific applications. Guided tissue regeneration (GTR) is an example in which a periodontal membrane barrier, either resorbable or permanent and requiring removal, maintains a space for

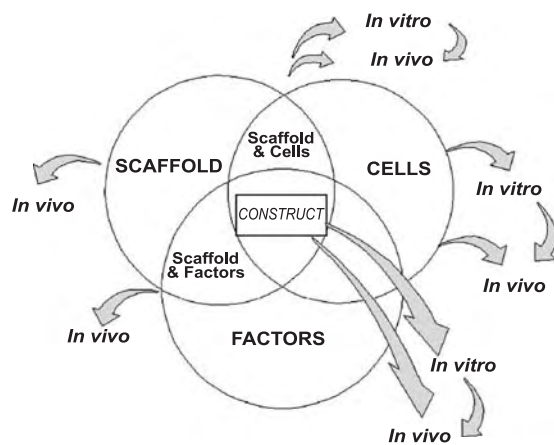

Fig. 1 Schematic for the design of engineered tissues. SCAFFOLD, CELLS, and FACTORS may be used separately or together in a construct to enhance neohistogenesis. The SCAFFOLD may serve three functions: 1) as a cell-free implant, it may support the ingrowth of needed tissue; 2) it may be a delivery system for factors, genes, or drugs; and 3) it may be a carrier for cells directly or following in-vitro growth and maturation. Autogenous CELLS may be harvested for direct transplantation or for intermediate in-vitro culture. FACTORS may be used for in-vitro or in-vivo delivery to direct the expansion of the needed tissue or to promote in-vivo integration.

osteogenesis while preventing epithelial invasion. Addition of bioactive signals, either as genes, soluble factors, or tethered agents, is an attractive way to guide a tissue response. An example is provided by a proof-of-principle study in which an RGD-containing peptide (i.e., with the tripeptide sequence arginine–glycine–aspartic acid that serves as the extracellular ligand for cell attachment) was used to coat a porous polylactic–glycolic acid scaffold and promoted the early stages of osseous ingrowth in a rat tibial wound.^[17] Scaffolds for cell-free use are designed to stimulate neohistogenesis, often by mimicking signals for anabolic processes (also called biomimetic implants).

For bone reconstruction, an alternate to synthetic replacements is a biological approach. Bone tissue is one of the few tissues that is capable of true regeneration. In situations where there is mobility, poor vascularity, or loss of tissue viability secondary to steroid treatment, for example, nonunion can result. There is extensive experience with various methods to promote osteogenesis. Research on the principles underlying the mechanisms by which bone regeneration is enhanced has led to advanced therapeutic approaches.^[18] Surgeons are often successful with the practice of curettage to bleeding bone to stimulate an indolent wound site. Autogenous bone grafting, or transfer of bone or particulate marrow, often from the iliac crest, is considered the gold standard for treating osseous deficiencies. Use of allogeneic, i.e., banked, segments of bone and bone-derived materials has increased because of their wide availability through accredited tissue banks.

Demineralized bone, properly prepared, is safe and consistent for osseous reconstruction.^[19–21] It invokes the mechanism of induced osteogenesis,^[22] in which nonosseous, connective, or muscle tissue is stimulated to form cartilage that is replaced by bone with hematopoietic marrow.^[23] The Bone Morphogenetic Protein (BMP) members of the TGF- β superfamily have been associated with the osteoinductive activity of demineralized bone.^[24] Use of demineralized bone implants or the BMPs may be considered examples of biological approaches to tissue engineering. The material stimulates the body to generate bone tissue by a process that resembles aspects of endochondral osteogenesis seen in embryogenesis and in fracture healing. In light of the schemes of tissue engineering (Fig. 1), demineralized bone may be viewed as a natural composite of an insoluble scaffold with factors or signals that induce osteogenesis in vivo. In-vitro studies to examine the molecular changes in cells targeted by osteoinductive material may reveal differences between embryonic skeletogenesis and postnatal induced osteogenesis that can be exploited for optimizing histogenesis.^[25]

Transplantation of cells from one part of the body, either directly or after expansion *in vitro*, is another approach for tissue construction (Fig. 1). It is clear from experimental^[26] and clinical^[27] studies that adult chondrocytes can be expanded *in vitro* and used to produce cartilage *in vivo*. Cartilage histogenesis has been investigated extensively, in large measure, because of its relative simplicity: cartilage is homogeneous in cell type and devoid of blood vessels. Adult articular cartilage has poor capacity for healing and requires innovative solutions for congenital and acquired degenerative cartilage lesions.^[28] Various scaffolds have been used to deliver chondrocytes and/or provide a template for cell distribution and matrix accumulation, including alginate gel,^[29] porous collagen sponges,^[30] and peptide hydrogels.^[31] There is great potential for stem cells as alternatives to harvesting normal chondrocyte cells for resurfacing joints and replacing damaged intervertebral disks and menisci.^[32] Marrow cells have been shown to be a source of chondrocyte progenitors/precursors and skin fibroblasts have been chondroinduced by culture with demineralized bone.^[33]

Standard concerns (Fig. 1) exist for engineering bone: source of cells, nature of the carrier, and effects of regulatory factors or genes.^[34] Bone tissue engineering has additional demands that highlight the differences between cartilage and bone: bone is a more rigid and vascularized tissue that is required to bear and adapt to great load. For *in-vitro* generation of functional tissues like bone, perfusion of medium improves the viability of cells within the mass and results in greater production of matrix.^[35] Marrow cells have the potential for differentiation into osteoblasts and supporting osteogenesis *in vivo*.^[36] Histogenesis of vascularized tissues can be approached by stimulating ingrowth of adjacent vasculature with angiogenic signals or by including capillary networks in the construct, for example, for stereolithography.

CONCLUSION

Histogenesis concerns the formation of tissue either in embryonic development, in spontaneous attempts to repair wounds, and in deliberate (or engineered) fabrication of missing parts. Understanding the mechanisms that the body uses to generate simple or complex tissues often provides direction for enhancing tissue regeneration. There are three considerations in designing a construct for engineered tissue: the source of cells, if any; the nature of the carrier or scaffold; and use, if any, of genes, factors, or adjuvants. Autogenous cells, often expanded *in vitro*, have been useful for cartilage tissue engineering. Stem/precursor/progenitor cells have shown potential for more complex tissues

like bone. Scaffolds may be a passive means to deliver and contain cells or to present factors or a micro-environment for histogenesis. The scaffolds can be modified to provide biological signals to augment repair and integration. The simplest solution for tissue deficiency would be to use an off-the-shelf scaffold made of a resorbable material that will have specific signaling factors on its surfaces. Thus, the scaffold could convey important regulatory information to reactive tissue, ensuring that it developed as desired. Other design elements could control the vascularization of the construct. It is unlikely that a combination of agents applied together would recapitulate the orderly sequence required for the generation of functional tissues. It would be desirable if the implant contained a single component that triggers the entire cascade of tissue development.

Many materials, design approaches, and manufacturing methods are amenable to tissue engineering for repair and regeneration. It is unlikely that a single approach will solve all problems of tissue and organ regeneration. Within the domain of musculoskeletal tissue and organ engineering, there are likely to be multiple solutions depending on the particular application. Fundamental studies of differentiation, growth, and postnatal tissue maintenance are likely to continue to inform design strategies. Less reliance on two-dimensional models of monolayer cell culture is needed for deconstructing and reconstructing the three-dimensional geometry of cellular interactions as they occur in tissues. Progress in materials design to ensure safe incorporation of new tissue must parallel advances in cell and tissue biology.

INTRODUCTION

The introduction of a medical device into a human host can cause injury to the body and induce a variety of host reactions that are aimed at healing the injury and restoring homeostasis to the body. Essentially, the body views the device as a foreign material, and the overall goal is to protect itself from any potential damage and toxicity caused by this foreign material. The extent of injury and response is dependent upon what is implanted (size, shape, and chemical and physical properties), the site of implantation, and the surgical procedure used (injection, insertion, or surgical implantation). Patient factors are also important; each patient is different, making each case unique. In turn, the extent of response often defines biocompatibility of the material.

The overall response of the body to introduction of a foreign element can be divided into four phases. Injury is the initial event. Acute and then chronic inflammation are the next phases. These phases are coupled to other response mechanisms such as blood coagulation, platelet aggregation, and other blood-material interactions. In addition, immunological responses are invoked such as those involving T and B cells, the complement system, and hypersensitivity reactions. Outcome of these responses ultimately determines the extent of tissue colonization of the material and acceptance of the implant into the body environment. If tissue colonization prevails and healing begins, granulation tissue begins to form at the foreign element's surface. Following this, a series of foreign body reactions commences and may continue for the life of the implant. This phase depends primarily on the form and topography of the implanted material. In time, these physical properties could also lead to formation of tumors around the implant. Finally, if healing has continued, remodeling, which typically involves fibrosis or fibrous encapsulation, ensues, signifying final healing or walling-off of the element.

INFLAMMATION

Inflammation is the reaction of vascularized living tissue to local injury.^[1] This reaction is presented clinically as redness, heat, and swelling at the site of the wound.^[4] Immediately following injury, regardless of

implant site, alterations to vascular flow, caliber, and permeability occur.^[1,4] These alterations open up the vascular system and, in effect, set up a delivery system for inflammation.^[2,4] Fluid, proteins, and blood cells needed for host response to injury can then travel toward and access the injured tissue.

Acute Inflammation

The acute phase of inflammation typically lasts only several minutes to days.^[1] Polymorphonuclear leukocytes (PMNs) and mononuclear leukocytes predominate during this phase of inflammation and their primary responsibility is to phagocytose microorganisms and other foreign materials present at the injury site. This function is facilitated by factors called opsonins located naturally in blood plasma that coat a foreign element and contain receptors that then allow leukocytes to attach to and phagocytose the element.^[5] The key opsonins are Immunoglobulin G and complement fragment C3b.^[1] Typically, the biomaterial is too large for a cell to phagocytose; this situation is known as frustrated phagocytosis.^[3] In these cases, leukocytes release proteases, free radicals, and lysosomal enzymes that attempt to slowly degrade the material.^[1,3] There is evidence that the larger the foreign element, the larger the amount of these substances released by leukocytes, suggesting that the degree of inflammation is modulated by implant size.^[3]

Chronic Inflammation

Persistent presence of inflammatory stimuli leads to chronic inflammation. These stimuli include not only the chemical and physical properties of the biomaterial but also its motion.^[3] This phase is generally short in duration as well and is usually characterized by infiltration of macrophages, monocytes, lymphocytes, foreign body giant cells (FBGCs), fibroblasts, and endothelial cells.^[1] Presence of these cell types indicates the initiation of healing.

Lymphocytes mediate antibody and cell-mediated reactions.^[3] Monocytes are recruited to the wound site by damage debris such as elastin and collagen fragments and endothelial cell pieces, as well as injury-response

factors such as interleukins and platelet-derived factors.^[3] Once at the site of injury, monocytes differentiate into macrophages, which start to remove any debris left at the site.^[3,4] Macrophages also secrete several substances such as chemotactic factors, coagulation factors, and complement components that are important for healing.^[1] FBGCs are multinucleated cells thought to form by fusion of macrophages and, in that capacity, contribute to the healing process and attempts by the body to isolate the foreign element.^[3] Fibroblasts and endothelial cells begin to release materials and organize themselves for the rebuilding of connective and vascular tissue.

GRANULATION TISSUE

If healing has initiated, granulation tissue can be seen as early as 3–5 days following implantation of a material. Granulation tissue contains four main components. Macrophages clear debris and begin to break down blood clots. Neutrophils attack bacteria that are present or are attempting to infiltrate the area.^[4] New small blood vessels, which have developed from proliferation, maturation, and organization of endothelial cells, begin to form. Finally, fibroblasts begin to synthesize components of connective tissue such as collagens and proteoglycans.^[1,2] In addition, some fibroblasts present have features of smooth muscle cells; these cells are thought to cause the tissue contraction seen during wound healing.^[1] The resulting tissue, called granulation tissue, is a transitional compilation of cells and tissue that are either in the process of being degraded from initial inflammation and clotting responses or are being built to contribute to the healing process.

FOREIGN BODY REACTION

The foreign body reaction consists of granulation tissue components, foreign body giant cells (FBGCs), and macrophages to varying degrees. This reaction and the extent of involvement of each component is highly variable depending on the form and topography of the biomaterial surface.^[1] The components of the foreign body reaction often form a layer that covers the surface of the biomaterial. This layer may persist throughout the life of the implant and is typically enclosed within the final fibrous capsule.

REMODELING

Remodeling is the last event in healing or repairing of the implant site and can involve regeneration of native

tissues present at the site prior to placement of the material or replacement with connective tissue known as the fibrous capsule.^[2] The predominant process is decided by two factors: the proliferative capacity of the cells in the tissue or organ receiving the foreign material and the extent of injury to the tissue framework, the supporting structure of parenchymal cells, of the implant site.^[1] Regeneration with the same or similar tissue and restoration of function is rare. Fibrosis or fibrous encapsulation is the more typical route and is the final walling-off of the implanted biomaterial. Granulation tissue that began to form earlier in the healing process builds to form a capsule that surrounds the implant and its associated foreign body reaction layer, isolating it from the local tissue environment.^[1,4] At this point, it is possible for normal local processes to resume, if the degree of injury or defect allows.

COMPLEMENT SYSTEM

The primary role of the complement system is the direct killing, opsonization, and clearance of microorganisms.^[5] The system is initiated by the presence of bacteria or immune response complexes and, once initiated, cascades to eventually involve at least 20 proteins.^[5,6] The various components are located in plasma and were named as they were discovered and found to be necessary for antibody-mediated bactericidal activity.^[1] As the system was elucidated, the components were placed in the order in which they occur in the cascade.^[4]

Two pathways can be initiated, depending on the initiator. However, the most pivotal step in both pathways is the activation of complement component C3. The classical pathway, discovered first, is typically activated by specific antibody-coated targets or antigen-antibody complexes.^[4] Specifically, immunoglobulins IgM, and most IgG subclasses, are capable of activating this pathway. The alternative pathway is triggered by more general initiators and is, therefore, the more commonly employed system of defense against infectious agents, as it is capable of clearing a wider variety of potential pathogens without the presence of specific antibodies.^[5] Liposaccharides of Gram-negative bacteria, a factor in cobra venom, and plasmin are some examples of initiators of the second pathway.^[4]

Classical Pathway

The first step in the classical pathway, as illustrated in Fig. 1, is the binding of activated antibodies to C1. This binding allows C1 to cleave C4 and C2, which results in three products. The most important is

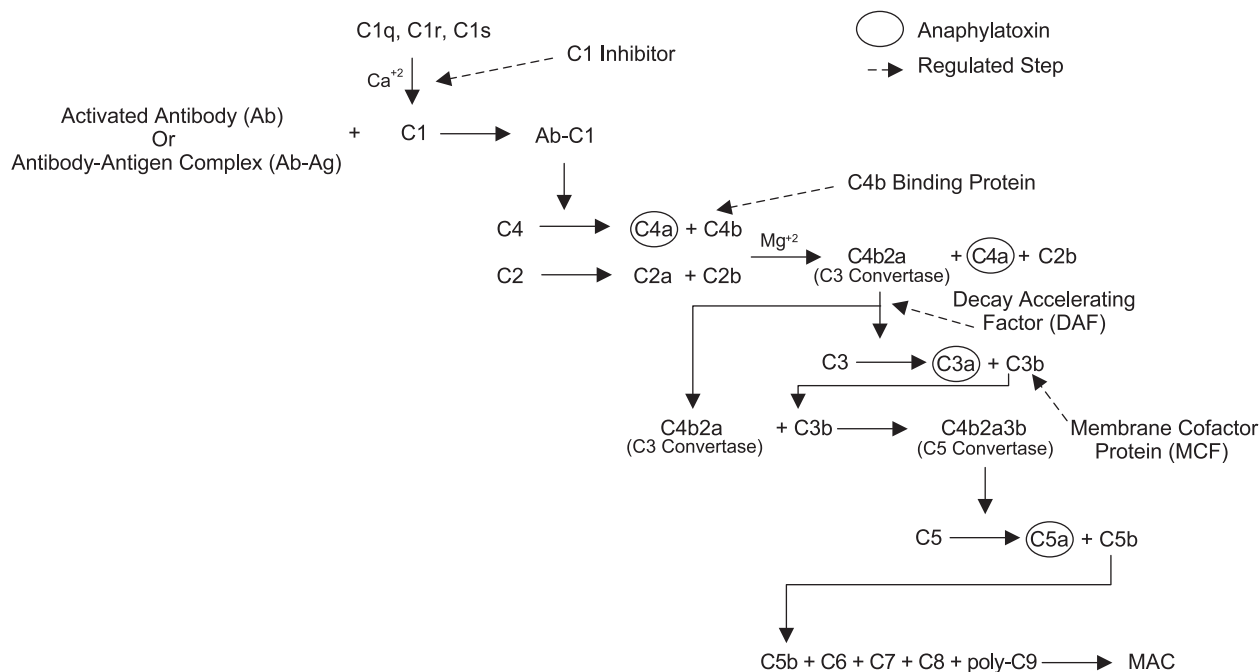

Fig. 1 The classical pathway of the complement system.

the C4b2a complex known as C3 convertase.^[4] C4a, a weak anaphylatoxin, and C2b, a kinin-like molecule that also causes vasodilation and increased vascular permeability, are also released.^[6] C3 convertase then cleaves C3 into C3a and C3b. This step is important for amplification of the classical pathway: One molecule of C3 convertase has the ability to cleave hundreds of molecules of C3.^[4] C3a, another anaphylatoxin, then causes the release of histamine from various cells, resulting in mast cell degranulation and increases in vascular permeability.^[4] Clinically, individuals with C3 deficiency are prone to severe pyrogenic infections such as pneumococcal pneumonia and meningococcal meningitis.^[6] Lack of C3 to bind to microorganisms leads to a large decrease in phagocytic activity.

This leaves C3b to activate C5 through C9. C5 is cleaved to C5a, another anaphylatoxin that has the same effects as C3a and acts as a chemotactic factor for phagocytic cells, and C5b. C5b, C6, C7, C8, and C9 then form a variety of complexes with one another to produce a series of reactions. C8 and C9 attach to and cause lysis of antibody-coated cells. C5b combines with C6 to begin formation of the membrane attack complex (MAC), eventually composed of C5b–C9. MAC inserts itself into the cell membrane of microorganisms, disrupting the cell membrane proteins and causing formation of hydrophilic membrane channels, eventually leading to cell lysis.^[6] One molecule of this complex is potent enough to penetrate and destroy a cell.^[4]

The classical pathway can also be initiated via antibody-independent activation. Mannose-binding lectin (MBL) can bind to mannose sugars on the surface of an antigen or microorganism. Once bound, MBL interacts with two mannan-binding lectin-associated serine proteases called MASP and MADSP2. This complex then cleaves C4 and C2, and the cascade continues exactly as the classical pathway. This pathway is often called the Lectin Pathway of complement activation.^[7,8]

Alternative Pathway

The alternative pathway, in contrast, is activated by direct interaction with pathogens and is, therefore, more important to the initial stages of the host response than the classical pathway. As shown in Fig. 2, the first step is activation of factor P (properdin) by alternative pathway triggering agents. In addition, hydrolysis of C3 is required to advance the cascade; interaction with water causes a change in conformation of C3, allowing it to contribute to the alternative pathway.^[4] Activated factor P then triggers factor D, which subsequently cleaves factor B and allows it to interact with altered C3. The proteolytic complex formed, C3bBb, is a C3 convertase that can, therefore, cleave more C3, starting a feedback amplification loop that intensifies the alternative and the classical pathway responses.^[6] C3b is created in the process and goes on to initiate formation of the MAC, as in the classical pathway.

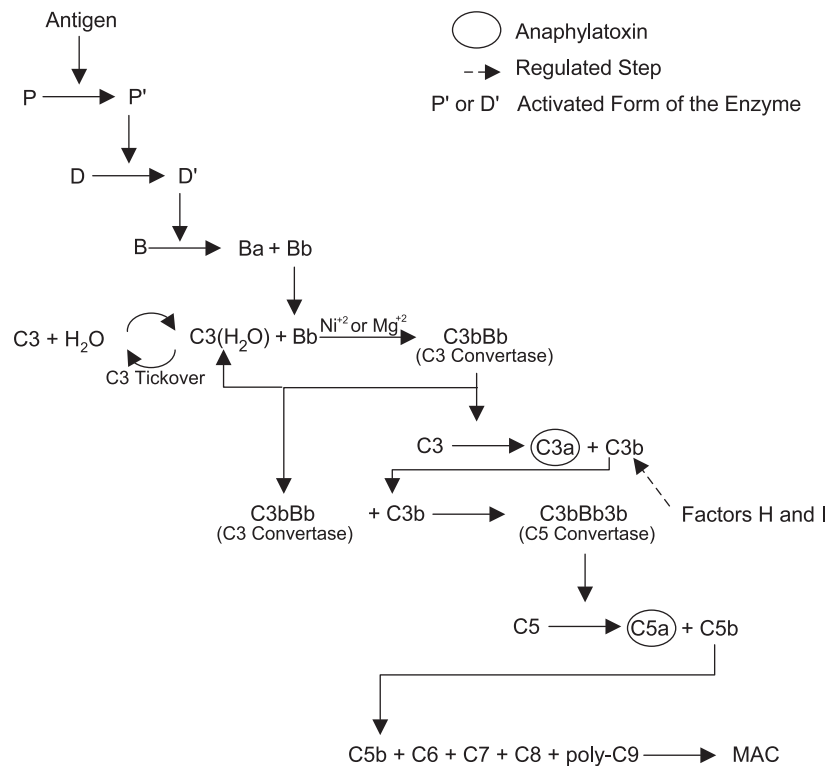

Fig. 2 The alternative pathway of the complement system.

Biologic Activities of Complement Factors and the Complement System

To summarize, there are five major active complement components. Factors C3a, C4a, and C5a are all called anaphylatoxins. Though C4a is probably the least important, these factors cause mast cells and basophils to degranulate and release histamine, leading to increases in vascular permeability. These responses are presented clinically as vasodilation, redness, swelling, and possibly smooth muscle contraction and mucus secretion in the airways.^[6] C5a is also an important chemotactic factor for PMNs, monocytes, and eosinophils.^[4] C3b is an opsonin, which binds to foreign elements that are present and contains receptors that then allow leukocytes to attach to and phagocytose the element. C3b also aids antibody-dependent cell-mediated lysis.^[6] Finally, C5b–C9 compose the MAC, which causes target cell lysis, as described above.

Creation and action of these factors is a key element in the success of the implanted biomaterial. In attempts to rid the body of the biomaterial, the complement factors aid destruction of any bacterial cells associated with the implant. These factors also help guide inflammatory and immune cells that are en route to the area in response to implantation and facilitate their actions, ensuring that the proper responses can continue to completion.

RACE FOR THE SURFACE: BACTERIAL VERSUS TISSUE COLONIZATION

Bacterial infection is a large risk factor for medical device implantation. The rate of infection can range from less than 0.5% for artificial hips to 100% for total artificial heart replacements.^[9] These rates are typical even with the use of systemic antibiotics. Infection can be triggered from an improperly handled implant or due to problems at the wound or incision site. The discussion below will focus primarily on infection due to the presence of the implant in the body.

Bacteria that most frequently populate medical device surfaces are *Staphylococcus aureus*, *Staphylococcus epidermidis*, and *Pseudomonas aeruginosa*.^[10] *S. aureus* is most frequently seen at metal implant surfaces, and *S. epidermidis* is typically seen in infections of polymeric implants. *P. aeruginosa* is most frequently associated with keratitis resulting from extended-wear contact lenses.

Prevention of bacterial colonization through tissue cell integration is the best approach to avoidance of infection. If a bacterial layer is allowed to adhere to the device surface before tissue cells can colonize, it is very difficult to rid the surface of the bacterial layer. Once adhered, bacteria are strong, aggressive, and capable of modifying the environment to support their livelihood. Infection ensues, and initiation of normal healing is

severely hampered, if not impossible. Often, relief comes only with outside interventions such as reoperation.^[10]

To avoid this catastrophe, tissue cells are involved in a race for the surface with bacteria immediately upon implantation of a biomaterial.^[10] If tissue cells are able to populate the device surface first, a protective layer composed of tissue cells and a supporting matrix of proteins and polysaccharides is formed. This layer is resistant to typical infection routes and provides an optimal environment for the function of other host mechanisms.^[9]

Developers of biomaterials take several approaches to promoting population of tissue cells, avoiding bacterial adhesion, and ensuring proper integration of the material into the body. Paramount is choice of a biocompatible material. Meticulous attention to and use of the sterile technique during implantation is another step in the prevention of bacterial colonization.^[11] Traditionally, treatment with systemic antibiotics prior to and following implantation has been the method of management. Surface modifications to the material and overall design of the implant are newer methods utilized to avoid initiation of infection. Texturing or addition of an outer layer of microbeads is one method that has been utilized successfully with orthopedic implants to improve the process of integration with bone. Preimplantation cell seeding and coating with local antibiotics or proteins that promote tissue cell attachment are other approaches.

As mentioned, compatible material choice is one of the first steps in implant development. The choices of materials are currently evolving with the advent of tissue-engineered materials, which consist partially or completely of materials that originate in the body.^[12] Host response to these materials is minimal, since the material is recognized as native. Already xenografts and homografts are used in some devices such as tissue heart valves. Tissue-engineering designs are becoming more and more complex with the development of composite materials that incorporate tissue and cellular components. The goal is seamless integration of these materials into the body so that they become a member of the functional and remodeling environment of the implant site.

BLOOD-MATERIAL INTERACTIONS

Another consideration for most implants and especially if the implantation site involves direct interaction with the bloodstream, such as a vascular graft or stent, is the response of blood components to the material. This response is often referred to as blood-material interaction (BMI). Implantation of a material or device into a blood-contacting site causes injury to the site.

More serious, the material itself is likely to be thrombogenic and induce response from the blood. The initial response is activation of blood cells known as platelets. When in a stable state, platelets are smooth and discoid in shape. However, they are easily activated, at which point these cells change shape, become sticky, release pseudopods, and secrete granule contents that activate additional platelets.^[1,13] These changes lead to aggregation of platelets, blood coagulation, and, eventually, formation of thrombus on the material surface. More serious, this thrombus could develop and occlude a vessel or be shed as an embolus and travel to the heart or brain, blocking blood flow and oxygenation.^[14]

Platelets become activated by interaction with sub-endothelial collagen located in blood vessel walls. This collagen becomes accessible when the endothelial layer is damaged by biomaterial implantation. Activated platelets have exposed surface receptors that interact with particular plasma proteins such as fibronectin, fibrinogen, vitronectin, and von Willebrand factor that are already adsorbed to device surfaces. The platelet receptor GPIIb/IIIa can bind to these plasma proteins.^[1,13,15] In addition, fibrinogen can serve as a platelet-platelet bridge, allowing platelet aggregation to proceed.^[16]

Aggregation is followed by coagulation. As in the complement system, two pathways for coagulation exist. These are illustrated in Fig. 3. The intrinsic pathway is activated by contact with and adsorption of factors contained in the vascular system onto a negatively charged surface. The extrinsic pathway is initiated by tissue factor (TF), which is expressed by white blood cells in response to tissue fragments in the blood and exposed vascular layers created by damage.^[1,16] Both pathways lead to a common point, however, and the result is fibrin formation and hemostasis.

The intrinsic pathway begins with cleavage of factor XII to factor XIIa. Contact activation then allows factor XIIa to convert factor XI to factor XIa, which, with the help of calcium ions, cleaves factor IX to factor IXa. With the additional help of calcium ions and factor VIII provided by platelets, factor IXa activates factor X.^[1] This step requires a platelet phospholipid surface. In the extrinsic pathway, TF activates factor VII, a vitamin K-dependent reaction. Factor VIIa results and activates factor X with help from circulating calcium ions.^[16]

With activation of factor X, the common pathway of coagulation begins. Factor Xa causes conversion of prothrombin to thrombin, a reaction that requires calcium and factor V as the platelet receptor for factor Xa, as well as platelet phospholipids.^[16] Thrombin then detaches from the platelet surface and activates a number of additional coagulation components, advancing as well as amplifying the coagulation cascade.

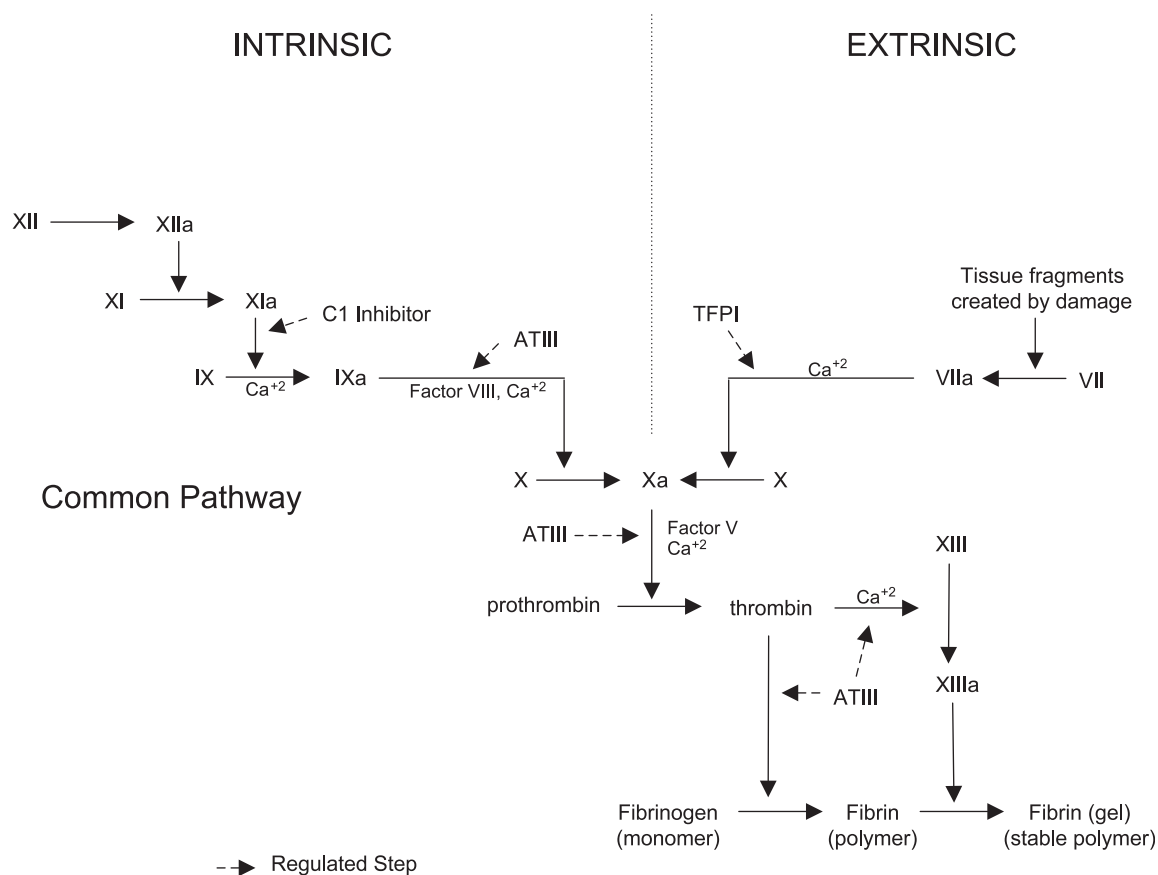

Fig. 3 The coagulation cascade.

First, it further activates factors VIII and V. Second, with the help of calcium, thrombin converts factor XIII to factor XIIIa. Third, it directly causes polymerization of the fibrinogen monomer to the fibrin polymer. Subsequently, activated factor XIIIa helps to stabilize the fibrin polymer by inducing crosslinking. Hemostasis is now well under way.

When the clot is no longer needed, fibrinolysis ensues. Plasminogen is activated to plasmin by tissue-Plasminogen Activator (tPA), which attaches to and digests the fibrin clot.^[16] Fibrin degradation products are then washed away from the clot site.

Throughout the coagulation cascade, there are a number of regulation factors that block its progression if necessary. Antithrombin III (ATIII) is the most active. It can block action of factor IXa on factor X, factor Xa on prothrombin, and thrombin on factor XIII and on fibrinogen. Clinically, action of ATIII can be enhanced by heparin.^[16] C1 inhibitor can block conversion of factor IX by neutralizing factor XIa. Tissue Factor Pathway Inhibitor (TFPI) is capable of blocking conversion of factor X.

Design of successful biomaterials requires attention to and minimization of these blood-material interactions. Researchers have developed a number of

strategies toward this goal. The obvious first step is to choose a blood-compatible material. Following this selection, form, topography, and possible surface modifications to the material are the next steps. One example is the use of expanded poly(tetrafluoroethylene) for the replacement of blood vessels. Replacement of large vessels with this material has been very successful; however, if the inner diameter of the prosthesis is too small, blood clot formation causes complete blockage of flow through the implant. One method designed to avoid this is systemic application of heparin or other anticoagulants prior to implantation and during healing. Another approach is the addition of an endothelial layer to the inside of the prosthesis.^[17] In native blood vessels, the endothelial layer provides a smooth contact surface for flowing blood. Presence of this layer in implanted prostheses may provide the same effect.

THE IMMUNE SYSTEM

The function of the immune system is to protect the body from any foreign presence, called an antigen, that could eventually lead to disease. Biomaterials and their

breakdown or wear products are one possible type of antigen. The body utilizes several mechanisms to carry out the steps of the immune response. The components of the response are organized in the lymphatic system and are in constant communication via the blood and lymphatic networks.^[6] Collectively, these components work together to protect the body from almost any antigen. First, the antigen must be identified as foreign; this is accomplished by antigen-presenting cells (APCs) such as macrophages, endothelial cells, and Langerhans' cells. These cells have the ability to break down the antigen into a form that the rest of the immune response system can recognize and attack. Macrophages also possess phagocytic capabilities and can lyse tumor cells and produce cytokines, as discussed in the following section.

Once the antigen is recognizable, lymphocytes respond and attempt to destroy the antigen. There are three types of lymphocytes. Initially, natural killer (NK) cells provide a generalized response, usually to tumor cells and virus-infected cells, during the time that the other two types of lymphocytes are being stimulated and amplified.^[4] These other lymphocytes, T cells and B cells, are actually programmed to respond to specific antigens. T cells are responsible for cell-mediated immune response. B cells are responsible for humoral immune response.

Cell-Mediated Immune Response

T cells act by producing cytokines and other factors that have the ability to fight a specific antigen. A T cell binds to an antigen via a receptor on its surface that recognizes an antigen only if the antigen is attached to an APC and has bound to a complex called the major histocompatibility complex (MHC), discussed later. Binding of the T-cell receptor to the antigen-APC-MHC complex requires presence of magnesium ions; furthermore, T cells cannot send a destruction signal to the antigen without the presence of calcium ions.^[6]

Cytokines, as discussed above, regulate the cellular response of the immune system. Their work usually involves communication between leukocytes; thus, many cytokines are called interleukins (ILs). Other categories of cytokines are interferons (IFNs), which focus on antiviral, immunomodulatory, and anti-proliferative activities, and tumor necrosis factors (TNFs), which regulate cytotoxic activity against tumor cells exclusively.^[1] Other cytokines function as growth factors, chemokines, and regulatory factors. For example, erythropoietin is a hematopoietic growth factor responsible for the development of red blood cells.^[6]

In general, cytokines have much in common. They are potent in the picomolar range, act through very specific cell surface receptors, are approximately

100–200 amino acids long, are typically glycosylated, and have overlapping synergistic or antagonistic activities. The most studied cytokine is IL-1, which has been found to promote coagulation and cellular accumulation at inflammatory sites and to further promote wound repair and fibrosis by inducing fibroblast cells to make collagen types I, III, and IV.^[1]

Humoral Immune Response

B cells are stimulated by attachment to a specific antigen via B-cell surface ligands called antibodies. Antibodies, also called immunoglobulins (Ig), bind specific antigens and, in effect, facilitate the work of the B cells. Once bound to the antigen, B cells can differentiate into plasma cells, which produce more antibodies against the particular antigen that is present. T cells can also stimulate B cells, leading to production of antibodies and further processing of these antibodies for even more specific actions or purposes.^[1]

As discussed above, antibodies bind to antigens and facilitate B-cell stimulation. This antigen-antibody complex is also an initiator of the classical pathway of the complement system. Antibodies have additional functions, as well. They can act as linkers between two antigens causing them to cluster; this corrals the antigens, making it easier for neutrophils and macrophages to phagocytose them. They have antibacterial activity and are, therefore, capable of neutralizing bacterial toxins or coating bacteria to aid in the recognition of the antigen for phagocytes. Finally, antibodies can combine with viruses and prevent them from entering cells.^[4]

There are five types of antibodies or immunoglobulins, but the basic structure of each is the same. As illustrated in Fig. 4, they are composed of two light and two heavy chains, connected by hydrogen and disulfide bonds. Only the end portion of the structure is variable, giving rise to the different types of antibodies. IgM antibodies are found predominantly in the intravascular space, as they are too big to gain access to other locations.^[4] They are typically involved in the

Fig. 4 Basic structure of an antibody.

primary immune response and are the most efficient antibody in activation of the complement system. IgD antibodies are observed in trace amounts in the serum and may play a role in B-cell maturation. Both IgM and IgD antibodies are located on the surface of B cells, the typical receptor for specific antigen, as discussed previously. IgE antibodies are usually found bound to immune cells and likely have a role in responding to the presence of parasites and anaphylaxis initiators. IgA antibodies are located in saliva, tears, and the mucosal coatings of the respiratory, gastrointestinal, and genitourinary tracts, preventing attack of these delicate surfaces.^[4,6] IgA antibodies are also effective in inducing the alternative complement pathway. The fifth type of antibody, IgG, is typically found in serum and is the only antibody with the capacity to cross into the placenta. Therefore, most antibodies in newborn babies are of type IgG and are, therefore, called maternal antibodies.^[4]

SYSTEMIC TOXICITY AND HYPERSENSITIVITY REACTIONS

At times, an immune response to an antigen can cause systemic toxicity and lead to damage to the tissues of the host. These types of reactions are called hypersensitivity reactions. It is difficult to predict or test the types and severity of immune responses invoked by the presence of a biomaterial because they are highly dependent upon the individual and the dose, composition, nature, and location of the implant.^[1] However, hypersensitivity reactions are and should be a concern for biomaterial and implant designers.

There are four types of systemic immune reactions.^[4] Types I, II, and III are fast-acting and mediated by immunoglobulins and the humoral immune response. Type IV takes longer to develop and is controlled by T cells and other cell-mediated responses. Type I, also called immediate-type or anaphylaxis, is usually induced by pollens, drugs, food, dust, and insect stings or bites. The anaphylactic response begins with interaction between an IgE-type antibody and the antigen. Subsequently, the antibody portion of this complex attaches to host cells, resulting in stimulation of the complement system and production of anaphylatoxins. Clinically, symptoms of Type I hypersensitivity can be hives, fever, asthma, and/or vomiting due to release from cells of substances such as histamine, serotonin, and other vasoactive substances.^[1] Immune cytotoxic or Type II reactions are similar to Type I reactions; however, the antigen attaches to the host cells and leads to interaction with IgG- and IgM-type antibodies, leading to the destruction of the cell or tissue via complement activation, phagocytosis, or NK

cell activity. Instances of stimulation of either Type I or Type II hypersensitivity reactions by biomaterials are rare.^[1]

Type III reactions are classed as immune complex hypersensitivity. The mechanisms are similar to those of Type II responses. These reactions occur following constant or recurring exposure to the same antigen, resulting in high levels of antibody to that antigen in the serum. Type III reactions can be divided into two categories, separated mainly based on the size of the immune complex involved.^[4] Arthus-type reaction is the precipitation of large antigen-antibody complexes that deposit in blood vessels, the kidneys, and the heart, especially at bifurcations and locations of high turbulence. The result is formation of anaphylatoxins, destruction of blood vessel walls, and activation of platelets, possibly leading to occlusive thrombi and even emboli. Serum sickness-type reaction is a result of excess circulating small and soluble antigen or antibody that can also deposit in blood vessel walls, leading to complement activation and necrotizing vasculitis.^[4] With the exception of biodegradable or drug delivery systems, Type III hypersensitivity due to biomaterials is unlikely.^[1]

Type IV or delayed-type hypersensitivity develops slowly, often over a 2–3-day period. Antibody is not employed in these reactions; they are cell-mediated. Delayed-type reactions are evident clinically as four main conditions. Most familiar is contact dermatitis such as poison ivy. Second, persistent infection from bacteria, viruses, or fungi can result in chronic infections such as the lesions observed with tuberculosis patients. Third, known as autoimmune disease, an immune response against self-antigens of the host can be initiated if the immune system cannot discriminate between foreign antigens and native components. Finally, graft rejection and deep tissue reaction is the fourth type of condition resulting from Type IV hypersensitivity. These reactions involve cytotoxic T cells and NK cells and are the result of a complex immunologic response to cell surface antigens of the graft. The major histocompatibility complex (MHC), the most significant factor in modern immunology, mediates this complex response.^[6] The MHC is a cluster of genes on human chromosome 6,^[4] and the protein coded by it is located on the cell membrane of APCs and almost all nucleated mammalian cells, depending on the MHC molecule class.^[6] It is this complex that determines if tissues and organs will be compatible between donors and recipients; in order for compatibility, the MHC genes of both must be the same. MHC molecules have a role in T-cell activation by forming the ligand between the antigen-APC and the T cell.

TUMORIGENESIS

Though it is often difficult to link it as a direct cause, there is evidence that implanted biomaterials can cause tumor growth and induce cancer. This situation is a major concern for biomaterial researchers. Formation of a tumor results from neoplasia, which is defined as excessive and uncontrollable cell proliferation. Neoplasia is likely caused by excessive foreign body reaction, and the cells that develop have immunity to the body's natural defense systems. If the growth cannot infiltrate the tissues or spread to other areas of the body, it is called benign; however, if it can access the lymphatic or blood circulation and spread, it is called malignant or cancerous.^[1] Solid materials with high surface area are most tumorigenic, and initiation of neoplasia depends primarily on physical not chemical characteristics of the implant.^[1] Though general studies have been performed for years, more recent research is focused on a deeper understanding of the mechanisms of biomaterial-induced tumorigenesis and how to avoid or minimize it.^[18–21]

CONCLUSION

The response of a host to implantation and presence of a medical device or biomaterial is complex. The severity of the response depends upon interrelations between many systems and the clues that these systems take from the implanted material. As a biomedical researcher, a keen understanding of these systems is essential in striving to minimize host response. Fortunately, information about host responses is constantly being enriched, guiding researchers toward optimal solutions to biomaterial and device challenges.

Department of Biomedical Engineering and Texas Materials Institute, University of Texas, Austin, Texas, U.S.A.

INTRODUCTION

Hyaluronan (HA, also called hyaluronic acid or hyaluronate), a high molecular weight glycosaminoglycan found in all mammals, is a unique and highly versatile biopolymer. HA plays a vital role in embryonic development, extracellular matrix homeostasis, wound healing, and tissue regeneration. Although it is clear that HA is critically involved in these processes, the exact mechanisms by which it influences cellular behavior are not yet elucidated. Complicating such studies is the fact that the behavior and cellular influence of HA is highly dependent on its concentration and molecular weight. Therefore, the biology and chemistry of HA is a current area of extensive scientific research. Biomaterials made from derivatized and cross-linked HA have received a great deal of attention in the bioengineering community and have been used in a wide variety of applications (e.g., orthopedic, cardiovascular, ophthalmology, and dermatology, as well as general applications in tissue engineering, surgery, and drug delivery). HA is naturally derived, nonimmunogenic and also has multiple sites for modification and inherent biological activities; therefore, this unique biopolymer has great potential for creative application in biomedical engineering. This article reviews HA's natural structure and function, and biomaterials made from derivatized and cross-linked HA, as well as a number of clinical, surgical, and bioengineering applications of HA.

THE NATURAL STRUCTURE AND FUNCTION OF HYALURONAN

Physicochemical and Structural Properties

Hyaluronan, an extracellular matrix (ECM) component, is a high molecular weight glycosaminoglycan composed of disaccharide repeats of N-acetylglucosamine and glucuronic acid (Fig. 1). This relatively simple structure is conserved throughout all mammals, suggesting that HA is a biomolecule of considerable importance.^[1] In the body, HA occurs in the salt form,

hyaluronate, and is found in high concentrations in several soft connective tissues, including skin, umbilical cord, synovial fluid, and vitreous humor. Notable amounts of HA are also found in lung, kidney, brain, and muscle tissues. In commercial production, HA is commonly extracted from rooster comb and human umbilical cord or manufactured in large quantities by bacterial fermentation.^[2]

The cellular synthesis of HA is a unique and highly controlled process.^[3] Most glycosaminoglycans are made in the cell's Golgi networks. HA, however, is synthesized at the plasma membrane and immediately extruded out of the cell and into the ECM. This process is carried out by a group of proteins called HA synthases, which are located in the cell membrane. For a review of HA synthases, see Ref. [3].

HA's structure imparts unique physicochemical and biological properties that depend on molecular weight.^[2] When extracted from tissues, HA is polydisperse in size, with an average molecular weight of several million. In physiological solution, HA conforms to a stiffened random coil with a contour length of about 2.5 μm for a 1×10^6 molecular-weight chain of about 2650 disaccharide repeats. Secondary hydrogen bonds form along the axis of HA, imparting stiffness and creating hydrophobic patches that allow the formation of ordered structures. HA solutions are highly viscoelastic; in other words, when shear rate is increased, the HA chains align in the direction of flow, resulting in a decreased solution viscosity. This shear thinning effect can be seen when delivering HA through a syringe.

HA is a highly hydrophilic polymer. Each glucuronic acid unit contains one carboxyl group, giving rise to HA's polyanionic character at physiological pH. In the presence of water, HA molecules can expand in volume up to 1000 times and form loose hydrated matrices.^[4] Because of this property, HA is thought to play several roles in the ECM, including space filler, lubricant, and osmotic buffer.^[4] By forming a hydrated polymer network, HA can act as a sieve, restricting the movement of pathogens, plasma proteins, and proteases.^[1,4] In addition, HA's polyionic structure is able to scavenge free radicals, which mediates inflammation by

Fig. 1 The structure of native HA. HA is a naturally derived polymer composed of disaccharide repeats of glucuronic acid and N-acetylglucosamine. The molecular weight of native HA is typically several million. Each disaccharide repeat of HA contains three possible modification sites: the hydroxyl, carboxyl, and acetamido groups.

imparting an antioxidant effect.^[1] For a thorough review of HA's structural and physicochemical properties, see Ref. [2].

Roles in the Extracellular Matrix and Interactions with Hyaladherins

HA plays several important organizational roles in the ECM by binding with cells and other components through specific and nonspecific interactions. For example, HA specifically interacts with several proteoglycans (e.g., aggrecan, versican) through HA-binding motifs,^[2] and modulates the organization of fibrin,

fibronectin, and collagen networks.^[5] In addition to contributing to the homeostasis of ECM structure and hydration, HA is also involved in a number of more complex signaling events relating to cell migration, attachment, and metastasis. Such processes are mediated through a group of proteins called hyaladherins. These proteins can be categorized into three types: those that are soluble, those that bind HA to other ECM molecules, and those that act as cellular receptors for HA.

Two hyaladherins, CD44 and RHAMM (Receptor for HA-Mediated Mobility) have been extensively studied. CD44 has been implicated as the major cell surface receptor for HA, and is expressed on a variety of cell types (e.g., leukocytes, fibroblasts, epithelial cells, keratinocytes, and some endothelial cells).^[6] The CD44 receptor is associated with various cellular processes, including adhesion, migration, proliferation, and activation, as well as HA degradation and uptake.^[1,4] (See Fig. 2 for a schematic of the signaling mechanisms associated with CD44.) In a number of cell types, the RHAMM hyaladherin has been found on the cell surface, as well as in the cytosol and nucleus.^[7] RHAMM has been implicated in regulating cellular responses to growth factors and plays a role in cell migration, particularly for fibroblasts and smooth muscle cells.^[7,8] For a comprehensive review of hyaladherins, see Ref. [8].

HA's Complex Influence on Cell Migration

As mentioned previously, HA may influence cellular behavior not only through direct mechanisms (e.g., specific binding with cellular hyaladherins), but also by indirect means (through altering the physical properties

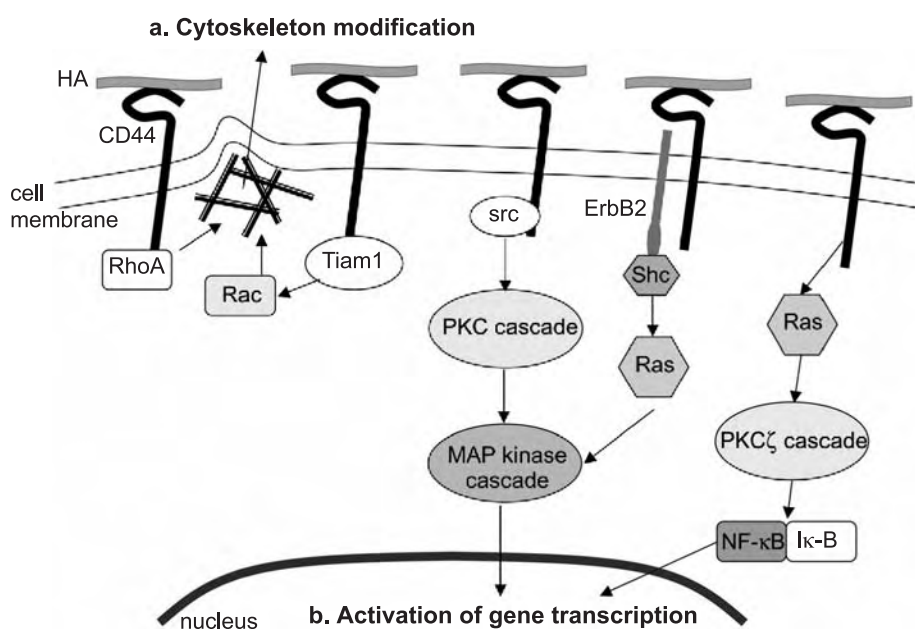

Fig. 2 Signaling pathways of the HA receptor CD44. The binding of HA and CD44 can result in signaling cascades that affect a) the modification of cytoskeletal proteins, leading to changes in cell migration, and b) the activation of gene transcription, resulting in changes in cell proliferation. Cytoskeletal assembly may be modified through signaling involving Rac and RhoA. The protein kinase C (PKC) and MAP kinase cascades may be involved in altering gene expression inside the nucleus. (Adapted from Ref. [3].)

of the ECM). HA's effect on cell migration is a remarkable illustration of this complexity. For instance, the binding of cellular hyaladherins to HA is involved in migration for a variety of cell types.^[5] Yet, it is evident that HA may also indirectly aid cell migration by contributing to more open and hydrated spaces in the ECM or by otherwise remodeling the environment through interactions with collagen and fibrin.^[3] Furthermore, as the main component of pericellular coats (matrices that are formed around migrating and proliferating cells), HA nonspecifically facilitates the detachment of cells from the ECM.^[8] Given such complexity, distinguishing between the effects of HA's biological activity and physicochemical properties is not straightforward.

HA Degradation

In mammals, the enzymatic degradation of HA results from the action of three types of enzymes: hyaluronidase (hyase), β -D-glucuronidase, and β -N-acetyl-hexosaminidase. Throughout the body, these enzymes are found in various forms, intracellularly and in serum. In general, hyase cleaves high molecular weight HA into smaller oligosaccharides while β -D-glucuronidase and β -N-acetyl-hexosaminidase further degrade the oligosaccharide fragments by removing nonreducing terminal sugars. Besides the degradation reaction, testicular hyase can catalyze the reverse reaction, transglycosylation. Therefore, HA is not simply degraded by this enzyme into disaccharide fragments. On the contrary, incubation of HA in a testicular hyase solution yields a mixture of fragment sizes, primarily made up of tetrasaccharides with smaller amounts of hexa-, octa-, and disaccharides.^[9] The cell types primarily responsible for hyase synthesis are macrophages, fibroblasts, and endothelial cells; consequently, each of these cell types have been associated with HA degradation in the body.^[10] In addition to enzymatic degradation, HA can also be degraded by reactive oxygen intermediates, a mechanism that has been implicated as a source of HA fragments at sites of inflammation.^[11] For a review of other nonenzymatic means of HA degradation (e.g., degradation induced by free radicals, ultrasound, pH, and temperature treatments), see Ref. [2].

HA in Wound Repair and Angiogenesis

High concentrations of HA can be found in many tissues undergoing remodeling, regeneration, and morphogenesis.^[8] Furthermore, in the early stages of wound healing, a matrix composed largely of fibrin and HA is formed, which aids in fibroblast and endothelial cell migration into the injury site. This matrix also supports granulation tissue formation, particularly in fetal tissue,

where HA has been implicated in aiding scar-free wound healing.^[1] For this reason, exogenous HA has been investigated in wound healing applications and has been found to be effective even in challenging conditions such as chronic wounds.^[1]

The exact role of HA in wound healing is very complicated. In a comprehensive review of HA and wound repair, Chen and Abatangelo suggest that HA plays a multifaceted role in each wound healing stage (i.e., inflammation, granulation tissue formation, re-epithelization, and remodeling).^[1] For example, HA aids in setting off the early stages of inflammation and initiating the wound healing response, and also moderates the later stages of this potentially damaging process. Furthermore, the granulation tissue that subsequently forms remains rich in HA, aiding cell migration, proliferation, and organization of the ECM.

Perhaps one of the most interesting roles of HA in wound healing is the ability of HA oligosaccharides to promote angiogenesis.^[10] Degradation products of 4–20 disaccharide units have been shown to stimulate in-vivo capillary growth and induce in-vitro endothelial proliferation, migration, and tube formation. The complex nature of HA, however, is again demonstrated: Although low molecular weight HA promotes angiogenesis, high molecular weight HA has been shown to inhibit new blood vessel growth. Researchers have attempted to better discern the direct and indirect effects of HA molecular weight on angiogenesis, but an exact understanding of this process remains to be elucidated. For a recent review of the role of HA in angiogenesis, see Ref. [10].

The Role of HA in Pathological Processes

Factors such as HA concentration and molecular weight distribution have been correlated with the development of certain pathological conditions and can therefore be used as diagnostic markers for disease. Increased serum concentrations of HA can be associated with the progression of certain inflammatory processes, such as rheumatoid arthritis, and have been used to evaluate the success of kidney and liver transplants.^[4] Changes in the properties of HA have also been associated with certain vascular diseases, including atherosclerosis and restenosis.^[12] Furthermore, high concentrations of HA have been linked to tumor development and in some cases can be used as a negative predictor of cancer patient survival.^[12] Presumably, one of the roles of HA in cardiovascular disease and tumor growth is to increase the free volume and fluidity of the ECM, allowing increased cell proliferation and migration. However, a detailed understanding of the role of HA in these conditions is far from complete.^[12]

DERIVATIZED AND CROSS-LINKED HA BIOMATERIALS

HA offers many unique advantages as a building block for biomedical devices. Specifically, HA is enzymatically degradable, naturally derived, and nonimmunogenic. Unlike proteins, which are easily denatured, HA is a carbohydrate polymer and can withstand demanding chemical modification procedures without losing its biological activity. Purified HA has found clinical uses in ophthalmology, osteoarthritis, and wound-healing applications.^[2] HA has many other potential applications, particularly as a biomaterial to deliver cells or proteins, but its use is limited because of its high water solubility and rapid degradation in the body. Thus, researchers have investigated methods to prolong the residence time of HA, using chemical modifications to yield materials with greater in-vivo stability. Two main approaches for

creating HA biomaterials have been utilized: derivatization and cross-linking (summarized in Fig. 3). Both approaches are used to modify chemically one or more of HA's three available reactive groups (hydroxyl, carboxyl, and acetamido; Fig. 1), while attempting to maintain biocompatibility and biological activity. This section provides an overview of several HA derivatization and cross-linking methods; however, this discussion is not comprehensive. For further information on modification strategies, including HA composites and blends, see Refs. [2] and [13].

HA Derivatives

Many studies focus on three main types of HA derivatization strategies: esterification, carbodiimide-mediated modification, and sulfation. These simple

HA Derivatives

Crosslinked HA

Fig. 3 Derivatized and cross-linked HA biomaterials. To tune HA's physicochemical properties for specific applications, HA has been modified in several ways. Uncross-linked HA derivatives, including modifications based on A) esterification,^[14] B) carbodiimide-mediated reactions,^[15] and C) sulfation^[18,19] have been created. Cross-linked HA has also been produced using several cross-linking agents, including D) diepoxies,^[20,21] E) biscarbodiimides,^[17] F) bifunctional amine cross-linkers,^[16] and G) divinyl sulfone,^[25,28] as well as H) photocross-linking methods. (From Refs. [31,32].)

modification strategies can be used to create HA derivatives that are suitable for direct application or for subsequent cross-linking procedures. This section will describe uncross-linked HA derivatives and the next section (“Cross-linked HA Biomaterials”) will include a discussion of cross-linking methods for these materials.

Ester derivatives

To create more hydrophobic forms of HA that have added rigidity and are less susceptible to enzymatic degradation, researchers have esterified HA's carboxyl groups.^[14] The modification is carried out through an alkylation step of HA with an alkyl halide, yielding derivatives with 0–100% modifications of the available carboxyl groups. As the percent of HA esterification increases, these materials become more rigid and more hydrophobic. An increased hydrophobic nature means that the HA derivatives are less soluble in water and less susceptible to enzymatic degradation. Fidia Advanced Biopolymers have created a range of HA esters, including ethyl esters (Hyaff-7; Fig. 3A) and benzyl esters of HA (Hyaff-11). Through a variety of processing steps, these HA esters can be shaped into fibers, membranes, sponges, and microspheres.

Carbodiimide-mediated derivatives

Reactions mediated by carbodiimides (e.g., 1-ethyl-3-(3'-dimethylaminopropyl)carbodiimide or EDC) are a common means of covalently binding the carboxyl group of one bioactive molecule with an amine of another (e.g., reactions between amino acids during peptide synthesis). However, carbodiimide reactions are very sensitive to pH and often result in the formation of an unreactive intermediate, acylurea, from carboxyl groups. Therefore, depending on the reaction conditions, carbodiimide-mediated reactions on HA can result in very low coupling yields. (For excellent discussions of the challenges to carbodiimide-mediated modifications of HA, see Refs. [15–17]). Pouyani and Prestwich gained a detailed understanding of these reactions, and as a result, chose hydrazide derivatization (Fig. 3B) as a means of increasing the utility of carbodiimide in HA modifications.^[15] Prestwich and coworkers have continued to develop a wide variety of HA-hydrazide derivatives for use as drug delivery devices, cellular probes, and HA-protein conjugates.^[13]

Sulfated derivatives

To create a blood-compatible molecule that mimics heparin, researchers have modified HA with sulfate

groups (Fig. 3C; Ref. [18]). The sulfation is completed through a reaction of sulfur trioxide pyridine with HA's hydroxyl groups, yielding a range of sulfation from one to four sulfur groups incorporated per HA disaccharide.^[19] This sulfation modification creates HA derivatives that are structurally and chemically similar to heparin;^[18,19] cardiovascular applications of these materials are described in more detail in a later section (see “Applications of HA Biomaterials”).

Cross-Linked HA Biomaterials

As already mentioned, HA presents many inherent advantages as a foundation for biomaterials. In addition to derivatization, cross-linking is another means of engineering HA's physicochemical properties. Depending on the cross-linking molecule and reaction chemistry, a wide variety of HA materials can be created, ranging from films with relatively low water content to highly swelling hydrogels. Most HA cross-linking methods fall into either of two general schemes: a one-step procedure consisting of the exposure of HA to a cross-linker, or a two-step procedure in which a highly reactive HA derivative is first synthesized and then cross-linked in a subsequent reaction. Following is a brief listing of common HA cross-linking techniques; see Refs. [2] and [13] for more detail.

Diepoxy cross-linking

Almost 40 years ago, Laurent and coworkers created diepoxy-cross-linked HA hydrogels using polyethylene glycol diglycidyl ether.^[20] Others have extended the utility of the diepoxy chemistry to other cross-linkers, including ethylene glycol diglycidylether (a bifunctional cross-linker) and polyglycerol polyglycidylether (a trifunctional cross-linker).^[21] Interestingly, detailed studies of this chemistry have shown that at low pH, diepoxy compounds form ester linkages between carboxyl groups, while at high pH, they form ether linkages between hydroxyl groups (Fig. 3D; Ref. [22]). Utilizing this fact, diepoxyoctane has been used to cross-link HA in a two-step double-cross-linking treatment: HA is reacted with diepoxyoctane at low pH, forming ester cross-links between HA chains, and then a second diepoxyoctane reaction is subsequently carried out at high pH, forming ether cross-links.^[22]

Carbodiimide-mediated cross-linking

As discussed above, carbodiimide-mediated reactions are commonly used for reactions between carboxylic acids and amines. These reactions, however, are highly sensitive to pH and readily form an unreactive acylurea

moiety when applied to HA reactions; therefore, the applications for which carbodiimides can be used with HA are somewhat limited. Fortunately, several researchers have found specific conditions under which carbodiimide-mediated reactions can allow HA cross-linking.

The simplest of these methods uses solely carbodiimide to induce inter- and intramolecular cross-links on HA;^[23] in other words, these materials can be synthesized without the use of exogenous cross-linkers. To form cross-links, the carbodiimide-mediated reaction is performed on films of at least 70 weight-percent HA in acetone- or ethanol-water solutions. Similar reactions carried out with HA in solution did not yield cross-linked materials, perhaps due to the formation of unreactive acylureas. Challenged by this tendency of carbodiimide-mediated reactions to form unreactive acylureas on HA, Kuo, et al. created a biscarbodiimide cross-linking technique (Fig. 3E; Ref. [17]). Several biscarbodiimides were synthesized and covalently bound to HA through a mechanism similar to the carbodiimide-mediated creation of an acylurea, producing aromatic or aliphatic cross-links between HA molecules.

Finally, several efforts have utilized carbodiimides to mediate reactions between HA's carboxyl groups and the amines of bifunctional cross-linkers (Fig. 3F). Bullpitt and Aeschlimann made use of reactions mediated with carbodiimide and 1-hydroxybenzotriazole (HOBt) to couple activated amines ($pK_a < 8.0$; e.g., adipic dihydrazide) to HA's carboxyl groups; carbodiimide and N-hydroxysulfosuccinimide (sulfo-NHS) were used for coupling reactions between HA and simple primary amines ($pK_a > 9.0$; e.g., 1,4-diaminobutane dihydrochloride).^[16] Similarly, Vercryse and coworkers have synthesized a wide variety of polyvalent hydrazide cross-linkers (2-6 hydrazides per cross-linker) for use in carbodiimide-mediated cross-linking reactions.^[24]

Aldehyde cross-linking

Formaldehyde and glutaraldehyde have long been used to cross-link proteins for tissue preservation. Formaldehyde is used to create Biomatrix's Hylan-A, a cross-linked form of HA that is water-soluble, but more viscous and elastic than native HA.^[25] Glutaraldehyde has been used to cross-link HA to yield materials with high resistance toward degradation. Tomihata and Ikade used glutaraldehyde in acidic acetone-water solutions to create cross-linked HA films of low water content.^[26] Hu et al. compared glutaraldehyde and carbodiimide-mediated reactions and found that glutaraldehyde yielded more highly

cross-linked materials suitable for use as three-dimensional tissue scaffolds.^[27]

Divinyl sulfone cross-linking

Insoluble HA hydrogels can be formed by cross-linking HA with divinyl sulfone (Fig. 3G), yielding materials such as Biomatrix's Hylan-B gel.^[25,28] At high pH, divinyl sulfone creates sulphonyl-bis-ethyl crosslinks between HA's hydroxyl groups. Depending on the reaction conditions, materials ranging from soft gels to firm solids (e.g., membranes and tubes) can be formed. Compared to native HA, Hylan-B has an extended residence time in vivo, particularly in sites where low mechanical force is imposed on the implant.

Photocross-linking

While the cross-linking methods discussed above yield a wide variety of stabilized materials, most of these techniques proceed under physiologically incompatible conditions. Furthermore, many of these methods cross-link immediately upon mixing of the HA with the cross-linker. Because HA forms highly viscous solutions, it is often difficult to obtain homogenous materials in this manner. Photocross-linking, however, is a method that reacts only upon exposure to the appropriate wavelength of light; therefore, the reactants can be thoroughly mixed before cross-linking is initiated.^[29] Furthermore, photocross-linking methods are capable of proceeding under physiological conditions without detrimental effects to copolymerized bioactive molecules or encapsulated cells. To this end, HA has been modified with several photocross-linkable groups, including cinnamoyl, coumarin, and thymine;^[30] methacrylic anhydride;^[31] glycidyl methacrylate;^[32] and styrene.^[33] (See Fig. 3H for a general schematic of photocross-linking methacrylated HA derivatives.) Additionally, sulfated HA has been modified with 4-azidoaniline, yielding an HA derivative suitable for patterning features as small as 100 μm ,^[34] which may be useful for directing cell growth or adhesion in new biomaterials.

APPLICATIONS OF HA BIOMATERIALS

HA's intrinsic physicochemical and biological properties suggest that this distinctive molecule is suitable for application in clinical therapies, diagnostics, tissue engineering scaffolds, and drug delivery devices. Unmodified, derivatized, and cross-linked HA have proven beneficial in a variety of applications, which are briefly described in the following sections. For comprehensive reviews of medical applications of HA, see

Table 1 FDA-approved HA products

Application	Tradename	Approval type	Company
Osteoarthritis	Hyalgan	Premarket	Fidia
	Synvisc	Premarket	Biomatrix/Genzyme
	Supartz	Premarket	Seikagaku
	Hylashield	510 k	Biomatrix
Ophthalmology	Healon	Premarket	Pharmacia
	Amvisc	Premarket	Bausch and Lomb
	Coase, Shellgel, Staarvisc	Premarket	Anika Therapeutics
	Amo Vitrax, Vitrax	Premarket	Allergan/Medtronic
	Provisc, Viscoat	Premarket	Alcon Laboratories
Wound healing	Bionect	510 k	Fidia
	Ialuset	510 k	IBSA
	Adcon	Premarket	Gliatech
Postsurgical adhesions	Intergel	Premarket	LifeCore Biomedical
	Seprafilm	Premarket	Genzyme
	Hyalomatrix	510 k	Fidia
Surgical scaffolding	Hylasine	510 k	Biomatrix
	Deflux	Premarket	Q-Med

(Adapted from Refs. [2,13] and [35].)

Refs. [2] and [13]. Table 1 provides a list of HA products currently approved by the FDA for clinical use.

Orthopedic Applications

HA plays a vital role in the development of cartilage, the maintenance of the synovial fluid, and the regeneration of tendons.^[8] High concentrations of HA can be found in the ECM of all adult joint tissues, including the synovial fluid and the outer layer of cartilage.^[36] In part because of its viscoelastic nature and ability to form highly hydrated matrices, HA acts in the joint as a lubricant and a shock absorber.^[37] In diseases such as osteoarthritis, the concentration and molecular weight of the HA naturally present in the joint are decreased, contributing to stiffness and pain. Viscosupplementation treatments aim to treat these conditions, and to this end, a variety of HA materials have been successfully applied as clinical therapies.^[36,37]

Researchers have also investigated cross-linked HA as cell delivery scaffolds for cartilage and bone tissue engineering. Esterified HA (Hyaff, Fidia Advanced Biopolymers) supports the growth of chondrocytes^[38] and the differentiation of bone marrow-derived mesenchymal progenitor cells into chondrocytes and osteoblasts.^[39] In fact, when compared to a well characterized delivery vehicle (porous calcium phosphate ceramic), Hyaff materials allowed greater amounts of bone and cartilage to be formed *in vivo* (as

determined from the image analysis of stained tissue sections).^[39]

Antiadhesion Applications

As HA is highly hydrophilic, it is a polymer that is well suited for applications requiring minimal cellular adhesion. Postoperative adhesions, which form between adjacent tissue layers following surgery, impede wound healing and often require additional surgical procedures to repair successfully. Barriers made from cross-linked HA have been effectively used to prevent such adhesions from forming.^[30] Furthermore, the adhesion of bacteria onto biomaterials can induce infections and great risk to the patient; with this in mind, esterified HA has also been used to prevent bacterial adhesion to dental implants, intraocular lenses, and catheters.^[40]

Cardiovascular Applications

In a manner related to its antiadhesive properties, HA has also proven to be effective for increasing the blood compatibilities of cardiovascular implants such as vascular grafts and stents. For example, biomaterial surfaces treated with cross-linked HA have been associated with reduced platelet adhesion and thrombus formation.^[25,34,41] Furthermore, sulfated HA derivatives

can act as heparin mimics,^[18,19] in fact, HA derivatives with higher degrees of sulfation are associated with increased abilities to prevent blood coagulation (as measured by longer times required for whole blood clotting).^[19]

Cross-linked HA is also a promising biomaterial for cardiac tissue engineering. In the embryo, HA is required for the normal development of the valves and chambers within the heart.^[42] Building upon this information, studies by Masters and Anseth have indicated that photopolymerized HA hydrogels are suitable materials for constructing tissue-engineered heart valves (K.S. Masters and K.S. Anseth, Department of Chemical Engineering, The University of Colorado at Boulder, 2003, personal communication). Valvular interstitial cells, which are the primary cell type found in heart valves, were found to adhere to and proliferate upon the HA hydrogels. Furthermore, the hyaladherins CD44 and RHAMM are present on the valvular interstitial cells, and these receptors were thought to be involved in promoting cellular proliferation in response to degraded HA hydrogel fragments.

Ophthalmology

HA, a natural component of the vitreous humor of the eye, has found many successful applications in ophthalmologic surgery.^[2] In part because it forms viscoelastic and highly hydrated matrices, HA is particularly useful as a space-filling matrix in the eye; thus, intraocular injection of HA during surgery is used to maintain the shape of the anterior chamber. Furthermore, HA solutions also serve as a viscosity-enhancing component of eye drops and an adjuvant to eye tissue repair.

Dermatology and Wound-Healing Applications

HA is naturally present in high concentrations in the skin and soft connective tissues. Therefore, HA is an appropriate choice for a matrix to support dermal regeneration and augmentation. For example, Prestwich and coworkers found that cross-linked HA hydrogel films accelerate the healing of full-thickness wounds (Fig. 4), presumably by providing a highly hydrated and nonimmunogenic environment that is conducive to tissue repair.^[43] Hyaff scaffolds cultured *in vitro* with keratinocytes and fibroblasts have been used to create materials similar to skin, including two distinct epidermal and dermal-like tissue layers.^[38] Moreover, as a result of its ability to form hydrated, expanded matrices, HA has also been successfully used in cosmetic applications such as soft tissue augmentation.^[44]

Fig. 4 Cross-linked HA hydrogel films to assist wound healing. Full-thickness wounds were created in the skin of Balb/c mice and a) treated with a cross-linked HA hydrogel film (adipic dihydrazide-modified HA that was cross-linked with polyethylene glycol dialdehyde) and covered with a wound dressing (Tegaderm, a thin polyurethane membrane dressing that is impermeable to microorganisms, 3M Health Care, St. Paul, MN), or b) covered with the wound dressing alone. After 10 days, the HA films were completely degraded and four out of six of the HA-treated wounds were associated with the formation of an epithelial layer and a collagen-rich dermal layer. The tissues treated with the wound dressing alone were less consistent and had reduced reepithelialization. Tissue extracted from an area peripheral to the wound is shown in c) as a normal tissue control. The sections are stained with Masson's Trichrome. D = dermis, E = epidermis, M = muscle. Scale bar = 100 μ m. Images reprinted from Ref. [43] with permission from Elsevier Science.

Neural and Glial Applications

HA treatments have also been associated with improved peripheral nerve regeneration. Injections of unmodified HA into a nerve guide have been associated with increased levels of physiological and functional regeneration.^[45] Furthermore, when strands of cross-linked HA are coated with polylysine, Schwann cells are able to attach and proliferate on these materials.^[27] It is possible that the presence of HA enables increased glial cell migration, more rapid neurite outgrowth or a more highly organized ECM between the nerve stumps. However, the exact mechanism by which HA may aid this process is not well understood.

General Tissue-Engineering and Surgical Applications

HA's unique biological properties have inspired the development of a variety of novel therapies for general surgical applications. For example, work in our lab has created photocross-linked scaffolds to support potentially a broad range of tissue engineering applications.^[32] Following cross-linking, these hydrogels maintained HA's biological activity and promoted similar levels of vascularization as fibrin positive controls. We have also used HA as a dopant during the synthesis of polypyrrole, an electrically conductive polymer that alone can promote repair in a variety of systems.^[46] When compared to polypyrrole films without HA, composite films of HA and polypyrrole were associated with higher levels of vascularization in subcutaneous implants. Therefore, HA-polypyrrole materials could be suitable for tissue-engineering applications that may benefit from electrical stimulation and enhanced angiogenesis. Other researchers have also utilized HA's antioxidant properties to assist in the prevention of inflammation. In-vitro studies have indicated that several materials, including unmodified HA, Hyaff, and a steroid-ester of HA, possess antioxidant activities.^[47,48] Such materials could aid in healing conditions such as chronic wounds and rheumatoid arthritis.

Drug Delivery

Because of its biocompatibility, biodegradability, and readily modified chemical structure, HA has been extensively investigated in drug-delivery applications. A variety of commercially available preparations of HA derivatives and cross-linked HA materials have been developed for drug delivery; these materials are created in forms such as films, microspheres, liposomes, fibers, and hydrogels. For excellent reviews on applications of HA in drug delivery, see Refs. [2] and [13].

CONCLUSIONS AND FUTURE DIRECTIONS

Through multidisciplinary discoveries about the structure, properties, biological activity, and chemical modification of this unique polymer, HA has found success in an extraordinarily broad range of biomedical applications. Future clinical therapies of HA-derived materials critically rely on a more detailed understanding of the effects of HA molecular weight and concentration and how this biomolecule specifically interacts with cells and ECM components in the body. Future directions of these materials will require finely tuned and controllable interactions between HA and its environment. Work in these areas is underway; for example, adhesive peptide sequences have been covalently bound to HA materials.^[49] Also, environmentally responsive materials have been synthesized from HA. These materials can be created to swell or degrade in response to inflammation,^[21] electrical stimulation,^[50] and heat.^[51] For an excellent online resource regarding the biology, modification chemistries, and various applications of HA, see the Glycoforum website.^[52]

INTRODUCTION

Synthetic and biologically based hybrid prostheses are reasonably successful when used as large-diameter peripheral vascular replacements (>5–6 mm), although outcomes do depend on the location of the replacement vessel and the status of the patient. However, treatment of both peripheral vascular disease (PVD) and coronary artery disease, the largest cause of mortality in the United States and Europe, is severely hampered by the inadequacy of the current synthetic and hybrid prostheses when used in these smaller-diameter applications. The autogenous saphenous vein and internal mammary artery continue to be the most widely used vascular grafts for small-caliber vessel reconstruction, but these substitutes are often not available or are unsuitable.

The predominant synthetic materials used in PVD, including below-the-knee procedures, are woven polyethylene terephthalate (Dacron™) and expanded polytetrafluoroethylene (ePTFE), while the latter is a poor but often only choice for cardiac surgery. The relative success of the autogenous vessel is largely due to the fact that it is a living, natural vessel with all the necessary attributes required of a blood vessel. A number of different biological strategies have been undertaken to mimic these natural qualities, which are required for reconstructing a functional vascular replacement. This review will outline some of the different approaches that have been explored to bridge the gap between the purely synthetic approach and the use of natural blood vessels. In particular, these hybrid approaches include 1) biological modification of conventional synthetic prostheses (sealants); 2) endothelial cell (EC) seeding of synthetic and biosynthetic prostheses; 3) mandrel-guided fibro-collagenous tubes (FCTs); and 4) tissue engineered vascular substitutes. The review does not include developments in the use of natural biomimetic scaffolds—for example, allografts, bovine ureter, bovine carotid heterografts, acellular matrix vessels, small intestinal submucosal substitutes—which may have the potential to remodel into hybrid blood vessels after implantation.^[1–3]

BIOLOGICAL SEALANTS FOR SYNTHETIC VASCULAR PROSTHESES

Synthetic polymer materials have been used successfully for a number of vascular procedures. The majority of these materials commercially available are composed of polyester textile materials (either knitted or woven) or ePTFE. The main disadvantage with the porous textile materials is their permeability to blood. While ePTFE is microporous and impermeable to whole blood, there is bleeding from the needle holes immediately postimplantation, or when the prosthesis is used as a vascular access device and regularly punctured in patients receiving dialysis for renal failure. The concept of coating or sealing these synthetic prostheses was introduced primarily to reduce this porosity and reduce bleeding at the time of implantation.^[4] In addition, these coatings provide a means of surface passivation that can prevent early thrombogenic responses.

Originally, preclotting of the prosthesis involved soaking the prosthesis in the patient's own blood. More recently, a number of materials including albumin, collagen, gelatine, fibrin, and alginate have been used as alternate biological compatible components to precoat woven or knitted polyester and ePTFE, to produce what has been colloquially referred to as a "biohybrid" device.^[5,3] The coating is intended to be a temporary sealant that resorbs with time to leave a patent porous prosthesis that allows sufficient host tissue in-growth to sustain its long-term function.

There are potential problems that might arise with biological coatings. For example, the concerns on the use of collagen in vascular coatings include immunogenicity, thrombogenicity, and complement activation. The potential immunogenic nature of collagen has been extensively reviewed.^[6] These issues can be minimized by the use of cross-linking agents to treat the collagen. Thus, some prostheses are lightly cross-linked with formaldehyde [e.g., Hemashield graft (Boston Scientific, Massachusetts, U.S.A.); Dialine warp-knitted polyester prosthesis (Cardial S.A., St. Etienne, France)], while others are more strongly cross-linked with glutaraldehyde [e.g., Hemaguard (InterVascular,

Florida, U.S.A.]). Although all of these devices are successful in preventing prominent transinterstitial bleeding after restoration of circulation, the thrombogenicity and particularly the wound healing responses vary between the different cross-linked collagen coated prostheses.

The patency of the vessels is largely attributable to the polyester component and appears to be independent of the coating. By and large, the polyester devices are prone to thrombosis and dilatations, and these consequences are not altered, favorably or adversely, by the additional treatment.^[7] The degree of cross-linking will have obvious effects on the rate of resorption of the protein material and in some animal studies, this has resulted in different healing responses. The lightly cross-linked sealants allowed good neointimal formation and rapid tissue integration in the inner capsule, while the more cross-linked prostheses showed a delayed resorption and reduced tissue integration.^[8,9]

Clinical studies using collagen-coated polyester prostheses have largely confirmed the safety of these biohybrid prostheses, showing acceptable patency and minimal occlusions or other complications such as thrombogenicity and adverse immunological responses.^[2,7,10] “Doubly” sealed collagen devices, which include an inner luminal coating, can be more prone to activating platelets and thrombus formation, while the more highly cross-linked prostheses may have less platelet deposition and subsequent thrombus formation.^[11,12]

A number of gelatine-sealed polyester (Gelseal™ and Gelsoft™ Vascutek Terumo) and ePTFE (SEALPTFE, Vascutek Terumo Ltd) prostheses are also currently available on the market. An *in vivo* study in a dog model showed that the use of a gelatine coating on an ePTFE prosthesis significantly reduced the bleeding from suture holes in the immediate post-operative period. The coating did not appear to effect the development of neointima, and the healing was similar to control ePTFE prostheses.^[13]

ENDOTHELIAL SEEDING OF PROSTHESES

Although there are a number of factors that contribute to the poor patency of conventional synthetic, biohybrid, and biosynthetic (see below) devices, in small-diameter vascular replacements in low-flow areas, thrombosis and subsequent occlusion is the key factor in failure. At the biological level, the predominant cells that are critical to preventing this process are the ECs that form a continuous surface monolayer in the natural blood vessel and are absent in “off-the-shelf” prostheses.

A minimal prerequisite to manufacturing a functional vascular prosthesis in culture or in animals is the process of actively isolating and expanding ECs and using these ECs to form a lining into the lumen of the device. Synthetic prostheses do not spontaneously form EC linings in humans, except for an occasional region near the anastomotic junction. The process of seeding should therefore, in theory, reduce the thrombogenicity of these artificial vessels. Unfortunately, to date, this tedious process has not been reliable for commonly used synthetic prostheses. Various strategies and tissue sources for retrieving autologous ECs have been reported, but to date there is still only limited optimism in the potential to use these cells reliably in the clinic. There are currently two broad strategies that are used in seeding: one involves a single stage (extraction of cells and immediate use), the other involves a two-stage process that includes prolonged cell culture prior to use. A variety of differing techniques that use a selection of different tissue sources (e.g., vein, artery, fat) have been used to retrieve ECs; these methods have been reviewed elsewhere.^[14] The limited availability of ECs is a key issue. More recently, alternate sources have been examined, including bone marrow derived cells and umbilical cord blood. Also, gene therapy approaches to introduce and optimize EC function have been developed.

Overall, cell seeding on Dacron and ePTFE prostheses has had disappointing outcomes, although there have been occasional reports of improved clinical patency with both ePTFE and Dacron grafts.^[15–17] These have used high-cell-density seeding (sodding) to counteract the hostile pulsatile environment and subsequent loss of seeded cells in culture. In the clinical study using two-stage EC seeding onto ePTFE, the high-density seeding was carried out using RGD-enriched fibrin glue.^[16] Even then, there is variability caused by the degradation or disattachment of the biological substrate. As a result of the variability of EC seeding, attempts have been made to improve the cell attachment and retention of seeded cells onto Dacron and ePTFE surfaces under arterial flow. Most of these approaches have involved the attachment of proteins, peptides, or surface chemical modification by methods such as plasma glow discharge. These included passivating proteins like albumin or albumin–heparin, which minimize platelet adhesion and activation, as well as proteins and peptides that could enhance EC binding in culture—gelatin, collagen, fibronectin, laminin, and RGD.^[15] Other approaches have included preclotting these surfaces with blood, plasma, serum fibrin glue, gelatin, and collagen without EC seeding, as discussed above.

In addition there have been developments in alternate polymer materials. One of the disadvantages with the ePTFE grafts is the issue of compliance mismatch.

The MyoLink graft is a compliant poly(carbonate-urea) urethane tube that has similar elasticity to the natural artery and has relatively better cell retention than ePTFE. Covalent attachment of RGD, heparin, or a combination of RGD and heparin to the surface can improve the initial binding of EC, but after 6 hr of pulsatile flow, the RGD/heparin was less thrombogenic.^[18] For single-stage cell seeding the initial time and extent of EC binding is critical. Fibronectin, or RGD-based peptides derived from fibronectin, is a natural integrin receptor on the EC, but fibronectin and peptides are normally susceptible to cleavage and proteolysis. Fibronectin-like engineered protein polymers containing multiple copies of RGD, in combination with heparin, have shown improved retention of ECs as well as the smooth muscle cells (SMCs) that are critical to the integrity of the blood vessel.^[19] Recently, a novel hyaluronan-based biomaterial (Hyaff-11) has been used and EC seeded onto these biodegradable scaffolds can produce a fully functional matrix.^[20] Also, fibrin gel, which is the only substrate that has been used clinically to retain ECs, could be used as a carrier for ECs and SMCs to allow rapid remodeling within cylindrical tissue constructs to generate a developing vessel that produces collagen and elastin fibers—a concept that is discussed later, in the section on tissue engineered prostheses.^[16,21]

The concept of EC seeding has also been extended to “off-the-shelf” porcine acellular matrix tubes and biosynthetic grafts [Omniflow Vascular Prosthesis™ (OVP)—discussed later]. The OVP is a hybrid device of collagen and Dacron that is produced *in vivo* and has a natural matrix coverage on the lumen surface, and so does not require further surface modifications to allow cell attachment and retention. Endothelial cell seeding on the OVP has demonstrated that the natural unmodified luminal surface can form a confluent monolayer of EC within 24–48 hr and that these cells are retained under physiological shear stress.^[22]

MANDREL-GUIDED FCTS

The basis for the development of FCTs as vascular replacements stems from the knowledge that implantation of synthetic materials into a host will lead to a foreign body fibrous tissue response, with the extent and nature of this response often dictated by the material itself. In the development of FCTs a variety of temporary mandrel supporting scaffolds have been used. Later, in the evolution of these FCTs, a variety of reinforcement synthetic meshes have been used to further strengthen the developing tube. These latter FCTs are true hybrid vascular devices integrating natural collagen with synthetic polymer and are

distinct from synthetic grafts coated with collagen or other biological molecules as sealants.

The Autogenous FCT

In 1953, Pierce and Baltimore reported on the first production and autogenous implantation of an FCT in dogs, using subcutaneously implanted polypropylene tubes. The 10 aortic implants remained patent up to 30 mo. The development of these autogenous “self-generating” tubes in soft connective tissue continued with a variety of different polymeric and metallic mandrel supports, although none of these could prevent the eventual development of aneurysms and vessel rupture. The early development of FCT devices has been reviewed previously.^[2,3]

Hufnagel suggested that implanted ePTFE mandrels could be surrounded with a polyester (Dacron) mesh to reinforce the FCT, and at the same time Assefi and Parsonnet used a reinforcing polypropylene mesh to generate an FCT that remained patent without signs of aneurysmal changes. In both instances, the reinforced mesh was infiltrated by inflammatory cells and became an integral part of the new collagenous network of the FCT, resulting in a true hybrid graft. These early studies were encouraging and formed the basis of the studies of Sparks and his “Sparks mandril” (sic).^[23] Sparks initially made use of slender cylindrical stainless steel mandrels. These so-called “tissue dies” consisted of an outer perforated tubular shell of stainless steel that would allow cell infiltration and an inner polished tubular mandrel of stainless steel that was wrapped around with Dacron, all over a central tie rod through the length of the mandrel.^[23] The tissue that formed over 1–6 mo was vascularized and was rich in collagen, and importantly the knitted Dacron had become an integral part of the hybrid FCT. Substitutions were made to replace the metallic die with a silicone mandrel. Studies from Parsonnet and colleagues demonstrated good long-term patency over 4 yr with no signs of aneurysm formation in these FCTs, which had been manufactured using a polyester (Dacron) or polypropylene mesh support over a silicone mandrel template. Similarly, Sparks, using this modified approach to generate FCTs, reported high patency rates in animal and limited human trials. The Sparks FCT, which was patented in 1973, was commercialized by Edwards Laboratories and used by many surgical groups. Following these favorable animal and early clinical results, the “Sparks mandrel” remained popular until subsequent clinical reports described poor results. For example, Hallin and Sweetman reported 100% patency in the ilio-iliac and ilio-femoral sites, but only 26% (10/38) in the femoropopliteal and 0% in the femorotibial and axillofemoral positions. Similar clinical findings were

also reported from other groups, showing very low patency rates of around 18%. The reasons for failure of these vessels were predominantly early thrombosis, aneurysm formation, and late thrombosis due to luminal narrowing. Studies from one of these groups had included a number of additional modifications to the design and manufacture of these FCTs. These variations included using xenogenic species like dogs, goats, and pigs, using fresh and frozen FCTs, and glutaraldehyde and enzyme treatment of the FCTs. After the initial promising animal studies, the use of autogenous FCTs in humans, based largely on the Sparks mandrel, did not continue and the technology was withdrawn from the market in 1976.^[2,3]

The Peritoneal-Grown Autologous Graft

A further development of the Sparks mandrel concept is the autologous cell–tissue hybrid blood vessel that is generated by peritoneal implantation.^[24] This approach is based on the prior knowledge that any foreign body that is implanted into the peritoneal cavity will induce a foreign body reaction that results in a tissue comprising collagen, myofibroblasts and a single outer layer of mesothelial cells. It is the presence of this layer of mesothelial cells that could have an impact on the generation of a nonthrombogenic graft. Typically, the peritoneal-grown vessel is reversed inside out to generate what seems to mimic a natural artery with, after reversal, an inner mesothelial cell lining, media comprising myofibroblasts, and an outer collagen-rich adventitia. Mesothelial cells, while not entirely the same as ECs, do have some common biological characteristics including secretion of prostacyclin and fibrinolytic activity. In initial studies in rats and rabbits using this approach, patency rates of 67% and 70% were obtained over 4 mo. Subsequent animal trials in dogs have shown improvements, but to date there is no indication of long-term performance and it is still too early for clinical trials.

An additional benefit of this artificial autologous hybrid graft is the ability to remodel under arterial shear stress.^[25] It is postulated that further differentiation of cells and tissue maturation within the hybrid graft occurs, a process that has not been demonstrated in human arteries. Alternatively, some of the animal experiments in rabbits were conducted without everting the graft so that the mesothelial cell layer remained on the outside. In these cases, ECs were found on the inner luminal surface, which could indicate migration of cells from the adjacent host artery.^[26]

Current FCT Vascular Prostheses

At present there is no autologous FCT in the clinic. However, a use of this technology to provide a

xenogenic off-the-shelf hybrid vessel has been successful and a commercially available device, the OVP (Bio Nova International, North Melbourne, Australia), is in current clinical use. The OVP is a glutaraldehyde-stabilized xenogenic FCT that is manufactured in sheep using a polyester (Dacron) covered silicone mandrel.^[27] This strategy of using a xenogenic host, a polyester reinforced mandrel support, and an effective stabilization process has generated a device that has proved to be effective for peripheral arterial replacement. The stabilization of the collagen in the hybrid device minimizes the extent of cross-species immunological reactivity to allow off-the-shelf transplantation into animals and into humans. The stabilization also allows the collagenous matrix to persist for long implantation times. Also, significant amounts of new collagenous tissue begin to deposit within the vessel wall soon after implant, and continue to accumulate with time, providing a very durable and patent prosthesis. The development of the OVP has been described in previous reviews.^[2,28,29] During production, the Dacron mesh within the OVP becomes fully encased with collagen during its implantation in sheep. The prosthesis comprises an organized extracellular matrix of collagen type I and a high content of collagen type III. While elastin is notably absent, the OVP does contain other microfibrillar elastic proteins, including fibrillin. Collagen is found in a circular array in regions surrounding the polyester fibers, but further away from the silicone mandrel, the collagen forms an elongated, highly aligned layered structure. The inner region of the OVP is somewhat less dense comprising loose connective tissue, and the thickness of this layer varies inversely with the presence of nodes of polyester fiber bundles. The OVP has a burst strength greater than 1688 mm Hg and maintains excellent physical integrity following both *in vitro* mechanical and fatigue testing.^[2,28,29]

Following the initial reports of the use of this prosthesis in animal models, it has undergone an extensive series of *in vitro* and *in vivo* tests, and is now used successfully in clinical applications.^[2,28,29] The patency of this collagen-based polymer composite prosthesis is comparable to, or better than, other available materials. Clinical studies have shown excellent long-term patency, and a study using the more recent OVP II as a femoropopliteal bypass showed a primary patency of 83% and a secondary patency of 91% over 3 yr.^[30] For use as a small-diameter (<3–4 mm) vascular replacement, the OVP has yet to be fully tested. The major issues here would be to generate a luminal surface that was a deterrent for platelet activation and thrombosis, but that was favorable for endothelialization. Further improvements to the manufacture of the device can produce an inner surface that is less undulated and more uniformly covered with

collagen, which can effectively protect the prosthesis against potential deleterious polyester breaking through the inner surface.^[31]

TISSUE ENGINEERED VASCULAR SUBSTITUTES

Tissue engineering in cell culture is an emerging multidisciplinary technology that combines basic engineering concepts with biological sciences to generate a functional tissue equivalent that can replace and allow regeneration of damaged tissues or organs. Tissue engineering should enable the fabrication of a regenerated blood vessel that is almost indistinguishable from the damaged one. The choice of cells and natural or synthetic polymer scaffolds that can direct the growth and differentiation of a cell type(s) into the appropriate tissue architecture is critical to the regenerated tissue. The basis of this approach arises from early studies on hybrid biomaterial scaffolds, as well as the concept of seeding these scaffolds with ECs *in vitro*. The distinction can be made in the choice of the biomaterial scaffold that is used with the early approaches mainly using biostable synthetic polymers, natural tissue scaffolds, or combinations of these to induce remodeling or cell seeding. The current approaches are predominantly using biodegradable polymer scaffolds and a selection of different cell types and seeding strategies.

The Basis for Tissue Engineering of Vessels

Following from the initial concept of engineering tissue-like structures by cell-based collagen contraction, Weinberg and Bell in 1986 paved the way for further refinements and developments of a tissue engineered vascular prosthesis (TEVP).^[32] In this instance, the tissue comprised autologous cell types remodeled in a collagen matrix to meet the demands of a functional living blood vessel. Weinberg and Bell produced the first biological TEVP using porcine skin collagen or rat tail tendon collagen with bovine aortic ECs, SMCs, and adventitial fibroblasts.^[32] The results were encouraging but the final prototype lacked the necessary mechanical strength to withstand moderate pressures, even with the inclusion of a supportive Dacron sheath(s). A number of factors may have contributed to the lack of appropriate mechanical strength. These included the random or longitudinally orientated SMCs compared with the circumferential arrangement in natural arteries, the switching on in culture of metalloproteinases that could be degrading the tissue, and the somewhat low densities of SMC and collagen, only around one-fourth to one-eighth of those of

natural vessels. The investigations that followed this initial approach seem to have taken some of these factors into consideration, but still there remains a huge gap in bringing this technology into the clinic.

Current TEVPs

There are three distinct layers that need to be designed and cultivated to mimic the natural artery: an intimal layer composed of a continuous monolayer of ECs designed to enhance hemocompatibility, a medium composed of SMCs designed to provide strength and elasticity, and an adventitial layer composed of fibroblasts designed to augment the durability and integration of the vessel.

Overall, three strategies have been documented including EC seeding alone or within a collagen or fibrin gel, layer-by-layer reconstruction of the EC-seeded intima and SMC-seeded media, and finally a three layered structured tissue with the additional fibroblast-seeded adventitia.^[33,34] Other differences in strategies have arisen from the use of a supportive synthetic mesh in some developments but not in others to generate a mechanically sound finished vessel.^[33,34] The layer-by-layer approaches are similar in conceptual design, and rely on stepwise sequential generation of layers of each type of tissue, using temporary tubular supports to generate the necessary vessel architecture.

A Japanese group from Kyushu University with others developed a self-organized tubular hybrid prosthesis using a selection of mold designs, collagen and SMC seeding densities that formed a media matrix after contraction, and that produced burst strengths around 100 mm Hg.^[35] Implantation of the vessels in the posterior vena cava of dogs from where the cells were derived resulted in massive bleeding due to vessel rupture within a few days. With a supportive outer Dacron mesh, 9 of the 14 implants remained patent at various times of explant from 1 to 24 weeks after implantation. In the patent explants, elastic lamellae were present, SMCs were contractile in nature, and there were signs of good tissue augmentation.^[33] Indeed, while EC retention is critical to the thrombogenicity of the engineered vessel, the remodeling of cells and tissues is equally critical to withstand the physiological shear stress. The supramolecular matrix assemblies of collagen and elastin, and the circumferential orientation of the SMCs are influenced by the different strategies used to build these vessels—as expected, more rapid and efficient remodeling occurs when all cells are used in a three-layer approach.^[36] In addition, various approaches have been used to influence the phenotypic switching and orientation of SMCs, including peristaltic flow, the use of perfusion

bioreactors, collagen contraction along the axis of the supporting scaffold, and magnetic fields.^[36]

Work from Laval University, using human vascular cells and human collagens similar to those described by others, failed to generate a mechanically sound vessel.^[37] While the use of a supportive Dacron mesh had been shown to augment the structural strength within the cultured vessel, a later study has outlined a modified method using similar sequential buildup of the various vessel layers, but without the need for any synthetic or exogenous biomaterial support.^[33,34] The SMCs were cultured with ascorbic acid and generated a cohesive cellular sheet, which was then further cultured around an appropriate temporary support to generate the media, prior to further seeding with ECs. The final cultured prototype was well organized with circumferentially orientated SMCs, numerous matrix proteins including elastin and desmin, and a functional EC layer. The three-layered vessel had a burst strength of over 2000 mm Hg, which was far in advance of the original tissue engineered vessel of Weinberg and Bell.^[32] Short-term implantation of these “human vessels” was performed in dogs and, as expected, there was only 50% patency owing to the xenogenic nature of the vessel. A later study, using similar culturing and testing of autologous ovine tissue engineered pulmonary arteries, has shown no early signs of aneurysmal changes.^[35,38] The tissue engineering strategy in this case was different in that the implanted vessel comprised a completely bioresorbable scaffold of poly (caprolactone-colactic acid) copolymer. The use of biodegradable synthetic scaffolds may offer advantages to further developments in this area—polyglycolic acid and polyglycolic acid-polyhydroxyalkanoate are polymers that have been used for two- or three-layer tissue engineering approaches.^[39] Alternatively, natural tissue scaffolds like elastin could be used with the current collagen-based multicell seeding approaches to increase the tensile strength of the cultured vessel.^[40]

CONCLUSIONS

A wide range of hybrid vascular prostheses have now been established, and from these a number of clinically effective devices have emerged. Typically, these devices work well at larger diameters, but there is still a significant unmet medical need for small-diameter prostheses, for example, for coronary artery replacement. This is where the emerging technologies of tissue engineering may produce significant benefits. However, there are still a number of issues that need to be addressed before the tissue engineering approach becomes the benchmark for further developments. The most obvious one is the long time that is needed to

produce one of these vessels. The system is highly advantageous in that it is designed for autologous arterial substitution. What is required is further research to elucidate matters like the amount of biopsy required, the source of materials that best suits the application, and optimization and quality assurance systems to guarantee generation of a vessel with the same biological features from batch to batch.

INTRODUCTION

Hydrogels refer to certain materials that are able to swell under conditions of excess water and hold a large amount of water in the wet state. Hydrogels generally consist of three-dimensional polymer networks that are cross-linked chemically and/or physically. The chemical properties of hydrogels are determined by the polymer backbone, the functional side chain in the monomer unit, and the cross-linking agent. The physical properties—for example, mechanical strength and swelling ratio—are controlled by the cross-link density. In general, hydrogels do not show any biodegradable behavior. Biodegradable hydrogels may be easily designed using natural polymers that are susceptible to enzymatic degradation or synthetic polymers that possess hydrolyzable moieties.

Biomaterials and biomedical engineering practices involve drug delivery carriers, tissue engineering scaffolds, and biomedical devices. Hydrogels provide adequate materials for these purposes. The research area of biomaterials is a multidisciplinary field composed of materials science, chemical engineering, medical engineering, and pharmacology. In particular, a biomaterial can play an important role as a bio-matrix and a bio-interface. Hydrogels provide excellent properties for improving conventional biomaterials, using such elements as copolymerization and polymer blends. As drug carriers, hydrogels can achieve stimuli-responsive drug release (for example, using pH or temperature) synchronized with enzymatic or non-enzymatic degradation. Hydrogels may be loaded with a variety of drugs and solubilizers or excipients. One major advantage of using hydrogels as a three-dimensional tissue reconstruction scaffold is the ability of these highly hydrophilic cross-linked polymer networks to swell and absorb sufficient amounts of cell culture medium. The permeability of the medium is important to the exchange of water-soluble molecules such as nutrients and gases. Widely used hydrogel medical devices include not only disposable materials, such as syringes, sample bags, and sample tubes, but

also artificial organs such as blood vessels. The most promising applications may involve lenses, muscle models, and artificial cartilage. Contact lenses are a major application of hydrogel products due to their high transparency.

This chapter focuses not only on fundamental principles but also on the use of recent anomalous hydrogels as biomaterials. Hydrogels can be classified as chemically cross-linked hydrogels for use as soft materials, and physically cross-linked hydrogels made of synthetic polymers, natural polymers, and their hybrids. In particular, a series of bio-inspired phospholipid polymers show unique properties for application as drug delivery carriers, tissue engineering scaffolds, and biomedical devices.

CHEMICAL GELS

The chemical gels, which are cross-linked by covalent bonds, are synthesized by polymerization of monomers with some difunctional monomers, called cross-linking agents, such as ethylene glycol dimethacrylate (Fig. 1a). The gel is affected by changes in pH, temperature, solvents, and other factors in the surroundings. A chemical gel shrinks or swells, showing a volume phase transition. That is, controlling the polymer network by a change in the surroundings will lead to a change in the gel volume. This phenomenon makes the gel especially useful as a functional material for medical devices.

Soft Contact Lenses

The foreign-body reaction often becomes a problem when artificial materials come in contact with the human body. A significant difference in the surface free energy between the material and the body is the cause of this undesirable reaction. A hydrogel can avoid this problem because the human body consists of network structures including biomacromolecules and water in a high percentage, which corresponds to the hydrogel

Fig. 1 Chemical structures of various monomers typically used for contact lens material.

structure itself. The surface free energies of the hydrogel and the human body are almost the same, so that the nonspecific interaction between the hydrogel and cell or protein is low, inhibiting protein adsorption following the foreign-body reaction. Therefore, the hydrogel is the most suitable biomaterial.

One of the remarkable properties of a hydrogel is softness, the property of an elastomer such as a rubber. Moreover, hydrogels are characterized by transparency and transmissibility of molecules through water flow. For the hydrogels in practical use, the soft contact lens (SCL) is the ideal manufactured article to take advantage of these properties. The eye naturally needs clarity for vision and the cornea needs oxygen by dermal respiration from the atmosphere. The properties of a hydrogel comply with these requirements.

Background on soft contact lens material

Poly(2-hydroxyethyl methacrylate) (HEMA, Fig. 1b), the first appearance of a soft biomaterial, was a great achievement by Otto Wichterle^[1] and can not

be omitted from a history of the SCL. Amazingly, this invention is still the main material used for SCLs some 40 years later. Moreover, poly(HEMA) and its copolymers have widened the range of application to include such products as intraocular lenses. Before poly(HEMA), poly(methyl methacrylate) (MMA, Fig. 1c) was known not to cause critical harm to the human body, a fact discovered when a pilot injured in the eye by a broken aircraft windshield made of poly(MMA) experienced no inflammation. As a consequence of this episode, poly(MMA) was used as the first plastic material for the hard contact lens (HCL). Poly(MMA) lenses not only have good optical properties for clear vision, including greater clarity than glass, but also properties of high strength, light weight, and ease of molding. However, poly(MMA) lenses have limitations of discomfort and prohibited long-term use because of low oxygen permeability. Wichterle thought that the introduction of hydrophilicity into the polymer could lead to amelioration of the defects of poly(MMA), so poly(HEMA) was the first material with hydrophilicity introduced in the polymer chain.

Increasing oxygen permeability

It is said that in addition to the anterior epithelium of the cornea, the endothelium of the cornea undergoes damage after long-term use of contact lenses having low oxygen permeability. As the physiology of the cornea has become understood, the oxygen permeability of contact lenses has been regarded as the important factor for homeostasis of the cornea. Without an adequate supply of oxygen, adverse events such as corneal edema may occur, followed by a number of possible physiological responses. Therefore, competitive efforts have resulted to develop materials with high performance in terms of regarding oxygen permeability.

The expression DK , where D represents the diffusion coefficient and K the partition coefficient of oxygen—inherent properties for oxygen transport through a material—has become familiar among contact lens manufacturers and users these days. There is a further relationship between oxygen flow and lens thickness; The transmissibility of a particular lens is thickness related and is given by the expression DK/t , where t refers to the thickness of the hydrogel.^[2] In the case of SCLs, there are two approaches to increasing oxygen permeability based on DK/t , that is, to reduce the thickness of the SCL or to increase the water content in the hydrogel, because oxygen permeability increases with water content. In the former case, a number of hyperthin poly(HEMA) SCLs (i.e., a center thickness of less than 0.05 mm) have been produced; however, such lenses turned out to be fragile, marked by poor mechanical properties, difficult handling, and difficult manufacture. In the latter case, the hydrophilicity of the polymer was a concern. Actually, the hydrophilicity of poly(HEMA) is too low to provide a water content of about 40%, indicating that not enough water is present to for carry sufficient oxygen to the cornea.

Water content may be adjusted by using various hydrophilic monomers to overcome poor oxygen permeability. For example, methacrylic acid, *N*-vinyl pyrrolidone, and glyceryl methacrylate are used for this purpose (Fig. 1d–f). However, the DK of pure water is less than necessary to supply the minimum oxygen needed for the cornea. There is naturally a limit to increasing oxygen permeability via increased water content in the hydrogel. The water content in the gel also plays an important role in controlling the mechanical properties of the hydrogel. The higher the water content in the gel, the lower the tensile strength. High water content and high tensile strength are ideal conditions for SCL material; however, a hydrogel cannot have it both ways.

Thus, the same problem that is associated with hyperthin SCLs, fragility, applies. Further, such lenses

tend to bind organic materials such as tear proteins, microbes from handling, or inorganic salts, especially those of calcium, all of which can affect oxygen permeability.

Silicone hydrogel

In the HCL field, a silicone-containing lens, poly(dimethylsiloxane) (PDMS, Fig. 1h), is famous for possessing a high DK and many other properties such as optical excellence, softness and flexibility similar to a hydrogel, and high tensile strength. The bulkiness of the siloxane group and the chain mobility are responsible for the high diffusibility of oxygen through siloxane-containing materials.^[3] Designing a hydrogel based on PDMS will lead to high performance in terms of oxygen permeability and good elasticity for comfortable wearing; however, the hydrophobicity of the siloxane component makes this difficult to realize. When a PDMS macromonomer is polymerized with some hydrophilic monomers, phase separation occurs and the resultant polymer is opaque.

Several strategies have been considered for improving the hydrophilicity of PDMS. Some macromonomers including PDMS and hydrophilic segments such as polyethylene oxide (PEO) in the molecule were synthesized and polymerized with some hydrophilic monomers such as dimethylacrylamide. The incorporation of a nonpolar fluorosubstituent (CF_2H) had a dramatic effect on the increased solubility with hydrophilic monomers.^[4] Those hydrogels based on PDMS macromonomers showed some improvement; however, the siloxane component, which tends to concentrate at the surface of the lens, and the low surface energy of PDMS result in very poor tear wetting, causing binding of tear lipids and lens adhesion to the cornea.

Adverse effects of fouling on the lens surface

With daily wearing of contact lenses, protein or lipid depositions create a biofilm on any kind of lens surface. Proteins have charge distributions, and they attract one another. This could result in the lens losing its ocular properties, and oxygen permeability will be disrupted. Moreover, it is possible for hydrophilic lenses to absorb chemicals into their naturally porous structure. This fouling of the SCL causes adverse events such as adherence of microbes to the lens. Bacteria can colonize in the lens and on its surface, so that the lens itself can become a potential pollutant source, a bacteria bed. This is the first stage in contact lens-associated microbial keratitis, which may ultimately lead to corneal ulceration and to blindness, in the worst case. Thus, lens cleaning and sterilizing are

crucial components of daily care, especially for SCLs. However, an inadequately cleaned and sterilized lens could also trigger these adverse events. Also, any sterilizing process, such as heat, peroxide, or chemical disinfection, can harm the lens material, leading to deterioration. Disposable lenses are a way of avoiding these risks. However, there is the problem of the cost and several other risks due to improper usage and mishandling, such as using the lens for more than a certain period.

Requirements for ideal lens material

Surface fouling is inevitably associated with any kind of lens. This fouling has unfavorable effects on both the lens and its user. Unfortunately, there are no SCLs using conventional materials that do not have problems. A matter of primary importance in providing easily handled and problem-free SCLs is biocompatibility, that is, the absence of negative effects due to contact with the constituents of a living organism and the absence of toxic or injurious effects on biological systems.

Poly(2-methacryloyloxyethyl phosphorylcholine) [poly(MPC), Fig. 1g], a bio-inspired material, was modeled on the surface of a natural biological membrane. The MPC polymers are highly effective in inhibiting the near-instantaneous protein adsorption and subsequent denaturation that can lead to thrombus formation, indicating true biocompatibility.^[5,6] Recently, a poly(MPC) hydrogel was made that showed a high swelling ratio, meaning high hydrophilicity.^[7] Using this MPC and HEMA, a biomimetic SCL was made.^[8] This SCL reduced not only protein adsorption but also the risk of infection by bacteria, exhibiting significantly lower bacterial adhesion *in vitro* compared to the standard poly(HEMA) SCL. Moreover, there has been an attempt to make a hybrid hydrogel having the high oxygen permeability of a silicone hydrogel and the surface of a biomembrane characteristic of the poly(MPC). The potential of a poly(MPC) hydrogel has not been fully realized; however, the poly(MPC) hydrogel assists in widening the range of usage in association with all biomaterials that need true biocompatibility.

Volume Phase Transition

Since Tanaka reported the volume phase transition of a hydrogel in solvent,^[9] many research studies on this phenomenon have been initiated, especially for medical devices such as drug delivery systems and tissue engineering. It is desirable to release the drug from the gel by shrinkage or swelling on stimulation. For example, if a hydrogel containing a drug changes volume according

Poly(*N*-isopropyl acrylamide (NIPAAm))

Fig. 2 Chemical structure of typical polymer used for gel system employing volume phase transition.

to a change in body temperature, patients can automatically receive the drug when they have a fever. The poly(*N*-isopropyl acrylamide) [poly(NIPAAm)] hydrogel is well qualified for this use (Fig. 2). Poly(NIPAAm) becomes insoluble in water due to dehydration of the polymer chain when the water temperature is over 32°C, which is well known as a lower critical solution temperature (LCST).^[10] With this property, the poly(NIPAAm) gel could swell under 32°C but shrink above 32°C, showing a volume phase transition.

Gel with functions

Phenylboronic acid and its derivatives are well known to form covalent complexes with polyol compounds including glucose. Taking advantage of this property, Kataoka et al. have made a hydrogel (NB gel) by polymerization of NIPAAm with 3-acrylamidophenylboronic acid and a small amount of cross-linker, which shows swelling-deswelling behavior in response to a change in glucose concentration (Fig. 3a).^[11]

The NB gel showed a volume phase transition at 22°C and pH 9.0; however, the temperature rose with increased glucose concentration from 0 to 5 g/L. In the case of a 1 g/L glucose concentration (the same level as for a healthy human), the NB gel would show a remarkable change in swelling in response to glucose in the range of 25 to 30°C. In fact, the repeated on/off regulation of insulin release from the NB gel in synchrony with a change in the concentration of external glucose was confirmed. Although there is still a problem with the difference in pH and temperature in the human body, this type of glucose-responsive gel would be good news for patients under diabetes treatment.

Miyata et al. made a hydrogel that can change its swelling ratio to increase the transmissibility of molecules in response to a specific antigen (Fig. 3b).^[12] They first prepared the monomers, the modified antigen and modified antibody, using rabbit immunoglobulin G (rabbit IgG) and goat anti-rabbit IgG (GAR IgG) as the antigen and antibody, respectively. They then synthesized the polymer GAR IgG using vinyl(GAR IgG) and acrylamide (AAm). In the presence of this polymerized

GAR IgG, an antigen-antibody semi-interpenetrated polymer network (semi-IPN) hydrogel was continuously prepared by the copolymerization of the vinyl(rabbit IgG), AAm, and some cross-linker. This semi-IPN type of hydrogel showed an abrupt increase in the swelling ratio on the addition of free rabbit IgG; however, it showed no reaction in the case of goat IgG, meaning that the hydrogel recognized a specific antigen. They suggest that the binding of the GAR IgG with rabbit IgG polymerized in the antigen-antibody hydrogel was much weaker than that to native rabbit IgG, due to denaturation of the modified rabbit IgG, causing the intra-chain grafted antigen-antibody binding to be dissociated by exchange of the grafted antigen for free antigen. Although the ratio of the volume change is small, by this unique antigen-specific type of hydrogel, it is possible to use the hydrogel to release a drug in response to the antigen as a result of the expression of cancer cells.

Quick response hydrogel

For this to be an effectively quick and sharp response to the stimulation, the volume phase transition of the hydrogel is necessary. However, the hydrogel volume change is dominated by the character of hydrogel; that is, the characteristic time of swelling is proportional to the square of the linear dimension of the hydrogel and is also proportional to the diffusion coefficient of the hydrogel network.^[13] Several research studies have been undertaken to overcome this limit. Forming pores in the hydrogel is one method to allow water to flow well. There are many ways to form a porous hydrogel—for example, preparing a hydrogel with a water-soluble porosigen, such as sodium chloride, sucrose, PEO, and so on, which can be removed after gelation. However, the pore size of the hydrogel depends on the size of the porosigens.

Park et al. successfully created a superporous hydrogel that quickly absorbed water and reached a high swelling equilibrium.^[14] They introduced many interconnected pores into the hydrogel that behaved as open channels to allow water flow through a capillary action. They utilized gas bubbles, CO₂, generated by mingling NaHCO₃ with acid, to form the pores in the hydrogel. The key point is how to maintain the bubbles during gelation, because the bubbles tend to fade away. They found the answer by mingling the pre-gel solution and a foam stabilizer, [poly(ethylene oxide)-poly(propylene oxide)-poly(ethylene oxide)] tri-block copolymers] (PEO-PPO-PEO) together to impart a high viscosity to the pre-gel solution, which helped to stabilize the foam during gelation. They obtained a superporous hydrogel showing up to 200 times faster absorption compared with an ordinary hydrogel.

Okano et al. have created a hydrogel system that quickly shrinks into tiny pieces with a change in temperature (Fig. 3c).^[15] They introduced hydrophobic chains into the matrix of poly(NIPAAm) to enhance the agglutinability, causing a hydrophobic interaction among the polymer chains. First, they made some poly(NIPAAm) macromonomers with different molecular weights by using telomerization of a NIPAAm monomer with 2-aminoethanethiol as a chain transfer agent and a continuous condensation reaction of amino semitelechelic poly(NIPAAm) with *N*-acryloxysuccinimide. They then synthesized several hydrogels by radical polymerization of the NIPAAm monomer and a NIPAAm macromonomer with a cross-linker, yielding a comb-type grafted polymer hydrogel in which the molecular architecture is different from that of the normal poly(NIPAAm) hydrogel, though the composition is the same. This comb-type grafted polymer gel could shrink much faster than the normal poly(NIPAAm) gel when the surrounding temperature climbs, and the rate of response depended on the length of the grafted polymer chains; that is, a hydrogel having a longer grafted polymer chain shrank faster.

Reentrant volume phase transition

Recently, a strange volume phase transition has been reported for the poly(MPC) hydrogel.^[6] Generally, the hydrogel swells in a good solvent and shrinks in a poor solvent. Water and ethanol are good solvents for poly(MPC); however, the poly(MPC) hydrogel shrank in certain water/ethanol mixtures. This phenomenon, in which the hydrogel once shrank and then reswelled according to the composition of the solvent, is called reentrant volume phase transition. The water or ethanol condition around polymer chains was altered by the introduction of ethanol or water, which triggered the phase change of the whole system.

The poly(NIPAAm) gel also showed this phenomenon in some water-miscible alcohol-aqueous solutions,^[16] but in the case of a poly(MPC) gel, the swelling and shrinking in response to the alcohol composition is dependent on the hydrophobicity of the alcohol. This means that the poly(MPC) gel has a molecular recognition property. By using this unique characteristic of the poly(MPC) gel and in combination with the functions of the hydrogel mentioned above, novel smart biomaterials with high biocompatibility can be realized.

PHYSICAL GELS

Physical gels, which are often called pseudo gels, are continuous, disordered, three-dimensional networks

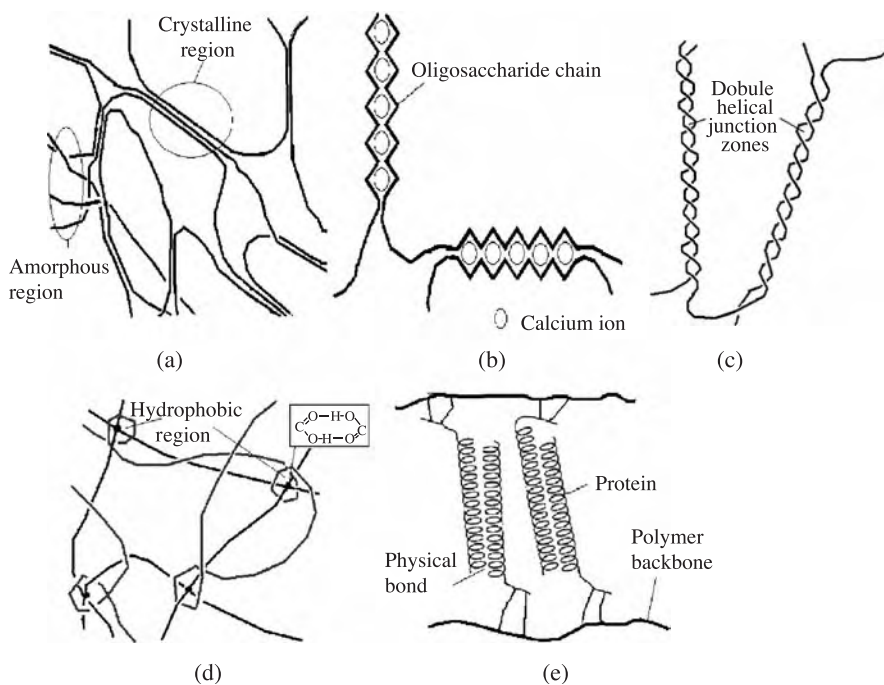

Fig. 4 Physical gels with multiple junctions. (a) Aggregation of the chains by crystallization. (b) Egg-box model created by specific ionic interaction. (c) Helical junction zone. (d) Hydrogen bond occurring in hydrophobic domain. (e) Hybrid hydrogel formation by coiled-coil proteins.

formed by associative forces capable of forming non-covalent cross-links.^[17] The noncovalent cross-links are formed by weaker interactions, and the cross-links are reversible. These interactions include hydrogen bonds, ionic interaction, hydrophobic association, stereo-complex formation, coiled-coil interaction, antigen-antibody interaction, crystalline segment cross-linking, and solvent complexation. These interactions would bring the polymer chains together and induce formation of a stable structure by forming a junction zone that would occur as shown in Fig. 4. These junction zones maintain the ordered structure inside the gels. A change in temperature, pH, or the addition of salts, for example, would form or modify the junction zones. The junction zones that had been formed between chain segments tended to stabilize as the segment number increased. Because the cross-linked junctions are not covalently bonded, breakdown of the network may occur due to a change in the environment (reversible phenomena).

Synthetic Polymers

Synthetic polymers that can be utilized for a hydrogel base material have several requirements. They need to be stimuli sensitive, but the most important requirement is biocompatibility, for they are destined to be used for biomaterials.

Poly(vinyl alcohol)

Linear poly(vinyl alcohol) (PVA) is a one of the most actively used synthetic polymers for physical

hydrogels. PVA is a polymer that has a thermo-reversible property. PVA hydrogel can be prepared by simply lowering the temperature. Due to its thermo-reversible property, the hydrogel will form a crystallized zone when the temperature is lowered. Cyclic freeze-thaw or blending a hydrophilic polymer such as poly(sodium L-glutamate) and poly(allylamine) HCl salt together with PVA increases the crystallinity and mechanical properties due to a complex between the PVA and the hydrophilic polymer.^[18]

Block copolymers

PEO, PPO, and poly(lactic acid) (PLA) are the materials most actively applied to biomedical and biotechnology because of their excellent physicochemical and biological properties. They are prepared in the form of block or triblock copolymers. Micelles are formed at low concentrations in aqueous solution, and thermoreversible gels are formed at high concentrations. This block copolymer hydrogel also shows LCST behavior, which allows it to be used for drug delivery. Multiblock copolymers of PEO and poly(butylene terephthalate) (PBT) can be prepared by melt condensation of PEO, butanediol, and dimethyl terephthalate. A phase-separated structure is formed with hard PBT domains, resulting in thermally reversible cross-linking, dispersed in the soft amorphous phase of hydrophilic PEO and amorphous PBT (Fig. 4a).^[19] The PEO-PPO-PEO triblock, also known as Pluronic, dissolves in cold water, forming a viscous solution. When the temperature is increased, the solution gels

due to phase transition as the polymer concentration is raised above a critical value. The increment in temperature leads to an increase in the micelle volume fraction (ϕ_m). When $\phi_m > 0.53$, the system becomes a gel by micelle packing (hard-sphere crystallization). A PLA–PEO–PLA block copolymer hydrogel can be prepared simply by immersing the polymer film or tablet in water. Phase separation of PEO and PLA induces the gelation. It has been reported that when the PEO to PLA ratio is strictly controlled, immersion into an organic solvent followed by the addition of water may produce a softer and more hydrophilic hydrogel.^[20]

Acrylamide polymers

One of the most commonly investigated acrylamide polymers for physical gelation is the linear homopolymer poly(NIPAAm). Poly(NIPAAm) is often formed as a gel by chemical cross-linking. However, its precipitation ability above 32°C due to LCST makes subject to the physical gelation process. Generally, an acrylamide polymer including poly(NIPAAm) becomes physically gelled when it is copolymerized with another polymer having a different property. Transparent aqueous polymer solutions of NIPAAm copolymers containing small amounts of acrylic acid are readily polymerized using free radical initiation in benzene and turn opaque as the temperature increases. When the temperature reaches 30–34°C, the solution turns into a gel. As more heat is added to the hydrogel, the gel collapses.^[21] Block and star copolymers of PEO and poly(NIPAAm) form aqueous solutions at low temperatures and transform to relatively strong elastic gels upon heating, multiple-arm copolymers appear to form gels via a physical cross-linking mechanism, and diblock copolymers gel due to a micellar aggregation mechanism.

Acrylic polymers

Acrylic polymers possess intra/interchain hydrogen bonds. Poly(acrylic acid) (PAA) and poly(methacrylic acid) (PMAA) form a complex with PEO. Swelling under oscillatory pH conditions reveals the dynamic sensitivity of poly(methacrylic acid-*graft*-ethylene glycol) gels and shows that network collapse (complexation) occurs more rapidly than network expansion (decomplexation). Hydrophobic interactions are very important for stabilizing the complexes. Poly(organophosphazene) is an organometallic polymer containing double-bonded phosphorus and nitrogen on the main chain with two organic side groups attached to the phosphorus atom. Polyphosphazene hydrogel, like other synthetic hydrogels, can be divided into two

major classes: neutral or non-ionic hydrogels and ionic hydrogels. Ionic hydrogels are formed by phosphazene polyelectrolytes, while non-ionic polyphosphazene hydrogels are based on water-soluble polymers ranging from ultimately hydrophilic, such as polyphosphazene containing glycosyl and glyceryl side groups, to less hydrophilic, including poly[bis(methylamino)phosphazene]. The difference in solubility is believed to be partially due to the exposure of skeletal hydrogen bonding to water.^[22]

Biomolecules

Oligosaccharides

Oligosaccharides are naturally occurring materials that can be modified for use as suitable biomaterials. Simple modification or a change in the environment may cause gelation phenomena.

Alginate. Alginate is one of most common oligosaccharides used for hydrogel synthesis. The cross-linking is carried out by injecting calcium ions with alignment of each sequence to form an array of cavities called an egg box. In this formation, carboxylate and oxygen atoms are organized into a cavity at room temperature and physiological pH (Fig. 4b). Monovalent cations as well as divalent cations such as magnesium ions do not induce gelation, whereas Ba^{2+} and Sr^{2+} ions induce very strong gelation. High concentrations of α -L-gluconic acid chain sequences lead to brittle gels, while low concentrations lead to more elastic gels.

Dextran. The reaction for the gelation of dextran is due to crystallization caused by the association of chains through hydrogen bonding, but gelation also occurs when potassium ions are added. Although dextran does not have ionic groups on the chain, the cage that is formed by six oxygen atoms from these repeating glucose units yields a cavity that is a perfect fit for potassium ions.^[23] However, instability in water makes it unsuitable for biomedical use.

Chitosan. Physical cross-linking has been used to prepare chitosan-based gels by the *O*- and *N*-acetylation of chitosan and the attachment of C_{10} -alkyl glycosides to chitosan. Acetylation yields either “rigidly solidified” or “fragile” gels with high- and low-molecular-weight chitosan, respectively, while the attachment of C_{10} -alkyl glycosides forms gels in acidic media at elevated temperature ($> 50^\circ\text{C}$).^[24]

Gellan and Pectin. Gellan can form either elastic or brittle gels, depending on cation concentration. Gellan

gels are soft and easily deformable below the critical calcium, concentration and, brittle above. Using a salt of ions other than calcium, such as Mg^{2+} or K^+ , may induce a relatively stronger gellan gel.

Pectins are divided into high-methoxyl (HM) pectins and low-methoxyl (LM) pectins according to the degree of esterification to pectin accomplished in the presence of methanol.^[17] In LM pectins, gel formation is influenced by the number and sequence of consecutive carboxyl groups and by the concentration of calcium. LM pectin + Ca^{2+} gels conform to the “egg box” model, while HM pectin gelation is governed by hydrogen bonds and hydrophobic interactions.

Agarose and Carrageenan. Agarose is soluble in water at temperatures above 65°C and, depending on the degree of hydroxyethyl substitution on its side chains, it forms a gel in the range of 17–40°C. Agarose gels are stable and do not swell at constant temperature or reliquefy until heated to 65°C. A commercially available agarose hydrogel is SeaPrep, a polysaccharide derived from red algae that melts at 50°C and gels at 7–18°C.

Carrageenan is gelled by salts such as KCl, but it can form a gel under salt-free conditions also. There are three types of carrageenan: kappa, iota, and lambda. Among these three, only the kappa type shows gel-forming characteristics in water. Potassium and calcium ions induce the gelation, while sodium ions do not. In the iota type, gelation occurs in the presence of calcium ions. At low temperature and high salt concentration, a double helical arrangement of the parallel polysaccharide chains can be formed (Fig. 4c). The temperature for gelation is about 25°C, and remelting occurs at 35°C.

Peptides, proteins, and glycoconjugates

Peptide, protein, and glycoconjugate hydrogels are formed by specific interactions called lock-and-key interactions, but in a different way from polysaccharides. The specific interaction may occur only when the molecules maintain three-dimensional structures such as coiled–coil interaction, or hydrogen-bonded β -sheets or strands.

Fibrin Gels. Fibrin plays an important role in natural wound healing and is used as an adhesive sealant in surgery. It is formed by the enzymatic polymerization of fibrinogen. Cross-linking of the fibrin oligomer can be executed by factor XIIIa. The main application of fibrin is as a scaffold matrix for tissue engineering. The fixation of the gel with poly(L-lysine) during the culturing period was introduced to solve the problems of gel shrinking and low stiffness. Inner tension in the gel

as a result of the tendency to shrink and the fixation may have led to the collagen synthesis.

Actin Gels. Globular actin monomer (G-actin) polymerizes to form an actin filament (F-actin), which forms a gel. Cross-linking of the actin network by α -actin can transform isotropic entangled networks into heterogeneous networks of microgels, whose macroscopic viscoelasticity is a complex of contributions from both dense and loose mesh networks.^[25] In the case of G-actin in vitro, the presence of a salt (K^+ , Na^+ , Ca^{2+} , Ba^{2+} , Li^+ , etc.) may activate the gelation process.

Lectin-Mediated Gels. Lehr elucidated the mechanisms of lectin-cell interactions and explored the pharmaceutical potential of lectin-modified drug carrier systems at epithelial biological barriers.^[26] The weak interaction between lectins and glycoconjugates can induce easy dissociation behavior at neutral pH, making lectin suitable for delivery systems.

Biomimetic Polymers

Biomimetic polymers are synthetic polymers that mimic biomolecules. The merit of this approach is that the advantages of synthetic polymers and biomolecules can be achieved at the same time.

Phospholipid polymers

A phospholipid is a substance that comprises the outline of the cell wall and is commonly mimicked by investigators. Its high permeability and biocompatibility have interested investigators for a long time. Ishihara et al. prepared MPC-based polymers, poly(MPC-*co*-methacrylic acid) (PMA) and poly(MPC-*co*-*n*-butyl methacrylate) (PMB) aqueous solution, to synthesize the hydrogel.^[27] The gelation occurs due to hydrogen bonds between the carboxyl groups of the PMA in the hydrophobic domain of the PMB (Fig. 4d). The formation can take place under either high or low aqueous conditions at room temperature. Thermoreversible and pH-reversible phenomena have also been observed, so that the phospholipid hydrogels can be utilized as peptide drug carriers.

Hybrid gels

Hybrid hydrogels refer to hydrogel systems that contain two or more components of distinct classes of molecules. The main purpose of a hybrid polymer is to create stimuli responsiveness to a change in the environment. Numerous research studies are underway

on covalently bonding a stimuli-sensitive polymer with double-stranded deoxyribonucleic acid (DNA). DNA forms double or triple strands with its complementary base pair by way of hydrogen bonding. This formation is reversible and is affected by a change in physical or chemical stimuli. Kopecek et al. designed hybrid gels composed of coiled-coil protein domains and a polymer backbone (Fig. 4e). The coiled-coil proteins were engineered by control of amino acid sequences. The coiled-coil formation is regulated by temperature, pH, and ionic strength.^[28]

Biomimetic/Synthetic Polymer Hybrid Gels

Biomimetic/synthetic polymer hybrid gels are good candidates for application in biomaterials and biomedical engineering. Most biomimetic polymers are capable of highly sophisticated functions. The hybrid technique is one of the promising approaches for further advancement in the area. In this section, recent biomimetic/synthetic polymer hybrid gels are discussed.

Bio-inspired/biodegradable polymer hybrid

A novel bio-inspired material based on the structure of the cell membrane has been proposed by Ishihara et al. They first succeeded with MPC having a phospholipid polar group.^[5] To fabricate the cell membrane surface, the MPC was copolymerized with *n*-butyl methacrylate (BMA) as a comonomer, and the resulting copolymer was coated onto a substrate. For a cell culture scaffold, further materials design would be

necessary for the MPC polymer. A new concept has been proposed based on a biodegradable polymer hybrid. An enantiomeric poly[L-(D-)lactic acid] [PL(D)LA] macromonomer has been newly synthesized and copolymerized with MPC and BMA.^[29] The resulting copolymers would spontaneously form the phospholipid polymer scaffold by stereocomplexation (Fig. 5a). The scaffold is a porous structure formed by a NaCl leaching technique. The enantiomeric PL(D)LA segment was utilized not only as a physical cross-link point but also as a protein adsorption domain in cell culture. One of the advantages was water intrusion into the phospholipid polymer scaffold, which was evaluated by the static contact angle of the water. The contact angle of the phospholipid polymer scaffold quickly decreased. This result suggests that water uptake was enhanced by the MPC unit. This is quite an important property for a porous scaffold to be used in three-dimensional tissue reconstruction.

Host/guest supramolecular gels

The field of supramolecular chemistry has been explored for constructing new molecular architectures such as molecular association by intermolecular forces and inclusion complexation. Supramolecular science is a new research area, and the study of supramolecular assemblies has progressed due to the study of biomimetic chemistry and molecular recognition in relation to such areas as enzymatic catalysis reactions. One of the major supramolecular structures is a polyrotaxane. Polyrotaxanes, in which many α -cyclodextrins (α -CDs) are threaded onto a PEO chain capped with bulky end

Fig. 5 Schematic illustrations of biomimetic/synthetic polymer hybrid gels. (a) Bioinspired/biodegradable polymer hybrid. (b) Host/guest supramolecular gels. (c) Organic/inorganic composite gels.

groups, have recently been demonstrated to be a molecular necklace. A biodegradable polyrotaxane consisting of α -CDs, PEG, and benzyloxycarbonyl (Z)-L-phenylalanine (L-Phe) introduced via ester linkages has been prepared as an implantable material for tissue engineering.^[30] The advantage of the polyrotaxane structure is its rapid and perfect degradation under physiological conditions. The specific structure of the polyrotaxanes may enable us to maintain the shape of the scaffold as a cell support and to achieve complete hydrolysis.

Using these perspectives, Yui et al. have designed PEG hydrogels cross-linked by hydrolyzable polyrotaxanes (Fig. 5b).^[31] In the hydrogel design, cyclic molecules in a polyrotaxane can be used as a cross-linking point. The cyclic molecules could be easily dethreaded onto the linear polymeric chain in response to terminal ester hydrolysis; then the cross-link density of the PEG hydrogel would decrease. The expected characteristics of the hydrogels include rapid and perfect disappearance based on supramolecular dissociation via terminal hydrolysis. PEG hydrogels cross-linked by the polyrotaxane were prepared and characterized to estimate gel erosion and identify the mechanism. It is assumed that terminal hydrolysis of the polyrotaxane cross-links can trigger dethreading of the α -CDs to induce a unique erosion behavior of the hydrogels.

Organic/inorganic composite gels

Mineralized tissues such as bone and dentin are indispensable elements in our body. For example, human bone consists of inorganic salts and organic substances such as collagen. The mineralized tissue has a well-organized structure, with inorganic salts, calcium, and phosphate. For this reason, organic/inorganic composites are good candidates for mineralized tissue reconstruction. In one technique, a hydroxyapatite composite has been produced by conventional flame spraying. The technique is limited to metal implants. In the case of organic substances such as polymeric gels, it is impossible to coat hydroxyapatite because of the heating process. A novel technique for preparation of organic/inorganic composite, especially hydroxyapatite, has been investigated. The hydroxyapatite was prepared by an alternative soaking process between $\text{CaCl}_2/\text{tris-HCl}$ (Ca solution) and Na_2HPO_4 (P solution) (Fig. 5c).^[32] Polymeric gels, such as PVA and poly(HEMA), were used as a template. The apatite crystal was formed not only on the surface but also in the gel through two subsequent steps.^[32] The apatite content and apatite formation rate were correlated with the gel swelling ratio. Three-dimensional gels/hydroxyapatite composites are of great importance in the fabrication of bonelike tissue.

CONCLUSION

This chapter summarizes the basic principles and recent topics concerning hydrogels as biomaterials. Hydrogels represent a diverse cross section of biomaterials, e.g., drug delivery carriers, tissue engineering scaffolds, and medical devices. Various chemical and physical properties are controlled by changing chemical reagents such as monomers and polymers and by the preparation conditions of the hydrogels. Hydrogels represent one of the most promising approaches for the fabrication of novel biomaterials.

INTRODUCTION

Hydroxyapatite (HA) is utilized as a bone-grafting material owing to its similarity in composition with the inorganic component of hard tissues (bone and tooth mineral). Synthetic, stoichiometric HA has the formula $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$ (Fig. 1) and belongs to a broad group of calcium-containing minerals based around the phosphate (PO_4^{3-}) group and is characterized by a calcium/phosphorus (Ca/P) molar ratio of 1.67. However, synthetic HA differs in composition from bone mineral, as, in addition to calcium, phosphorus, oxygen, and hydrogen ions, bone mineral contains a number of ionic substitutions in its lattice and can also be non-stoichiometric with $\text{Ca} \neq 1.67$.^[1]

HA is a bioactive material and, as such, encourages direct bone apposition when implanted into a skeletal site (Fig. 2). It is used clinically in granular, porous, and dense forms, as coatings on metallic implants^[2] and as a filler in composite materials.^[3–5]

This entry provides an overview of the structure and properties of HA and ionically substituted apatites and details the methods used to characterize the material chemically, physically, and biologically. The entry discusses the preparation and processing of HA and substituted apatites, for clinical application, and addresses the research that has been performed to characterize bone response to these materials.

HA PROPERTIES

Physical and Chemical Properties

During the 1980s, there was a great deal of interest in the physical and chemical properties of HA. Clearly the methods by which the materials are prepared will influence the values obtained, but the properties may broadly be summarized as shown in Tables 1 and 2.

Crystallography

HA possesses a hexagonal Bravais lattice and a $\text{P6}_3/m$ space group with cell dimensions of $a = 9.4211$ and $c = 6.8810 \text{ \AA}$.^[6] Fig. 1 shows a schematic diagram of the crystal structure of HA. Table 3 illustrates the atomic fractional coordinates and occupancy values of the atoms in the HA unit cell.^[7]

CHEMICALLY AND PHYSICALLY MODIFIED HA

One disadvantage of HA implants, in comparison with bioactive glasses and glass ceramics, is that the reactivity of HA with existing bone is relatively low^[8,9] and this has implications for the time required for patient recovery. One approach toward improving the osseointegration rates of HA has been to incorporate biological entities such as growth factors, proteins, and cells into the HA implant.^[10–12] As an alternative to modifying the biology of the implant, HA may also be chemically doped with small amounts (up to 20 mol%) of elements (e.g., carbonate and zinc) that are commonly found in physiological bone.^[1] These substitutions play a role in influencing the dissolution rate of apatites, which enhance the proliferation of human osteoblast-like cells in vitro^[13] and may favor osseointegration.^[14]

Substituted Apatites

The crystal structure of HA can accommodate substitutions by various other ions. Substitutions can occur for the Ca^{2+} , PO_4^{3-} , and OH^- groups present in HA. The ionic substitutions can affect the lattice parameters, crystal morphology, crystallinity, solubility, and thermal stability of HA. Table 4 summarizes the qualitative effects of some common ionic substitutions on the lattice parameters and crystallinity of HA.^[15]

Fig. 1 The structure of HA. (Adapted from Ref. [7].)

Cationic substitutions

Cationic substitutions occur in the sites normally occupied by the calcium atoms. Elements such as sodium, magnesium, potassium, strontium, and manganese can be accommodated in the HA lattice, although, as highlighted in Table 4, these substitutions have not been observed to increase crystallinity. Imbalances in the charges of the substituting ion can cause disorder within the crystal structure of HA. The difference in valency caused by such a substitution requires a reduction in anionic charge to maintain charge balance.^[16]

Anionic substitutions

Fluorapatite and chlorapatite are common examples of anionically substituted HA. They display a similar structure to HA, but the F^- and Cl^- ions substitute for OH^- .

Carbonate Substitution. The most extensively studied synthetic substituted HA is carbonate HA (CHA), as

Fig. 2 Environmental scanning electron microscope image, illustrating bone growth directly along the surface of an HA-coated titanium hip replacement at 261 days in vivo. Image taken in backscattered electron mode. (From Ref. [35].)

Amjad, Ed.; Plenum: New York, 1995, 271–282.)

carbonate is the most abundant substitution in bone mineral (3–8 wt%).^[1,17,18] Carbonate ion substitution has been shown to increase rates of bone apposition around dense HA implants as compared to pure HA.^[19] The increased bioactivity of CHA has been attributed to be owing to the greater solubility of the CHA.^[20,21]

There are two types of carbonate substitution proposed in the literature, these being the substitution of CO_3^{2-} for OH^- (Type A)^[20] and CO_3^{2-} for PO_4^{3-} (Type B).^[22] In the Type A substitution, the exchange

(From Ref. [7].)

of the larger planar CO₃²⁻ group for the smaller linear OH⁻ group results in an expansion in the *a*-axis and a contraction in the *c*-axis and occurs when HA is treated with dry CO₂ at 1000°C.^[17] In the Type B substitution, CO₃²⁻ substitutes for PO₄³⁻, in HA,^[18] this causes a decrease in the length of the *a*-axis, while the *c*-axis increases as the carbonate content is raised.^[17] The change in lattice parameter has been attributed to the planar carbonate ion being smaller than the tetrahedral phosphate ion.

Studies have also highlighted that the two types of carbonate substitution, A- and B-type, can occur simultaneously resulting in a mixed AB-type CHA.^[18,24–26] This mode of substitution occurs almost exclusively by aqueous precipitation reactions and results in a more complex substitution mechanism. As for the B-type substitution, the mixed AB-type substitution involves the cosubstitution of sodium or ammonium ions from the reaction mixture to maintain charge balance. The calcium phosphate apatite that

(From Adapted from Ref. [15].)

constitutes bone mineral is considered to be of a mixed AB-type (predominantly B-type) substitution.^[27] It is, therefore, this more complex substitution type that is of most interest when developing a synthetic carbonate-substituted HA as a bone-substitute material.

Driessens, Verbeeck, and Kiekens^[28] produced evidence for a sodium-containing mixed AB-type CHA by an aqueous precipitation involving CaHPO₄ and CaCO₃ solutions. Na₂CO₃ was introduced into the reaction mixture as the source of carbonate ions. Carbonate contents of up to 15.4 wt% were determined by gravimetric analysis of CO₂ evolved from placing the samples in acidic aqueous solutions. Barrelet, Best, and Bonfield^[29] synthesized sodium-containing mixed AB-type CHAs over a wide range of reaction temperatures (3–90°) and carbonate concentrations (up to 640 mM sodium bicarbonate). Barrelet, Best, and Bonfield proposed an AB-type carbonate substitution mechanism [Eq. (1)], whereby the carbonate ions occupy both A and B sites in equal proportions.

Vignoles et al.^[30] also reported that, where carbonate content is low, A-type carbonate substitution occurs, and that with increasing carbonate content, B-type sites are favored to the exclusion of all A-type substitution.

Although the chemical and structural properties of CHAs prepared by aqueous precipitation methods have been studied extensively, it is clear that as long as there is the cosubstitution of sodium or ammonium ions with the carbonate ions, the true role of only carbonate substitution on the chemical, physical, and biological properties of synthetic B-type (or AB-type) CHAs cannot be determined.

Recent studies by Gibson and Bonfield^[31] described a novel aqueous precipitation method to produce a pure, sodium and ammonium ion-free, AB-type CHA. The experimental process devised by Gibson and Bonfield involved two fundamental steps. Firstly, the Ca/P molar ratio of the reactants was deliberately calculated as being greater than the stoichiometric value of 1.67. By making the reaction mixture calcium rich, but in the presence of carbonate ions, an overall Ca/(P + CO₃) molar ratio could be maintained by the substitution of carbonate ions. The second aspect involved the introduction of carbonate ions into the reaction mixture. Instead of using an inorganic carbonate compound such as sodium carbonate or ammonium carbonate, carbonated water (carbonic acid) was used as the source of carbonate ions. As described in Eq. (2), Gibson and Bonfield^[31] were able to produce a mixed AB-type CHA

free of any additional cation substitutions, with carbonate contents of up to 4.1 wt%.

Silicate Substitution. Recent studies have focused on the development of silicate-substituted HA (SiHA).^[6,19,32] The rationale for these studies was the results of series of experiments by Carlisle,^[33] suggesting that silicon plays a critical role in the bone-calcification process. In vivo studies, comparing the rates of bone apposition to HA and SiHA ceramic implants, demonstrated a significant increase in amount of bone apposition and organization to around silicon-substituted HA (SiHA) implants, illustrating their potential as bone graft materials.^[19]

Several attempts have been made to prepare SiHA by a variety of synthesis routes. It is important that the ionic substitution of silicon does not result in the thermal instability of the SiHA, where sintering would result in the decomposition of the SiHA to undesirable second phases. Gibson, Best, and Bonfield^[6] produced phase-pure SiHA by an aqueous precipitation of a calcium-containing solution and a phosphate-containing solution at high pH, using silicon acetate as the source of silicate ions. They proposed the following substitution mechanism given in Eq. (3) below

Structural analysis has demonstrated that silicate (SiO₄⁴⁻) ions can substitute for the PO₄³⁻ sites in HA.^[6,19] The substitution of silicate ions in HA is feasible as the ionic bond lengths of a P–O bond (0.157 nm) with tetrahedral coordination are comparable to a similarly coordinated Si–O bond (0.166 nm).^[34] The effect of silicate substitution on the crystal structure is to cause a decrease in the *a*-axis and an increase in the *c*-axis of the unit cell of HA.^[6,35]

CHEMICAL SYNTHESIS

There are numerous methods for the preparation of synthetic apatites, which can be generally considered in three groups: aqueous reactions, solid-state reactions, and hydrothermal reactions. HA powders produced by aqueous reactions tend to be calcium deficient as a result of cationic substitution, which results in the formation of α -tricalcium phosphate (TCP) upon

sintering and, if conditions are highly basic, carbonate substitution may occur.

Aqueous Techniques

These may be divided into two groups, precipitation and hydrolysis methods.

Precipitation

By far the most common method used to prepare HA is aqueous precipitation, not only because it is closer to the *in vivo* situation, but because it is a relatively simple procedure that can give a wide variety of apatite particle sizes and morphologies. The precipitation method involves mixing reactants together in the presence of water (usually at a controlled temperature, atmosphere, and pH 10 and leaving the resulting precipitate to age under conditions of continuous stirring for periods of up to 12 hr. If the pH is not well controlled, HA powders produced by precipitation methods often result in powders with deviations from stoichiometry (i.e., Ca/P \neq 1.67) resulting in additional secondary phases such as TCP or calcium oxide (CaO). Once aged, the precipitate is thoroughly washed, filtered, and dried. The two most common methods quoted in the literature are that of Akao, Aoki, and Kato,^[36] [Eq. (4)], and Hayek and Newesely,^[37] [Eq. (5)].

In the first method, [Eq. (4)], HA is prepared from the reaction of acid, H_3PO_4 , and alkali, $\text{Ca}(\text{OH})_2$ solutions. In the second method [Eq. (5)], aqueous solutions of calcium nitrate and ammonium phosphate are prepared (ammonium hydroxide may be added to control the solution pH). The phosphate solution is then added drop-wise to the stirred calcium solution. This method does have drawbacks in that other ions such as ammonium are necessary to attain the required pH and these ions are incorporated into the structure. There have been few investigations concerning the possible effect of these ions on mechanical properties or biocompatibility.

Hydrolysis

Hydrolysis methods involve the hydrolysis of acid calcium phosphates (e.g., dicalcium phosphate dihydrate) in carbonate, fluoride, chloride, ammonium,

sodium, or potassium hydroxide solutions depending on the desired composition of apatite.^[38–41] This method has drawbacks in that it introduces additional ions into the reaction procedure.

Solid-State Reactions

In solid-state reactions HA is produced via the stoichiometric mixing of reactants at specific temperatures. Examples of this method are given in Eqs. (6) and (7). The calcium compounds are mixed, formed, and then sintered above 950°C.^[42]

This procedure is prone to the production of materials that are inhomogeneous at the final processing stage. Also it is difficult to estimate the time required to produce a homogeneous end product.

Hydrothermal Transformations

The third method of synthesizing HA is that of hydrothermal transformation. This process employs the use of elevated temperatures, pressures, and controlled atmospheres to convert one substance into another via an exchange reaction. The reactions in Eqs. (5) and (6) could be carried out hydrothermally by heating at approximately 250–300°C under steam pressure of 80–100 MPa. Although this route is relatively time consuming, it has the added benefit of the option to preserve the original architecture, as illustrated by the production of porous HA from calcium carbonate corals.^[38]

SINTERING HA

The most common method used to sinter HA is heating in air by means of an electric furnace at atmospheric pressure. Recent studies into the sintering behavior of HA have concentrated on the effects of temperature, time, and atmosphere on the levels of density and decomposition.

Stoichiometric HA can thermally decompose by two mechanisms. At relatively low sintering temperatures, dehydroxylation can occur, resulting in the formation of oxyHA (OHA) and water according to the reaction mechanism described by Eq. (8).^[43] At relatively high sintering temperatures, HA decomposes to TCP and

tetracalcium phosphate (TeCP) according to the mechanism described in Eq. (9).^[44]

where V = vacancy

The densification and phase purity of HA powders is dependent on heating rate and sintering dwell time. In addition to powder characteristics and sintering conditions, variations from stoichiometry in the starting apatite play a major role on the densification and decomposition process of HA. An excess of calcium (Ca/P > 1.67) will favor the formation of a CaO phase. In contrast, if the Ca/P molar ratio is < 1.67, then TCP phases are likely to form.

PREPARATION OF HA, CHA, AND SiHA CERAMICS FOR CLINICAL APPLICATION

HA has achieved application in a number of forms, including dense monolithic ceramics, porous scaffolds into which the host bone can regenerate and heal, granules (dense and porous), as coatings on metallic stems, fillers (either in fibrous^[45,46] or particulate form^[3]) in composites, and finally as calcium phosphate bone cements.^[47] As a ceramic material, HA exhibits relatively poor tensile strength and toughness and, therefore, clinical usage has mainly be concentrated on where the material would confer bioactivity to otherwise nearly inert implants or in situations where mechanical performance is not an issue. The following section describes several frequently employed processing techniques.

Dense Monolithic Ceramics

The conventional method of preparing dense ceramics involves three fundamental aspects. The first step involves the preparation and processing of powder with a suitable particle size for compaction. The second step involves the compaction of the powder to form a green body of desired size and shape and, finally, the green body is consolidated into a dense ceramic by sintering.

The density of ceramics is typically described in terms of a percentage of the maximum theoretical density, this being 3.156 g/cm³ in the case of HA. The process of sintering is unlikely to lead to a fully dense material—the final product will contain some microporosity.

Porous Scaffolds

HA scaffolds may be designed with inherent porosity, such that they mimic the architecture of natural trabecular bone. A number of techniques may be employed to fabricate porous HA scaffolds:

- “Burn-out.”
- Hydrothermal conversion methods.
- Sponge impregnation.
- Foaming methods.

All of these methods have their relative advantages and disadvantages, including control of pore size and interconnectivity and the requirement for the optimization of structural integrity of the struts between the pores. HA scaffolds with macroporosity greater than 100 μm have been utilized clinically for application such as spinal fusions, bone tumors, fractures, and in the replacement of failed or loose joint. More recently, there has been a trend toward engineering bone grafts with interconnected porosity between the macropores of the scaffolds. Pore interconnections with size 30–100 μm act as pathways between the macropores to favor cellular and vascular penetration, assuring improved bone ingrowth into the pores of the scaffold.^[47]

Granular Implants

An advantage in the use of granular implants compared to blocks or cylinders is that granules can fill voids of complex geometry, avoiding the need to cut and shape the implant during surgery. Furthermore, the morphology and the manner by which the granules can be “packed” into a defect site can be optimized to produce voids/spaces for bone ingrowth.

Biomedical Coatings

The philosophy behind adding a coating to a biomedical device is to improve either the wear properties or the biological properties of the implant. A number of different applications for ceramic coatings have been investigated and these have been used in dental implants and hip and knee replacement prostheses. Commercially, the most important production method for coatings is via plasma spraying.

One of the major innovations in the last 20 years has been to plasma spray the femoral stems of hip prostheses with HA (Fig. 3). The clinical results of HA-coated implants reveal that they have much longer life times after implantation than uncoated devices and they have been found to be particularly beneficial for younger patients.

Fig. 3 Coated femoral component of a hip prosthesis (Furlong).

Although the plasma-sprayed coatings are highly successful, they may have inherent flaws and are sometimes subject to problems of reproducibility in terms of crystallinity and mechanical properties. Other issues include the potentially poor adherence of the coating to the substrate, non-uniformity of the thickness of the deposited layer, and the integrity of the structure and composition of the coating. In addition, long-term *in vivo* studies have shown that the separation or loss of plasma-sprayed HA coating was progressive with time *in vivo*, which may cause cell-mediated osteolysis and subsequent implant loosening.^[48,49] Therefore, the need to make a more adherent, thinner, and uniform bioactive coating on metals with high mechanical strength is imperative. For these reasons, a number of other sputtering techniques such as magnetron sputtering^[50–52] and “low temperature” techniques are also being investigated, including electrophoresis and bone-like apatite coatings through simulated body-fluid treatments. Apatite coatings may be produced by soaking the metal stem in simulated body fluid (SBF) containing physiologically relevant ions (NaCl, KCl, $K_2HPO_4 \cdot 3H_2O$, $MgCl_2 \cdot H_2O$, CaCl₂, and Na₂SO₄) in

distilled water at pH 7.4.^[53] Apatite layer-coated titanium bone-bonding implants have been shown to bond firmly to the substrate and bone,^[54] with significant improvement over non-coated metallic stems. SBF-coated implants therefore offer an attractive alternative to plasma-sprayed implants for orthopaedic applications.

Fillers in Composites

One approach toward improved mechanical performance of HA ceramics is to design composite materials comprising both the ceramic HA phase and a polymeric phase.^[3–5] Composites of polymer and ceramic can confer favorable mechanical properties, including strength via the ceramic phase, toughness and plasticity via the polymer phase, and graded mechanical stiffness. An area of interest in recent years has been the development of calcium phosphate/collagen biocomposites. Because of their compositional similarity to natural bone, the main focus of their application has been the repair of bone defects. A number of initiatives have sought to develop HA/collagen biocomposites with a high degree of structural similarity to mature bone,^[4,5,54] with some of these producing materials whose resemblance to bone extends even to the nanometer scale. Such biomimetic composites have been produced by precipitating HA on to the collagen fibril template under alkaline conditions^[55] Future research effort will now aim to use a bottom-up approach to develop macroscale biomimetic scaffolds.^[56]

Calcium Phosphate Bone Cements

In the 1980s, the idea of a new bone substitute material was introduced, and the materials were referred to as calcium phosphate bone cements. These materials offer the potential for *in situ* moulding and injectability. There are a variety of different combinations of calcium compounds (e.g., α -TCP, and dicalcium phosphate), which are used in the formulation of these bone cements, but the end product is normally based on a calcium-deficient HA.^[57,58]

CHARACTERIZATION OF HA CERAMIC IMPLANTS

The characterization of HA implants has typically involved chemical, physical, and biological techniques. The results obtained from such studies are inter-related, and to understand the mechanisms underlying the bioactivity of HA ceramics, it is important to perform comprehensive studies that incorporate chemical, physical, and biological assessment. The aim

Fig. 4 XRD trace of phase pure HA sintered at 1200°C. (From Ref. [45].)

of this section is to provide a general overview into some of the techniques used to characterize HA, CHA, and SiHA ceramics.

Chemical Characterization

Chemical characterization involves the assessment of crystal structure, phase purity, chemical content, and the type and amount of ionic substitution present within the sample. The methods commonly used to characterize HA ceramics include X-ray diffraction (XRD), X-ray fluorescence spectroscopy (XRF), inductively coupled plasma spectroscopy (ICP), C–H–N elemental analysis and infrared spectroscopy.

XRD

XRD is a versatile technique that can be used to determine the lattice parameters within a crystal structure and thus identify the phase or phases present within a material. XRD provides information about the phases rather than the combination of elements and can be used to assess the phase purity of a material. Fig. 4 shows typical XRD traces for sintered HA.

The scan is comparable to the International Centre for Diffraction Data (ICDD) standard diffraction pattern for HA and was performed over a 2θ range of 25–40°, with a step size of 0.02° and a dwell time of 5 sec. This 2θ range is typically selected because it is in this region that the major HA peaks and the main impurity peaks are present. In addition to phase analysis, XRD can also be used to qualitatively assess the degree of crystallinity of a sample as indicated by the sharpness of the peaks in the XRD pattern. Similarly, stresses within a crystal lattice can be evaluated by peak broadening and peak shifting.

ICP, XRF, and carbon hydrogen nitrogen elemental analysis

ICP and XRF are commonly used to determine the levels of impurities and the levels of ionic substituents that may be present within a sample. ICP can measure most elements, but is best suited to measuring low concentrations, such as trace elements, or significantly diluted bulk compositions such as fluorine and chlorine in HA. XRF is also used to measure most elements ($Z > 10$), but is best suited for element concentrations > 0.1 wt% or 1000 ppm, such as the levels of elements that can form oxides at high temperatures.

Carbon hydrogen nitrogen elemental analysis is a useful technique to determine the levels of carbonate within a sample. This technique is based on an analysis of the gases that result from the combustion of a sample. The levels of carbon, hydrogen, and nitrogen can be determined by the amount of CO_2 , H_2O , and NO_x that pass through three pairs of thermal conductivity detectors.

Vibrational spectroscopy

Infrared spectroscopy is a non-destructive technique that enables the presence of certain bonds in a material to be established. Infrared spectroscopy is particularly useful in determining the presence of carbonate groups and their probable locations in the lattice of carbonate-substituted HA. There are two types of vibrational spectroscopy techniques: Fourier transform infrared (FTIR) spectroscopy (Fig. 5) (Table 5) and Raman spectroscopy (Fig. 6) (Table 6). FTIR is concerned with the vibrations of polar bonds where a change in dipole moment occurs as a result in vibration. Raman spectroscopy is associated with vibrations of non-polar covalent bonds where polarization can be induced.

	OH (stretch)	CO ₃ ν_3	PO ₄ ν_3	PO ₄ ν_1	CO ₃ ν_2	CO ₃ ν_4	OH (vibration)	PO ₄ ν_4	PO ₄ ν_2
HA	3572	—	1020, 1068, 1086	964	—	—	648	590, 617	478
1.70CHA	3571	1419, 1473, 1508, 1550, 1570	1018, 1083, 1145	968	883	759	648	567, 590	451, 474

All values correspond to the wave numbers (/cm) of the different hydroxyl, carbonate, and phosphate bands (unpublished data).

FTIR spectroscopy

FTIR spectroscopy allows the identification of the different functional groups present within the apatite structure of the samples, i.e., the phosphate, carbonate, and hydroxyl groups. The analysis technique is non-destructive and produces peaks/bands according to the way in which the bonds within functional groups vibrate in response to infrared radiation at specific characteristic frequencies. A common method of determining the type of carbonate substitution in HA is by FTIR. In addition to phosphate and hydroxyl bands, the FTIR spectra of CHA consist of additional peaks because of carbonate ions. The vibrations owing to carbonate ions may be either stretching or bending types. The carbonate ion is a trigonal planar ion that has four normal modes of vibration of which ν_2 (out of plane bending), ν_3 (asymmetric stretching), and ν_4 (planar bending) are infrared active and the symmetric ν_1 is not infrared active. A typical FTIR trace for HA is shown in Fig. 5. Both carbonate ion and silicate ion substitution affect the infrared spectral properties of HA. A-type carbonate substitution is characterized by the presence of a ν_2 peak at 878/cm and ν_3 peaks at 1450/cm and 1550/cm. B-type carbonate substitution is

Fig. 6 Raman trace for pure HA sintered at 1200°C for 2 hr.

characterized by the presence of a ν_2 peak at 875/cm and ν_3 peaks at 1410/cm and 1460/cm.^[59]

Physical Characterization

Physical properties such as micro- and macrostructure have been reported to influence the bioactivity of HA implants. For example, the bioactivity of porous HA is dependent on the geometry and size of the pores.^[60] The microstructure (in particular the grain size) may affect the solubility and the mechanical properties of HA in vivo.

BONE RESPONSE TO SYNTHETIC HA

Osseointegration may be defined as the ability of a material to support bone growth directly along its surface when placed in the vicinity of bone or differentiated bone-forming cells (as highlighted previously, in Fig. 2). A wide range of animal models have been used to demonstrate the efficacy of HA implants in vivo. Several studies have investigated the HA/host-tissue interface in vivo, and the majority of these reported that bone “bonds” directly on the surface of HA implants. Although the true definition of bone “bonding” to HA implants has not been resolved, the term has generally been applied where bone directly apposes an implant surface without the formation of an interfering fibrous layer. Considerable efforts have been made to unravel the mechanisms of material and biological responses that underlie bone-bonding capacity. It is commonly believed that the mechanism of bone bonding to HA implants may be explained by the proposed “dissolution–reprecipitation” theory for apatite nucleation. Dissolution of calcium and phosphate ions from the outermost surface of the HA implants leads to a local increase in concentration of these ions that favors biological (carbonated) apatite precipitation heterogeneously on proteins in the vicinity of the coating or directly on the coating surface itself (Figs. 7 and 8).^[8,61–64,65–72] This process may

^aUnpublished data.

occur through the surrounding environment (extra-cellular fluid) and may also be actively mediated by osteoclast cells^[73] Subsequently, this modified surface rapidly absorbs more proteins and promotes cell adhesion, particularly osteoblasts.

Studies have reported that the degradation processes of calcium phosphates are primarily influenced by chemical composition,^[8,35,63,65,66] crystallinity,^[67,68] porosity^[47] and microstructure of the materials.^[35,69,70] As Ca:P ratio decreases, both the solubility and the speed of hydrolysis of calcium phosphates increase. The rate of biodegradation of TCPs and HA between pH 6.2 and 7.2 follow the order^[70]

TCP > TeCP ≫ HA

Daculsi, LeGeros, and Mitre^[14] reported that the dissolution of calcium and phosphate ions from HA ceramics was initiated at microstructural defects

Fig. 7 TEM micrograph of grains of 0.8 wt% SiHA within the implant at six weeks in vivo. *Black arrow* shows surface dissolution of the grains. (From Ref. [73].)

such as dislocations and grain boundaries. Electron microscopy studies have reported that ionic substitutions modify the series of events occurring at the interface between the HA and the surrounding bone by altering the grain boundary structure of the ceramic.^[71–73] For, example, it has been suggested that substitution of silicate ions into the HA lattice modifies the sintering properties of HA and decreases the grain size (Table 2).^[71] The smaller grain size and formation of a less-ordered grain boundary phase in the SiHA increase the solubility and may affect both the morphology and the timing of apatite deposition at the bone–implant interface^[72,73] Despite the preponderance of evidence supporting the improved performance of physically and chemically modified HA implants as compared to HA, the mechanism by these modifications increases the bioactivity of HA remains unresolved.

CONCLUSIONS

Synthetic HA offers the potential for bone repair and regeneration, and has been in clinical use for a number of years. The future for the material will be in the development of new compositions either with enhanced bioactivity, or the ability to be resorbed in vivo. Alongside, the development of more chemically and biochemically active materials will be the continued search for improvements in the design of structures suitable for use as tissue-engineering scaffolds.

INTRODUCTION

The use of plasma-sprayed hydroxyapatite (HA)-coated implants in the clinics over the past 10 years has initiated substantial controversy in the field of dental implantology. One of the greatest concern about the use of plasma-sprayed HA coated implants is the general lack of long-term documentation on implant survival. Over the years, vast amount of in vivo research has indicated biocompatibility with HA-coated implants and a better performance when compared to noncoated titanium (Ti) implants. The better performance of plasma-sprayed HA implants is because of rapid initial osseointegration, and the high bone contact and interfacial strength between implants and bone.^[1-4] However, the advantages of plasma spraying HA on Ti implants are mired in considerable controversy owing to a lack of correlation between implant success and the specific surface properties of HA. It is known that the properties of HA coatings are altered during the coating process. Although, there is a lack of appreciation for the effects of altered HA coating properties on bone cell activity, the rationale for coating implants with HA grew out of the desire to combine the strength of Ti implant with a bioactivity HA surface.^[5-10] However, there are problems with plasma-sprayed HA coatings, including variation in the coating-metal adhesion strength, nonuniformity in coating thickness between vendors, alteration in structural and chemical properties during the coating process, and nonuniformity in coating density.^[1-10] As a result of these problems, there is controversy over whether or not HA coatings are beneficial to implant success. However, these problems are not shortcomings inherent in the rationale for

HA coating, but rather in the plasma spray technology currently used for depositing HA coatings on implant surfaces. This article will provide the current research on plasma-sprayed HA implants, including some plasma spraying techniques, in vivo study, clinical applications, as well as future developments.

PLASMA SPRAYING

Plasma spraying is the current commercial method for producing HA coatings on implant surfaces. As shown schematically in Fig. 1, a d.c. electric arc is struck between two electrodes, and an ionized high temperature gas (up to 30,000°C) is resulted, as a stream of gases passes through this electric arc. The increase in gaseous temperature resulted in an expansion of the gas and causes the carrier gas stream to pass through the arc at approximately the speed of sound. The coating powder, suspended in the carrier gas stream, is then fed into the plasma flame. The heat content of the plasma flame, and thus the ability to increase the temperature of a particle, is strongly dependent on the type of gas used. In addition, the longer the particle remains in the plasma flame, the higher will be the plasma temperature. Ideally, only a thin outer layer of each powder particle gets into the molten plastic state, which undergoes some phase transitions. This molten plastic state is critical to ensure an adhesive and dense coating. As a result, properties of plasma-sprayed coatings is highly dependent on particle size, type of gas used, speed of the plasma, the distance between the implants and plasma nozzle, and the cooling rate for the desired structural and chemical properties.

Fig. 1 Schematic representation of the plasma spraying process.

Apatite is known to be thermodynamically unstable during plasma spraying at high temperatures. When HA is plasma sprayed in air, calcium oxide is usually formed and its concentration will affect the integrity of plasma-sprayed HA coatings. A poor coating integrity is resulted from the high concentration of calcium oxide reacting with water. In addition, an increase in calcium oxide can also be resulted from the presence of a gas carrier having high hydrogen concentration. The use of hydrogen gas as a carrier resulted in a lower flame velocity and a more flame enthalpy as compared to the use of nitrogen gas, thereby resulting in more melting and decomposition of HA particles.

Plasma-sprayed HA coatings on orthopedic and dental implants usually have a thickness of 50–100 μm . Coatings become brittle when coating thickness exceeds 80 μm . However, a fast resorption may occur with very thin HA coatings. In addition, significant porosity within the HA coatings weakens the coating's mechanical strength and increases the resorption rate. It is desirable to have plasma-sprayed coatings that are completely dense and consist of pure HA. As such, the calcium-to-phosphorus ratio in the plasma-sprayed coating should be as similar to natural HA ($10/6 = 1.67$). Although mixtures of HA with tricalcium phosphate (TCP) have been investigated, clinical applications of these mixed coatings are rare. This is mainly attributed to the faster degradation rate of TCP as compared to HA and the fear that these mixed coatings may result in an unpredictable or uncontrolled degradation of the entire coating. In addition to TCP, coatings of calcium phosphates phases such as brushite, fluorapatite, and brushite have also been investigated, although there are no reported advantages to justify their clinical use.

IN VIVO STUDY

Although there are numerous reports indicating direct bone contact with plasma-sprayed HA-coated implants,^[11] only a few of these reports quantified and compared the percentages of bone contact with

Fig. 2 Representative scanning electron micrograph of plasma-sprayed hydroxyapatite (HA) after one year loading in a dog's mandible followed by pull-out testing. Fracture (indicated by the black arrow) took place between the titanium (Ti) substrate and the HA coating during pull-out testing. The white arrow shows the plasma-sprayed HA coating.

implants. Animal studies have also demonstrated a higher bone implant contact for plasma-sprayed HA as compared to noncoated Ti implant surfaces, although no significant difference in bone contact length between the plasma-sprayed HA and plasma-sprayed titanium (TPS) surfaces has been reported.^[11]

In addition to the above observations with regard to bone contact length, our studies have also indicated no significant difference in mean ultimate interfacial strength between plasma-sprayed HA, TPS, and noncoated Ti implants at 12 weeks after implant placement and at one year after loading.^[11] As shown in Fig. 2, scanning electron micrographs of the mechanically tested implants at one year after loading indicated a weakness at the coating-substrate interface. From the above observations, the lack of correlation between bone contact percentage and interfacial strength suggested a different bonding mechanisms for plasma-sprayed HA and TPS implants, with a chemical bonding occurring between bone and plasma-sprayed HA surfaces, whereas a mechanical interlocking occurring between bone and TPS surfaces (Fig. 3).

APPLICATION OF HA COATING IN CLINICS

The HA is commonly plasma sprayed on implants used in dentistry, total hip arthroplasty, total knee arthroplasty, total elbow arthroplasty, and total shoulder arthroplasty. The long-term clinical success of plasma-sprayed HA-coated endosseous dental implants has been excellent, with a survival rates in excess of 90% for

Fig. 3 Representative fluorescence micrograph of the plasma-sprayed Ti implant-bone interface at eight weeks after implantation (original magnification, $\times 100$; arrowhead = NB).

implants at greater than five to eight years' follow-up. In a clinical study at three study sites evaluating the five-year postrestoration safety and efficacy of 2062 threaded, plasma-sprayed HA-coated implants placed and restored among 720 patients, the surgical success rate at exposure was reported to be 98.3%.

From the clinical point of view, HA coatings have excellent success. However, peri-implant bone loss, rapid bone resorption, and a higher failure rate for HA-coated implants have also been reported. During a five years follow-up (mean 7.9 yr, range, 5.3–9.1 yr), one (1%) out of the 131 HA-coated threaded cups, two (2%) out of the 109 porous-coated press-fit cups, and 21 (11%) out of the 188 plasma-sprayed HA-coated press-fit cups were revised owing to aseptic loosening.^[11]

The prerequisites for achieving bone-dental implant osseointegration include the use of biocompatible materials, primary stability of the implant, atraumatic surgical procedure, and surgical protocol with unloaded submerged implants during three to six months healing.^[12] In 1985, Furlong emphatically insisted on fulfilling conditions of contact, stillness, and stressing in order for plasma-sprayed HA-coated implant to integrate with bone.^[13] In addition to the presence of plasma-sprayed HA coatings, implant design and suitable surgical procedures are equally critical in providing the initial total implant immobility (primary fixation), so that bone ingrowth (secondary fixation) can occur.

RETRIEVAL STUDIES

Implant retrieval studies are important in not only highlighting the success of the implant, but also in providing failure information that would allow the improvement of future implants. In examining six clinically successful

plasma-sprayed HA-coated cementless acetabular components that were retrieved at autopsy between 3.3 and 6.6 yr after implantation, bone growth onto the implant was indicated for all cups and with a bone-implant contact of $36.5 \pm 13.5\%$.^[14] The extent and thickness of plasma-sprayed HA coatings were reduced in specimens obtained from old patients and in specimens associated with a longer duration of implantation. Osteoclastic degradation of plasma-sprayed HA coatings was observed. Although loose HA granules were observed near the coatings, no adverse tissue reaction to these granules was reported.

In examining five-year plasma-sprayed HA-coated implants retrieved at autopsy from three patients who died from nonhip-related causes, Bauer et al.^[15] described excellent clinical performance of all involved implants with implantation time varying between 4 and 25 mo. An average coating thickness of $40 \mu\text{m}$ was observed on all plasma-sprayed HA-coated explants, with no observation of coating delamination and no correlation between length of implantation and coating thickness. The lack of correlation between coating thickness and length of implantation suggested minimal early loss of coating to extracellular fluid. A uniform layer of bone, ranging from 32% to 78%, was reported over the HA coating circumference, with more bone fixation observed in the distal parts of the coating area. The average area of osseointegration was observed to be greater than 60% of available HA surface. In the 25 mo retrieved sample, focal areas of osteoclastic resorption on the plasma-sprayed HA coatings were observed. Once bony coverage of the coating was obtained, the process of physicochemical dissolution was suggested to be arrested. However, as observed in the 25 mo retrieved sample, a cellular process of coating degradation caused by osteoclastic activity was observed, and that the osteoclastic resorption of plasma-sprayed HA coatings was replaced by bone. This suggested that with longer implantation period, the plasma-sprayed HA coating will be replaced by autologous bone, while preserving the quality of osseointegration. There was no fibrous tissue formation in these HA-resorption areas. In addition, degradation of the plasma-sprayed HA coating was more pronounced in the proximal femur as compared with the more cortical middle and distal stem area, suggesting a relationship between coating degradation and rate of bone remodeling. However, the quality and amount of fixation in all retrieved samples were not affected by degradation of the plasma-sprayed HA coatings.

CURRENT PROBLEMS

Aside from the weak coating-metal interface, vast amount of investigations have indicated that there are

no accepted standards for producing HA coatings on implant surfaces and that all HA coatings are not identical.^[1,9,10] As such, variability in coating quality has resulted in many conflicting animal and clinical observations. Although plasma-sprayed HA coatings on implant surfaces have been indicated to enhance implant stability, such findings have not been universal. These equivocal findings likely stem from the fact that HA coatings are poorly characterized. Typical plasma-sprayed HA coatings have been reported to consist primarily of partially dehydrated HA, with amorphous calcium phosphate and other more soluble phases such as TCP produced during the high-temperature deposition process. Although plasma spraying has the ability to produce coating crystallinity in the range 30% to 70%, the crystallinity for plasma-sprayed HA coatings produced under normal deposition process is approximately 65%. In addition, the use of plasma spraying technology often results in coating properties that differs from the starting HA powders.

The ratio of HA to TCP has been reported to be crucial for bone regeneration. It has also been reported that the dissolution rate of an HA coating is dependent on the biochemical calcium phosphate phase of the coating. As coating crystallinity increases, dissolution rate of the coatings decreases. In addition, increasing the amorphous and TCP concentration within the coatings are thought to predispose HA coatings to dissolution. In addition to the coating integrity, the local concentrations of calcium and phosphate in the pericellular environment are known to influence cellular response. Enrichment of the calcium and phosphate ions in the localized biological environment, as a result of dissolving CaP coatings, may promote the formation of bone apatite-like minerals. However, a high calcium concentration is also known to induce apoptosis of bone-forming cells and to promote the formation of osteoclasts.^[16] As an example of the influence of indirect dissolution on bone biological response, the effect of coating crystallinity on cellular response is shown in Fig. 4. From the figure, it was observed that varying the crystalline content of the HA coatings significantly affects the bone-implant interfacial strength. Lacefield and Soballe have also identified several other coating properties that affect bone response, including surface texture, porosity, and the presence of trace elements.^[17,18] As such, there is a need to address the optimal crystallinity, porosity, texture, and presence of trace elements within the coatings to maximize implant success.

FUTURE DEVELOPMENTS

There is no standard guideline for depositing HA coatings on medical devices. At present, most of the coatings were performed using the plasma spraying

Fig. 4 Push-out strength at the implant–bone interface using a rat femur model.

technology because of its rapid deposition rate and sufficiently low cost. However, despite these advantages and the reported clinical success, there are problems associated with plasma-sprayed HA coatings. These problems included poor adhesion and variation in bond strength between the coatings and metallic substrates, as well as alterations in HA properties as a result of the coating process. The nature of the substrate plays an important role in the adhesion between plasma-sprayed coatings and metallic substrates. The bonding of plasma-sprayed coatings to the metallic substrate appears to be entirely mechanical in nature, and a highly roughened substrate surface is needed to ensure coating–metal adhesion.

To overcome the problems associated with plasma spraying, experimental deposition processes such as electrophoretic codeposition, sputter deposition, and high-velocity oxy-fuel combustion spray deposition have been investigated.^[10] Although these experimental processes have been successful to overcome some of the problems associated with plasma spraying, there are limitations with all of these processes. For example, sputtering has been reported to have ability for controlling the physical and chemical properties of HA coatings produced on dental and orthopedic implants.^[12] The advantages of radio-frequency magnetron sputter-coating over other coating processes include a highly dense coating with high metal-implant bonding strength (40 MPa for sputtered coatings vs. 9 MPa for plasma-sprayed HA coatings), and a highly uniform and continuous coating.^[9,10] Another important advantage of the sputtering process is that the highly adhesive coatings can be performed on mirror-polished surface.^[10] However, despite these advantages, the sputtering process has a very low sputtering rate, and thus is not economical.

As the biological apatite is nanosize, the synthesized nano-HA is expected to be recognized as biocompatible. The nano-HA should be involved in the natural bone remodeling process rather than being phagocytized like polymer debris.^[19] At present, there is a huge interest in nanotechnology including the production of nano-HA that can be used to optimize osseointegration. It has already been reported that nano-HA supported the attachment and the spread of human osteoblast cells.^[20] Although this study and many other studies on nano-HA have shown promise, more studies are needed before nano-HA can be used in clinical applications.

CONCLUSIONS

New promising coating processes are continuously being investigated. Investigators are presently exploring nanotechnology and biomimetics in the hope to optimize coating properties for rapid osseointegration. These investigations have included better materials characterization, understanding bone responses to implant surfaces of different properties, and the use of various biological factors. Although it is generally accepted that plasma-sprayed HA and TPS coatings improve bone strength and initial osseointegration, optimum coating properties required to achieve maximum bone response are yet to be achieved. As such, coating methodology, the use of HA and other calcium phosphate phases, together with well characterized implant surfaces in cell culture, animal, and clinical studies, should continue to be investigated to provide basic understanding of bone-implant interactions, and that an improved HA-coated implants are needed to optimize osseointegration.

ACKNOWLEDGMENTS

The studies presented were funded by NIH/NIDCR (DE12276), NIH/NIAMS (AR46581), and collaboration was also supported in part by a Grant-in-Aid for Scientific Research B (No. 15390612) of the Japanese Ministry of Education, Science, Sports and Culture. The authors would also like to thank Friatec AG, Germany for some of the implants used in the book chapter.

INTRODUCTION

Total hip arthroplasty (THA) is enormously successful in restoring mobility and quality of life to millions of individuals. This article covers a history of total hip arthroplasty, current technology, clinical concerns, and future developments. The history of total hip arthroplasty is particularly pertinent to biomaterials science because it is one of the best illustrations of how an implant first used over a century ago has achieved such high success, primarily because of advances in biomaterials. In general, total hip arthroplasty evolved from interpositional membranes inserted between the femoral head and acetabulum, to cups that fit over the femoral head, to short-stemmed prostheses, and finally to long-stemmed total hip prostheses. Clinical issues associated with biomaterial degradation basically break down to four: 1) the amount of material released from the implant; 2) where the material is transported and in what quantity; 3) the chemical form of released degradation products (e.g., inorganic precipitate versus soluble organometallic complex); and 4) the pathophysiological interactions and consequences of biomaterial degradation.

The clinical concerns portion of this article focuses on what is known (and is of orthopedic clinical concern) regarding biomaterial degradation (through wear and electrochemical corrosion), dissemination of debris, and consequent local/systemic effects. Currently total hip arthroplasty is typified by a metal alloy femoral stem with metal femoral head that articulates on a polymer acetabular cup. This article focuses on the metals that compose THA and why particular alloys are used for specific components. However, there exist many variations on this archetype, including variations in materials and geometry. Despite the enormous success of modern THA, current efforts to improve implant performance center on the development of new materials and on small, incremental changes in implant design.

HISTORY OF TOTAL HIP ARTHROPLASTY

The earliest attempts to restore mobility to painful and deformed hip joints took place in the 1820s (White,

1822, and Barton, 1827) and centered on simply removing the affected femoral and acetabular bone involved. This evolved in the 1830–1880s into ghastly attempts to restore mobility using interpositional membranes between the femoral head and acetabulum, where materials such as wooden blocks and animal (e.g., pig) soft tissue were tried. The first prosthetic hip replacement dates to 1890, when Gluck published a description of a carved ivory femoral head replacement using bone cement like materials such as pumice and plaster of paris to secure the implants in place.^[1,2]

Most popular was the interpositional membrane strategy that continued into the twentieth century with the use of new implant materials in the early 1900s (1900–1920), including organic materials (e.g., pig bladders and peri-implant soft tissues) and inorganic materials such as gold foil. The use of an individual's own soft tissues was the most popular method of interpositional membrane hip surgery. The limited success of this procedure prevented widespread use, although the treatment of painful, disfigured, and frozen (ankylosed) hip joints with other implant materials remained commonplace into the 1920s.

Mold arthroplasty

In 1923 Marius Smith-Peterson was credited with ushering in the modern era of total joint replacement with the development of mold arthroplasty (Fig. 1), made of glass and inspired by a shard of glass found in a patient's back, surrounded in a benign, synovial membrane. This mold, or cup, arthroplasty was designed as a cup that fit between the femoral head and the acetabular cup, and articulated on both surfaces using a cartilagelike layer. Despite the fanfare, his desire was simply to develop a better interpositional membrane than had been in use for the previous 100 years. The efforts of Smith-Peterson and colleagues over the years 1923–1938 were spent improving the fracture resistance of the glass mold arthroplasty cup design, using materials such as early polymers (e.g., celluloid or phenol-formaldehyde Bakelite or Formica) and improved glass (e.g., Pyrex). It was not until 1939, when the first metal—a cobalt alloy termed Vitallium—became available and was used by Venable, Stuck, and Beach,

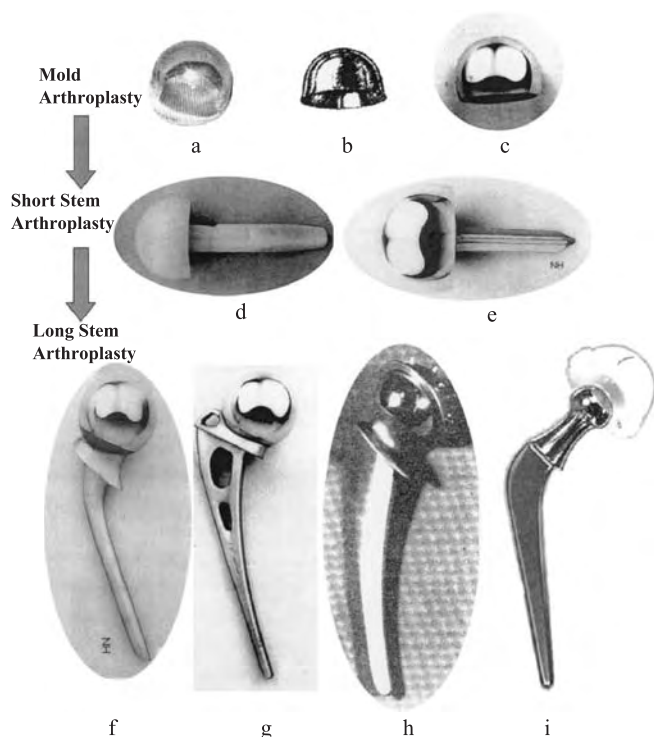

Fig. 1 Array of implants representing the history of THA evolution. (a) Marius Smith-Peterson in 1923 is credited with ushering in the modern era of total joint replacement with his mold arthroplasty made of glass; (b) Venable, Stuck, and Beach used a cobalt alloy in 1939 named Vitallium, possessing superior corrosion resistance; (c) Vitallium alloy facilitated further design modifications of the mold arthroplasty by Otto E. Aufranc; (d) the Judet brothers in Paris, in 1946 used polymethylmethacrylate to manufacture short-stemmed prostheses; (e) a Judet brothers Vitallium (cobalt-chrome alloy) prosthesis, which replaced acrylic in short-stem designs in 1951; (f) 1950 designs of Frederick R. Thompson; and (g) Austin T. Moore, which ushered in the era of long-stemmed prostheses; (h) the 1951 McKee-Farrar prosthesis evolved quickly to incorporate a true spherical femoral head undercut at the neck to reduce impingement of the head on the rim of the acetabular prosthesis and provide for greater range of mobility; (i) a 1962 Charnley low-friction arthroplasty remains the prototype of total hip arthroplasty performed today.

that the corrosion resistance of the hip arthroplasty provided sufficient biocompatibility and performance (Fig. 1).

In 1937 Venable, Stuck, and Beach published a landmark article that was the first to analyze in systematic fashion the electrolytic effects of various metals on bone and tissues (e.g., aluminum, copper, iron, nickel, lead, gold, magnesium, silver, stainless steel, and other alloys), and arrived at the conclusion that Vitallium (a cobalt chromium alloy) was superior to other metals in corrosion resistance and in the mechanical

properties required for an implant.^[3,4] By observing the effects of corrosion and proposing guidelines for performance, Venable, Stuck, and Beach set the standard by which future metallic alloys would be selected for use in hip and other types of implants.

The superior material properties of the Vitallium alloy facilitated further design modifications of the mold arthroplasty by Otto E. Aufranc (Fig. 1). Aufranc removed the rim of the Smith-Peterson mold (often the cause of adhesions, cup freezing, and subsequent pain and immobility), and machined matching curves on the inner and outer surface to meet at the rounded outer edge. Despite the high short-term success rates (<4 years) reported by Aufranc (>82%), the overall failure rate remained high (>50%). Another design modification of the mold arthroplasty in the 1940–1950s was fixation of the mold to the acetabulum rim with screws by physicians such as Albee-Pearson and Gaenslen. Although used in only four cases, Gaenslen reported using a cobalt alloy mold fixed to the acetabulum and another fixed to the femoral head, creating a metal-on-metal total hip replacement. The popularity of mold arthroplasties endured into the 1970s when they remained touted as the treatment of choice for traumatic arthritis of the hip by leading orthopedic surgeons.^[5] Back in the 1930s, however, the natural progress in THA development was the progression from mold arthroplasty to short-stem prosthesis.

Femoral head prostheses/short-stem prostheses

Femoral head prostheses were first made of such materials as ivory (Gluck, 1890) and rubber (Delbet, 1919), and were cemented for stability.^[1,2] At about the same time, these replacement heads were first fitted with a short stem by Earnest Hey Groves, who used an ivory nail to replace the articular surface of the femur. These types of implants were rare and remained unpopular compared to mold arthroplasties until 1937 when Harold Bohlman, using the work of Venable and Stuck, designed a corrosion-resistant cobalt–chrome alloy femoral head replacement with a short stem. This design was popularized by the Judet brothers in Paris in 1946, who used polymethylmethacrylate (presumed to be biologically inert *in vivo*) to manufacture short-stemmed prostheses (Fig. 1). Initial good results were soon replaced with problems of implant fracture and excessive wear debris, and by the early 1950s, these implants were losing favor and being removed by surgeons. Vitallium (cobalt–chrome alloy) eventually replaced acrylic in several other short-stem designs. However, there were sound short-stem designs as early as 1938, when Wiles introduced the cobalt alloy femoral shell attached to the femur with a central nail. This design was popularized by Peterson in 1950, when he

used a similar Vitallium shell design with a central nail and a plate attached to the nail for added stability. Others (including J. Thompson, 1951, and Rossignal, 1950) adopted and adapted the Judet brothers' design using Vitallium. Rossignal designed large threads onto the stem to aid in fixation. These short-stem designs were subject to what was deemed high shear stress, and resulted in early loosening and failure in some patients. Short-stem designs were gradually replaced by longer stem designs that provided less stress concentration.

Long-stem prostheses

Long-stem prostheses continued the trend established by short-stemmed prostheses (i.e., increasingly more weight-bearing forces were transferred to the femur though an intramedullary stem). The pattern for long-stem prosthesis was established in 1940 by Bohlman in collaboration with Austin T. Moore, in which they implanted a 12-inch Vitallium prosthesis that replaced the femoral head and had long supports screwed into the outside of the femoral shaft.^[6] Although there were innovations in long-stem design in the 1940s (such as the doorknob design of Earl McBride, where a threaded stem was screwed into the intramedullary canal of the femur for fixation and load transfer), these designs were not popular. It was not until the 1950 designs of Frederick R. Thompson and Austin T. Moore that long-stemmed prostheses became popular (Fig. 1). These designs were cast in Vitallium (cobalt-chrome alloy) and required the removal of the femoral head but only part of the neck. The design of Moore differed from Thompson's in that it had fenestrations through the implant to allow bone growth, and it had a rear vane to enhance rotational stability. Initially these implants were used without bone cement. The success of the designs of the Thompson and Moore prostheses is proved by their continued use with only slight variations. Despite the excellent design of these early long-stemmed prostheses, they were primarily successful when used to replace diseased femoral heads, and did not work well when acetabular reaming was required. This inadequacy prompted the development of the total hip replacement arthroplasty.

Total hip replacement arthroplasty

Philip Wiles is credited with the first total hip arthroplasty in 1938, when he used a stainless steel ball secured to the femur with a bolt and a stainless acetabular liner secured with screws.^[7] The results of this design were disappointing because of the poor corrosion resistance of early stainless steel in vivo, the high stress concentrations of short-stemmed prostheses, etc. An adaptation of this design that proved successful was

developed by G.K. McKee and J. Watson-Farrar in 1951. They used a stainless steel cup and long-stemmed prosthesis (Thompson stem) that rapidly failed due to the poor corrosion resistance of the stainless steel. The cup was changed to cobalt-chrome alloy with greater success. The McKee-Farrar prosthesis evolved quickly to incorporate a true spherical femoral head, undercut at the neck to reduce the impingement of the head on the rim of the acetabular prosthesis and to provide for greater range of mobility (Fig. 1).^[8]

The next milestone in the evolution of modern total hip arthroplasty was the advent/popularization of acrylic dental bone cement, first used by Sven Kiar in 1950 to attach a plastic prosthesis to bone.^[9] Later that year, the Hospital for Joint Diseases in New York used polymethylmethacrylate (acrylic) bone cement as a means of fixation in total hip arthroplasties.^[10,11] The development of acrylic bone cement dramatically reduced the rates of loosening associated with metal-metal total hip arthroplasty. The Stanmore metal-metal design, which used a horseshoe-shaped cup, was popular but led to excessive wear and was replaced by a complete cup. McKee and Watson-Farrar adapted their design to facilitate bone cement with a land-minelike studded acetabular cup designed to maximize mechanical fixation.

The 1950s marked the introduction and popularization of the total hip arthroplasty, in which replacement arthroplasty became simple and reliable enough to be practiced on a wide scale by the average orthopedic surgeon. However, the squeaking reported to occur in Judet's and in some later metal prostheses was identified by Charnley to be a result of the relatively high frictional forces in the joint. These high-torque and frictional forces resulted in the generation of significant metallic debris that (purportedly) resulted in early loosening. In 1960 Charnley developed a low-friction arthroplasty device using shells of Teflon on the femoral and acetabular sides, which resulted in early/immediate failures because of massive debonding and wear debris. This was quickly followed by a thick-walled Teflon acetabular component articulating on a small head designed to reduce the shearing forces and torque. However, this design also generated excessive wear debris, which produced immediate and severe inflammation and failure of the prosthesis. Charnley then replaced the Teflon with high-density polyethylene that was not as friction-free as Teflon but was 1000 times more wear-resistant. This prototype of total hip arthroplasty, developed in 1962, was the basis for future designs that remain the most popular form of total hip arthroplasty performed today (Fig. 1).

The basic design of Charnley was modified by Muller with variable neck sizes and larger heads. During the same period, metal-on-metal designs by Smith, Ring,^[12] and others were unsuccessful challengers to the basic

Charnley metal-on-polymer design. Other currently adopted design modifications were developed by Ling, Aufranc, Turner, Amstutz, Harris, and Galante, which include such innovations as femoral prosthesis geometrical modification for increases in stability and mobility, modular components for increased customization, porous coatings, surface texturing/coating to increase fixation and bone ingrowth, etc. Charnley is often deified in orthopedic literature as the metaphorical spark that lit the flames of innovation in prosthetic design. This is typical surgeon-centered glorification. Other implant designs that predate Charnley (such as the all-metal McKee-Farrar THA implant) have enjoyed success rates similar to those reported by Charnley. More important, total hip arthroplasty has evolved over the last century through the innovation of many investigators, and has benefited most significantly from recent advances in areas of materials technology, biomechanics, biochemistry, immunology, infectious diseases, thrombosis, and pharmacology.

TOTAL HIP ARTHROPLASTY, CURRENT TECHNOLOGY

Today the total hip implant remains much as it was in the 1970s, albeit with more variety of implant materials and geometries (Fig. 2). The current THA is typically constructed of a titanium or cobalt–chromium alloy femoral stem (cemented with PMMA or press-fit into place), connected to a modular cobalt–chrome alloy or ceramic head that articulates on an ultrahigh molecular-weight polyethylene (UHMWPE) or ceramic acetabular cup fitted into a titanium or cobalt–chromium cup liner that is cemented, screwed, or press-fit into place (Fig. 2). Despite this simple archetype of the total hip replacement, there exist hundreds of variations on this theme (Fig. 3) offered to today's orthopedic surgeons, with little in terms of absolute guidelines as to which type of implant is the best (or which of more than 10 major manufacturers produces the best) for well-defined orthopedic disease states. However, there are some general guidelines. Typically implants in older individuals (>80 years of age) are cemented into place with bone cement, because the chance for revision is minimal when compared to younger individuals (<60 years), and removing bone cement is technically challenging and may compromise the availability of bone stock. Generally, there are choices of surface roughness, coating, geometry, material composition, etc., and each manufacturer claims that its product is superior to the rest. This, in combination with the lack of much publicly available information tracking the performance of each type of implant, precludes accurate scientific analysis of which implant materials and which design perform best. Additionally, stiff competition between

Fig. 2 Common type of total hip arthroplasty—titanium alloy stem, with cobalt-based alloy (ASTM F-75) modular head bearing on an ultrahigh molecular-weight polyethylene (UHMWPE) liner within a titanium alloy cup. Also shown is a ceramic head and three acetabular sockets with various surfaces for both cemented and cementless fixation. (Photograph courtesy of Zimmer, Inc.)

manufacturers and the extent of commercial promotion required to compete in the marketplace have resulted in a dizzying array of new implants released each year, each claiming to be improved over the previous year's model (see Fig. 3). These claims are clearly baseless, because the typical total hip replacement enjoys a success rate of over 90% at 7 years. In most cases, therefore, a minimum of 7 to 10 years must transpire before such claims can be substantiated; even then, proof of

Fig. 3 Hundreds of THA components designed by dozens of manufacturers present an array of choices to modern orthopedic surgeons, charged with the responsibility to select the best-performing implants.

superior performance is compromised by myriad external factors such as surgeon, region of the country, average activity of patient populations, etc. This conflict between science, marketing, and market share may represent the single greatest obstacle to the scientific determination of superior implant design and progress. The responsibility rests with the U.S. Food and Drug Administration (FDA) to prevent the zeal and economic pressure of the market from undermining implant design in a regressive fashion.

Polymers

Total hip arthroplasty typically consists of an acetabular cup of ultrahigh molecular-weight polyethylene (UHMWPE) articulating against a femoral ball of cobalt–chromium alloy. The resultant wear of the polyethylene bearing produces billions of submicron-sized wear particles annually, predominantly in the 0.5-micron range. Extra cross-linking of polyethylene (using chemical and radiation techniques) has only recently improved its abrasion resistance in hip arthroplasty. Wear testers have shown that the wear resistance of UHMWPE is improved by cross-linking with gamma irradiation at 2.5 to 10 Mrad. However, this can negatively affect such physical properties as tensile strength. Therefore, care is taken and processes patented to minimize negative oxidation effects while preserving high-wear characteristics. The ultimate performance of new, highly cross-linked polyethylene and the subsequent oxidation remain an area of active research.

In order to maximize the performance characteristics of polyethylene, it is cross-linked prior to fabrication into an acetabular cup. Typically an extruded bar of polyethylene is cross-linked using conventional gamma irradiation and then heated to reduce free radicals. The remaining oxidized surface layer of the irradiated bar is discarded prior to or during acetabular cup machining. There have been claims of negligibly small polyethylene debris produced by hip simulators when using highly cross-linked UHMWPE, due to the increase in surface wear resistance.

Ceramics

Alumina (Al_2O_3) and Zirconia (ZrO_2) ceramics have been used in THA for the past 30 years. The first ceramic couple (Alumina/Alumina) was implanted in 1970 by Pierre Boutin. The theoretical advantage of hard-on-hard articulating surfaces was low wear. Ceramics, because of their ionic bonds and chemical stability, are also relatively biocompatible. Initial concerns about fracture toughness and wear have been addressed by lowering grain size, increasing purity, lowering porosity, and improving manufacturing techniques (e.g., hot

isostatic pressing, HIP). Early failures of these couples were plagued with both material-related and surgical errors. The very low wear rates combined with steadily decreasing rates of fracture (now estimated to occur at the rate of 1 in 2000 over 10 years) have resulted in the growing popularity of all ceramic bearings. In general, ceramic debris is purportedly chemically stable; thus, most problems are associated with the amount of debris and not with particle toxicity.

Zirconia was introduced in 1985 as a material alternative to Al_2O_3 for ceramic femoral heads, and has been gaining preference because of its mechanical properties superior to Alumina. Femoral heads of Zirconia can typically withstand 250 kN (or 25 tons), a value exceeding that possible with Alumina or metal femoral heads.

Metals

Metals remain the central material component of state-of-the-art total hip arthroplasties. Metals provide appropriate material properties such as high strength, ductility, fracture toughness, hardness, corrosion resistance, formability, and biocompatibility necessary for use in load-bearing roles required in fracture fixation and total joint arthroplasty (TJA). Implant alloys were originally developed for maritime and aviation uses where mechanical properties such as high strength and corrosion resistance are paramount. Three principal metal alloys are used in orthopedics, particularly in total joint replacement: 1) titanium-based alloys; 2) cobalt-based alloys; and 3) stainless steel alloys. Alloy-specific differences in strength, ductility, and hardness generally determine which of these three alloys is used for a particular application or implant component. However, it is the high corrosion resistance of all three alloys, more than anything, that has led to their widespread use as load-bearing implant materials. These material properties of metals (Table 1) are due to the miraculous nature of the metallic bond, molecular microstructure, and elemental composition of metals.

Stainless steel alloys

Stainless steels were the first metals to be used in orthopedics in 1926. However, it was not until 1943, when ASTM 304 was recommended as a standard implant alloy material, that steels became reliable as an implant alloy. All steels are composed of iron and carbon, and may typically contain chromium, nickel, and molybdenum. Trace elements such as manganese, phosphorus, sulfur, and silicon are also present. Carbon and the other alloy elements affect the mechanical properties of steel through alteration of its microstructure.

Table 1 Approximate weight percent of different metals and other element within major orthopedic alloys

^aIndicates less than 0.05%.

^bAlloy compositions are standardized by the American Society for Testing and Materials (ASTM vol. 13.01).

The form of stainless steel most commonly used in orthopedic practice is designated 316LV (American Society for Testing and Materials (ASTM) F138). 316 classifies the material as austenitic, L denotes the low carbon content, and V denotes the vacuum under which it is formed. The carbon content must be kept at a low level to prevent carbide (chromium-carbon) accumulation at the grain boundaries.

Although the mechanical properties of stainless steels are generally less desirable than those of the other implant alloys (lower strength and corrosion resistance), stainless steels do possess greater ductility, indicated quantitatively by a threefold greater percentage of elongation at fracture when compared to other implant metals. This aspect of stainless steel allows it to remain popular as a material for cable fixation components in total knee arthroplasty, and as a low-cost alternative to Ti and Co alloys.

Cobalt-chromium alloys

Of the many Co-Cr alloys available, currently only two are predominantly used as implant alloys (Table 1). These are cobalt-chromium-molybdenum (CoCrMo), which is designated ASTM F-75 and F-76, and cobalt-nickel-chromium-molybdenum (CoNiCrMo), designated ASTM F-562. Other Co-alloys approved for implant use include one that incorporates tungsten (W) (CoCrNiW, ASTM F-90) and another that incorporates iron (CoNiCrMoWFe, ASTM F-563). Co-Ni-Cr-Mo alloys, which contain large percentages of Ni (25–37%), promise increased corrosion resistance, yet raise concerns of possible toxicity and/or immunogenic reactivity (discussed later) from released Ni. The biologic reactivity of Ni released from Co-Ni-Cr alloys is cause for concern under static conditions, and due to their poor frictional (wear) properties, Co-Ni-Cr alloys are also inappropriate for use in articulating components. Therefore, the dominant implant alloy used for total joint components is CoCrMo (ASTM F-75).

Cobalt alloys are generally cast into their final shape because they are susceptible to work-hardening at room temperatures. That is, the improvements in strength and hardness gained by cold-working are not worth the loss in fracture toughness. Thus, Co-Cr-Mo alloy hip implant components are predominantly manufactured using lost wax (investment) casting methods.

Although Co-Cr-Mo alloys are the strongest, hardest, and most fatigue-resistant of the metals used for joint replacement components, care must be taken to maintain these properties because finishing treatments may function to reduce them (Table 2). For example, sintering of porous coatings onto femoral or tibial TJA Co-Cr-Mo stems can decrease the fatigue strength of the alloy from 200–250 MPa to 150 MPa after heating (annealing) the implant at 1225°C.

Titanium alloys

Titanium alloys were developed in the mid 1940s for the aviation industry and were first used in orthopedics around the same time. Two post-World War II alloys—commercially pure titanium (CPTi) and Ti-6Al-4V—remain the dominant titanium alloys used in implants. Commercially pure titanium (CPTi, ASTM F67) is 98–99.6% pure titanium. Although CPTi is most commonly used in dental applications, the stability of the oxide layer formed on CPTi (and consequently its high corrosion resistance) and its relatively higher ductility (i.e., the ability to be cold-worked) compared to Ti-6Al-4V have led to the use of CPTi in porous coatings (e.g., fiber metal) of TJA components. Generally, joint replacement components (i.e., TJA stems) are made of Ti-6Al-4V (ASTM F-136) rather than CPTi because of its superior mechanical properties (Table 2).

Titanium alloys are particularly good for THA components because of their high corrosion resistance compared with stainless steel and Co-Cr-Mo alloys. A passive oxide film (primarily of TiO₂) protects both Ti-6Al-4V and CPTi alloys. Generally, Ti-6Al-4V has mechanical properties that exceed those of stainless steel, with a flexural rigidity less than stainless steel and Co-Cr-Mo alloys. The torsional and axial stiffness (moduli) of Ti alloys are closer to those of bone and theoretically provide less stress-shielding than do Co alloys and stainless steel. However, titanium alloys are particularly sensitive to geometrical factors, notch sensitivity in particular. This reduces the effective strength of a component by increasing the material's susceptibility to crack propagation through the component. Care is therefore taken in both the design geometry and fabrication of Ti alloy components. Perhaps the greatest drawback to Ti alloys is their relative softness compared to Co-Cr-Mo alloys (Table 2), and their relatively poor wear and frictional properties. Ti-6Al-4V is >15% softer than Co-Cr-Mo alloys and also results in significantly more wear than Co-Cr-Mo when used in applications requiring articulation, e.g., TKA or THA femoral heads. Ti alloys are thus seldom used as materials when hardness or resistance to wear are primary concerns.

New Alloys and Surface Coatings

The quest for new THA metal alloys with improved biocompatibility and mechanical properties is ongoing. The use of Ti alloys, Co-Cr-Mo alloys, or stainless steels in a specific application generally involves trade-offs of one desirable property for another. Examples of this are the sacrifice of chemical inertness for hardness (wear resistance), as is the case with Ti alloy for Co-Cr-Mo in TJA bearing surfaces, and the compromise

of strength for ductility when using stainless steel instead of Ti and Co–Cr–Mo alloys for bone fixation cables. Although new alloys claim to be just that—new—they are often merely variations of the three categories of implant metals previously described (and already approved for use as implant materials). These improved alloys usually contain only the minor addition of new elements to protect assertions of substantial equivalence to existing ASTM- and FDA-approved alloys, thereby easing the burden of regulatory approval. These new alloys generally fall under one of four categories—titanium alloys, cobalt alloys, stainless steels, and (less approved) refractory metals.

New titanium alloys

One new group of Ti alloys put forward for orthopedic component use employs molybdenum at concentrations greater than 10%. The addition of Mo acts to stabilize the BCC (beta) phase at room temperature; these alloys are thus referred to as beta Ti alloys. These beta Ti alloys promise 20% lower moduli, which are closer to bone and thus provide better formability with maintenance of other mechanical properties typical of Ti-6-4.

Other attempts at improving traditional Ti-6Al-4V alloys seek to improve biocompatibility and mechanical properties by the substitution of vanadium (V, a relatively toxic metal) with other less toxic metals. Two such Ti alloys are Ti-5Al-2.5Fe and Ti-6Al-17Nb, which substitute Fe and Nb for V, respectively. These alloys have properties similar to traditional Ti-6-4, yet they claim higher fatigue strength and a lower modulus, thus enhancing bone-to-implant load transfer (Table 2).

New cobalt alloys

Some new cobalt alloys are identical in composition to traditional alloys, but use novel processing techniques to manipulate the microstructure of the implant materials to improve their mechanical properties. One such example recently patented, TJA-1537, although compositionally identical to ASTM F-75, claims enhanced wear resistance and fatigue strength through elimination of carbide, nitride, and second-phase particles (Allegheny Technologies). These particles normally form at the grain boundaries within a standard F75 CoCrMo alloy, and act to decrease wear and fatigue resistance. Other new Co alloys under development for use in orthopedics seek to improve biocompatibility by eliminating Ni, and improve mechanical properties by reducing carbon content, thus avoiding carbide precipitation at grain boundaries.

New stainless steels

The relatively poor corrosion resistance and biocompatibility of stainless steels compared to Ti and Co–Cr–Mo alloys provide incentive for development of improved stainless steels. New alloys such as BioDur 108 (Carpenter Technology Corp.) attempt to solve the problem of corrosion with an essentially nickel-free austenitic stainless alloy. This steel contains a high nitrogen content to maintain its austenitic structure, and boasts improved levels of tensile yield strength and fatigue strength, and improved resistance to pitting and crevice corrosion compared to nickel-containing alloys such as Type 316L (ASTM F138).

Refractory metals

Metals characterized as refractory include zirconium (Zr), tantalum (Ta), molybdenum (Mo), and tungsten (W) because of their relative chemical stability (passive oxide layer) and high melting points. Because of their stability, they are also highly corrosion-resistant. Corrosion resistance generally (although not always) correlates with biocompatibility because more stable metal alloys tend to be less chemically active and less participatory in biologic reactions. Additionally, some of these refractory metals (Mo and W) also possess high hardness properties, which makes them ideally suited for wear-resistance applications. However, these materials are difficult to form and machine. TJA components can be manufactured through the process of hot isostatic pressure using alloys such as copper to catalyze the binding of the refractory powder into a solid component. But removing binding metals that remain within components as grain boundary impurities is problematic and remains a technical barrier to the use of these alloys as implant materials.

CLINICAL CONCERNS OF MODERN TOTAL HIP IMPLANTS

Implant Degradation

Wear

The generation of wear debris and subsequent tissue reaction are central to the longevity of total joint replacements. In fact, particulate debris are currently extolled as the primary factor affecting the long-term performance of joint replacement prostheses, and as the primary source of orthopedic biomaterial degradation (based on overall implant mass or volume lost). Particulate debris generated by wear, fretting, or fragmentation induce an inflammatory reaction that, at a certain

point, promotes a foreign-body granulation tissue response that has the ability to invade the bone-implant interface. This commonly results in progressive local bone loss that threatens the fixation of both cemented and cementless devices alike.

Wear involves the loss of material in particulate form as a consequence of relative motion between two surfaces. Two materials placed together under load will only come into contact over a small area of the higher peaks or asperities. Electro-repulsive and atomic binding interactions occur at the individual contacts and, when the two surfaces slide relative to one another, these interactions are disrupted. This results in the release of material in the form of particles (wear debris). The particles may be lost from the system, be transferred to the counter face, or remain between the sliding surfaces. Three primary processes can cause wear: 1) abrasion, by which a harder surface plows grooves in the softer material; 2) adhesion, by which a softer material is smeared onto a harder counter surface, forming a transfer film; 3) fatigue, by which alternating episodes of loading and unloading result in the formation of subsurface cracks that propagate to form particles shed from the surface. During an initial wearing-in period, the relative motion of surfaces causes a large number of asperities to break, resulting in a high wear rate. After this initial period, the actual contact area increases and the two surfaces can be said to have adapted to one another. Over time, the wear rates decrease and eventually become linearly dependent on the contact force and sliding distance represented by the steady-state wear equation:

$$V = KFx$$

where V is volumetric wear (mm^3/year), K is a material constant of the material couple, F is the contact force (N), and x is the distance of relative travel (mm).^[10]

In general, the softer of two bearing materials will wear more rapidly. In the most popular joint replacement couple (a metal-on-polymer pair), the polymer wears almost exclusively, whereas in the case of a metal-on-ceramic pair, the metal wears to a greater extent. The in-vitro wear rates for the socket (in hip joint simulation studies) range from 0 to $3000 \text{ mm}^3/\text{year}$ depending on the type of couple employed and the environment (e.g., lubricant). A great deal of variability is associated with in-vivo wear rates of orthopedic biomaterials, which are generally measured by radiographic follow-up studies. Radiographic wear measurements are expressed as linear wear rates, whereas in-vitro studies generally report volumetric wear. Volumetric wear can be directly related to the number of wear particles released into periprosthetic fluids (typically on the order of 1×10^9 particles per year). The most common wear couple for hip and knee arthroplasty currently in use in the United

States is a cobalt-based alloy head (most commonly a Co–Cr–Mo alloy ASTM F-75) bearing on an ultrahigh molecular-weight polyethylene (UHMWPE) cup or liner. The wear rates of this couple are generally on the order of $0.1 \text{ mm}/\text{year}$, with particulate generation as high as 1×10^6 particles per step or per cycle. Clinically, implant wear rates have been found to increase with physical activity and weight of the patient, size of the femoral head (32 vs. 28 millimeters), roughness of the metallic counterface, and oxidation of the polyethylene.

Corrosion

Electrochemical corrosion occurs to some extent on all metallic surfaces, including THA implants. This is undesirable for two primary reasons: 1) the degradative process may reduce the structural integrity of the implant; and 2) the release of the products of degradation is potentially toxic to the host. Metallic biomaterial degradation may result from electrochemical dissolution phenomena or wear, but most commonly occurs through a synergistic combination of the two. Electrochemical processes include generalized corrosion uniformly affecting an entire surface, and localized corrosion affecting either areas of a device relatively shielded from the environment (crevice corrosion), or seemingly random sites on the surface (pitting corrosion). Additionally, these electrochemical and other mechanical processes interact, potentially causing premature structural failure or accelerated metal release (e.g., stress corrosion cracking, corrosion fatigue, and fretting corrosion), (Fig. 4). Corrosion of orthopedic biomaterials is a multifactorial phenomenon, dependent on five primary factors: 1) geometric variables (e.g., taper crevices in modular component hip prostheses), 2) metallurgical variables (e.g., surface microstructure, oxide structure

Fig. 4 Modular THA junction taper connection showing corrosion of taper connections. Macrograph of deposits of CrPO_4 corrosion particle products on rim of a modular cobalt-chrome femoral head.

and composition), 3) mechanical variables (e.g., stress and relative motion), 4) solution variables (e.g., pH, solution proteins, enzymes); and 5) the mechanical loading environment (e.g., degree of movement, contact forces). Current investigational efforts to minimize the corrosion of orthopedic biomaterials deal directly with the complex interactions of these factors.^[13]

Metal ion release

There has always been concern with the release of chemically active metal ions from implants into surrounding tissues. Although these metal ions may stay bound to local tissues, they may also bind to protein moieties and then be transported via the bloodstream or lymphatics to remote organs. Normal human serum levels of prominent implant metals are approximately: 1–10 ng/ml Al, 0.15 ng/ml Cr, <0.01 ng/ml V, 0.1–0.2 ng/ml Co, and <4.1 ng/ml Ti. Following total joint arthroplasty, levels of circulating metal (Al, Cr, Co, Ni, Ti, and V) have been shown to increase (Table 3).^[14–17] The values in this table show that following successful primary total joint replacement there are measurable elevations in serum and urine Co, Cr, and Ti. Transient elevations of urine and serum Ni have been noted immediately following surgery. However, urine and serum Al and V concentrations have not been found to be greatly elevated in patients with TJA (Table 3). In-vitro investigations indicate that specific metals in ionic form can affect the functionality of a variety of peri-implant cells such as fibroblasts, osteoclasts, macrophages, and lymphocytes within the ranges of metal concentrations reported to exist in periprosthetic tissue. Generally, the most toxic metal ions are Ni, Fe, Cu, Mn, and V, whereas others such as Na, Cr, Mg, Mo, Al, Ta, and Co demonstrate relatively less cellular reactivity in vitro.

Particle distribution

Generally, metal particles found disseminated beyond the periprosthetic tissue are <10 μm in size. Although variables influencing accumulation of wear debris in remote organs are not clearly identified, numerous case reports document the presence of metallic, ceramic, or polymeric wear debris from hip and knee prostheses in regional and pelvic lymph nodes. In fact, metallic wear particles have been detected in the para-aortic lymph nodes in up to 70% of patients with total joint replacement components (Fig. 5).^[18,19]

Hypersensitivity Responses

Dermal metal hypersensitivity is a phenomenon that purportedly affects about 10–15% of the population.

The incidence of metal sensitivity among patients with TJA implants is approximately 25% (roughly twice as high as that of the general population), and the average incidence of metal sensitivity among patients with a failed implant (i.e., one in need of revision surgery) is approximately 50–60%.^[20] Some patients with metallic orthopedic implants experience excessive eczema or other inflammatory reactions directly associated with implanted metallic materials.^[20,21] This reactivity has in some cases been shown to satisfy Koch's postulate (that exposure or implantation induces reaction that disappears upon removal of the metal stimulus and reappears upon reexposure).^[20–26] In addition to direct immunogenic responses, metal degradation products may mediate indirect immunologic effects that manifest as hypersensitivity-like responses in more predisposed (i.e., susceptible) individuals. It is likely that cases involving implant-related metal sensitivity have been underreported due to the difficulty of diagnosis. The biologic mechanisms by which in-vivo metal sensitivity occurs, remain incompletely characterized. Current efforts using Lymphocyte Transformation Testing are being made to establish whether metal hypersensitivity may elicit an overaggressive immune response that contributes to implant failure.^[20] These and other improvements in immunologic testing methods will likely enhance future assessment of patients susceptible to hypersensitivity responses.

Carcinogenesis

The carcinogenic potential of the metals used in TJA remains an area of concern and has been documented in animal studies. Whether metal release from orthopedic implants is carcinogenic remains conjectural because causality has not been established in human subjects and the actual numbers of tumors associated with orthopedic implants are likely underreported. However, the incidence of cancer at the site of implantation is rare.

FUTURE DEVELOPMENTS AND CONCLUSIONS

Current strategies to address the problem of THA failure are primarily aimed at decreasing the periprosthetic particulate burden and its effects. Recently there has been a great deal of innovation regarding stronger, more wear-resistant polyethylene. These more highly cross-linked UHMWPE polymers show demonstrable decrease in polyethylene wear with potential for less particulate-induced bioreactivity/osteolysis and therefore greater implant performance. In the same vein, femoral heads with diameters of 32 mm have been associated with increased volumetric polyethylene wear; to combat this, smaller 28 mm heads are currently

extolled as more biocompatible. Manufacturing flaws such as fusion defects and foreign body inclusions have also been suggested as contributing to adverse polyethylene wear properties. The elimination of polyethylene is another approach being investigated clinically in various centers. With the realization that early problems may have been related to the design and not the articulation, there has been renewed interest in the application of metal-metal and ceramic-ceramic bearings. Future designs that attempt to reduce wear include improved tolerances between polyethylene inserts and their metal backing, improved surface finish on metallic concave surfaces, secure locking mechanisms, and the avoidance of holes on the convex portion of the acetabular prosthesis.

Electrochemical corrosion of orthopedic implants remains a significant clinical concern. Although the freely corroding implants used in the past have been replaced with modern corrosion-resistant super alloys, deleterious corrosion processes have been observed in certain clinical settings. Attention to metallurgical processing variables, tolerances of modular connections, surface-processing modalities, and appropriate material selection can diminish corrosion rates and minimize the potential for adverse clinical outcomes. A need to further investigate the mechanical-electrochemical interactions of metal oxide surfaces in implants persists. Characterization of the stresses and motion needed to fracture passivating oxide films and the effects of repeated oxide abrasion on the electrochemical behavior of the interface (and ultimately the implant) remain avenues of active investigation.

Although beyond the scope of this article and generally a realm inaccessible to nonclinically-oriented biomedical engineers, it is worthwhile to note THA implant performance is intimately related to the skill of the

surgical technician. Improvements to surgical methods are significant in that greater ease, standardization, and timeliness of properly executed rigid fixation will more adequately facilitate bone ingrowth and performance by minimizing motion between the bone and implant, resulting in reduced debris and longer implant life. For example, methodological improvements in PMMA bone cement installation to facilitate a uniform-thickness cement mantle will diminish the likelihood of cement mantle defects (debris generation), a cause of osteolysis.

THA implants are one of the great success stories of modern medicine and biomedical engineering, with well over 300,000 performed every year, allowing mobility, independence, and a quality of life that would otherwise be drastically compromised. However, in certain situations mechanical and electrochemical degradative processes can compromise the clinical outcome and potentially lead to adverse local or systemic effects. Continued awareness and investigation of these issues will enhance understanding of implant degradation phenomena and lead to improvements in biomaterial and implant performance.

Implanted Medical Devices, Power Sources For

Erik R. Scott
Craig L. Schmidt
Paul M. Skarstad

Energy and Component Center, Medtronic, Inc., Brooklyn Center, Minnesota, U.S.A.

INTRODUCTION

Electrically powered implanted devices treat and diagnose a variety of conditions, providing greatly enhanced quality of life to those who use them. Most of these implants derive their power from batteries that are neither rechargeable nor replaceable. Therefore, the battery's finite energy supply often limits the service life of an implant, and battery depletion necessitates a surgical procedure and replacement of the device. It is desirable, from the standpoint of patient risk and expense to society, to reduce the frequency of such replacement events. Thus, the power source is a critical component of an implanted device.

For any electrical device (implanted or not), power and energy requirements are the main criteria for selection of a power source. However, the requirements of implanted power sources do not end with power and energy. For example, implanted devices must be of small enough size and appropriate shape that they can be continuously worn with minimal intrusion on activity and comfort. Because the battery is often the largest component of a device, having a shape that packages efficiently within the device is crucial. However, the most important requirement of implanted power sources is to provide safe and reliable operation. This is especially true for devices that are critical to human health or life. This article will briefly describe the function, design, and applications of power sources for a majority of devices commercially available today: batteries based on lithium chemistry.

HISTORY OF POWER SOURCES FOR IMPLANTABLE MEDICAL DEVICES

The first successful use of an electrically powered implantable device came in the early 1960s with the introduction of the implantable cardiac pacemaker.^[1,2] Throughout the 1960s and early 1970s, the zinc/mercuric oxide battery was the power source used in most such devices.^[3,4] Although this battery system enabled the birth of implantable cardiac pacing, it had a number of drawbacks. These included: generation of hydrogen gas, which prevented hermetic sealing of the

pacemaker; little warning of depletion at end-of-service; and significant self-discharge at body temperature. Although significant efforts were made to overcome these limitations, two different approaches were made in the late 1960s to develop other power sources with higher longevity than zinc/mercuric oxide batteries. These include nuclear power sources that used plutonium to heat thermoelectric generators^[5] and cadmium/nickel oxide (NiCAD) secondary batteries that could be recharged transcutaneously by electromagnetic induction.^[6] Both of these approaches were successful in creating reliable systems with significantly improved longevity. However, both also had serious drawbacks. These drawbacks included regulatory requirements for tracking nuclear power sources and, in particular, for ensuring proper disposal of explanted devices. For the NiCAD system, the need to recharge placed a significant burden on the patient in managing the device.

The advent in the early 1970s of highly reliable, stable, and small primary batteries based on lithium as the anode material revolutionized cardiac pacing and obviated the previously mentioned approaches. The first lithium-powered pacemaker was implanted in 1972, using a lithium/iodine battery invented by Schneider and Moser^[7,8] and improved by Wilson Greatbatch and coworkers.^[9,10] Although the inherent power capability of this system was low, it was well matched to the power requirements of cardiac pacing. Moreover, the system provided a deliverable energy density as high as 1 Wh/cm³, more than a twofold increase in deliverable energy density over alternatives available at the time. The absence of gas evolution meant both battery and pacemaker could be hermetically sealed. In addition, the system provided high reliability, and had a versatile shape factor.

Several other lithium-based battery systems were developed for use in cardiac pacemakers within a few years of the lithium/iodine system. These included lithium/thionyl chloride, lithium/manganese dioxide, lithium/silver chromate, lithium/cupric sulfide, and others.^[11-13] All had energy densities close to that of lithium/iodine. However, these battery systems all gave way to the lithium/iodine battery system, which has remained overwhelmingly the most frequently used

power source for this application since the early 1980s. It is likely that in the 30-year history of the lithium/iodine battery, more than five million cardiac pacemakers have been implanted with this power source.

In the 1980s new applications of implantable pulse generators were developed that required higher power than lithium/iodine batteries could produce efficiently. These included implantable neurological stimulators and implantable drug delivery systems. Most devices of these types have used batteries based on lithium/thionyl chloride. Recently, these devices have turned increasingly to lithium batteries based on organic electrolytes with higher deliverable energy densities at application rates. These battery systems include lithium/silver vanadium oxide, lithium/carbon monofluoride, and lithium with blends of carbon monofluoride and silver vanadium oxide.

The 1980s and 1990s also saw development of implantable cardioverter-defibrillators (ICDs) that treat ventricular fibrillation, a major cause of death.^[14] These devices monitor and analyze the electrical activity of the heart and can function as cardiac pacemakers, drawing tens of microwatts of power. If an ICD detects a potentially lethal arrhythmia, the battery must deliver power in the range 5–10 W to charge high-voltage output capacitors quickly so that a life-saving shock can be delivered to the heart within a few seconds to terminate the arrhythmia. The requirements of long-term stability at low power coupled with the ability instantaneously to deliver power as much as five orders of magnitude higher place severe demands on a battery system. The earliest implantable defibrillators used lithium/vanadium oxide batteries as power sources.^[15] This system was supplanted in the late 1980s by lithium/silver vanadium oxide (Li/SVO), developed for the application by Wilson Greatbatch, Ltd.^[16,17]

The revolution in readily accessible computational power in 1980s and 1990s fostered development of accurate, physically based predictive models of battery performance to aid in the development of optimal custom batteries for implantable devices. Such models have been described in some detail for the lithium/iodine pacemaker batteries^[18] and for lithium/silver vanadium oxide ICD batteries.^[19] Development of these models required quantitative understanding of underlying chemical processes in these battery systems.

As pacemakers were developed in the 1990s that included microprocessors, memory, sensors of various types, and long-range telemetry, it became increasingly difficult to meet the demand for pulse power using lithium/iodine batteries. Moreover, new therapies were developed with higher power requirements, including treatment of atrial fibrillation and congestive heart failure. New medium-rate power sources were needed that had energy density comparable to that of lithium/iodine, with up to two orders of magnitude greater

pulse power capability. Lithium batteries with silver vanadium oxide cathodes have been used, but they fall short of matching lithium/iodine for energy density. Carbon monofluoride cathodes have also been used. These have comparable energy density and twice the rate capability of lithium/iodine. However, the medium-rate system that has come to be used most frequently uses a blend of carbon monofluoride and silver vanadium oxide as the active cathode material.^[20] Batteries based on this cathode system have improved energy density, rate capability, and end-of-service characteristics, compared with carbon monofluoride alone. They have found application in devices that treat heart failure and atrial fibrillation and are likely to find application in other devices.

BASICS OF BATTERIES

Electrochemical Power Generation

A battery consists of one or more electrochemical cells that convert chemical energy into electrical energy. For simplicity in this article, the term battery implies a single cell unless otherwise noted. The three most fundamental electrical characteristics of a battery are the amount of power that it delivers, its operating voltage, and the energy it delivers over its lifetime. In the battery industry, power and energy are frequently expressed in watts (W) and watt-hours (Wh), respectively. Power, voltage, and energy are determined by the relationship between battery chemistry, design, and the battery's interaction with the device circuit. To understand this relationship, it is necessary to briefly review the basic electrochemistry of batteries. For more detailed treatments of general battery science, please see introductory chapters in references.^[21–24]

Electrochemical cells contain at least two electrodes in contact with an ion-conducting electrolyte. Electron transfer reactions (also known as redox reactions) at the two electrodes of a cell result in an electromotive force that is the basis for a battery's generation of electrical energy. During discharge, oxidation occurs at the negative electrode (anode) while reduction occurs at the positive electrode (cathode). Lithium is an attractive anode material due to its highly electro-positive nature, large specific capacity, and stability in a large number of organic electrolytes. Lithium batteries are made using a variety of cathode materials, depending on battery application. An illustrative example is the lithium/iodine (Li/I₂) battery, which is presently used to power bradycardia pacemakers.^[25] The anode and cathode reactions are:

and

The total cell reaction is the sum of these two half-cell reactions:

It should be clear from Eqs. 1a-c that the rates of the reduction and oxidation reactions are perfectly balanced; the number of electrons liberated at the anode is identical to the number consumed at the cathode. This flow of electrons between the electrodes is the current that powers a device.

In addition to electronic flow, discharge also involves transport of ionic species from one electrode to the other, to preserve electroneutrality. The movement of ions takes place through the electrolyte. For a lithium battery, the electrolyte may consist of an organic solvent system into which a suitable lithium salt is dissolved, or it may be a solid-state Li^+ conductor. Aqueous solvents are incompatible with Li batteries due to the high reactivity of Li with water. Two desirable properties of an electrolyte are stability over the range of potentials found in the battery, and sufficiently high ionic conductivity to support device application currents without causing significant energy losses. Another function of the electrolyte layer is to prevent electrical contact between anode and cathode, which would otherwise cause an electrical short that could quickly deplete the battery. To prevent such shorts, liquid electrolyte battery systems typically incorporate the liquid into a porous polymer film, known as a separator.

Voltage and Current: Chemical Thermodynamics and Kinetics

A difference in potential energy (i.e., voltage) between electrons released at the anode and those consumed at the cathode determines the maximum amount of work that the electrons can do in a circuit. The electrical potential is determined by the change in molar free energy (ΔG_{rxn}) of the whole cell reaction according to:

$$V_{oc} = \frac{-\Delta G_{rxn}}{nF} \quad (2)$$

where V_{oc} is the open circuit (i.e., zero current) potential, n is the number of equivalents of charge passed per mole of species reacted, and F is Faraday's constant (96485 C/mol).

When a battery experiences a current load, the operating voltage is always lower than the open-circuit value. A simple expression of this effect is given in Eq. 3. Here, the battery voltage (V_b) under load is given as the open-circuit value (V_{oc}), minus the ohmic drops resulting from current flow (I) through the sum of the series internal resistive elements (R_i):

$$V_b = V_{oc} - I \sum_i R_i \quad (3)$$

It is often practical to use ideal resistors to describe the internal resistive elements of a battery. However, it should be understood that while batteries do include some components (e.g., current collectors and electrolyte) that closely approximate ideal resistors, other elements of batteries do not always behave in a linear and stationary fashion. These so-called nonohmic resistances include charge transfer resistance and concentration polarization resistance. The charge transfer resistance is related to the reaction kinetics at an electrode that is described by the Butler-Volmer equation:^[26]

$$i = i_o \left[\exp \frac{-\alpha F \eta}{RT} - \exp \frac{(1-\alpha) F \eta}{RT} \right] \quad (4)$$

where i is the current density, i_o is the exchange current density, and α is the charge transfer coefficient. The overpotential, η , is a measure of the deviation of the electrode potential from equilibrium. In the low overpotential range (less than a couple tenths of a volt, corresponding to low to moderate power output), the current-voltage relationship is effectively linear, resulting in a constant value of the charge transfer resistance. However, at higher power levels, the I-V relationship becomes exponential, resulting in a charge transfer resistance that decreases with applied current. Another nonohmic resistance results from concentration polarization, which is the buildup and depletion of ions within the electrolyte due to mass transfer limitations within the electrolyte or the electrodes themselves. Unlike the charge transfer resistance, the concentration polarization resistance increases with current, as well as with time of operation. Despite being nonohmic in a general sense, both charge transfer resistance and concentration polarization resistance may often be practically treated as ohmic over the normal operating range of a given device.

Another attribute of the electrical response of batteries is capacitance, which results from charge accumulation (both electronic and ionic) at interfaces. The unique combination of resistances and capacitances of a battery comprises its impedance, which, along with the open-circuit voltage, determines a battery's response to time-varying power demands.

Fig. 1 Equivalent circuit for a Li/I₂ battery. R_{ohmic} is the ohmic resistance due to the electrolyte and cathode, C_g is the geometric capacitance, R_{ct} is charge transfer resistance, and C_{dl} is the double-layer capacitance. The concentration polarization is represented as an overpotential η_{conc} rather than a resistance. (Adapted from Ref. [27].)

Characterization of impedance in the form of a battery equivalent model allows accurate prediction of battery performance in a device. An example of an equivalent circuit used to model a Li/I₂ battery is shown in Fig. 1.^[27] An important aspect of battery impedance is that it is usually not constant over a battery's lifetime. The degree by which impedance changes depends primarily on cell chemistry. For a lithium/silver vanadium oxide (Li/SVO) cell, the resistance increases by about a factor of two,^[19] while for a Li/I₂ cell, the increase is more than two orders of magnitude.^[28]

Power, Capacity, and Longevity

Electrical power is the product of voltage and current. Current demands on medical batteries can range by about six orders of magnitude, from about 10 μA to 10 A, depending on device. By contrast, the operating voltage covers a narrow range, between about 2 and 4 V. Because voltage is nearly constant compared with current, power is roughly proportional to current, and the two terms are loosely interchangeable for describing rate of battery discharge.

The power capability of a battery is determined by the battery voltage and internal resistance. If the internal resistance is approximated as an ohmic quantity, the peak power that can be delivered by the battery is

$$P_{\text{max}} = \frac{V_{\text{oc}}^2}{4R_{\text{int}}} \quad (5)$$

where V_{oc} is the open-circuit voltage of the battery and R_{int} is the internal resistance. To achieve this peak power in practice requires a close matching of circuit impedance with that of the battery. However, most devices operate below this peak level.

A battery's delivered capacity is the integral of current over its total time of operation, and is

commonly expressed in ampere-hours (Ah). The maximum theoretical capacity is equal to the lesser of the stoichiometric capacities of the cathode or anode. Stoichiometric capacity for an electrode is computed from the formula:

$$Q_s = \frac{nFm}{3.6M} \quad (6)$$

where n is the number of equivalents of charge passed for mole of active species reacted, F is Faraday's constant (96485 C/eq), m is the mass of active material present (g), and M is the active formula weight (g/mol). However, the practical deliverable capacity is always less than Q_s . Factors that reduce the deliverable capacity include losses due to parasitic reactions (self-discharge), imperfect utilization of active material, and load-dependent depression of the battery voltage.

Battery capacity determines the longevity of a device, which is the length of time over which the operating voltage of its battery remains above that needed to operate the device. Both longevity and capacity are directly proportional to the energy delivered by a battery, which can be computed from the area under a discharge curve (voltage versus capacity). Discharge curves are given for several battery chemistries in Fig. 2. A general feature of most of the chemistries shown is that the voltage reduces as the current drain (i.e., power) increases, due to resistive and polarization losses. For most chemistries, this results in a concomitant decrease in deliverable capacity. Two exceptions to this are lithium/thionyl chloride (Fig. 2B) and, to a lesser extent, the lithium/iodine (Fig. 2A) systems. Both of these experience significant capacity loss due to self-discharge at lower currents.

Primary Versus Secondary Batteries

Primary batteries can be discharged only once. Secondary batteries may be recharged. The ability of a battery to be recharged depends on whether the cell reactions are practically reversible. Many redox systems, while chemically reversible, are not reversible in a practical sense due to phase changes that occur during charge and discharge. Therefore, the most highly energetic batteries (on a per-cycle basis) are not rechargeable. However, because secondary batteries can be recharged many times, they deliver much more total energy over their lifetime than do primary cells. As secondary cells age, they experience a gradual decrease in the per-cycle energy. Because of this wear-out process, known as capacity fade, even a device with a rechargeable battery will have a limited service life.

The majority of implanted batteries today are primary cells. This is because in most applications,

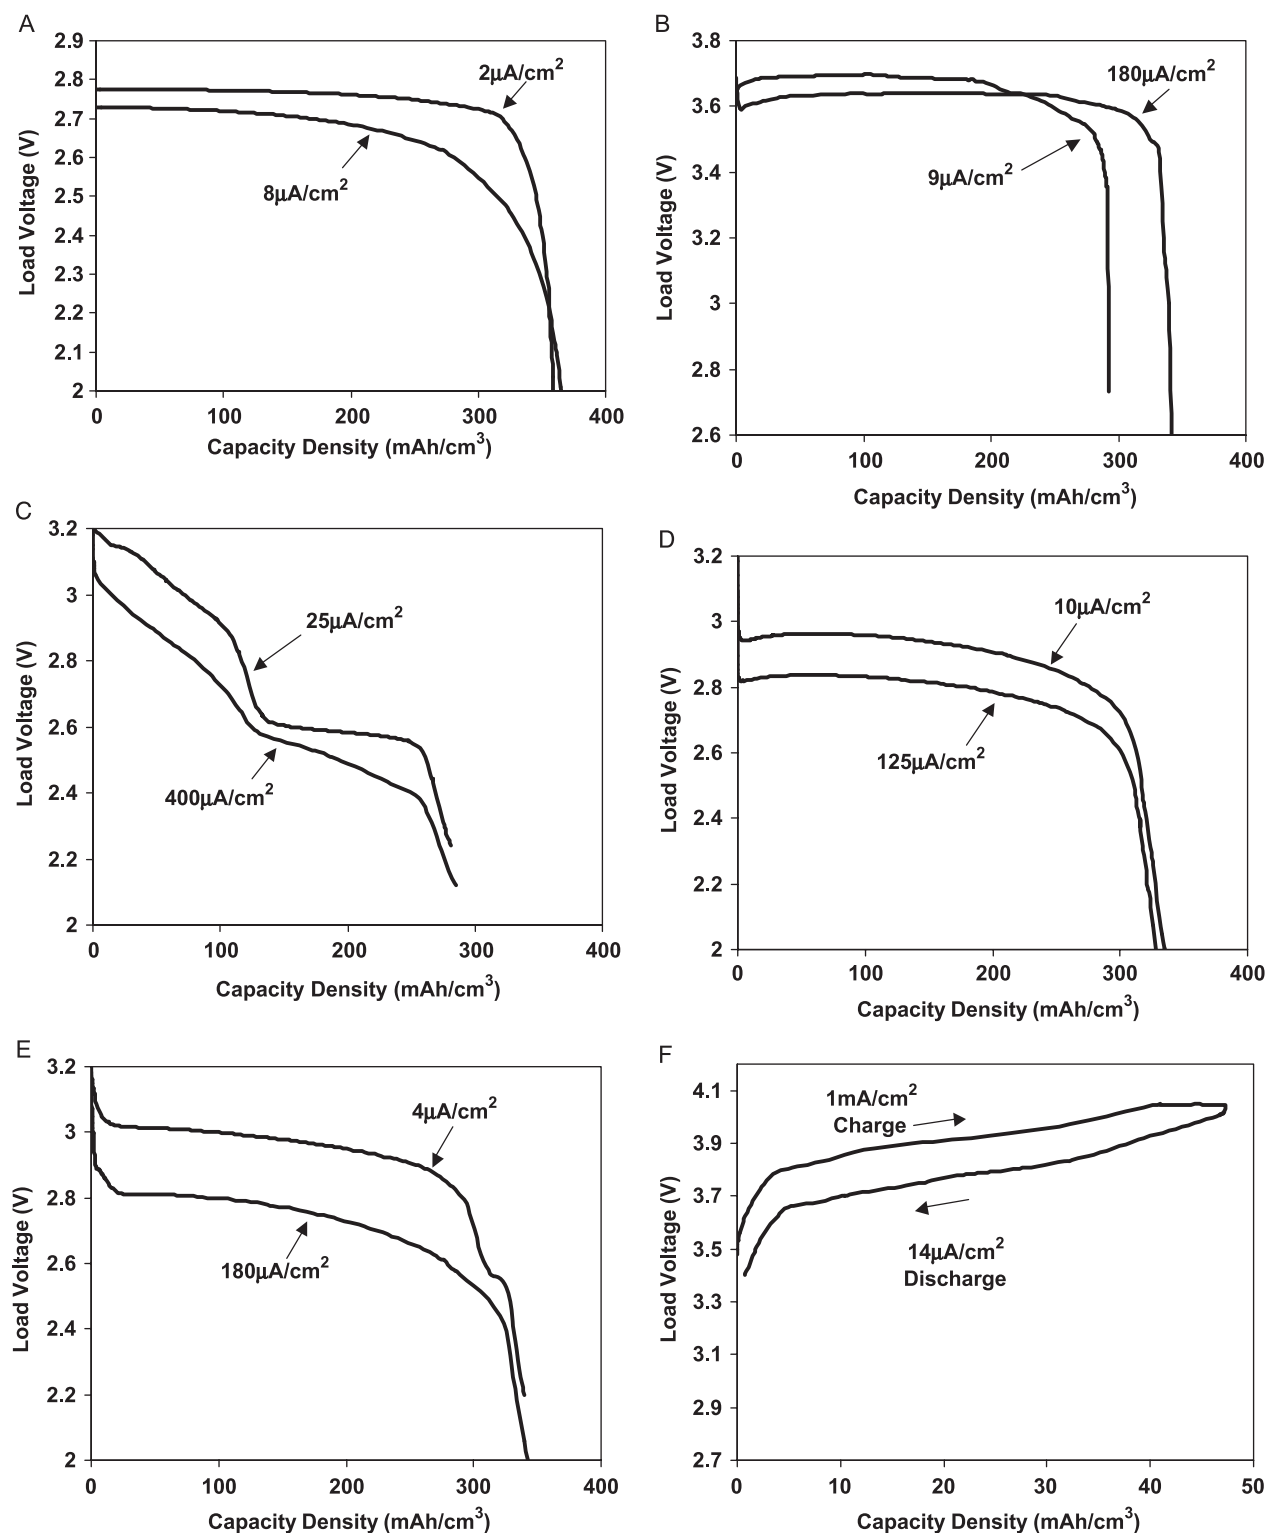

Fig. 2 Discharge curves for five primary battery chemistries and one rechargeable chemistry. Capacity is normalized to battery volume (mAh/cm³) and to electrode area (μA/cm²). A) Li/I₂ at 2 and 8 μA/cm²; B) Li/SOCl₂ at 9 and 180 μA/cm²; C) Li/SVO at 26 and 400 μA/cm²; D) Li/CF_x at 10 and 125 μA/cm²; E) Li/CF_x/SVO hybrid cathode at 4 and 180 μA/cm²; F) Li ion rechargeable, charged at 1 mA/cm² and discharged at 14 μA/cm².

primary batteries have sufficiently high energy density that they provide acceptable longevity in reasonably sized packages, without the overhead that is associated with a rechargeable device. This overhead includes the volume associated with the recharge circuit as well as the inconvenience of needing to recharge on a regular basis. One challenge with implanting a rechargeable power source is ensuring that the recharge schedule provides continuity of therapy for the patient. This concept is most important if the device sustains one's life. Two examples of secondary batteries in critical applications are the left ventricular assist device (LVAD) and the totally implantable artificial heart. Both of these devices receive operating power (and battery recharge power) nearly continuously from an external appliance, and the batteries serve a backup function.^[29,30]

Important Aspects of Implanted Batteries

Implantable batteries must meet a set of requirements that, taken in their entirety, distinguish them from all other batteries. Most important among these is safe, reliable (i.e., predictable), and stable performance at 37°C, over a period that can last up to 10 years. For devices whose function is critical to life or health, the requirement of predictability also mandates some form of a detectable warning that the battery's end-of-service is approaching. This warning enables continuation of therapy by giving the clinician a window of opportunity to replace the device before battery depletion occurs. Other requirements include containment of reactive and potentially corrosive materials, volumetrically efficient packaging within a device, and absence of excessive swelling during use. The above requirements translate into a set of physical characteristics that generally include the following:

- The materials, design, and device requirements have been characterized to the point of creating scalable, predictive models of performance longevity under application conditions.
- As battery depletion approaches, there is a change in some measurable intrinsic property (e.g., a slope in voltage or impedance) that can be interpreted as an indication of a certain minimum amount of capacity remaining.
- The materials are stable and are sealed within a hermetic package.
- The combination of chemical system and mechanical design results in adequate power density, energy density, and shape factor, when configured into the device's allotted size and shape.
- There is an acceptably low rate of self discharge.

MECHANICAL DESIGN

Power capability and energy density are two critically important characteristics of an implantable battery. Both are determined by the choice of battery chemistry and mechanical design. Unfortunately, optimization of a mechanical design for increased power typically results in decreased energy density, and vice versa.

As was mentioned previously, a battery's power capability is proportional to the square of its open-circuit voltage and inversely proportional to its internal resistance (Eq. 5). Voltage is determined by the battery chemistry, but the internal resistance is largely influenced by the mechanical design, varying inversely proportional to the electrode surface area. High-power batteries, incorporating electrodes with large surface area, contain a greater proportion of inert material (e.g., current collector and separator) than do high-energy batteries. This leads to an inverse relationship between power capability and energy density for a given battery chemistry. Thus, the mechanical design of a battery must be optimized to meet the specific power requirements for a given application without unduly reducing energy density.

Implantable batteries can be generally categorized into one of two general design types. Batteries that have low- to moderate-power requirements are typically designed similar to Fig. 3, while batteries requiring high power are similar to Fig. 4. There are certain characteristics, however, that are common to both designs. The batteries are hermetically sealed to

Fig. 3 Schematic of low-to-moderate power (single plate) battery design.

Fig. 4 Schematic of coiled prismatic design used for high-power primary and lithium ion designs.

prevent leakage of electrolyte and possible damage to other components of the implanted device. The case and cover are made of corrosion resistant materials, typically stainless steel or titanium. The electrical feedthrough consists of a metal ferrule welded to the battery cover, a corrosion resistant glass insulator, and a metal pin. The cover (with feedthrough) is welded to the battery case, and the electrolyte (or in some cases, a liquid cathode material) is filled through a small port located in the cover. A metal button is welded over the fill-port to complete the hermetic seal.

The low- to moderate-power batteries are characterized by relatively thick electrodes with surface areas ranging from about 3 to 15 cm² (see Fig. 3). The example shown has a central anode with a cathode on both sides (a case-positive design). However, the battery can also be constructed with a central cathode (case-negative) or with a single anode and cathode (either case polarity). For simplicity, these designs are all referred to as single plate. The cathode is often a pressed powder pellet. The active cathode material is often mixed with a conductivity enhancer (usually carbon) and a binder material to facilitate the formation of an electrically-conductive pellet. Alternatively, the cathode can be a material that is added as a liquid and allowed to solidify in situ (e.g., the cathode of a Li/I₂ battery, Fig. 5). In all cases, the anode is lithium metal. A number of different methods are used to establish electrical contact with the cathode (i.e., current collection). These include direct contact of the cathode with the case, pressing the cathode into a metal cup or ring that is then welded to the case or

Fig. 5 Schematic of Li/I₂ battery.

feedthrough pin, or by embedding in the cathode a metal grid that is then welded to the case or feedthrough pin.^[31,32] Since lithium is highly conductive, current collection is easily accomplished by embedding the feedthrough pin in the lithium (central anode design), or by pressing onto the lithium a metal grid with a tab that can be welded to either the case or the feedthrough pin. With the exception of the lithium/iodine battery, all of these designs use a thin, porous separator material that prevents direct electrical contact of the anode and cathode. A major advantage of the single plate design is that the profile of the plate can be any shape. An especially popular cell shape is the so-called D-shape, which uses a deep-drawn can with a rounded bottom (see Fig. 3). This shape packages efficiently in the rounded profile of an implanted device.

The coiled prismatic design of Fig. 4 is used for high-power primary batteries, which are characterized by very thin electrodes whose surface areas range from about 40 to 90 cm².^[33] The cathode is formed from a powdered mixture of active material plus conductivity enhancer and binder. This mixture is pressed onto a metal grid current collector. The function of the cathode current collector is twofold: it serves as a substrate for mechanical attachment of the active material and it uniformly distributes the electric field across the large cathode area. The current collector has one or more tabs that are welded to either the case or the feedthrough pin. The anode is lithium and incorporates a metal grid current collector similar to

the cathode. With the high conductivity of lithium, however, the primary function of the current collector is to preserve electrical continuity as the lithium is consumed during discharge. A microporous separator material is placed between the electrodes, and this assembly is then wound into a coil and placed into a case.

Rechargeable lithium ion cells have a coiled construction that is similar to the high-power design described earlier, although the package may be cylindrical rather than prismatic. With lithium ion cells, both electrodes are prepared from a slurry containing the active materials, a conductivity enhancer, and a binder. The slurry is coated onto a thin metal foil current collector and then dried and compressed. Tabs are welded to the foil current collector to permit a subsequent weld to either the case or the feedthrough pin. Again, a microporous separator material is placed between the electrodes before they are wound into a coil. Surface areas of these cells can be in excess of 100 cm².

A limitation of the coiled battery design in Fig. 4 is that the cell designs are typically limited to rectangular prisms that may not package efficiently in a device. There are variations of the coiled design that can get around this limitation, however. These include the use of multiple cathode and anode plates, or individual cathode plates with a continuous anode.^[34]

BATTERY CHEMISTRIES

Five primary battery chemistries and one rechargeable chemistry comprise the majority of power sources for implanted devices. A common feature of the primary batteries is a lithium anode, for reasons mentioned previously. Lithium batteries are made using a variety of cathode materials, depending on battery application. The following discussion describes the chemistry of lithium primary batteries as well as the lithium ion rechargeable battery.

Lithium/Iodine

The Li/I₂ battery is among the highest energy density batteries (about 1.0 Wh/cm³). The net cell reaction is given in Eq. 1c and a schematic view is shown in Fig. 5. The cathode material is prepared by thermally reacting iodine with a small amount of poly-2-vinylpyridine (P2VP). This reaction produces a two-phase material composed of crystalline iodine and a conductive, tarlike liquid. Molten cathode is filled through the fill-port and allowed to solidify in situ. The battery case serves as the cathode current collector. A unique aspect of the lithium/iodine battery is that no separator

material is placed between the anode and the cathode. Upon filling the cell with cathode, the lithium and iodine react to form a layer of lithium iodide at the interface. LiI is an ionic conductor that serves as both an electrolyte and a barrier to continued reaction between anode and cathode. Therefore, no other separator is needed. Should the LiI barrier be damaged for any reason, it would simply reform. The simple battery design and the self-healing nature of the LiI electrolyte impart extreme robustness and reliability to this battery.

As the Li/I₂ battery is discharged, the LiI layer increases in thickness and becomes a major contributor to the internal resistance of the battery. Coating the lithium anode with a thin film of P2VP dramatically reduces the resistance of the lithium iodide layer. Nonetheless, the resistance of the electrolyte is large and increases with discharge. Depletion of the iodine in the cathode also causes large resistance increases. The battery resistance can reach several thousand ohms, limiting the battery to extremely low-power applications. Pacemakers, which require only a few tens of microwatts for typical operation, are the main application for lithium/iodine batteries.

The Li/I₂ battery has an open-circuit voltage of 2.8 V throughout discharge. Virtually all loss of voltage during discharge results from the continuously increasing internal resistance. Discharge curves for the battery are shown in Fig. 2A. The relatively large loss of voltage and delivered capacity, for even very small increases in current, is characteristic of a battery with a high internal resistance. The increased slope in discharge voltage near the end of its service life is a useful feature, allowing for battery voltage to be a reliable indicator of impending depletion.

Lithium/Thionyl Chloride

The lithium/thionyl chloride (Li/SOCl₂) battery has a porous carbon cathode and a SOCl₂:LiAlCl₄ active material/electrolyte. It is constructed similar to the battery in Fig. 3. An unusual feature is that the thionyl chloride is both the electrolyte solvent and the active cathode material. The cell reaction is

The sulfur and sulfur dioxide that are formed are initially soluble in the thionyl chloride. As thionyl chloride is consumed, there is a slight buildup of pressure from the sulfur dioxide and some precipitation of sulfur in the porous carbon cathode. The lithium chloride is not soluble and precipitates in the cathode throughout discharge.

The lithium anode is protected from excessive direct reaction with the thionyl chloride by a thin lithium chloride layer that forms at the interface, analogous to the lithium/iodine battery. This results in excellent shelf-life. However, when the battery is discharged after a quiescent period, the resistive lithium chloride layer produces a brief voltage drop (known as voltage delay) until the layer is removed by discharge of the lithium. During continuous discharge, the prolonged reaction of thionyl chloride with the freshly exposed lithium can lead to significant self-discharge. Fortunately, the total capacity lost to self-discharge plateaus as the discharge rate decreases.

Implantable lithium/thionyl chloride batteries have power capabilities in the tens of mW range. The open-circuit voltage is 3.65 V throughout discharge and the typical operating voltage is in the 3.5 to 3.6 V range. The energy density can reach 1.0 Wh/cm³, but self-discharge reduces the delivered energy density by about 15% at typical application discharge rates. Figure 2B shows typical discharge curves for this cell, illustrating that the delivered capacity is decreased at lower current. Another trait of the thionyl chloride system, a rapid loss of voltage at the end of discharge, gives little warning of battery depletion. This is one reason that this chemistry has generally been limited to other than life support applications.

Lithium/Silver Vanadium Oxide

The cathode of this battery is a porous material composed of silver vanadium oxide (SVO), carbon, and a binder. The electrolyte is typically 1M LiAsF₆ in a mixture of equal parts (by volume) of propylene carbonate and dimethoxyethane (i.e., PC/DME). Details of the cathode reduction products are not definitively established, but the reaction stoichiometry of the cell is

The battery is constructed for either medium-power applications (e.g., neurological stimulators) using the design in Fig. 3, or for high-power defibrillator applications using a design similar to Fig. 4.^[35] The power capability ranges from tens of mW for the medium-power design to about 10 watts for the high-power design. Energy densities are about 0.8 Wh/cm³ for the medium-power design and about 0.6 Wh/cm³ for the high-power design. The open-circuit voltage of the battery has two plateaus. The first occurs at 3.25 V and the second at 2.5 V, as shown in Fig. 2C. The battery performance is extremely stable with the exception of a small, time-dependent resistance increase that occurs in the second half of discharge.^[19]

Lithium/Carbon Monofluoride

The cathode for this battery is a porous material comprised of carbon monofluoride (CF_x where x ≈ 1), carbon, and a binder. The most common electrolyte is LiBF₄ in δ-butyrolactone (GBL) or PC/DME. Carbon monofluoride is among the highest energy density cathode materials (on a gravimetric basis). The cathode material has only moderate rate capability, so the implantable designs are limited to those similar to Fig. 3. The simplified net cell reaction is

The LiF precipitates in the cathode as the cell is discharged.

The power capability of implantable Li/CF_x batteries is on the order of tens of mW. Battery performance is very stable over the life of implanted device and energy densities in excess of 0.9 Wh/cm³ can be achieved. The theoretical open-circuit voltage of the cell is about 4.5 V, although this value is never attained in practice. Typical load voltages are in the range of 2.9 to 3.0 V throughout most of discharge. Discharge curves are shown in Fig. 2D.

Lithium/CF_x/SVO Hybrid Cathode

These cells are similar to the Li/CF_x batteries described earlier, except that the active cathode material is a mixture of CF_x and SVO. The advantage of this hybrid over CF_x is improved power capability, improved energy density (over 1.0 Wh/cm³), and a stepped voltage near end-of-discharge that is useful in signaling a necessary replacement. The high energy density and good power capability make this chemistry suitable for many applications, including possibly replacing the Li/I₂ cell for pacemakers in the future. Discharge curves are shown in Fig. 2E.

Lithium-Ion Rechargeable

Lithium-ion cells use lithium intercalation compounds as the active materials. As the battery is charged and discharged, lithium ions are exchanged between the positive and negative electrodes. A coiled prismatic cell design similar to Fig. 4 is typical, but coiled cylindrical cells are also used. The active negative material is some form of carbon, frequently graphite. A variety of positive materials are used, but the most common is lithium cobalt oxide (LiCoO₂). The cell reaction for a LiCoO₂ battery is

The open-circuit voltage at full charge is about 4.1 to 4.2 V and decreases throughout discharge to about 3 V. The average cell voltage over the discharge cycle is about 3.7 V. Recharge times can be less than two hours, but actual times may be limited by other factors, such as the maximum rate that the recharge energy can be delivered. A low-capacity fade rate makes the cycle life for this chemistry very high. Typically, thousands of charge/discharge cycles can be completed with most of the original capacity remaining.^[29,30] In addition, self-discharge of a lithium ion cell is low compared to other rechargeable batteries. A typical charge/discharge curve is shown in Fig. 2F.

COMMERCIAL APPLICATIONS

Given a variety of medical grade battery systems available, the choice of power source for a given device is driven by the match between the device's set of power, longevity (energy) and size requirements, and the corresponding capabilities of the battery. These capabilities result from the combination of a battery chemistry with its mechanical design. Because a battery's energy and size are inversely related to each other, the design process includes balancing the competing needs for a small, comfortable device with adequate power and longevity. Table 1 lists approximate ranges of power and longevity for several representative types of implanted devices currently available.

The devices can be classified into three categories, according to power needs:

- Low-power (10 to 100 μ W) devices that provide sensing or low-level electrical stimulation, such as bradycardia pacing.
- Medium-power (100 μ W to 10 mW) devices that pump drugs or stimulate the spinal cord or brain.
- High-power (≥ 10 W) devices that pump blood defibrillate the heart.

Within the classification scheme above, the ICD is unique because it is both a low- and high-power device. Most of its life is spent in a low-power mode (sensing and low-level pacing). But when needed, it may deliver many watts of power to a high-voltage capacitor for several seconds in preparation for applying a defibrillation shock to a heart. Three devices in Table 1 receive their power from external sources: the LVAD, artificial heart, and cochlear implant. For all three, the power is transmitted from outside the body, sometimes using wired connections (certain LVADs), but usually using transcutaneous inductive coupling. With inductive coupling, a transmitting coil located outside the body generates an alternating magnetic field that induces a

current in a receiving coil on the implant. The receiving coil converts the magnetic field to an electric current that is conditioned for use to power a device (or recharge a battery). The first two of these devices (i.e., LVAD and artificial heart) are critical to sustaining life and therefore, employ rechargeable batteries as backup when the external power is interrupted. For cochlear implants, the reason for an external power source is different. This device employs a continuous RF telemetry link between the implant and its external signal processor, which is also used to power the device with no added inconvenience. Therefore, because of the small size and high power density requirements of cochlear implants, the battery has been excluded from the commercial designs thus far. For externally powered devices, longevity is not driven by battery capacity, and is therefore omitted from Table 1.

Data from Table 1 have been transformed into a map of power and energy (Fig. 6) by making the simplifying assumption that the devices are used at the midpoint of the stated power and longevity ranges. The three externally-powered devices are represented by broad arrows at the right-hand side of the graph. There is an absence of battery-powered devices that operate at power levels above 10 mW for sustained times on Fig. 6. This is not a result of a shortage of therapies that would potentially require such power levels. Rather, the 10 mW threshold indicates the limit of present battery technology to provide sustained high power in small packages and over practically long lifetimes.

FUTURE POWER SOURCES

To a large extent, power sources are significant factors that limit the ability to decrease size and increase longevity of implanted devices, and there are many driving forces to push power source technology forward. These include: the continual development of new therapies; development of nontherapeutic device features (such as continuous long-range telemetry of patient data); and the therapeutic and competitive marketing advantages of smaller, longer-lived devices. It is therefore likely that there will be continued demand for power sources with ever-greater power and energy density. Advancements in power source technology are occurring at a rapid pace in many nonmedical fields (such as consumer electronics devices and electric vehicles). Some of these technologies are expected to find their way into medical implants, provided that they can be shown to meet the unique requirements of implanted sources outlined earlier. The latest power source technology is more likely to gain its foothold in power-hungry devices

Table 1 Common commercially implanted electric devices and their power sources

Disease treated or diagnosed	Device	Range of typical values			Battery chemistry	Battery design
		Power (w)	Longevity			
Bradycardia, heart failure (ventricular dysynchrony), sleep apnea	Pacemaker	10–100 μ W	7–10 yr		I ₂ , SVO, SVO/CF _x hybrid	Primary single-plate
Ventricular tachycardia, atrial fibrillation, heart failure	ICD	10–100 μ W (background), 10 W (peak)	5–8 yr		SVO	Primary coiled or multiplate
Syncope, epilepsy	Cardiac and hemodynamic monitors	10–100 μ W	1–3 yr		SOCl ₂	Primary single-plate
Parkinson's, essential tremor	Deep brain stimulator (DBS)	100 μ W–1 mW	3–8 yr		SVO	Primary single-plate
Pain, spasticity, diabetes	Implantable drug pump	100 μ W–1 mW	4–10 yr		SOCl ₂	Primary coiled
Sensorineural hearing loss	Cochlear implant	100 μ W–1 mW	n/a*		n/a	n/a
Chronic pain of trunk and limbs	Spinal cord stimulator	1–10 mW	< 1 yr–8 yr		SVO, SOCl ₂ , transcutaneous induction*	Primary single-plate
Heart failure	Left Ventricular Assist Device (LVAD), artificial heart	10–100 W	n/a*		Li ion (backup only)	Secondary coiled

*At present, commercial cochlear implants have no internal battery and receive power continuously via transcutaneous inductive transmission from an external source. The LVAD and artificial heart use either induction or a transcutaneous feedthrough for primary power, but they also include a secondary battery for backup purposes.

Fig. 6 Map of power versus energy for several classes of implanted devices. Externally powered devices are represented as arrows on the right-hand axis.

that are not life-sustaining. An example could be neurostimulators for pain management. For such devices, rechargeables may offer a substantial increase in device longevity, with the possibility of reduced device size. As the batteries move down in size and up in reliability, the degree of inconvenience of a rechargeable device is diminished. It would therefore not be surprising to see an increased prevalence of such cells in medical implants that will increase over time. A particularly exciting area is that of rechargeable lithium ion cells. These batteries are showing steady improvements in the energy density and reliability of^[30] since their commercialization in the early 1990s.

Even more advanced power technologies may exist over the horizon. Thin-film, solid-state batteries, in development for many years, appear to be approaching commercial use. Such cells can theoretically be made very thin (with thickness on the order of tens of μm) and have been shown to withstand extremely great numbers of cycles with little wear-out.^[36] Miniaturized fuel cells are being reported in the literature, which promise high energy density, but the problems of refilling them in an implant have yet to be addressed. Further down the road, we may see systems that harvest energy from the body itself. These may include piezoelectric systems that scavenge kinetic energy from motion of the body, or fuel cells that consume chemical fuel in circulating body fluids.^[37]

ACKNOWLEDGMENT

Infection of Medical Devices

Lori L. Burrows

Hospital for Sick Children Research Institute, Toronto, Ontario, Canada

Antoine E. Khoury

Hospital for Sick Children, Toronto, Ontario, Canada

INTRODUCTION

The past century has seen tremendous advances in medicine that have translated into longer, healthier lives for patients. However, changes in delivery of healthcare, mainly from in-hospital care to increased outpatient or transitional care, mean that hospitalized patients are generally sicker than in the past and require more interventions. Aided by excellent innovations in the biomaterial and bioengineering fields, modern medicine makes frequent use of medical devices, which range from temporary venous catheters to long-term, completely implanted artificial joints. It is likely that most individuals in developed countries will use biomaterials and medical devices at some point in their lives. However, despite the advantages offered by the use of biomedical devices, infection remains a serious limitation to their use and a source of their malfunction.

OVERVIEW

Infection of Medical Devices... Magnitude of the Problem

While medical devices, particularly in the hospital (nosocomial) setting, are common and necessary forms of medical intervention, they can also be a major contributor to patient morbidity. For example, urinary tract infections (UTIs) compose approximately 40% of nosocomial infections in the U.S., and, of these, 80% are catheter-associated urinary tract infections (CAUTIs). Approximately 25% of hospitalized patients have urinary catheters placed with an incidence of CAUTI of 5% per day and with related bacteremia in 4% of patients.^[1] Medical devices are heavily used in the seriously ill patients that populate intensive care units (ICUs). A recent study of nosocomial infections in medical-surgical ICUs in the United States showed that the majority of reported infections were pneumonias (31%) (83% of which were associated with mechanical ventilation), UTIs (23%) (97% of which were CAUTIs), and primary blood-stream infections

(BSIs) in 14% of patients, related in 87% of cases to the presence of central lines.^[2] Table 1 lists the most commonly used devices in the United States with their estimated rates of infection and attributable mortality.^[3]

Costs Associated with Medical Device Infections

There are considerable socioeconomic consequences of device-related nosocomial infections, which are commonly manifested in increased hospital stays with associated costs. Nosocomial BSIs and pneumonia are associated with up to 35% and 30% attributable mortality, respectively.^[4] BSIs are directly responsible for 62,500 deaths per year in the United States, a number that appears to be increasing over time.^[5] A CAUTI is estimated to increase hospital stays by 1–4 days and costs nearly \$600 per day. A bloodstream infection is estimated to increase hospital stays by 7–21 days with increased costs of up to \$40,000. Pneumonia is expected to increase hospital stays by 7–30 days with approximately \$5,000 in added costs. These numbers do not consider the further, potentially dramatic, increases in cost that could occur if the organism(s) causing these device-related infections are resistant to antibiotics. The latter scenario is becoming increasingly likely as the incidence of resistance increases—especially since the presence of invasive devices is a well-documented risk factor for infection with antimicrobial-resistant microbes.^[6]

Both mortality and morbidity caused by device infections are important to consider. Infections of some devices, such as mammary or penile implants, are rarely life-threatening but cause significant morbidity through disfigurement and associated psychological trauma.^[3] Infections of both urinary catheters and joint prostheses are associated with low attributable mortality, but the latter have an increased substantial medical and economic impact. Replacement of an infected prosthesis is itself a risky proposition since the

Table 1 The magnitude of the problem of device-associated infections

Device	Estimated no. inserted in the United States per year	Rate of infection, %	Attributable mortality ^a
Bladder catheters ^b	>30,000,000	10–30	Low
Central venous catheters ^{b,c}	5,000,000	3–8	Moderate
Fracture fixation devices ^b	2,000,000	5–10	Low
Dental implants ^d	1,000,000	5–10	Low
Joint prostheses ^b	600,000	1–3	Low
Vascular grafts ^b	450,000	1–5	Moderate
Cardiac pacemakers ^{b,d}	300,000	1–7	Moderate
Mammary implants, in pairs ^c	130,000	1–2	Low
Mechanical heart valves ^d	85,000	1–3	High
Penile implants ^{b,d}	15,000	1–3	Low
Heart assist devices ^d	700	25–50	High

^aSemiquantitative scale for attributable mortality: low, <5%; moderate, 5%–25%; high, >25%.

failure rate of reimplanted devices is higher than that seen for first-time implants.

FACTORS INFLUENCING INFECTION OF MEDICAL DEVICES

Bacterial Factors

Biofilms

What leads to infection related to medical devices? The innocuous, biocompatible materials from which modern devices are constructed provide an inert surface for microorganisms to colonize. Once microorganisms gain access to the surface or lumen of a device, they attach and, through cell division, expand into multicellular, polysaccharide-enclosed communities called biofilms. Biofilms are the preferred mode of growth for bacteria in natural systems, offer the microorganisms protection from predation and noxious substances, and likely increase access to nutrients through cooperative behavior and metabolism. Though biofilm formation has long been recognized as a problem in industrial systems, only more recently has the medical significance of this process been appreciated.^[7]

Etiological agents of medical device infection

Both bacteria and fungi are capable of biofilm formation and can colonize a wide variety of surfaces.

Depending on the source of the colonizing microflora and the length of exposure of the device to the relevant environment, biofilms can be composed of a single species, which is common in medical device infections, or may be a mixture of organisms. The sources of microorganisms include those naturally present on the skin and mucosal surfaces of the patient as well as those introduced from the surroundings. Environmental flora includes organisms present on healthcare workers, in tap water, or on surfaces in the patient's vicinity. The majority of medical device infections are due to pathogens of low virulence to healthy hosts, including staphylococci and enterococci, viridans streptococci, and Gram negatives such as *Escherichia coli*, *Klebsiella spp.*, *Pseudomonas aeruginosa*, and *Proteus mirabilis*.^[1] Strain-specific differences in biofilm formation are typically found within any species, and those strains that elaborate factors that enhance biofilm formation are more commonly isolated from device infections than strains lacking these virulence features. For example, staphylococci expressing the *ica* locus, which is associated with exopolysaccharide production, are more frequently recovered than *ica*-negative strains.^[8] Of note, fungi such as *Candida*, which are typically isolated from immunocompromised patients treated with antibacterials, are also capable of forming biofilms on medical devices.^[9] These fungi are often isolated from line infections in patients who have undergone antibacterial therapy—especially those being treated with peritoneal dialysis or with long-term venous access catheters.

Fig. 1 Formation of a biofilm. (From Ref. [10].)

The process of biofilm formation

Biofilm formation occurs via a series of predictable events, as shown in Fig. 1.^[10] Microorganisms encounter a surface and interact with it via self-produced adhesins, which can be either proteinaceous, polysaccharide, or both. The magnitude and stability of initial attachment can be influenced by the physicochemical properties of both the bacterial and biomaterial surfaces. However, modelling of the initial interaction by representing the organisms as simple spheres subject to Van der Waals, ionic, and hydrophobic interactions is generally an oversimplification due to the variety of adhesins that can be elaborated and to their ability to actively interact with surfaces at a distance from the cell body.^[11] Attempting to predict the ability of specific microorganisms to interact with various surface types is difficult since the conditions (e.g., temperature, pH, flow) under which adherence occurs can influence the results, and anti-biofilm interventions that are successful *in vitro* may not work under clinical conditions.^[3]

In vitro studies of biofilm development have shown that, after attachment, the microorganisms begin to divide and form a monolayer of attached cells that develops into mounded microcolonies of cells and eventually into mature, polysaccharide-encased mushrooms or towers of cells separated by water channels. The open structure of the biofilm allows nutrients to penetrate and waste to exit. The structure of a mature biofilm is influenced by its composition and environment, but it is strikingly reproducible under a given set of conditions. The process of biofilm formation has been likened to a form of microbial development in which single cells progress through reproducible states into a differentiated, three-dimensional community. The ability of the cells to communicate with one another via small, diffusible signaling molecules helps to orchestrate biofilm development. Disruption of

signaling results in defects in biofilm structure and physiology.^[12]

Interestingly, a mature bacterial biofilm behaves as a viscoelastic or rubbery material and can be deformed under flow. Biofilms formed under high-shear stress are actually physically stronger and more firmly attached to the substratum than those formed under low shear.^[13] Bacteria can be disseminated from a biofilm either as individual free-swimming cells, broken fragments, or clumps of biofilm. Physicians are familiar with the consequences of the disintegration of biofilms (vegetations) on artificial heart valves. The released fragments lodge in small capillary beds and lead to embolisms (an embolic shower).^[14]

Treatment challenges associated with biofilms

The most striking and medically relevant phenotype of microorganisms growing in biofilms is their markedly increased tolerance of antimicrobial agents and immune system components. Numerous studies have demonstrated that biofilms can resist up to thousands of times the minimal inhibitory concentration (MIC) of antimicrobials that can kill planktonic (free-swimming or unattached) cells of the same strain.^[7] Similarly, biofilms are resistant to complement, antibodies, and professional phagocytes due to their physical bulk and the production of antiphagocytic exopolysaccharides. This tolerant phenotype is not a result of mutation, since cells that are mechanically dispersed from a biofilm can be killed by standard antibiotic concentrations and are susceptible to killing by immune cells. For this reason, phenotypic or biofilm-growth related resistance is more correctly referred to as tolerance to distinguish it from genetically-encoded antimicrobial resistance.^[15]

A number of hypotheses have been advanced to explain the ability of biofilms to withstand high levels of antibiotics.^[15] They include:

1. Slow growth with concomitant reduction in susceptibility to antibiotics that affect physiological pathways.
2. Reduced exposure due to the diffusion barrier created by the exopolysaccharide matrix surrounding the cells.
3. Escape from the normal process of programmed cell death by a subset of biofilm cells.
4. Biofilm-specific alterations in gene expression and physiology resulting in a more resistant phenotype.

In reality, it is likely that a combination of these factors results in the observed tolerance of biofilms to typical concentrations of antibiotics. Older biofilms that have been allowed to mature and fully develop their

three-dimensional architecture demonstrate markedly increased tolerance compared with younger biofilms.

Because of their resistant phenotype, biofilms are difficult to treat *in situ*. Although antibiotic therapy can often reduce the amount of biofilm present and kill bacteria that have dispersed from the nidus of infection, withdrawal of therapy inevitably leads to recrudescence. For this reason, prevention of initial biofilm formation on a device is more practical and preferable to attempting treatment of the fully developed and drug-tolerant form.

Device-Related Factors

Site of device use and associated risk of infection

There are several factors that influence the susceptibility of a medical device to colonization with microorganisms. Exposure of the device to the external milieu is a risk factor. Devices with an exit site, such as venous or urinary (Foley) catheters, are at higher risk of colonization compared with completely implanted devices. Dental devices are particularly subject to continuous exposure to a variety of microorganisms in a warm, moist environment that promotes colonization. Semi-permanent devices with exit sites, such as peritoneal dialysis catheters or Hickman lines are also at risk, especially prior to successful tissue integration at the cuff. However, even completely implanted devices are vulnerable to contamination at the time of implantation. Some implanted devices, such as prosthetic heart valves, can become latently infected via hematogenous seeding.

Physical factors; design and composition

The physical design or construction of a medical device can influence its risk of colonization. Complex devices offer increased surface area for colonization as do devices with lumens. The material of which a device is constructed can influence colonization in that its physicochemical properties, such as hydrophobicity, may reduce or increase adherence of specific types of microorganisms. Duration of use is an important variable; time indwelling is positively correlated with incidence of infection. The texture of the surface material (roughness) can influence colonization; rough surfaces are more readily colonized than smooth surfaces.^[16]

Host Factors

Conditioning films

Regardless of their surface composition and characteristics, most types of materials are rapidly covered with

host molecules after introduction in a process known as conditioning film deposition.^[17] Formation of a conditioning film on a device surface provides alternative receptors for pathogenic microorganisms and attenuates the effect of antibiofilm coatings designed to reduce bacterial adhesion. The properties of a conditioning film varies and depends on the site of introduction of a device, *i.e.*, whether it is in contact with blood, urine, or saliva, all of which contain unique components. The site of device placement also influences the rate of conditioning film deposition as does its exposure to specific volumes and flow rates of host fluids. Many pathogenic bacteria produce receptors for host molecules such as fibronectin, which tend to accumulate on foreign bodies exposed to human fluids. Receptors for human molecules promote adherence of the bacteria to a coated surface and, in turn, encourage further deposition of human proteins onto the surface of the adherent bacteria. A noteworthy example of this phenomenon is the development of large bacterial biofilms or vegetations on prosthetic heart valves.

Other host factors

What about other host factors? The immune status of the individual receiving the medical device can influence the rate of colonization.^[18] For example, low numbers of skin microorganisms introduced with a new venous catheter might ordinarily be scavenged by a healthy immune system, but they may survive to become irreversibly attached to a device in an immunocompromised individual. Similarly, the presence of perioperative antibiotics in the circulation of the patient may reduce biofilm formation by killing transient microorganisms before they are able to attach to a device and develop into a biofilm. Depending on the site, the presence of the device will initially elicit an immune response against the foreign body, which may coincidentally mop up small numbers of organisms before they can form a resistant biofilm. However, long-term presence of the medical device can impair local immune responses and increase the risk that bacteria may be able to colonize.^[19] The site of device implantation can influence infection rates. Sites that are moist or difficult to clean will harbor increased numbers of microorganisms with increased risk of device contamination.

COLONIZATION VERSUS INFECTION

While colonization of a medical device by bacteria or fungi is common, if not inevitable, it does not lead inexorably to disease. In fact, the mechanisms by which biofilm formation leads to disease are not completely understood. Examination of implants such

as intrauterine devices retrieved from asymptomatic women showed they can be heavily contaminated with bacteria that presumably migrated from the plastic tail used for vaginal location of the device for removal.^[1] It is difficult to predict whether colonization of a device will lead to overt disease, but the combination of decreased host immune status, increased duration of exposure to a colonized implant, and level of pathogenicity of the colonizing strain(s) will affect the progression of infection.

Some disease manifestations are more easily understood, including the development of urinary tract and bloodstream infections from cells or cell clusters that become dislodged from indwelling catheters. Other diseases related to biofilms may present a more subclinical and chronic picture, such as the development of extensive scarring or capsule formation surrounding a device that is colonized with a bacterial biofilm of low pathogenicity. Such chronic irritation of the immune system has been implicated in the formation of thickened capsules of scar tissue around silicone breast implants.^[20,21]

An area of growing concern is the increasing prevalence of multidrug-resistant bacteria associated with medical device infections. Since the biofilm mode of growth already affords considerable protection against antimicrobials, the development of biofilms by drug-resistant organisms has the potential to lead to completely intractable infections. In fact, the formation of biofilms can encourage the development of drug resistance since the bacteria within biofilms that are unsuccessfully treated with antibiotics may be exposed to suboptimal drug levels that present opportunities for resistant mutants to be selected. The exchange of mobile genetic resistance factors such as plasmids, transposons, and bacteriophages has been shown to be enhanced in the biofilm environment, which is probably due to the physical proximity of the bacteria that facilitates transfer.^[22]

DETECTION OF MEDICAL DEVICE-RELATED INFECTIONS

Diagnosis of a medical device-related infection is not always straightforward. As mentioned above, bacterial colonization of a device can occur without evidence of infection. This scenario is common in the case of urinary catheters, particularly in the short term. Simple colonization of a device can precede symptoms of infection by days and is probably due to the requirement for sufficient numbers of microorganisms to accumulate before the immune response produces symptoms, which may include reddening of tissue at exit sites, fever, leukocytosis, and pain.

It is relatively easy to detect microorganisms using semiquantitative staining or plate-count techniques on a

suspicious device that has been removed from the patient. However, accurate diagnosis of potential infection of in situ devices is much more difficult and key to the difficult clinical decision of whether a device should be removed. For totally implanted devices, such a decision may mean increased morbidity to the patient from surgical procedures required to effect device removal. Analysis of CVCs removed for suspected infection show that as few as 15% may actually be infected,^[23] which emphasizes the need to establish a specific diagnosis of device-associated infection. Traditional approaches to confirm a suspected infection of totally implanted devices include assays of erythrocyte sedimentation rate, C-reactive protein level, site aspiration, advanced radiologic imaging, and nuclear medicine scans.

One of the techniques recently developed to determine whether CVCs are an infectious nidus without removal of the device is the use of differential blood samples taken both from the catheter and a peripheral site. If the sample from the catheter contains 5 to 10 times more organisms on quantitative plate counts or becomes culture-positive more than two hours before the peripheral sample, the catheter is deemed to be the source of the infection.^[24] This technique is limited because it requires that the organism causing the infection be culturable under standard laboratory conditions and that it grows within a reasonable timeframe for differentiation to be made. However, if these criteria are met, differential time-to-positivity has a high sensitivity and specificity for diagnosis of the common agents causing catheter-related sepsis.

One novel approach to detection of implant infections in situ is the recent development of technetium 99m-labelled antimicrobial agents, including ciprofloxacin (commercialized under the brand name Infec-ton), fluconazole, or antimicrobial peptides.^[25-29] These substances are injected prior to standard nuclear imaging of a patient to differentiate suspected bacterial or fungal infections from sterile inflammatory processes, and function by accumulating in the target organisms, if present. This approach has proven to have reasonable sensitivity and specificity in identifying device-related infections and has also been used to monitor the success of long-term antimicrobial therapy in patients with confirmed implant infections. This type of non-invasive imaging modality is likely to play a much larger role in future diagnoses of implant-related infections.

APPROACHES TO PREVENTING INFECTION OF MEDICAL DEVICES

Infection Control and Design Considerations

The most important antibiofilm approach in medicine is prevention. Stringent infection control is important

in preventing colonization of the device at placement and during its contact with the patient. Also, thoughtful design of medical devices to minimize the potential contact with bacteria when possible helps to reduce the incidence of infection. The usefulness of such measures was apparent early on with the redesign of urinary catheters from open drainage systems that were highly susceptible to luminal colonization to completely closed drainage systems with aseptic access ports and antimicrobials in the drainage bag to prevent retrograde access to the lumen. While closed drainage systems have significantly reduced infections associated with catheter lumens, they are not as useful at preventing ascension of bacteria to the bladder along the external surface of the catheter.

Central venous catheters are used for a variety of interventions including the administration of blood products, medications, nutrient solutions, or supportive fluids as well as permitting the sampling of blood from the patient. They are also the most common source of blood-stream infections (BSI). Skin flora, particularly coagulase-negative staphylococci, are the primary pathogens. They colonize the external surface of the catheter from the skin or enter the lumen via the catheter hub. Use of stringent asepsis during catheter placement by trained personnel is key to reduction of infection rates. Redesign of CVCs in recent years to include ports that can be flushed or locked with antiseptic or antibiotic solutions has had a significant impact in reducing BSI.

Interventions Targeting Colonization Reduction

Non-biomaterial based, and largely unsuccessful, strategies to reduce colonization of urinary catheters have included: disinfection of the meatus prior to catheter insertion or use of antimicrobial lubricants; irrigation of the catheter and bladder with antimicrobial agents; or using systemic antibiotic prophylaxis of catheterized patients.^[30] Systemic ciprofloxacin therapy was successful in preventing catheter blockage in one study^[31] and was possibly due to binding of the drug to the device surface. Ciprofloxacin is secreted in urine in an active form and has been shown to prevent adhesion of bacteria to catheters that have been pretreated by soaking in the drug.^[32] A recent study demonstrated that oral therapy with fluoroquinolones led to deposition of the drug on ureteral stents at levels above the minimal inhibitory concentrations for common uropathogens such as *Escherichia coli*, *Pseudomonas aeruginosa*, *Enterococcus faecalis*, and *Staphylococcus aureus*.^[33] The accumulation of systemically or orally administered antibiotics onto urinary catheters or stents may therefore contribute to the

perceived usefulness of this therapy at preventing CAUTI.

In the case of CVCs, application of topical antimicrobial ointments at the exit site to prevent line infections has met with limited success. Povidone-iodine,^[34] mupirocin,^[35] and polysporin^[36] all help to reduce infections in hemodialysis patients, particularly in long-term situations. Compared to a urinary catheter, the exit site of a CVC is in a more exposed and accessible location. Also, CVCs have cuffs that allow tissue integration in the longer term. These considerations make peripheral antimicrobial therapy more practical and successful.

Surface Modification

There have been many creative attempts to stop biofilms from forming or remove biofilms from surfaces. Unfortunately, no single method has been successful. Modification of the physicochemical properties of surfaces to reduce bacterial adhesion has been largely ineffective since microorganisms display a range of cell surface properties and the presence of conditioning films quickly negates any short-term gains in colonization prevention. Because of their resistance to biocides, mechanical removal and treatment with harsh chemicals are the industrial standard for remediation of biofilms. Since these tactics are generally not practical in medical systems, other measures are necessary.

Alteration of the base materials of which urinary catheters are made does not appear to significantly affect bacterial colonization, but it has been shown to influence the rate of catheter encrustation. Specifically, silicone leads to less encrustation than latex, siliconized latex, or Teflon.^[37] Since the risk of catheter infection increases with indwelling time, patients that are able are encouraged to use intermittent self-catheterization (IC) with a clean catheter. The practice of IC has led to modifications in catheter surface coatings to increase their hydrophilicity and lubricity for ease of insertion.^[38,39] While available data suggests that use of hydrophilic catheters for IC may reduce bacteriuria and urethral stricture formation, there are no prospective randomized multicenter trials that address these issues. One of the most popular and prevalent methods for biofilm reduction has been coating or impregnation of surfaces with antimicrobial agents. This approach is based on the acknowledgement that bacterial adhesion cannot currently be completely prevented. Instead, as a pre-emptive strike, the surface of a device is modified to elute high local concentrations of antimicrobial that kill any adherent organisms before they have a chance to develop into a resistant biofilm. This tactic has been widely applied to

the most frequently used devices, such as urinary (Foley) catheters and central venous catheters (CVCs).

Urinary Catheters

With a focus on prevention of biofilm formation on urinary catheters, a variety of surface modifications have been tried over the past two decades. The most successful experimental approaches have been coating of the inner and outer surfaces or impregnation of the catheter material with single or combinations of antimicrobials or with various forms of silver. Antimicrobial catheters that were efficacious in prevention of bacterial colonization *in vitro*, and have been put into widespread commercial distribution, include nitrofurazone-impregnated catheters,^[40] minocycline/rifampin-impregnated catheters,^[41] and silver-coated catheters.^[42] Other surface modifications that have been tested include antiseptics such as chlorhexidine,^[43] tobramycin,^[44] and ciprofloxacin.^[45]

Unfortunately, there are few large, randomized controlled trials that examine the usefulness of antimicrobial-treated urinary catheters. A recent review of completed trials on silver catheters found that majority of studies done to date were not designed with sufficient quality standards to permit the formulation of recommendations on the use of silver catheters.^[46] Another potentially contentious issue is the markedly increased cost of modified catheters compared with standard catheters. This is clearly an area that requires further research efforts to demonstrate the cost-effectiveness of treated catheters and justify their widespread use.

CVCs

CVCs coated or impregnated with silver, silver/chlorhexidine, silver-carbon-platinum, or minocycline/rifampin have been tested clinically. Similar to urinary catheters, as described above, there are as yet few large-scale, well-designed clinical trials on which usage recommendations can be based. To date, the minocycline/rifampin combination appears to demonstrate good efficacy and potential cost savings when patients have the catheter in place for at least two weeks.^[47] Issues with these catheters include duration of antimicrobial release, particularly important in long-term devices, and the mechanism of action, whether bacteriocidal or bacteriostatic.

ADJUNCT APPROACHES TO TREATMENT OF MEDICAL DEVICE INFECTIONS

In recent years, there have been attempts to use non-chemical modes of treatment or adjunct treatments for

remediation of biofilms on medical devices. While these approaches can be shown to be efficacious in a laboratory setting, it is not yet practical for them to enter widespread clinical use in their current form. These techniques include exposure of biofilms to ultrasonic or electrical energy.

Several studies have shown that ultrasound (US) can potentiate the antibiofilm activity of antimicrobials, both *in vitro* and when tested in an animal model.^[48] However, the energy levels required for biofilm disruption may be high enough to result in collateral tissue or device damage, and targeted delivery of US to the affected device can be difficult to achieve. Interestingly, the ability of sonic energy to disrupt biofilms on surfaces has prompted the development of novel medical devices, specifically dental instruments and toothbrushes that employ sonication or ultrasonication in conjunction with mechanical shear forces to remove dental plaque from teeth.

Work done in the early 1990s showed that biofilms placed into low-voltage electrical fields demonstrated increased susceptibility to antimicrobials compared with control biofilms, which is termed the bioelectric effect.^[49] The iontophoretic effect of low-voltage fields can help antibiotics penetrate biofilm matrices. Also, it has been hypothesized that the electrical field causes increased generation of oxygen within the biofilm with concomitant increases in bacterial growth and associated enhancement of their susceptibility to antimicrobial agents.^[50] The electrical field can generate protons, hydroxyl ions, and reactive oxygen species within the biofilm structure, all of which may contribute to bacterial killing.

FUTURE APPROACHES TO PREVENTION AND THERAPY OF MEDICAL DEVICE INFECTION

Novel Polymers

Among the approaches currently under development for the treatment of biofilm infections is manipulation of polymer design to incorporate antibiotics that are released only in response to infection. For example, polyurethanes containing integral ciprofloxacin residues embedded via chemical linkages susceptible to inflammatory cell enzymes such as cholesterol esterase have been developed and demonstrated to release therapeutic levels of drug *in vitro*.^[51] These smart polymers release drug in the presence of an inflammatory process in proportion to the level of inflammation present. Once the drug kills the infecting organism, the inflammatory response and related release of antibiotic subsides. This type of construct may reduce the overall amount of antibiotic released into the environment by a loaded device.

Non-Antibiotic Approaches

Inhibitors of bacterial communication

Although device coatings containing antimicrobial agents are currently one of the more useful antibiofilm approaches, concerns over increased resistance to these agents has prompted the search for nonantibiotic options. Alternatives to antibiotics or metals as catheter coatings that may become useful in the future include compounds that interfere with bacterial cell–cell communication (quorum sensing), thus prevents or disrupts the ability of the organisms to generate a biofilm. Such compounds have been identified in the secretions of marine plants, which naturally inhibit the formation of biofilms on their surfaces through the production of halogenated furanones.^[52] Use of peptides that naturally suppress quorum sensing in staphylococci has been demonstrated to reduce virulence and biofilm formation by these bacteria.^[53] There is some speculation that modulation of quorum sensing circuitry may be useful in promoting the dispersal of biofilm cells by mimicking the natural signals produced by the organisms during that phase of biofilm development. While this is an attractive idea, encouragement of biofilm dispersal by use of quorum sensing signals or mechanistic means, such as exopolysaccharide-degrading enzymes, could have deleterious consequences in patients if large amounts of organisms are released into the circulation, potentially causing sepsis or inflammation in response to bacterial components such as lipopolysaccharide or peptidoglycan.

Essential nutrient limitation

Recent studies of the effects of lactoferrin^[54] and catecholamine inotropes^[55] on biofilm formation have demonstrated that manipulation of iron availability in the host plays an important role in reducing biofilm formation. Chelation of iron by lactoferrin reduced biofilm formation by *P. aeruginosa* by decreasing the number of cells binding irreversibly to a biomaterial surface. In contrast, the ability of *S. epidermidis* to utilize iron complexed with inotropes like norepinephrine enhanced biofilm formation on CVCs. These studies imply that development of medical device materials or adjunct treatments that scavenge iron or other essential growth factors may result in decreased biofilm formation.

Matrix disruption

Another potential target to reduce or prevent biofilm formation is the polysaccharide matrix surrounding and protecting the biofilm cells. This component

plays many roles in biofilm physiology. Reducing or preventing its synthesis may result in sufficient impairment of biofilm defenses that they may be susceptible to more conventional treatment strategies. An example of this approach is the demonstrated effect of macrolide antibiotics, which can inhibit biofilm formation at subminimal inhibitory concentration levels by reducing polysaccharide synthesis.^[56] Combination therapy using low levels of macrolides with conventional levels of bacteriocidal antimicrobials may aid in reducing biofilm infections.

Probiotics

One novel concept of interest related to the reduction or prevention of medical device infection is bacterial interference. This idea is based on the observation that commensal bacteria (normal flora) can interfere with or prevent the establishment of pathogens or transients in the body. It may be possible to use commensal or probiotic bacteria or their products to block or remediate the adhesion of pathogenic bacteria to medical devices. As an example, application of some strains of probiotics to artificial voice prostheses in a model throat system was shown to reduce the presence of the fungal pathogen *Candida* by up to 96%^[57] and mixed bacterial/fungal biofilm formation by up to 100%.^[58]

CONCLUSIONS

Medical device use will continue to grow as our population ages and as new devices are introduced into widespread use. As infection remains a primary complication of these devices, innovative approaches to prevention and treatment of biofilms are required. Also, diagnostic techniques that can accurately detect device-associated infection without removal or interference with the device will be extremely useful in preventing unnecessary interventions and guiding therapy. There are indications that antimicrobial catheters can have an impact on patient care—both in reducing morbidity and in saving healthcare dollars. However, large, well-designed clinical trials are necessary to justify their widespread usage outside of high-risk environments.

Inner Ear Implants

Graeme M. Clark

University of Melbourne, East Melbourne, Victoria, Australia

INTRODUCTION

The cochlear implant is an electronic device that brings useful hearing to severely to profoundly deaf people through multiple-channel electrical stimulation of the auditory nerves in the inner ear. This is required if their inner ears are so badly damaged by injury and disease, or so inadequately developed, that they cannot provide sufficient hearing for communication, even when the sound is amplified with a hearing aid. By stimulating the nerve directly with patterns of electrical pulses, the implant bypasses the normal function of the sense organ of hearing in the inner ear to partially reproduce the coding of sound. It consists of a wearable speech processor that picks up sound with a microphone, analyzes the signal, and then sends it by radio waves to the implanted receiver stimulator, which decodes the message and stimulates the electrode wires inserted into the inner ear (Fig. 1).

NORMAL HEARING

With normal hearing, the external ear or pinna collects sound, which then passes along the external auditory canal to the eardrum (tympanic membrane) (Fig. 2). The eardrum vibrates to the sound, and these vibrations are transmitted through three small articulated bones (ossicles)—(malleus, incus, and stapes)—in the middle ear to the inner ear or cochlea. The ossicles amplify the sound waves, and this overcomes the greater resistance of fluid in the inner ear to the transmission of sound. The transmission to the fluid in the inner ear is via the stapes, whose footplate lies in an opening in the inner ear (oval window). The vibrations in the fluid cause a membrane placed across the cochlea (the basilar membrane), on which lies the sense organ of hearing (organ of Corti), to vibrate (Fig. 3). The basilar membrane acts as a filter for sound frequencies, with the high frequencies, producing a maximal vibration at the basal end (i.e., where the sound enters) and the lower frequencies at the more distant apical region. The hair cells of the organ of Corti convert sound waves into electrical signals. This electrical activity initiates temporal and spatial patterns of action potentials in the auditory nerve and higher brain centers, thus encoding the sound. Deafness occurs if

the structures or pathways are damaged or diseased. Deafness is referred to as conductive if the sound cannot be conducted to the inner ear. Deafness is sensorineural if the cochlea or auditory nerve is damaged.

PRINCIPLES OF THE COCHLEAR IMPLANT

Principles underlying the cochlear implant are firstly the partial reproduction of the coding of frequency and intensity of sound. The coding of frequency is illustrated in Fig. 4. As shown, the temporal coding of frequency is the result of action potentials locked to the same phase of the sine wave and the detection of this information through coincidences in the arrival of the action potentials at central auditory neurons. The place coding of frequency first occurs as a result of filtering by the basilar membrane of the cochlea, with the maximal displacement of the membrane for the high frequencies in the basal turn, moving to the apical turn for the low frequencies. The filtering is due to the mechanical properties of the membrane, which is stiffer at the basal end. This ordering of frequencies on a spatial basis is preserved throughout the auditory system via connections between the cochlea and the higher centers in the central auditory pathways. The spatial or tonotopic organization of the brain is used with a cochlear implant electrode array to stimulate different fibers in the cochlea, conveying frequency information on a place basis. The auditory nerves in the inner ear are splayed out for the transmission of frequency information on a place-coding basis. The amplitude of the sound is converted into current level.

The reproduction of the coding of sound frequency and amplitude with electrical stimulation is imperfect, and thus the interface between the world of sound and the central auditory pathways can be considered an electroneural “bottle-neck.” For this reason, the information from speech in particular must be carefully chosen so that the most relevant data is effectively coded for transmission along the central pathways.

Cochlear implants are effective in providing speech understanding only if they are multichannel, and improved place coding of sound has been responsible for the greatest advances in cochlear implant speech perception to the point where the results are comparable

Fig. 1 The cochlear implant. The components are a) microphone; b) behind-the-ear speech processor; c) body-worn speech processor; d) transmitting aerial; e) receiver-stimulator; f) electrode bundle; g) inner ear (cochlea); h) auditory or cochlear nerve. (From Ref. [1].)

to someone with a severe loss of hearing using a hearing aid to good effect.

IMPLEMENTATION OF SPEECH PROCESSOR

The external speech-processing unit of a cochlear implant is now small enough to be worn behind the ear, or a more versatile one for an extended range of advanced strategies can be worn on a belt or in the pocket (Fig. 1). The speech processor has a directional microphone that converts sound into electrical voltages, and these are sent to the speech processor. The speech processor filters this waveform into frequency bands. The outputs of the filters are referred to a map containing the patient's electrical current thresholds and comfortable listening levels for each individual electrode in the inner ear. A code is produced for the

Fig. 2 Diagram of the outer, middle, and inner ears and auditory nerve passing to the central auditory system. A) pinna; B) external auditory canal; C) eardrum; D) ossicles; E) Eustachian tube; F) inner ear; G) auditory (cochlear) nerve. (From Ref. [2].)

Fig. 3 A cross section of the human cochlea showing the scala tympani (ST), the scala media (SM), and the scala vestibuli (SV), separated by the basilar membrane (BM) and the Reissner's membrane (RM). The basilar membrane is attached externally to the spiral ligament (SL) and internally to the spiral lamina (SpL). The stria vascularis (StV) generates the endolymphatic potential in the scala media. This powers the production of cochlear microphonics in the organ of Corti (OC), and the resulting action potentials pass along the peripheral processes in the spiral lamina to the spiral ganglion cells (SG) in the spiral canal in the modiolus. (From Ref. [2].)

stimulus parameters via electrode site and current level. To represent the speech signal at each instant in time, this code together with power is transmitted by radio waves via a circular aerial through intact skin to the implanted receiver-stimulator section that is embedded in the mastoid bone behind the ear. The receiver-stimulator decodes the signal and produces a pattern of stimulus currents in a bundle of electrodes that are inserted around the first turn of the inner ear so that the auditory nerve fibers, particularly in the speech frequency range, can be stimulated. The electrode bundle lies close to but not attached to the spiral ganglion cells in the inner ear, the first station for processing information.

The sound is converted into electrical signals by a directional microphone that increases in sensitivity from 1500 Hz up to approximately 5000 Hz at 6 dB per octave before falling off at 18 dB per octave. This emphasizes the high frequencies of speech that are important for intelligibility but low in intensity. The signal passes to the speech processor via a cable. The speech processor has an analogue front end to amplify the signal to a level that can be best handled by the speech processor (Fig. 5). The front end also has an automatic gain control (AGC), which is a compression amplifier to keep the variations in the amplitude of the speech signal within an acceptable range. The time taken for the AGC to operate (attack) and cease (release) must be carefully controlled for optimal processing of the speech sounds.

Fig. 4 Left: the temporal showing the phase-locking of the brainstem cell responses to the sine wave. Right: the place coding of frequency showing how the sound is first filtered by the cochlea and then connected to higher brain centers in an orderly way so that a frequency scale is preserved. (From Ref. [3].)

The next important function for the speech processor is to filter the sounds into component frequencies and detect the energy level in each frequency band (Fig. 6). Switched-capacitor filters are used as they have greater flexibility in selecting the center frequencies and the slope of the upper and lower frequency cutoffs. The resulting analogue representation of the sound is digitized with an analogue-to-digital converter (ADC) for further processing. Alternatively, the signal from the front end is first digitized and then filtered using a Fast Fourier Transform (FFT). There are 20 filters for the Nucleus SPEAK and ACE strategies (Fig. 7). The first seven have center frequencies distributed lineally over the range from 140 to 1000 Hz, and the remaining ones are logarithmically spaced up to 6000 Hz, the upper limit for speech frequencies. Although there is a logarithmic

distribution of frequency versus distance along the basilar membrane, the above frequency to electrode allocation gives a better emphasis to the frequencies of importance for speech intelligibility. The fixed filter strategies for presenting the CIS strategy have six to eight filters with center frequencies ranging from 250 to 5500 Hz and distributed on a logarithmic basis.

The correspondence between formant or filter frequency and electrode can be determined from psychophysical studies. The electrode to be stimulated for each frequency band is assigned from a table in the digital memory. The person's threshold and maximum comfortable level for each electrode is also stored in memory as a reference map for setting the stimulus levels to be transmitted to the receiver-stimulator. Microprocessors are used to control the signals for implementing the different strategies.

The data from the speech processor to instruct the receiver-stimulator on the electrical stimulus settings are transferred serially as a digital stream of information. This is more effective than analogue transmission as it provides immunity to noise and component variations. The signal parameters from the microprocessor are fed to the transmitter section. The microprocessor controls the times at which the electrical parameter values are sampled and configures the radio frequency signal for transmission to the implanted receiver-stimulator with alignment ensured through magnets incorporated in the centers of both coils. The transmitted code is made up of a digital data stream representing the stimuli and transmitted by pulsing the radio frequency (RF) carrier. Data for stimulation are transmitted in frames with the Nucleus system. The data in each frame are coded as the number of cycles in bursts of RF. Each burst consists of a number of cells or just discriminable RF cycles. Successive frames are separated by an interframe gap.

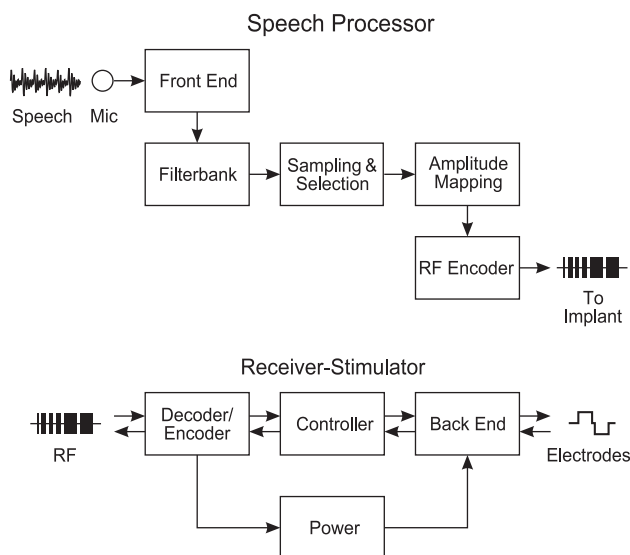

Fig. 5 Top: the principal components of a speech processor. Bottom: the principal components of the receiver-stimulator. (From Ref. [2].)

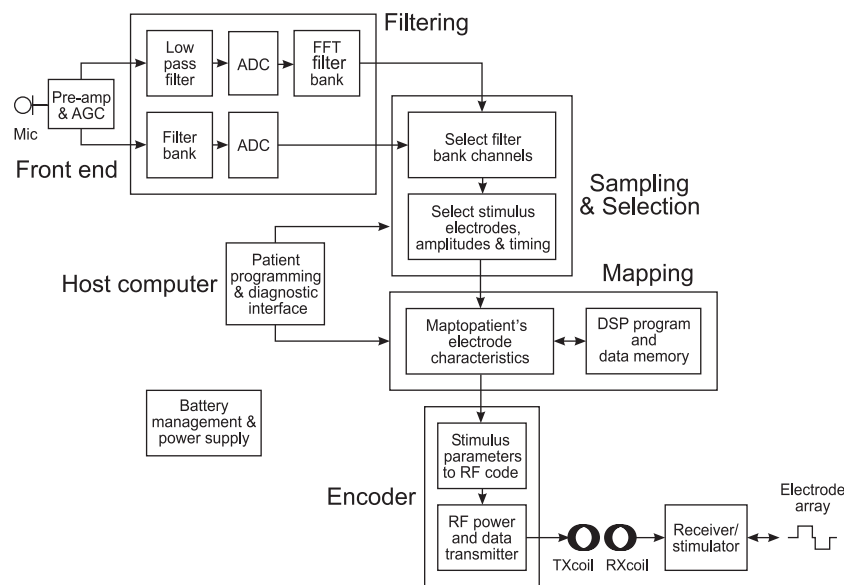

Fig. 6 The Nucleus behind-the-ear and body-worn speech processors are implemented using either a standard filter bank or Fast Fourier transform (FFT) filter bank, respectively. The front end sends the signal to a signal processor chip via a filter bank or to a digital signal processor (DSP) chip, which carries out an FFT and signal processing. The signal processor selects the filter bank channels and the stimulus electrodes and amplitudes and then maps these to the patient's requirements. An encoder section converts the stimulus parameters to a code for transmitting to the receiver-stimulator on a radio-frequency (RF) signal together with power to operate the device. ADC, A-to-D converter; RX, receiver; TX, transmitter. (From Ref. [4].)

IMPLEMENTATION OF RECEIVER-STIMULATOR

The receiver-stimulator decodes the information into instructions for the selection of the electrode mode of stimulation (bipolar, common ground, or monopolar), current level, pulse width, and interpulse gap. Power to operate the receiver-stimulator is also transmitted by the radio frequency carrier. The receiver-stimulator has circuitry for decoding the transmitted signal and also for converting the energy in the radio frequency signal into power for its operation and stimulation of the auditory nerve fibers.

Electrical charge is the important parameter for stimulating nerves, and this will vary if there are alterations in the impedance between the electrode and the tissue. To avoid this problem, constant current stimulation is used. Bipolar stimulation localizes the current

Fig. 7 The Nucleus Spectral Maxima (SPEAK) sound processor. (From Ref. [5].)

to separate groups of nerve fibers. In this case, the electrical current passes between one of the electrodes and a neighboring one usually separated by one intervening electrode. Common-ground stimulation provides localized stimulation, and this occurs with the passage of current from an active electrode to all the other electrodes on the array shorted to form a common ground. Finally, monopolar stimulation provides localized stimulation if the electrode is placed close to the nerve fibers to be stimulated, and it has the added advantage in that a lower threshold is achieved, enabling smaller processors to be used with longer battery life. It is important that the electrical pulses be biphasic so that one cancels out the other to ensure there is no buildup of DC at the electrode-tissue interface as this can be damaging to tissue. In addition, stimulators have a capacitor in series to ensure there is a high impedance for any DC in the circuit. Another important principle in stimulating the nerve fibers in the cochlea is non-simultaneous stimulation; otherwise there will be an interaction of the electrical fields and unpredictable variations in loudness. The number of stimulus channels or electrodes to be used will vary depending on whether the strategy is formant extraction, spectral selection, or fixed filter. Multiple-channel devices are used with channel numbers varying from 6 to 22. The fixed-filter strategies require only up to eight channels. Formant selection or spectral maxima strategies perform better as they use up to 22 channels. Studies with acoustic models and electrical stimulation indicate that up to 22 channels are especially necessary for the best speech perception in the presence of background noise.

The intensity of the stimulus can be varied through the current level or the pulse width. Both current and pulse width alter the charge presented to the nerve

membrane. There are other parameters such as rate and total charge that also affect neural stimulation and the perception of loudness. It is also important that charge density and charge per phase be kept within certain strict limits as they can cause corrosion of the electrode and gassing if a charge density of $300 \mu\text{C cm}^2$ geometric phase is exceeded. Lower charge density levels may still cause neural damage especially if presented at high rates of stimulation. Consequently, the charge and charge density of the neural stimulators need to be controlled and will depend upon the strategy to be used as well as the geometry of the electrodes. Animal experimental studies are required to confirm the safety and efficacy of the speech processing strategies and electrode designs.

In implementing the instructions from the speech processor, the receiver-stimulator has circuitry that sends the data via a clock unit to control the timing and then to an output controller to determine the instructions required for producing the stimulus parameters (Fig. 8). These instructions are then fed through an electrode decoder to control the mode and duration of stimulation. With bipolar stimulation, the current flows first in one direction when the voltage rail V_{dd} is connected to the V_{ss} and then in a reverse direction to complete the stimulus. The second phase of the pulse is identical in magnitude but opposite in sign to the first. This technique makes it possible to match the current in both phases of the pulse and not produce an imbalance.

In addition, receiver stimulators have telemetry. This allows the voltages on electrodes generated while delivering a stimulus pulse to be transmitted back to the external programming system (Fig. 9). The voltages can help determine the tissue impedance around the electrodes and thus assess any pathological changes

Fig. 9 A diagram of telemetry showing I , the stimulus current; V_i , the voltage between electrodes for the calculation of the impedance; V_{cap} , the compound action potential or voltage from the auditory nerve and brainstem; EABR, the electrically evoked brainstem response and cortical evoked potential. (From Ref. [6].)

occurring in the neighboring tissue. In addition, the telemetry permits the recording of compound nerve action potentials from the auditory nerve. This enables the neural stimulus thresholds and dynamic ranges to be gauged for infants and young children who cannot easily respond and explain the sensations they are receiving. Thus the speech processing maps in young children can be made more efficiently.

ELECTRONEURAL INTERFACE

The electrodes required to stimulate the auditory nerve are insinuated along the basal turn of the cochlear spiral at a surgical operation (Fig. 10). They are introduced through a small opening drilled in the bone overlying the scala tympani, one of the fluid compartments in the inner ear. The electrodes either lie

Fig. 10 A drawing of the banded array passing around the basal turn of the cochlea in the scala tympani. (From Ref. [7].)

along the outer wall or have a precurved spiral so that they come to lie closer to the neural elements in the central column of the cochlea.

The electrodes must be inserted with the right mechanical properties so that they will pass up the tightening spiral far enough to lie close to the fibers conducting the speech frequencies to the brain with minimal trauma. It was found they needed to have graded stiffness with more flexibility at the tip so that the delicate inner ear structures were not injured, which would in turn lead to the loss of the neural elements it was necessary to stimulate. The electrode carrier also needed to be free-fitting to minimize trauma and not stretch or tear vital structures. Furthermore, it had to be smooth without protruding electrodes so that it could be easily taken out and another one inserted should there be any failure or breakages of the wires.

It is essential to make sure that middle ear infection will not extend around the electrode bundle into the inner ear and thence to the meningeal linings of the brain leading to serious meningitis, particularly in young children. Experimental studies at the University of Melbourne showed the importance of using a fibrous tissue seal packed around the entry point to prevent the ingress of infection (Fig. 11). The series of basic experimental studies demonstrated that a sheath extending from middle ear around the single component electrode into the cochlea is important in preventing meningitis. This sheath enables three lines of defense by the body to counter the entry of infection from the middle ear. The first is through a change in the lining cells that extend around the sheath to ones that produce mucus that slows down the spread of bacteria, the hair cells of these lining cells sweep the

Fig. 11 Photomicrograph showing a cat cochlea and a spontaneous middle ear infection several weeks after implantation. An envelope has formed around the prosthesis inside the scala tympani, the round window membrane is thickened (R), and the round window niche is filled with mucosal folds (M); the organ of Corti and neurons are intact. (From Ref. [8].)

mucus and bacteria away. The second line of defense is through phagocytosis. When the invasive organism causes the blood vessels around the sheath to dilate, the granulocyte white cells enter the tissue and engulf the bacteria. The third line of defense is also facilitated through the sheath around the single component array. The sheath allows the entry of specialized cells; the type B lymphocytes produce antibodies and the type T lymphocytes kill the bacteria directly. Meningitis can, however, be a problem in children who have a congenital deformity of the cochlea, as they often have a large communication between the inner ear and the fluid-filled subarachnoid space around the brain.

CLINICAL ISSUES

Once the receiver-stimulator and the electrode carrier are correctly placed at the operation, the electrode carrier needs to be fixed at a point in the temporal bone that does not move relative to the inner ear in young children. This avoids changes in head growth leading to its slippage.

The cochlear implant and speech processor have been used in tens of thousands of adults and children in over 120 countries. Clinical studies have shown that speech processing strategies that extract speech frequencies and present them to appropriate electrodes around the cochlea on a frequency to place basis as well as presenting voicing as rate of stimulation or amplitude variations produce very significant improvements in speech understanding (Fig. 12). The average deaf adult who had hearing before going deaf can understand running speech without the need to lip-read at a level comparable with that of a person with severe hearing loss who has residual hearing and uses a

Fig. 12 The open-set CID sentence and CNC word scores for the Nucleus F0/F2, F0/F1/F2, "Multippeak," and SPEAK strategies. (From Ref. [9].)

hearing aid. Similarly, the same applies to children who are born deaf, especially when they are operated on at a young age even as early as 12 months.

With young children it is also important for them to speak correctly and to develop language. There is an interrelationship between their ability to perceive speech and their language development. It has been found, however, that like children with severe hearing loss and a hearing aid, the language levels on average do not always reach those of children with excellent hearing but can do so with extra training.

The level of success can be partially predicted in adults and children. The important factors are age when deafened, age at implantation, duration of deafness, duration of implantation, the presence of residual hearing, speech reading ability, speech processing strategy, the communication strategy before and after surgery, and other factors such as multiple handicaps.

The Nucleus first and second formant and “Multi-peak” speech processing strategies were approved by the U.S. Food and Drug Administration as safe and effective for children older than two years in 1990. Studies on children also showed they obtained better results when they were operated on at a younger age.

Before operating on children under two years, it was essential to evaluate three safety issues. These were firstly ensuring that infections in the middle ear, which are frequent in this age group, would have minimal risk of extending to the inner ear and lead to meningitis; secondly determining that the effect of head growth, which is rapid at this age, would not lead to the extraction of the lead wires from the inner ear; and thirdly establishing that electrical stimulation did not have an adverse effect on the maturing nervous system. Once these issues were found not to present special difficulties for children under two, operations were carried out down to 12 months, especially as it is now possible to diagnose hearing loss accurately with steady-state evoked response audiometry.

To further improve speech processing strategies, it was found desirable to develop an electrode array that could pass around the spiral of the inner ear and lie close to the central axis where the ganglion cells of the hearing nerve lie. This was a complex bioengineering task. The electrode array had to be made as a spiral and then held straight with a stylet. After partial insertion, the stylet is withdrawn and then the electrode advanced to curl around the cochlea. These electrodes achieve lower thresholds of stimulation and more localized stimulation of the nerve elements.

CONCLUSION

The cochlear implant has been a major achievement in the management of profoundly deaf children. It is

the first significant improvement since Sign Language of the Deaf was developed at the Paris Deaf School 200 years ago. It is also the first clinically established interface between the environment and the central nervous system and a major step forward in the corrective management of brain disorders.

Insulin Delivery

Robert S. Parker

Department of Chemical and Petroleum Engineering, University of Pittsburgh, Pittsburgh, Pennsylvania, U.S.A.

INTRODUCTION

Insulin is an endogenous protein that facilitates the cellular uptake of glucose in the body. After release from the pancreatic β -cells, circulating insulin interacts with cellular receptors that, through a cascade of intracellular events, increases the transport of glucose across the cell membrane. Patients suffering from diabetes have either little or no endogenous insulin production (type I diabetes) or a combination of insulin resistance and insufficient pancreatic insulin release (type II diabetes). Type I and type II diabetes sufferers may require insulin, and a key issue in disease treatment is the delivery of the hormone so as to regulate patient glucose levels within a fairly narrow band (70 to 120 mg/dl). Classical delivery techniques have relied on the administration of insulin into a subcutaneous depot. A variety of insulin formulations have been employed, each characterized by its respective profile of insulin release into the bloodstream. Given that optimal glucose-control performance is limited to a significant extent by the insulin delivery mechanism, advances in this area are necessary.^[1] These advances may be accomplished in any of three primary areas, discussed in greater depth in the following sections: route of delivery, insulin formulation, and novel approaches to insulin delivery.

DELIVERY ROUTES FOR INSULIN

At the time of Banting and Best (1923), early insulin preparations were delivered intramuscularly and at high volume. This resulted in significant pain for the patient, as well as medical complications (e.g., abscess) due to the large required delivery volume. Developments since have focused on reducing the volume of the insulin preparation delivered subcutaneously, increasing patient quality of life by developing less invasive methods for insulin delivery and normalizing the glucose distribution in the patient by using delivery routes other than the subcutaneous (subQ). This last aim is partially driven by the natural pathway for insulin release.

Healthy patients release insulin into the portal vein, such that insulin first passes through the liver and is

then distributed throughout the systemic circulation. The high concentrations of insulin in the liver promote storage of glucose as glycogen, and the systemic insulin levels are decreased by the so-called “first pass effect,” in which the liver extracts a significant fraction of the insulin entering the organ (approximately 40%).^[2] In contrast, the exogenous delivery of insulin is rarely to a space that drains into the portal vein (implantable pumps excepted). The result is a glucose distribution weighted heavily toward the periphery because the lower liver insulin concentrations reduce the amount of glucose stored as glycogen in the liver and the elevated systemic insulin levels promote glucose storage in the muscle and fat cells. Based on the preceding discussion, the choice of delivery route plays a significant role in the quality of treatment, and hence patient quality of life.

Subcutaneous Delivery

The classical insulin delivery method has been injection to the subcutaneous tissue space. This creates a small depot of insulin that diffuses into the circulation over a period of time. A variety of factors impact the effectiveness of this treatment.^[3] The stability of an insulin formulation will establish the maximum theoretical bioavailability of subQ insulin. Practically, the bioavailability may be lower than this maximum due to the concentration-dependent nature of insulin release from subcutaneous depots. Surrounding tissue may metabolize some of the injected insulin; also, after a period of time, there may be an insufficient concentration of insulin in the depot to further drive diffusion to the bloodstream. In addition to the magnitude of insulin that reaches the circulation, rate of appearance in the bloodstream is important. The rate of absorption from the depot affects such important characteristics as peak insulin concentration, time of peak concentration, and duration of insulin action. The rate and magnitude of insulin effect can be altered by changing the formulation and biochemical structure of the injected insulin, as discussed in the section titled “Insulin Formulations.”

As an alternate path to multiple daily injection therapy, there has been an ongoing push to develop insulin pumps.^[4] Typically these pumps contain a

two- to three-day supply of insulin that is administered through a flexible tube; the distal end resides in the (typically abdominal) subcutaneous tissue of the patient. This transcutaneous line is positioned by the patient via a needle, and the location is changed every 2–3 days to maintain viability of the delivery site. The development of patient-friendly pumps and intermediate-duration indwelling tubing has resulted in continuous subcutaneous insulin infusion (CSII) therapy. Here, regular insulin is infused continuously at a low rate to a subcutaneous depot over a period of a few days. This produces a more consistent basal insulin pattern than multiple daily injections of longer-acting insulin preparations. Generally, the aim is to satisfy basal insulin requirements using CSII and to use injection therapy to address meal effects. While this doesn't eliminate the need for injections altogether, it does reduce the necessary number of transcutaneous punctures. Alternatively, some pumps include priming mechanisms that allow them to deliver boluses or (square-)waves of insulin. In these cases, the patient can eliminate injection therapy by instead activating the pump before consuming a meal. An issue with CSII is the possibility that the infusion port will become blocked, thereby stopping insulin delivery to the patient. As long as patients consistently monitor their blood glucose, effective treatment can continue. Recent studies have shown the effectiveness of CSII therapy versus traditional multiple daily injections in reducing HbA_{1c}, a measure of “overall” glucose control performance in diabetic patients.^[5]

Alternate Routes of Administration

The development of non-subQ insulin delivery approaches is generally motivated by the desire(s) 1) to improve the pharmacokinetics or pharmacodynamics of either acute or basal insulin administration, and/or 2) to reduce the lifestyle impact of multiple daily subQ insulin injections. Different routes offer advantages in either or both goals; however, there are typically additional complications associated with these alternate delivery locations that challenge scientists, engineers, and clinical practitioners.

Oral enteric insulin

A primary challenge in developing an oral insulin dosage form that targets intestinal absorption is the need to protect the sensitive protein from denaturation by stomach acids and intestinal enzymes. Even with successful arrival of insulin in the intestinal tract, the bioavailability of the protein is still significantly less than that achieved by injection therapy.^[6,7] Finally, the absorption profile is poorly understood at present, and

the variability of meal content could significantly complicate the establishment of repeatable uptake. The two primary advantages associated with this approach provide sufficient incentive to continue development in spite of the aforementioned concerns. A key advantage of this technique is patient compliance, as it is far more convenient and acceptable (in the personal and societal sense) to take a pill than a self-administered injection. Furthermore, uptake of insulin from the intestinal tract is into the portal vein. This is an important biological advantage, as the insulin available to the body undergoes the “first pass effect” in the liver. This should lead to a normalization of the glucose distribution in the body (liver instead of peripheral storage) and an elimination of the undesirable systemic hyperinsulinemia observed in peripheral delivery.

Ocular, nasal, and buccal mucosa delivery

Ocularly delivered drugs are generally swept away by tearing and blinking to the nasal mucosa, where they are absorbed.^[8] The properties of mucosal absorption are reasonably similar, thereby allowing simultaneous discussion of ocular, nasal, and buccal (or mouth) delivery. All of these approaches avoid the pain associated with injection therapy. Also, transport across mucosal layers is quite fast, and buccal studies have shown insulin appearance in the circulation in about 10 minutes.^[9] However, there are some issues in these delivery pathways that limit the utility of insulin delivery. Ocular and nasal delivery often requires absorption enhancers to improve the uptake of larger (6000 kDa) proteins and to reduce the clearance rate from the nasal cavity. Unfortunately, many of these enhancers are irritants of some form (eye stinging, mucosal irritation, etc.). In addition, insulin bioavailability is less than 10% for nasal absorption, so that significantly greater amounts of insulin will be required. By using an ocular device (gel insert), the duration of insulin effect and bioavailability may be markedly increased; the long-term effects of this approach have yet to be evaluated. Buccal delivery is another option, and a mist-based system has been developed.^[9] Although the bioavailability appears to be markedly reduced, more than 10 times less than subcutaneous injection, the systemic insulin profile has a short time to peak (about 30 minutes) that would aid in rapid reduction of meal-induced hyperglycemia.

Insulin inhalation

Inhalation of insulin is another route that avoids the pain associated with injection therapy. In this case, either liquid droplets or powders with size 1–3 μm are inhaled with slow even breaths so that the drug will be

deposited in the alveoli of the lungs.^[10] The particle size is important as particles outside this size range are deposited in the mouth or on the walls of the bronchial tubes. While the bioavailability is reduced versus subcutaneous injection (10–40% of total inhaled dose absorbed),^[11,12] the concentration versus time profile of inhaled regular insulin is similar to that of insulin lispro delivered subcutaneously.^[12] Along with the apparent advantages, there are several concerns. There have been no studies evaluating long-term safety of inhaled insulin formulations, although the expected levels of particulates are less than the current recommended maximum set by the American Council of Governmental Industrial Hygienists. Inhaled insulin response is reproducible, but any factor influencing lung operation (lung disease, common cold, etc.) could alter the drug absorption. Since 80% of the inhaled dose reaches the alveoli, while only 10–40% reaches the circulation in the healthy patient, overabsorption could lead to potentially lethal hypoglycemia. Finally, the use of inhaled insulin is primarily for acute dosing and meal compensation, as there are no ongoing studies on inhalation therapy using long-acting insulin formulations.

Transcutaneous transport

Delivering drugs across the skin offers some significant advantages versus alternate delivery routes, including no gastrointestinal degradation (oral), steady delivery (acute therapies), and better compliance (injection). However, a major challenge is the transport of large compounds, such as insulin, across the stratum corneum—the upper layer of skin and the generally accepted rate-limiting layer of the epidermis.^[13,14] By changing from hypodermic to microneedles, the depth of penetration can be reduced, thereby reducing the level of pain associated with insulin delivery.^[15] However, the rate of insulin delivery would be reduced due to the significant reduction in needle size. Increasing skin permeability provides an alternative to puncturing the skin with micro- or hypodermic needles. Methods for increasing transcutaneous transport include chemical, electrical, and sonic approaches. Low-frequency ultrasound (~20 kHz) has proven effective for the transcutaneous delivery of insulin, which is similar in size (molecular weight) to insulin.^[13] An added benefit of ultrasound is the pain-free nature of the technology. Further improvements in transport rate result from synergistic effects between ultrasound and chemical or electrical (e.g., electroporation, iontophoresis) means. Synergistic approaches may result in increased skin irritation by chemical transport enhancers or the electric voltages associated with iontophoresis and electroporation.

Intravenous administration

In order to mimic the human body, insulin would have to be administered intravenously (IV) to the patient. While this has significant advantages, such as reducing the rate of progression of diabetic nephropathy,^[16] it has drawbacks of equal or greater importance. Clearly, the bioavailability of a compound delivered IV is 100%. Furthermore, there is no delay from administration to changes in the circulating concentration, so regular insulin can be used and the onset of action would be nearly immediate. Likewise, a stoppage of insulin would immediately eliminate insulin appearance; this would be important in the case of exercise or hypoglycemia compensation. However, this immediate effect of stopped insulin would be problematic if undesired; glucose concentration rise would initiate much sooner than under other forms of therapy. Also, it is impractical given current technology to maintain an indwelling intravenous line for drug delivery. Blockage by immunoreaction may occur, sterility for a transcutaneous port would be a major concern, and stability and rupture of the venous blood vessel are serious safety issues. With the possible exception of implantable pumps, which could deliver to the portal vein, the point of insulin delivery would likely be systemic. Hence the benefits of IV delivery would be lost, to an extent, by not having the liver “first pass effect,” and therefore the misdistribution of stored glucose would occur including elevated peripheral glycogen levels and a reduced capacity of the liver to buffer glucose demand changes. So while IV delivery of insulin to the portal vein is the ideal scenario, safety and technological concerns currently limit this approach to clinical (intensive care) settings and basal mode implantable pumps.

INSULIN FORMULATIONS

Insulin has traditionally been delivered into subQ depots, from which it would diffuse into the circulation. Effective subQ therapy has been dependent upon a variety of issues, including insulin preparation stability, bioavailability, biocompatibility, and rate of release from the depot. By selecting the proper dose and formulation of insulin to accomplish glucose regulation, which typically requires a finite set of insulin preparations and doses, reasonable control of glucose can be achieved.^[17,18]

Two primary issues must be addressed in insulin delivery, and hence these impact the formulation of delivered insulins: basal insulin replacement and acute insulin demand. In healthy patients, the pancreas releases a continuous stream of insulin to satisfy the basal tissue need.^[19] This basal secretion maintains the blood glucose concentration within the normoglycemic

range of approximately 70 to 120 mg/dl.^[17] In addition to this requirement, acute perturbations, e.g., meals, can dramatically upset the physiological glucose concentration. In this case, additional insulin is typically administered to reduce the hyperglycemic (>150 mg/dl) excursion. Of concern is that aggressive acute dosing may lead to an increased risk of hypoglycemia (glucose <60 mg/dl) after the meal. In general, the basal and acute insulin requirements are met using different insulin formulations and schedules.

Acute Insulin Delivery

The action of insulin produced by the pancreas is rapid. This is important, as glucose concentrations often rise in less than 30 minutes after the start of meal consumption. Hence, the body must act quickly to avoid overt hyperglycemia. Likewise, diabetic patients need an insulin formulation that acts quickly after administration. Rapid absorption is also beneficial for hypoglycemia avoidance because short-acting insulin formulations do not have the extended response profiles of subQ-delivered regular or longer-acting insulins. Hence, insulin release from the subcutaneous depot occurs during meal absorption, rather than extending well beyond the duration of meal uptake.

Early regular insulins were bovine or porcine in origin, but advances in recombinant DNA technology and production in *E. coli* made available “regular” human insulin. The pharmacokinetics and pharmacodynamics of regular insulin are identical to natively produced insulin when administered intravenously, but subcutaneous delivery results in a delayed absorption (30 minutes to IV appearance), time of peak action (peak at about 80–230 minutes), and duration of action (4 to 6 hours).^[20] When administered subcutaneously, regular insulin has a tendency to form dimers, hexamers, and aggregates. In order to diffuse out of the subcutaneous depot, insulin must be in monomeric form. Hence, the delays in absorption and time to peak action, as well as the extended absorption profile, are a function of the time required for dissociation of the insulin aggregates, hexamers, and dimers.

Insulin lispro and insulin aspart are regular human insulin derivatives designed to reduce the degree of insulin self-association. Lispro inverts the position of lysine (B29 → B28) and proline (B28 → B29) on the B-chain.^[20] Aspart replaces the B28 proline with aspartic acid.^[20] These two insulins both have rapid action onset (≤15 min), a reduced time to peak (45–60 min), and double the peak concentration of regular insulin, with similar total exposure when delivered subQ.^[20] This time profile is much closer to that of healthy patients, which improves overall glucose control by reducing the postmeal glucose peak magnitude as well as

the frequency of hypoglycemic episodes.^[20] Unfortunately, rapid-acting insulins have some drawbacks. They are more expensive, and the reduced duration of action may result in a more rapid onset of ketoacidosis in the case of infusion pump failure or basal insulin absorption loss. For patients not on intensive insulin therapy, there is also an increase in the number of daily injections required for glucose control. However, given the potential improvements in glucose performance provided by intensive insulin therapy^[17,18] combined with rapid-acting insulin, the case is stronger than ever for patients to switch to more intensive treatment of their disease. In spite of the drawbacks, most patients using injection therapy to treat their disease are currently employing rapid-acting insulin analogues as a part of their therapy. These analogues are also useful for inhalation therapy, as the rapid uptake times improve glucose control for these patients as well.

Basal Insulin Replacement

Basal insulin in the healthy patient is a continuous secretion from the β -cells of the pancreas.^[21] Ideally, the delivery of basal insulin to diabetic patients would match the profile of endogenous healthy-patient production. Key to this approach is the development of long-acting insulins that diffuse out of a subcutaneous depot at rates significantly slower than the regular insulins previously discussed. Early developments of this type include neutral protamine Hagedorn (NPH) and (70% ultra-/30% semi-)lente insulins. Both of these insulins display a peak of action between 4 and 5 hours after subcutaneous injection, followed by a decrease in action after about 6 hours,^[21] with a total duration of action of approximately 12 hours. This peaking and nonflat behavior does not represent native insulin secretion in the healthy patient; furthermore, the peak concentration and subsequent loss of activity for twice-daily injections occurs in the middle of the night and is a significant contributor to overnight hypoglycemia and morning hyperglycemia, respectively.

Like the rapid-acting insulins, amino acid modification of insulin can be used to tune the subcutaneous insulin release profile. Insulin glargine is formed by substituting a glycine for the asparagine on the A-chain at position 21 and adding two arginines to the B-chain after position 30.^[20] The result is an insulin with a modified isoelectric point that precipitates upon administration to subcutaneous tissue. This insulin formulation is peakless and has a duration of action of approximately 24 hours. Hence, a single nightly dose results in an insulin release profile that does not induce overnight hypoglycemia (no insulin peak), counteracts waking hyperglycemia (no loss of action over 12 hours), and approximates the flat healthy-patient

insulin release profile. The use of insulin glargine improves overall glycemic control (as measured by HbA_{1c}) and fasting glucose levels, while reducing the frequency of hypoglycemic episodes experienced by patients.^[20] Two drawbacks are associated with insulin glargine use. First, it cannot be mixed with shorter-acting insulins due to its isoelectric point, resulting in an increase in the number of daily injections.^[20,21] Second, the amount of rapid-acting insulin required at mealtime may be increased.^[20]

INDUSTRIAL CONTRIBUTIONS TO INSULIN DELIVERY

It is estimated that 6% of the United States population suffers from diabetes, and treating this disease requires a collection of products provided by the corporate sector. While it is infeasible to provide a comprehensive review of the industrial contributions to glucose management and insulin delivery, representative corporate contributions are summarized here. In the context of diabetes care, the necessary components include a glucose sensor and an insulin delivery device. For diabetic patients to properly estimate their insulin needs, a measurement of glucose is required. In the current state of clinical practice, this has meant a (finger-)prick to obtain a drop or two of blood, which is analyzed by a glucose-sensing strip.^[22] Strip technology typically relies on an enzymatically catalyzed reaction of glucose plus oxygen converting to gluconic acid and hydrogen peroxide in the presence of glucose oxidase.^[23] More advanced glucose-sensing technologies take advantage of glucose transport through the skin (in reverse iontophoresis^[24]) or subcutaneous glucose sensors (such as the continuous glucose monitoring system^[25]). These automated systems aim to reduce patient discomfort in glucose measurement (versus the finger-prick) while providing significantly more information regarding glucose dynamics during treatment. Where as transcutaneous measurements are taken four to six times daily, these automated devices record glucose concentrations as rapidly as every 10 minutes. Furthermore, measurements are continued during the nighttime hours, such that dangerous overnight hypoglycemia can be diagnosed and treated.

The ability to deliver insulin keeps a diabetic patient alive. Since its discovery, insulin has been delivered via syringe in a variety of preparations;^[26,27] those preparations currently employed for diabetes treatment have already been detailed. For subcutaneous delivery via injection, the needle gauge (diameter) contributes to the level of discomfort and healing time for an injection. There is a continual push for smaller needles, in terms of both width (pain) and length (stability of the needle), as well as prefilled delivery systems (such

as the insulin pen), as patient comfort and convenience are as important here as in glucose sensing.^[28] As an alternative to injection therapy, insulin pumps can be employed.^[5] Continuous infusion pumps are either implanted or worn externally, with the latter having a transcutaneous line for subcutaneous delivery.^[29] These pumps may also be primed to deliver a pulse or profile of insulin when commanded by the patient. In this way, it is possible for extracorporeal pump users to forgo the insulin injection normally taken with a meal in favor of additional insulin delivery from the pump. Ideally, the continuous pump system could be integrated with the glucose sensor in such a way that insulin delivery would automatically be adjusted to the glucose dynamics observed in the patient. This is a mechanical replacement for the natural pancreas, known as the artificial pancreas. A closer look at this insulin replacement technique concludes this article.

NOVEL INSULIN DELIVERY APPROACHES

Physiological Insulin Replacement

A key reason for the development of fast-acting and long-acting insulins, as well as the evaluation of various delivery routes, was the number of issues associated with tissue-based insulin replacement.^[30–32] First among these is the need for transplanted or implanted tissue to be histocompatible with the recipient. Histoincompatible tissue is attacked by the recipient's immune system unless immunosuppression is employed; while beneficial in controlling blood glucose, this approach compromises the immune system of the patient, so it is rarely employed unless the pancreas is cotransplanted with another organ (such as the kidney).^[33] Allogeneic grafts of β -cells have proven successful in the absence of immunosuppression,^[34] although this approach uses a genetically modified cell line that requires long-term antibiotic treatment to keep the growth of the grafted islets under control. Given the difficulties encountered when employing the above approaches, the bulk of research on tissue-oriented insulin delivery has focused on the implantation of either islets of Langerhans or just the insulin-producing β -cells in a manner that partitions foreign tissue from that of the host.

Microencapsulation using a cross-linked polymer gel is one approach proposed for the development of a bioartificial pancreas. These gels may contain islets^[35] or cells that will mature into islets.^[36] The success of this style of approach is dependent upon a collection of factors.^[37] The cells within the gel must remain viable; sufficient oxygen and nutrients must reach the islets to maintain cellular function. Furthermore, the cells must be able to sense their extracellular environment, and

that environment must be representative of the physiological state. Hence, glucose transport rates through the gel must be fast enough that the encapsulated islets can respond to the fluctuations in physiological glucose levels. The diffusion characteristics of the gel must allow insulin produced by the islets to escape into the surrounding tissue and hence the circulation. Finally, the gel coating must protect the encapsulated cells from the immune system of the host. For islet microencapsulation, Weir and coworkers used a high-mannuronic acid alginate cross-linked with BaCl_2 .^[35,36] This membrane provided superior performance in islet protection, and hence glucose control, through its durable mechanical properties and nonreactivity with the host immune system.

Another islet-protection approach is macroencapsulation. This approach uses larger capsules (millimeter size and larger) to hold islets rather than coating small numbers of islets as in microencapsulation. This makes the implanted device(s) easier to remove or to reload with islets. The diffusion limitations of these larger systems are more severe than in microcapsules,^[31] leading to a potential trade-off between islet viability and immunoblocking capability. This drawback can be overcome, to a certain degree, by reducing the size of the macrocapsule.^[38] Given the diffusion characteristics, the physiological location of the implant will play a more dominant role. For devices with reduced diffusion rate, increased vascularization and blood flow is necessary for both device performance and cell survival. Hollow fiber macrocapsules containing islets were implanted in the intraperitoneal cavity of diabetic mice.^[39] Blood glucose was returned to normal, the islets remained viable, and insulin release from the macrocapsule had the characteristic biphasic profile in response to a glucose challenge.

Polymeric Delivery Systems

Polymeric delivery systems have been extensively examined for the purposes of providing long-term reproducible insulin delivery to diabetic patients.^[40] Polymer gels that respond to pH changes are made glucose-sensitive through immobilization of glucose oxidase to the polymer network. In the presence of this enzyme, glucose reacts with oxygen to produce gluconic acid and hydrogen peroxide. The gluconic acid produced alters the pH of the device microenvironment. The pH change leads to an increase in membrane porosity and release of insulin from the polymer device. Obviously, insulin induces physiological glucose removal, causing a decrease in the blood glucose concentration, and a slowing of the aforementioned glucose reaction within and around the gel. This leads to a decrease in porosity and a decrease in insulin release.

In this way, the membrane is a combined glucose sensor and feedback control system, sensing the glucose concentration and adjusting membrane porosity to yield an appropriate insulin flux.

Reservoir systems represent another formulation of implantable insulin delivery devices. As described previously, an environmentally sensitive polymer membrane separates the bloodstream from an insulin reservoir. Horbett and coauthors performed experimental^[41,42] studies on potential membranes for these systems, demonstrating insulin release in the physiological glucose range (50–400 mg/dl glucose) across macroporous and pressurized homogeneous polymer membranes. A theoretical study^[43] examined the oxygen limitations to glucose sensitivity in membrane devices. An alternate reservoir device design was presented by Siegel and Firestone.^[44] A pH-sensitive polymer membrane would respond to glucose in the bloodstream through the same glucose-to-gluconic acid reaction. The expansion of the membrane in response to high glucose concentrations would exert pressure on an intermediate fluid, thereby forcing insulin release through an orifice opposite the “sensor” membrane. Decreased glucose concentrations would induce a deswelling of the polymer membrane and a corresponding cessation of insulin release. Although the study examined direct pH effects (rather than glucose-imparted pH changes), the swelling and deswelling behavior was shown to be repeatable, such that periodic insulin release in response to meal consumption was feasible.

Intelligent (“smart”) polymer systems provide an alternate approach to the pump or reservoir systems. These devices represent an “all-in-one” philosophy, where the environmentally sensitive polymer would also contain insulin, thereby acting as a unified sensor, controller, and reservoir. Goldraich and Kost^[45] examined cross-linked polymethacrylate polymer disks for insulin delivery. Although these systems responded to glucose, the response was not entirely within the physiological range, and insulin had difficulty escaping the polymer disks. Peppas and coauthors^[46,47] utilized different monomers to construct cross-linked disks and microparticles for glucose-induced insulin delivery. Insulin was introduced to these devices through imbibition, and catalase was incorporated to improve oxygen permeability and eliminate hydrogen peroxide. Response to glucose was at low concentrations, but insulin release was significantly greater than in the earlier disk system.

The Artificial Pancreas

Insulin delivery, as it is currently practiced, requires direct patient interaction in the roles of sensor (taking

glucose measurements), controller (determining the proper insulin dose to deliver), and actuator (delivering the insulin). Hence, the quality-of-disease treatment is directly impacted by patient decisions including the timing and rate of glucose measurement and insulin injections, and these decisions may include quality-of-life concerns such as pain, risk assessment, convenience, and others. Automated insulin delivery could lead to significant improvements in glucose control (reduced HbA_{1c}, fewer hypoglycemic episodes, etc.) by removing the patient from the control loop. A schematic of this approach is shown in Fig. 1. One formulation of a device of this type would be implantable and would include a glucose sensor, a dosage adjustment algorithm (controller), and a variable-rate insulin pump with reservoir. Alternatively, the hardware could be an external device with subcutaneous glucose sensing and insulin delivery. In either case, the pump mechanism is currently available, and the sensor is a current topic of intense academic and industrial interest.^[48,49] Key to the success of the artificial pancreas is the performance of the control algorithm that converts a glucose measurement into a safe and effective insulin pump delivery rate.

Mathematical models of the patient can be employed in the development of algorithms for glucose control. This yields a model-based approach to controller design, and model-based control is the current state of the art. However, it is important to note that the performance of a model-based controller is directly related to the quality of the model, such that model quality limits theoretically achievable controller performance.^[50] As a result, there is a significant focus on the control-relevance of models for drug delivery.^[51] The objective is to employ a mathematical model of minimum complexity to represent the behaviors of the system of interest, such as the diabetic patient, as accurately as possible.

Modeling has been a focus of glucose-insulin interaction analysis since the 1960s. A variety of models for

Fig. 1 Schematic of an automated closed-loop insulin delivery system. A glucose sensor collects a measurement of patient glucose concentration, which is sent to a control algorithm. This controller transmits a desired insulin delivery rate to the insulin pump, which delivers the corresponding amount of insulin to the patient.

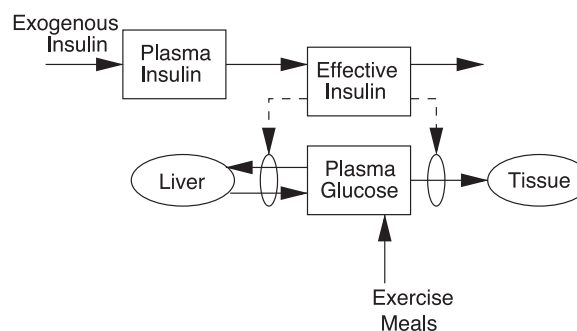

Fig. 2 Schematic representation of Bergman's minimal model.

representing the human glucose-insulin system have been suggested, ranging from the very simple and aphysiological (two linear differential equations^[60]) to the physiologically motivated and complex (tens of coupled nonlinear differential equations). Schematic representations of two control-relevant models are shown in Figs. 2 and 3. Figure 2 depicts the Bergman minimal model,^[52] which was designed to capture glucose and insulin dynamics using a minimum number of equations (three) and only six parameters that need to be fit from data. This empirical model is adequate for representing composite behavior under certain conditions, but it offers little insight into physiological mechanisms that impact insulin delivery needs. Figure 3 shows a physiologically motivated compartmental model representing the pharmacokinetics and pharmacodynamics of glucose, insulin, and glucagon (a counterregulatory hormone).^[53,54] While physiological models are far more time-consuming to construct, specific metabolic effects are easily incorporated within the model structure, as each differential equation corresponds to a physiologically measurable quantity.

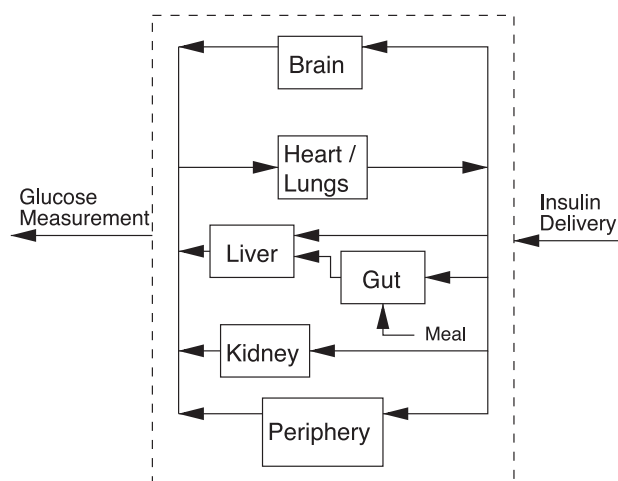

Fig. 3 Schematic representation of a physiologically based pharmacokinetic/pharmacodynamic model.

Furthermore, a controller designed for a patient using a relevant physiologically motivated model would have better performance than one designed for the same patient using the minimal model.

$$\min_{\Delta U(k|k)} \{ \|\Gamma_y(R(k+1|k) - Y(k+1|k))\|_2^2 + \|\Gamma_u \Delta U(k|k)\|_2^2 \} \quad (1)$$

Model predictive control is a model-based control algorithm that has been successfully applied to biomedical problems, such as diabetes,^[55] blood pressure control,^[56] and depth of anesthesia.^[57] As measurements are collected, the model predictive control algorithm solves the preceding optimization problem online. The first term penalizes for deviations of model-based glucose predictions (Y) from the desired glucose reference (R), and the second term penalizes insulin delivery adjustments (measurement noise effects). The relative importance of glucose control performance and pump wear can be adjusted by changing the weighting matrices, Γ_y and Γ_u , respectively. This routine is employed in a “receding horizon” strategy, where the insulin delivery rate is adjusted each time a glucose measurement is taken. The model accuracy determines the quality of the glucose predictions (Y) based on past insulin delivery rate information, and therefore model quality explicitly impacts the controller performance. This algorithm was employed with a linear version of the model shown in Fig. 3 to counteract a 50 g glucose challenge initiated at time $t = 50$ min by delivering insulin intravenously. The results are plotted in Fig. 4. Significant improvements in glucose control are possible by employing this insulin delivery algorithm, including a reduction in meal-induced hyperglycemia and a more rapid return to normoglycemia. The appearance of a hypoglycemic excursion (around $t = 230$ min) is a function of a modest overdelivery of insulin because of the aggressively tuned controller. The magnitude of this episode is dependent on the quality of the model and may increase as the model is less representative of the patient, but the degree of hypoglycemia can be systematically altered by adjusting the controller tuning parameters.

The objective in Eq. 1 is commonly employed in engineering problems and penalizes equally for deviations of glucose above or below the reference. From a medical perspective, however, these deviations are of unequal importance. Hypoglycemia is immediately dangerous, while hyperglycemia is generally associated with the long-term complications of diabetes. Hence, it is more clinically relevant to penalize deviations below the glucose target more heavily than hyperglycemic excursions. Furthermore, the dynamics of insulin action previously discussed are not instantaneous. Many medical metrics of glycemic control relate to glucose concentrations at a point time-distant to meal

Fig. 4 A comparison of closed-loop glucose control with variable-rate insulin delivery (solid) versus basal insulin delivery (dashed). The 50 g glucose challenge took place at time $t = 50$ min, and insulin delivery was to the intravenous space.

consumption (2 hours after, for example). Finally, glucose control objectives are generally prioritized. An ordered example set might include 1) avoid overt hypoglycemia; 2) keep glucose below an upper threshold; and 3) maintain glucose as near to a reference value as possible. The types of objectives discussed here force a reformulation of the original control problem and employ more complicated optimization methods to solve.^[58,59] The use of a more clinically relevant formulation requires a more powerful computer for online solution, but the more powerful control algorithm can reduce the incidence of hypoglycemia without sacrificing meal compensation performance.^[58]

Integrins

David G. Simpson

Department of Anatomy and Neurobiology, Virginia Commonwealth University,
Richmond, Virginia, U.S.A.

INTRODUCTION

The integrins are a family of extracellular matrix (ECM) receptors that bind to a broad variety of ligands. The prototypic binding event mediated by these receptors establishes a continuum that physically anchors the extracellular environment to the intracellular environment. These binding events allow a cell to detect and respond to specific extracellular constituents, essentially allowing the cell to “evaluate” the composition of the surrounding microenvironment. The molecular architecture of any one integrin provides at least two potential routes for the transduction of information across the plasma membrane. First, integrin ligation to a target molecule establishes a physical continuum that mediates the propagation of mechanical perturbations across the plasma membrane. Second, the accessory signal proteins that accumulate in association with the cytoplasmic domains of the integrins provide a site for the initiation of intracellular signal cascades. Classically, signal transduction is considered as a response of a cell to events that originate in the extracellular environment. However, mechanical and biochemical signals that originate within the intracellular space can be transduced by the integrins into events that impact the local microenvironment that surrounds the cell. The identity and profile of integrins present on the cell surface may be modulated in response to developmental events and in the progression of pathophysiological disease states. A shift in integrin identity under these conditions may be a reflection of an adaptive process that allows cells to detect and respond to new environmental conditions.

OVERVIEW OF INTEGRIN STRUCTURE/FUNCTION

The functional integrin receptor is a bidirectional signaling complex that is composed of two transmembrane subunits, an *alpha* (α) and a *beta* (β) chain.^[1,2] The α (120–180 kDa in mass) and β (90–110 kDa) chains are transcribed from separate gene sequences and delivered to the cell surface as an intact heterodimeric receptor. Approximately 18 different α chains and eight distinct β chains exist, forming at least

26 separate, and functional, receptors.^[1] Not all of these receptor isotypes exist in humans. Numerous splice variants exist, further increasing the molecular and structural variability that can be observed in the functional receptor.^[3] Alternative splicing events can occur as a function of tissue type,^[4] the state of tissue differentiation, and in parallel with the onset and progression of disease. The full significance of alternative splicing events remains to be determined; however, in embryonic stem cells, a shift from the β_{1A} to the β_{1D} variant is associated with changes in adhesion, migratory activity, and the state of differentiation.^[5] Specific splice variants also have been correlated with the degree of malignancy in some tumors.^[6] Post-translational modifications, in the guise of tyrosine phosphorylation to the cytoplasmic tail of the β chain, also exist and serve to modulate integrin function during platelet aggregation.^[7]

Integrin Fine Structure

The α and β chains of the integrin receptor each exhibit an intracellular, a transmembrane, and an extracellular domain (Fig. 1). The intracellular domains of the prototypic integrin project a short distance into the cytosol, usually less than 50 amino acids. In the cytoplasmic space, the terminal domains of the β chain are indirectly anchored to elements of the cytoskeleton through interactions mediated by a multimolecular complex of accessory proteins. These domains play a central role in the assembly of the heterodimeric receptor complex.^[8] The transmembrane domains of each integrin chain exhibit a helical structure and pass through the lipid bilayer, anchoring the receptor within the plasma membrane. These domains, in concert with the cytoplasmic domains, function in the clustering and assembly of integrins into the mature cell–matrix adhesion structure called the focal adhesion.^[9,10]

The α and β chains both project from the cell surface and into the extracellular space in one of three, gross conformational configurations.^[11–13] These extracellular domains can be further subdivided into a series of subdomains. Analysis of the crystal structure of the $\alpha_V\beta_3$ integrin^[14] reveals a proximal β tail domain located immediately adjacent to the plasma membrane,

Fig. 1 Integrin structure. The prototypic integrins exist in one of three gross conformational states. This figure depicts each of the three states: (I). folded, closed state; (II) folded, open state; and (III) extended, open state. Talin plays a central role in promoting integrin activation and the transition to high-affinity binding. In the masked state, talin is sequestered from binding to integrins. With unmasking, talin binds to the integrin and promotes activation. Integrin sub domains and an inventory of structural and cell-signaling molecules associated with this receptor are provided in the final panel of the illustration.

where the subunit emerges from the lipid bilayer. This domain is followed by a series of epidermal growth factor (EGF) repeats, a plexin semaphorin integrin (PSI) domain, a hybrid domain, and a distal β A domain. In the α chain, there is a proximal calf domain, a thigh domain, a β propeller, and a distal α A-domain (summarized in Fig. 1). The α and β chains of the functional receptor are typically depicted as a pair of elongated stalks projecting into the extracellular environment. However, the entire receptor can fold into a compact shape that brings the distal ligand-binding domain into close proximity with the plasma membrane. Folding occurs in the transition between the EGF/PSI domains of the β chain, and between the calf/thigh domains of the α chain. The domains subject to folding have been referred to as the knee of the receptor.^[11] There is evidence that the folded conformation functions to limit ligand accessibility; disruption of the folded conformation with antibodies extends the receptor and promotes ligand recognition/binding.^[15]

The head of the prototypic receptor is formed by the distal β A domain of the β chain and the α A-domain of the α chain. These structural features combine to form a cleft that functions as the ligand-binding site. The identity of the α and β chains present in the receptor dictate the conformation of this domain, and serve to define the range of binding interactions that can be mediated by the receptor. Specific amino acid sequences within each head domain and a metal ion-dependent adhesion site (MIDAS) further modulate

the structure and function of the ligand-binding site.^[11] Given the wide variety of potential sites where integrin structure can be modulated, it is not surprising that ligand-binding events are subject to a complex pattern of regulation.

Regulation of Integrin–Ligand Binding

It is useful to conceptualize integrin–ligand binding events as a lock and key interaction. However, this simplified model understates the true complexity of the events that control ligand binding. Integrins may exhibit unique, redundant, and overlapping binding activity to different ECM substrates. For example, $\alpha_7\beta_1$ integrin binds to laminin; both $\alpha_1\beta_1$ and $\alpha_2\beta_1$ integrin bind to collagen and laminin; the $\alpha_5\beta_1$ and $\alpha_v\beta_1$ bind fibronectin and not collagen or laminin, and the $\alpha_3\beta_1$ binds to collagen, laminin, and fibronectin.^[1] Binding affinities, a reflection of binding strength, can be described for each of these interactions and are unique to each integrin–ligand binding partner.

Intrinsic Factors that Regulate Integrin-Binding Events

Identity of the α and β chains

Integrin specificity and ligand binding are regulated, first and foremost by the identity of the α and β chains

that are present within the receptor.^[1,3,16] The primary sequence and tertiary architecture of the α and β subunits serve to define the range of structural and conformational features that are available to the distal β A and α A domains of the receptor. The α A domain encodes the bulk of the information necessary to determine ligand specificity (Table 1). Integrin–ligand binding events, once established, are stabilized by electrostatic (ionic) and hydrophobicity-based interactions.^[11] The molecular, crystallographic, and

functional evidence describing the ligand-binding event compliment one another to a high degree.

Activation state of the integrin receptor

The prototypic integrin complex exists in a low-affinity and a high-affinity state. The actual ligand-binding event is initiated within the intracellular space when talin, a cytoskeletal protein, becomes physically

Table 1 Integrin ligands

Integrin <i>beta</i> chain	Integrin <i>alpha</i> chain	Classical ECM binding partners
<i>Beta</i> ₁		
β_1	α_1	Collagen, ^c laminin
β_1	α_2	Collagen, ^c laminin
β_1	α_3	Laminin, collagen, and fibronectin
β_1	α_4	Lymphocyte trafficking, VCAM-1
β_1	α_5	RGD, classic fibronectin receptor
β_1	α_6	Laminin
β_1	α_7	Laminin
β_1	α_8	RGD peptide
β_1	α_9	Tenascin, non-RGD-dependent binding to fibronectin ^b
β_1	α_{10}	Collagen
β_1	α_{11}	Collagen
<i>Beta</i> ₂		
β_2	α_L	Leukocyte-specific receptor
β_2	α_M	Leukocyte-specific receptor
β_2	α_X	Leukocyte-specific receptor
β_2	α_D	Leukocyte-specific receptor
<i>Beta</i> ₃		
β_3	α_{II_b}	RGD peptide, highly promiscuous ^a
<i>Beta</i> ₄		
β_4	α_4	Plaque proteins, plectin, and others ^c
β_4	α_6	Laminin
<i>Beta</i> ₇		
β_7	α_E	Leukocyte-specific receptor
β_7	α_4	Lymphocyte trafficking, VCAM-1
Other		
$\beta_1, \beta_3, \beta_5, \beta_6, \beta_8$	α_V^d	RGD peptide

^aRGD-dependent binding interactions are often promiscuous in nature. This target sequence is a common motif in many ECM structural proteins. The $\alpha_{II_b}\beta_3$ binds to fibrinogen, vWf, fibronectin, and vitronectin.

^bThe α_9 has several unusual binding/functional properties. In myogenic lines, the binding of ADAM12, a disintegrin metalloproteinase, to the $\alpha_9\beta_1$ integrin mediates cell-to-cell adhesion, leading to the onset of myogenic fusion and differentiation. (From Ref. [17].)

^cConcentrated in hemidesmosomes of epithelial tissue, the β_4 exhibits specialized cytoplasmic domains for docking proteins and cytoskeletal elements of the intermediate filament network.

^dInitial characterization of integrins composed of the α_V integrin subunit suggested the expression of this subunit was an in vitro artifact. Subsequent accumulation of data demonstrates that this subunit, in combination with the listed β chains, forms physiologically relevant receptors. For example, $\alpha_V\beta_1$ plays a role in myofibroblast differentiation, a process selectively associated with fibrotic encapsulation of implanted materials. (From Ref. [18].)

^eCollagen represents the classical ligand for this receptor; extensive and redundant binding activity with laminin is observed.

associated with the cytoplasmic tail of the β chain.^[19,20] This event initiates a transition from the low to the high-affinity ligand-binding state. This transition, commonly referred to as integrin activation, is correlated with unfolding at the knee, conformational deployment of the stalks, and the extension of the receptor away from the plasma membrane.^[15] Determining how talin induces these rather dramatic changes in conformation remains the subject of intense interest. Integrin activation primes the receptor to recognize extracellular ligands and precedes the high-affinity ligand-binding event. Signals that originate in the extracellular space may serve to initiate and/or facilitate the activation process, providing an alternative path leading to high-affinity binding. The integrin-binding site on talin appears to be masked when the integrin is in the low-affinity state. Partial digestion of talin with calpain *in vitro* unmasks the integrin-binding site and promotes talin–integrin interactions.^[21] Talin-mediated activation may or may not represent a generic control checkpoint for all integrins. The physiological signals that regulate talin–integrin interactions remain to be fully defined.

The observation that integrins can bind to extracellular ligands in the low-affinity conformation complicates any discussion describing the molecular events leading to ligand recognition and binding. A comprehensive working model to rectify this complication with existing models of talin-initiated activation of the receptor complex has not been developed. From a functional standpoint, binding in the low-affinity state may underlie events where low-avidity (i.e., “low strength”) adhesion is necessary, for example, in cell migration.^[22,23] In cells undergoing active translocation across a surface, a subset of integrins exists in the low-affinity state. As an increasing proportion of these receptors undergo the transition to the high-affinity state, there is a cessation of motility and the formation of stable cell–substrate contacts. Leukocytes are attached with low affinity and continuously roll along the endothelium without sticking, in an integrin-dependent fashion. Upon activation, in response to chemokine proadhesive signals, this cell type will selectively arrest and undergo firm attachment to the underlying endothelium.^[24]

Closed and open state considerations

Local changes in the conformation of the binding pocket can also modulate integrin ligation. The α A domain exists in two distinct structural states,^[25] a closed and an open conformation. High-affinity ligand binding is correlated with the open state configuration.^[26] Experimentally locking this domain into the open configuration (a process that may be equivalent

to the integrin activation in response to an extracellular event) in lymphocytes is sufficient to initiate the transition from rolling adhesion to firm attachment.^[27] The exact relationships between integrin activation in response to talin, global changes associated with unfolding at the knees, and the conformational rearrangements that can occur in the ligand-binding pocket, all remain active areas of research.

In summary, structural studies suggest that the integrin receptor exists in three distinct conformational states.^[12,13] In turn, these different conformational states appear to correspond to three distinct ligand-binding states. These conformational states include:

- A folded conformation at the knees in which the distal head domains of the ligand-binding site are adjacent to the plasma membrane. The distal ligand-binding pocket exists in a closed state. This conformation correlates with low-affinity binding.
- An extended unfolded conformation associated with talin-initiated activation with the distal ligand-binding site in a closed state. This represents an intermediate conformation; the binding properties are unclear and may be expected to be intermediate between the fully bent state and fully extended conformation in the open state.
- The extended unfolded conformation with the distal ligand-binding site in the open state. This conformation represents the state associated with high-affinity ligand-binding activity.

Extrinsic Factors that Regulate Integrin-Binding Events

Aspartic acid- and glutamic acid-based target sequences

If integrins represent the receptacle in the lock and key analogy of ligand binding, a key to specificity may be envisioned in the composition, primary sequence, and tertiary structure of the target molecules. Aspartic acid- or glutamic acid-based residues located within flexible loops that project from the surface of ECM target molecules are features common to many integrin ligands. The majority of integrins recognize aspartic acid-based structures; these include the amino acid sequence arginyl–glycyl–aspartic acid (RGD) and closely related tripeptides.^[16,28] A small number of integrins bind to glutamic acid-based sequences through events mediated by the α A domain of the integrin α chain. Considering the narrow range of peptide sequences that function as substrates for the integrins, the degree of specificity that members of this class of receptors actually exhibit for target

ligands is surprising. The native ECM is composed of a very complex mixture of materials, yet cells selectively bind and interact with specific constituents of this network.

Ligand accessibility

The molecular identity of a target ligand defines a surface topology; amino acid sequences surrounding the aspartic acid- and glutamic acid-based target sequences dictate the availability of these substrates for binding. The role of these flanking sequences in the presentation of the integrin-binding peptides should not be underestimated. It is only when the contribution of these ancillary characteristics are taken into consideration that it is possible to use just two, three-peptide sequences to accommodate in a specific manner the bulk of all integrin-binding events. These flanking sequences present the tripeptide target sequences to the external environment, in a topology that can be recognized and undergo integrin ligation.

Synergy sites

In addition to the role that flanking sequences play in regulating integrin–ligand binding events, sites that are more distal to the target peptide sequence also have been implicated in the modulating the binding event. Synergy sites within fibronectin act to modify the affinity of the $\alpha_5\beta_1$ integrin to the target RGD site of this glycoprotein in a strain-dependent fashion. In the unstrained state, the synergy site resides approximately 32 Å away from the RGD tripeptide integrin-binding site.^[29] Mechanical perturbations that separate the spatial distance between the RGD sequence and the synergy site reduce the binding affinity of the $\alpha_5\beta_1$ integrin for the target sequence. In effect, the synergy site functions as a mechanosensory switch.^[30] There is also precedence for the masking of integrin recognition sites in ECM molecules. Proteolytic and/or physical perturbations to the structure of the matrix can uncover these cryptic sites and make them available for binding. For example, partial proteolytic digestion alters the conformation of Type IV collagen and disrupts the $\alpha_1\beta_1$ integrin-binding site and uncovers an $\alpha_v\beta_3$ binding site.^[31] Cryptic sites also have been identified in laminin^[32] and can be expected to be present in a variety of other matrix molecules. In perhaps what might be considered a converse pattern of regulation, actin-based contraction induces changes in fibronectin structure that lead to the fibrilogenesis of this matrix glycoprotein.^[33]

Local cation concentration

Divalent cations can modulate the functional state of integrins that exhibit the αA domain. Under normal circumstances, a single cation occupies the MIDAS site of the central β sheet. The ions Ca^{2+} , Mg^{2+} , and Mn^{2+} all support physiological binding at micromolar concentrations; however, at millimolar concentrations, Ca^{2+} appears to inhibit ligand binding.^[16]

The activation of synergy sites and/or the unmasking of cryptic sites can be expected to modulate the identity, density, and/or avidity of integrin-binding events. In turn, these changes may lead to increased and/or decreased migratory activity, altered rates of proliferation, and/or specific changes in gene expression and protein content. These integrin-mediated events may effectively limit the range of materials that can be effectively used in some tissue-engineering applications. Conversely, with the proper fabrication strategies, it may be possible to exploit integrin-mediated events to selectively induce cell migration, regulate cell distribution, and/or modulate cell phenotype (differentiation).

Postadhesion Events

Once ligand recognition and binding occurs, integrin–matrix interactions appear to exist along a continuum of structures, ranging from the focal complex or focal contact to the focal adhesion. The use of a continuum to describe these structures, rather than referring to specific classes of structures, is exploited in this discussion to emphasize the dynamic nature of the adhesion event. The focal complex (contact) exists at one end of the adhesion continuum.^[34] The architecture of this type of adhesion is relatively “rudimentary” in nature and appears to represent the minimal valiancy of an integrin–ligand binding event. High-resolution microscopic mapping of focal complexes in living cells suggests that these structures represent a cluster of three to four integrins.^[35] A binding event mediated by a single cluster of integrins may not represent a site of firm attachment to the surrounding environment. However, when taken in an aggregate as a population of binding events scattered over the entire surface of the plasma membrane, even this type of structure can serve to anchor a cell in place. A single embryonic fibroblast has an estimated $3\text{--}7 \times 10^5$ integrins on the cell surface.^[36] The aggregate number of adhesive events within any given organ system is staggering when the total number of integrins on each individual cell are considered and the total number of cells are tallied. These cell–matrix interactions may have profound effects on the degree of resting tension that is present within the ECM.

The focal adhesion exists at the other end of the adhesion continuum. Focal contacts can “mature” through the sequential recruitment of other structural and cytoskeletal proteins, to form more elaborate, stable, and long lasting focal adhesions.^[37] Most of the ensuing discussion describes cell–matrix adhesions within the context of tissue culture experiments. However, these focal adhesions are not limited to the cultured cell; structures that exhibit homologous molecular identity, architecture, and function exist *in vivo*. Examples include the dense plaques of smooth muscle, the myotendinous junctions of skeletal muscle, the Z-disks of cardiac muscle, and the hemidesmosomes of the epithelium.^[38–41] It should be noted that the molecular identity^[42] and mechanical properties^[43] of any one focal contact or focal adhesion site vary within a cell. This degree of heterogeneity may represent different stages of maturation and/or functional states that exist along the adhesion continuum.

The formation of focal complexes requires an integrin substrate,^[44] and is closely allied with changes in actin polymerization states.^[45] The structural properties of the actin-based cytoskeleton are regulated by the ras homology protein (RHO), a member of the ras superfamily of small guanosine triphosphatases (GTPases). The principal members of this family, ras-related c3 botulinum toxin substrate (RAC), Cdc42, and RHO each occupy a critical site in the signal transduction pathways that modulate distinct architectural aspects of the microfilament network. For example, RAC induces G-actin to undergo polymerization into F-actin in a process associated with the formation of lamellipodia at the cell periphery.^[46] The Cdc42 protein drives actin assembly in the fine filipodial projections that emanate from the leading edge of lamellipodia. The formation of stress fibers^[47] by bundling small-scale actin fibrils into larger order assemblies^[45] is promoted by RHO. The coordinate regulation of these distinctive structures is essential in the promotion of directed cell motility.

Real-time microscopic examination of focal complex assembly reveals that integrins are carried along in the plane of the plasma membrane by underlying actin fibrils that are undergoing polymerization.^[35] The movement of integrins by this process may facilitate initial integrin–ligand interactions and the subsequent formation of the focal complex, the “smallest unit” of adhesion. Prior to incorporation into a focal complex, clusters of integrins appear to be freely diffusible in the lipid bilayer. The integrins in this freely diffusible compartment are presumably in an unactivated, low-affinity, closed state. Once activation and a nucleation process have been initiated, the integrins localized to a nascent focal complex become substantially less mobile in the plasma membrane.

The molecular events that mark the transformation of the focal complex into a more elaborate adhesion site are ill defined. However, under baseline conditions, nominally RHO-dependent events are necessary to induce this transformation in most cell types.^[48] Unlike the actin polymerization-dependent assembly of focal complexes, the assembly of actin stress fibers does not directly induce the formation of focal adhesions.^[49] Rather, it is the mechanical signals associated with the contractile forces generated by these fibrils that promote the clustering and concentration of integrins into specific domains on the plasma membrane. Strain applied across the plasma membrane is sufficient to drive these processes, even when endogenous contractile events are experimentally suppressed.^[50] Nonspecialized domains of the plasma membrane may exhibit 50–400 integrins/ μm^2 ; by comparison, the fully elaborated focal adhesion may have 700–1200 integrins/ μm^2 .^[35]

As noted, the cytoplasmic and transmembrane domains of the receptor complex facilitate the accumulation and clustering of integrins into higher order adhesion sites.^[9,10] In parallel with this clustering process, a multimolecular complex of accessory structural and intracellular signaling proteins accumulate in association with the cytoplasmic domain of the β chains. Elegant studies using live cell imaging have been used to map the accumulation of these accessory proteins in space and time.^[35,37,43,51]

It is unclear as to how the mechanical perturbations are coupled to the processes that regulate the assembly of focal adhesions. The RAC and RHO-induced changes in the organization of the actin-based cytoskeleton can occur independently of any detectable change in the organization of adhesion sites. This observation argues that RAC and RHO are proximal to the signals that ultimately couple actin dynamics to the assembly of adhesion sites.^[45] There is evidence that microtubules “fine tune” the assembly process. Physical perturbations to the cytoplasmic compartment induce global changes in microtubule dynamics, and the disruption of this cytoskeletal network suppresses RAC and RHO deployment in response to mechanical signals.^[52] Perhaps more importantly, the regional assembly of microtubules modulates the degree of strain present within specific domains of the cell;^[53] providing a potential mechanism for the regulation of adhesion site assembly and structure, through subcellular or local changes in the viscoelasticity of the cytosol. A local increase in the stiffness of the cytosol, induced by microtubule assembly, can be expected to increase the amount of contractile force necessary to initiate changes in integrin distribution and the assembly of focal adhesions. Consistent with this model, the pharmacologic disruption of microtubules leads to an increase in the surface area of

existing focal adhesions.^[54] Conversely, when drug induced microtubule depolymerization is reversed during washout experiments, the focal adhesions' surface area is reduced in parallel with the assembly of the recovering microtubules.^[55] These are intriguing results and demonstrate the fundamental role that mechanical forces play in regulating internal cytoarchitecture.^[40,41,56–59]

The intimate correlation between changes in actin organization and the onset of integrin mediated-adhesion indicates that cytoskeletal links are present at the earliest stages of the adhesion event. These nascent interconnections serve to “prime” the processes that promote the subsequent elaboration of focal complexes into focal adhesions. Molecular modeling predicts that RAC, RHO, actin polymerization states, and focal complex assembly/maturation, all function within an elaborate feedback loop that self-regulates the assembly process.^[60] In aggregate, the dispersed focal contacts appear to function as a population of receptors for mechanical perturbations. When a mechanical perturbation exceeds some threshold of force, the assembly process is favored and tipped toward the formation of stable focal adhesions. The mechanical regulation of integrin clustering and the assembly of focal adhesions allow the cell to adapt and respond to mechanical events that originate in the external microenvironment. Simultaneously, this regulatory program allows the cell to selectively transmit contractile forces to the surrounding environment. A relevant example of this type of regulatory pattern is observed in endothelial cells subjected to shear forces. Changes in shear directly modulate the elaboration of focal adhesion structure,^[60] and insure the elaboration of formation of adhesions sufficient to firmly anchor these cells to the underlying basement membrane in a challenging hemodynamic environment.

The subtle balance of internally and externally derived forces that modulate integrin-mediated adhesion, intracellular signaling, and cell phenotype in native tissues is difficult to recapitulate within a tissue-engineering scaffold. This is one reason that many design criteria for this type of engineered material include specifications that allow for the biodegradation and replacement of implanted materials with endogenous ECM materials.^[61,62]

Integrin Deadhesion

An aspect of integrin binding that is often underappreciated is a consideration of how an established integrin–ligand binding interaction might be terminated. The cyclic regulation of cell adhesion must routinely occur during cell division and active motility, and provides the stationary, adhesive cell the capacity

to become mobile. These transitions also occur during the native wound healing process, and underlie the events that allow a cell to interact with implanted biomaterials and devices. The physiological events that mediate deadhesion are not fully defined, and a comprehensive molecular model to fully account for all of the events that have been correlated with the disruption of integrin-mediated binding is just beginning to emerge. Experimental data suggest that deadhesion is not a simple reversal of the assembly process.

Integrin-mediated binding events may be altered through multiple pathways. Because models of disassembly are drawn from many different cell types (normal vs. transformed vs. genetic knockouts vs. functional knockouts vs. cells from different tissues) and models of adhesion (in vitro migration vs. in vitro static cell adhesion vs. dynamic live vs. non-live-cell imaging) using techniques of varying fidelity, a note of caution is in order. Developing molecular models of deadhesion are further complicated by the observation that the composition of adhesion sites varies as a function of the assembly process (i.e., the degree of maturation along the adhesion continuum). Defining how different intracellular signals interact during integrin deadhesion promises to be an evolving area of research.

Intracellular events in the regulation of deadhesion

Prior to the accumulation of a specific protein entity and/or a critical mass of accessory proteins, the integrity of integrin-dependent adhesion sites is likely to be regulated through a dynamic interaction between RAC- and RHO-sensitive events.^[60] At the focal adhesion end of the adhesive continuum, cell culture experiments have identified several candidate signaling events/proteins that are associated with the loss of adhesion. During the elaboration of focal adhesions, the signal peptide, FAK (focal adhesion kinase), accumulates in association with integrin-positive adhesion sites.^[54] The FAK protein plays a dual role in these structures; first, it functions as a scaffolding protein for the assembly of a signaling complex; second, it functions as a signal peptide. FAK has specific binding activity against a number of accessory proteins that localize to integrins, including talin, paxillin, ezrin, mitogen-activated protein kinase kinase kinase 1, and other target substrates.^[63] Over time, additional accessory proteins including ILK (integrin linked kinase), α -actinin, and vinculin and other cytoskeletal elements accumulate in the multimolecular signaling complex, and FAK begins to undergo phosphorylation on tyrosine residues. Early in the assembly process, the concentration of FAK and the relative amount of FAK phosphorylation increase in parallel with the

accumulation of the other accessory proteins. At some, as of yet to be precisely defined, levels of FAK phosphorylation (and/or other accessory proteins), focal adhesion structure begins to deteriorate.

Relative changes in FAK content at adhesion sites exhibit a high correlation with the assembly/disassembly process. Several observations link the functional state and distribution of FAK, microtubule dynamics, and focal adhesion structure into a coherent model of deadhesion. Cells null in FAK develop extensive focal adhesions and display reduced rates of cell migration.^[64,65] Inducing microtubule assembly in the FAK null cell fails to grossly alter focal adhesion structure.^[55] Introducing functional FAK into this phenotypic background rescues the defect, and leads to the disassembly of focal adhesions and the restoration of migratory activity. Microtubule assembly plays a subtle and critical role in these processes. High-resolution microscopy has revealed that a subset of microtubules terminate within molecular distances of adhesion sites.^[66] These microtubules are associated with dynamin, a GTPase that regulates endocytic events.^[67] In working models, dynamin is delivered to the vicinity of the focal adhesion site by these microtubules, and then, just prior to the onset of deadhesion, dynamin coimmunoprecipitates with FAK.^[55] The adaptor protein, Grb2 (growth factor receptor-binding protein 2), which also functions in endocytic pathways,^[68] also becomes associated with FAK at this critical juncture in the process.^[69]

Subsequent to the interactions of dynamin-FAK-Grb2, cell-surface integrins are observed within an intracellular vesicular compartment.^[35] These internalized receptors may ultimately be delivered to a lysosomal compartment and/or are recycled back to the cell surface. Dynamin participates in concert with Grb2 in the internalization of EGF receptors.^[70] However, the nature of the molecular events that link the formation of the dynamin-FAK-Grb2 complex and the delivery of integrins to the intracellular vesicular compartment remains a black box. Not all integrins are processed to the vesicular compartment during deadhesion. A subset of integrins undergo an increase in mobility and diffuse in the plasma membrane away from adhesion sites.^[35]

In tissue culture, the adhesion sites of actively migrating cells are disrupted by a proteolytic event that severs intracellular links between the integrin complex and the cytoskeleton through a calpain-sensitive pathway.^[23] In this process, integrins remain attached to the substrate as the moving cell translocates forward.^[35,71] Little or no detectable cytoskeletal or associated accessory proteins appear to be associated with the cast off receptors, suggesting that proteolysis occurs very close to the cytoplasmic domains of the integrin complex.^[72] This would seem to be a rather

energetically expensive regulatory strategy, and the physiological significance of this type of proteolytic processing *in vivo* is unknown. There is limited evidence that selective ectodomain shedding of integrins occurs during rapid transitions in growth and onset of pathology in the heart,^[73,74] and in cancer cell metastasis.^[75] In fibroblasts, matrix metalloprotease (MMP) inhibitors stabilize focal adhesion structure, suggesting that proteases may play an active role in integrin ectodomain processing.^[76] Disruption of matrix conformation by MMPs and/or other proteases also undoubtedly plays a role in regulating the deadhesion process within intact tissues by perturbing the structure of existing ECM ligands.^[31] The MMP-1 binds directly to the $\alpha_2\beta_1$ integrin, when keratinocytes migrate on type I collagen.^[77]

There is a constantly growing constellation of signal peptides that interact to regulate cell adhesion events. For example, FAK-related nonkinase (FRNK) is a distinct protein species, composed of the C-terminal domain of FAK. Unlike FAK, FRNK inhibits the assembly of focal adhesions, potentially by competing for FAK-binding sites in the integrin-signaling complex.^[78] In selected tissues, the RHO-related peptides, Rnd (“round”), promote focal adhesion breakdown, the loss of cell-substratum adhesion and cell rounding.^[79] The loss of Src-kinase, a proto-oncogene protein, activity suppresses the activation and localization of calpain to focal adhesion sites, stabilizes FAK against proteolysis, increases focal adhesion area, and suppresses cell motility.^[80,81] The loss of Src theoretically impairs the proteolytic processing and shedding of integrins; the adhesion defects are probably further exacerbated because interactions between Grb2 and FAK are Src dependent.^[82] Blocking RAS, another proto-oncogene protein, impairs focal adhesion breakdown and compromises cell motility.^[83] Consistent with this observation, a high percentage of malignant cancers, which commonly exhibit defects in adhesion-dependent growth, have constitutive RAS activity.

Extracellular events in the regulation of deadhesion

Integrin adhesion also can be inhibited by extracellular events. For example, ADAMs (a disintegrin and metalloprotease)^[84] are a family of transmembrane glycoproteins that function as binding partners for integrins.^[85] The ligation of integrins to an ADAM forms a heterodimeric complex that mediates a cell-to-cell binding event.^[86] Heterotypic binding of integrins and cadherin molecules (cadherins normally mediate cell-to-cell interactions in a homotypic fashion) also have been identified, providing yet another potential (and “unorthodox”) regulatory site for the control of

integrin-binding events.^[87] The formation of heterodimeric complexes can be expected to indirectly alter cell–matrix interactions, intracellular strain patterns, actin dynamics, and intracellular signaling.

From a research perspective, there are peptides that can be used to disrupt integrin-mediated adhesion. The integrin target sequence RGD can be prepared as a cyclic peptide. This synthetic molecule competes for adhesion sites, suppresses integrin clustering, and blocks adhesion. Peptides isolated from the venom of pit vipers, called disintegrins, disrupt and block selected integrin-mediated binding events.^[88] This particular class of antiadhesive agents is a potent inhibitor of platelet aggregation.^[89] Antibodies that selectively block specific integrin subtypes have long been a mainstay of adhesion research. These agents may be designed to inhibit adhesion through blocking specific receptor isotypes or through the targeting of binding moieties present in extracellular ligands. Conversely, antisera can be designed to activate cluster integrins in the extracellular space, and initiate downstream intracellular signal transduction events. Microinjection can be used to deliver antisera to the cytosolic compartment. Various adenoviral^[58] and small siRNAs^[90] also can be used to examine integrin-dependent events. A variety of nonspecific and specific inhibitors directed against intracellular signal peptides also have been developed.

Blocking deadhesion processes does not necessarily interrupt all of the events associated with cell motility. For example, inhibition of RAS pathways suppresses the focal adhesion turnover and the directed cell migration in wound assays of motility, but does not appear to impact the formation of lamellipodia.^[83] This result emphasizes the structural and functional compartmentalization that characterizes actin dynamics (e.g., RAC, RHO, and Cdc42 regulated events) and the continuum of adhesion events. This discussion of integrin-associated regulatory peptides that modulate deadhesion is by no means exhaustive. The specific regulatory events that transpire during deadhesion are likely to vary with the degree of maturation of the adhesion site. Signal transduction events that disrupt integrin-mediated adhesion may occur both in a linear (i.e., unique substrates that must interact in a serial fashion, A to B to C) or parallel pattern of regulation (where events do not have to happen in a specific sequence). Events that are redundant and carried out through alternative pathways most certainly exist within the processes that regulate deadhesion.

Functional Considerations: Integrin-Mediated Signaling

The integrin complex is far more than a simple tether that functions to anchor the cell and provide traction

against the surrounding environment. Integrins represent a site for the active transmission of phenotypic information across the plasma membrane. Classically, cell-signaling events describe processes in which information from the extracellular environment is transmitted into the intracellular space. This process is referred to as “outside-in signaling.” In the context of integrin-based signaling, this type of pathway functions in the detection and transduction of phenotypic information that is stored in the composition and tertiary structure of the ECM.^[91] Integrins also mediate the transmission of information from the intracellular space into the extracellular environment, in a process termed “inside-out signaling.” This provides a pathway for the cell to manipulate physical or chemical characteristics of the local microenvironment.^[1]

Intracellular signal transduction pathways are isolated, synergistic and antagonistic, redundant, and unique. It is possible to map many of the specific signal events initiated by integrins with a high degree of certainty. Intracellular signal transduction pathways may function in a “response”- and/or “tissue”-specific pattern of regulation. A response-specific pattern describes events that occur in the majority of cell types through a common intracellular pathway(s). The potential number of these pathways is multiplied by the observation that intracellular signals may be initiated by the ligation of different integrin receptors (e.g., $\alpha_1\beta_1$ in one cell type and $\alpha_2\beta_1$ in another). Tissue-specific patterns refer to events that occur in a particular cell type, in response to an integrin-generated signal. Because of the enormous variability that response- and tissue-specific events exhibit, it is more productive in this type of monograph to survey some specific signal pathways and examples of the downstream, end effects of integrin-based signaling. Outside the laboratory setting, few intracellular signals occur in a vacuum, a characteristic that is important to recognize in any discussion of this topic.

Outside-in signaling

In the outside-in mode of signaling, the integrin receptor represents an antenna that functions to detect extracellular ligands. Integrin ligation can transmit information to the intracellular space through at least two distinct pathways. First, binding events between an integrin and a target ligand establishes a physical continuum that can be traced from constituents of the ECM, across the plasma membrane at the integrin, through elements of the cytoskeleton and into the nuclear matrix. Physical perturbations propagated across this network can impact nuclear structure, DNA organization, and rates of gene transcription.^[92] The degree of specificity that can be encoded by signals

that are physically propagated to the nucleus is open to question. Integrin ligation and mechanical signals also induce the formation of microcompartments that in turn function to induce the accumulation and concentration of mRNA and ribosomes to the vicinity of focal adhesions,^[93] providing the potential for the site-specific synthesis of proteins.

Integrin ligation can detect, encode, and transduce more specific information through the complex of soluble accessory structural and signaling proteins that accumulate in association with fully elaborated adhesion sites. Many of the intracellular signals induced by the integrins act, in concert, with growth factors to modulate cellular phenotype. At least 20 distinct protein species become associated with the cytoplasmic domains of the integrin receptor. Signals propagated through this multimolecular complex can be divided into five broad categories of downstream events; these include signals that: (I) control cell survival; (II) regulate gene transcription; (III) modulate rates of cell proliferation; (IV) regulate cell motility; and (V) modulate cytoskeletal organization (for an excellent overview, see Ref. [1]). Like nearly all the signaling events, there is considerable overlap in many of these processes.

(I) *Integrin Mediated Control of Cell Survival (i.e., Anchorage-Dependent Survival)*. In many cell types, integrin ligation is associated with the accumulation and activation of ILK. This leads to the signaling through phosphatidylinositol 3 kinase and nuclear factor-kappa B (NF-kappaB), and the phosphorylation of protein kinase B (PKB) and a transcription factor (Akt).^[94] The loss of down stream signals propagated through this particular pathway, and specifically the inhibition of PKB/Akt activity, lead to increased rates of apoptosis in many different cell types, including fibroblasts,^[95] keratinocytes,^[96] endothelial cells^[97] embryonic hippocampal neurons,^[98] and a variety of other normal cell types. The loss of signals through ILK pathways also leads to apoptosis in prostate cancer cells^[99] and other transformed cell types. Conversely, overexpression of ILK results in oncogenic transformation; the potential for using this signal molecule as a therapeutic target in the treatment of cancer has been noted by several researchers.

(II) *Regulation of Gene Transcription*. Several specific examples of genes induced by integrin ligation can be readily cited. For example, ligation of the $\alpha_5\beta_1$, a fibronectin receptor, induces collagenase gene expression through an activating protein 1 and/or polyomavirus enhancer activator 3; a member of the ETS family of transcription factors, c-fos (an oncogenic protein)-dependent pathway(s).^[100] In chondrocytes, $\alpha_5\beta_1$ integrin-specific signals induce the expression of several different proinflammatory cytokines through NF-kappaB.^[101] In NIH 3T3 cells, FAK signals

through c-SRC, Grb2, and Ras to activate the mitogen-activated protein (MAP) kinase and extracellular response kinase 2 (ERK2).^[63] The ERK2, and related family members, phosphorylate cytoplasmic proteins, freely enter the nucleus, and activate targets in the nucleus that regulate gene transcription. Activation of the ERK pathways, a relatively promiscuous signal in nature, modulates the expression of many different gene families associated with proliferation and differentiation.

(III) *Modulation of Cell Proliferation*. The MAP kinase pathways are activated in a nearly ubiquitous pattern in response to integrin ligation. This pathway is activated in response to the autophosphorylation of the transmembrane protein, receptor tyrosine kinase (RTK), a class that includes many growth factor receptors. This event establishes docking sites on the cytoplasmic domains of RTK for Grb2 and son of sevenless protein (homolog of the *Drosophila melanogaster* SOS). In turn, SOS interacts with the Raf-1 (a serine threonine kinase), which phosphorylates MEK1 and MEK2 (also known as mitogen activated protein kinase kinase) leading to phosphorylation of Erk1 and Erk2 (MAP kinase family, extracellular response kinase). The Erk peptides, once activated, can translocate to the nucleus and activate transcription factors that regulate the cell cycle. Integrins potentiate signals through this pathway by increasing RTK autophosphorylation and the efficiency of Raf-1, MEK, and Erk signaling.^[102]

Experiments conducted with NIH 3T3, human embryonic kidney, and umbilical vein endothelial cells indicate that anchorage-dependent regulation of the progression into G1 is mediated by integrin- and growth factor-derived signals through c-Jun N-terminal kinase (JNK).^[103] In this particular regulatory path, FAK initiates events through an Src kinase, P130^{CAS} (Crk-associated substrate), Crk (oncogene protein with homology to Src), and ultimately JNK. In endothelial cells, integrin activation leads to a transient tyrosine phosphorylation of janus kinase 2 (JAK2, a family of cytoplasmic signal molecules) and signal transducer and activator of transcription (STAT5). Subsequent to these events, STAT5 localizes to the nucleus and induces c-fos expression.^[104] It should be noted that c-fos represents a member of the early growth response genes; as such, it is upstream of many of the processes that mediate the onset of cell proliferation.

(IV) *Regulation of Cell Motility*. The interplay that exists between the formation of adhesion sites and rates of cell motility has been discussed to some degree in previous sections (see Ref. [105] for a review of RAC, cdc42, and RHO). A variety of signal molecules that are associated directly and tangentially to RAC and RHO have been characterized. For example, RAC

resides within a complex web of signal events. This peptide can activate p21-activated kinase, which, in turn, targets filamin. Filamin is a multifunctional protein that crosslinks F-actin, a function necessary for the formation of lamellipodial ruffles. The RAC protein can simultaneously inhibit myosin activity, thereby suppressing contractile activity, stress fiber formation, and the assembly focal adhesion signaling complexes, processes that suppress the formation of stable cell-matrix adhesions and allow the cell to sustain motility. Integrin-derived signals can indirectly support cell migration by regulating protease activity, allowing the cell to remodel, penetrate, and migrate through the ECM. As already noted, signals propagated by the $\alpha_5\beta_1$ induce collagenase gene expression.^[100] In immortalized keratinocytes, signals propagated by the $\alpha_3\beta_1$ integrin increase the half-life of MMP-9 gelatinase mRNA.^[106] The $\alpha_2\beta_1$ integrin of normal keratinocytes binds MMP-1, localizing protease activity to the immediate vicinity of the cell.^[77]

(V) *Modulation of Cytoskeletal Organization.* The regulation of the actin-based cytoskeleton by integrin-derived events is intimately associated with the formation of cell-matrix adhesion sites and the process of cell migration as discussed. Direct and indirect connections between the integrins, the actin cytoskeleton, and other cytoskeletal elements also can be defined. In the epithelium, intermediate filaments terminate at the plasma membrane in association with hemidesmosomes. These cell-matrix junctions, essentially an *in vivo* correlate to the focal adhesion of cultured cells, anchor epithelial tissues to the basement membrane. Clusters of $\alpha_6\beta_4$ integrins are concentrated in these domains, linking intermediate filaments to the plasma membrane and forming a continuum that anchors this cytoskeletal network to the external environment.^[107] The cytoplasmic tail of β_4 integrin exhibits specialized cytoplasmic structures that function as docking domains for accessory proteins that link intermediate filaments to the hemidesmosome.^[108] Considerable efforts have been directed at identifying the molecular signature of the proteins necessary to form these elaborate structures. The hemidesmosome is subject to regulation, at least as complex as actin-associated focal adhesions. Intermediate filament networks undergo assembly and disassembly in parallel with the progression of the cell cycle. The disruption of hemidesmosomes in the autoimmune disease, *bullous pemphigoid*, causes epithelial blistering and compromises the intermediate filament network.

Inside-out signaling

Inside-out signaling typically refers to the process of integrin activation. Integrin activation and

ligand-binding events impact the local mechanical environment and may lead to signals that modulate the biochemical composition of the immediate surroundings of the cell. Cardiac fibroblasts migrating on a collagen gel apply tension to this type of extracellular network through integrin-mediated processes.^[109] This cell-derived tension represents a mechanical perturbation that can be propagated to adjacent cells. The potential role of this type of signaling has not been investigated to any great extent. However, in the heart (and potentially other organ systems, i.e., the skin), it is possible that the aggregate effect of the tension applied to the ECM by the resident interstitial cells could have an impact on ventricular wall compliance. We can only speculate how the selective pharmacologic disruption of interstitial cell-matrix interactions might effect cardiac performance in the normal and failing heart. Suppression of tensile forces generated by dermal fibroblasts has been used in attempts to manage scar formation during wound healing. The integrin-mediated regulation of MMP expression and distribution can modulate ECM structure, the degree of tension present in this network, and initiate the release of growth factors and cytokines that are bound to constituents of the ECM.^[31,77] Integrins also indirectly modulate the biochemical composition of the ECM by modulating cytokine expression.^[101]

CONCLUSIONS

Integrins function as a critical interface between the intracellular and extracellular environments. These receptors are multifunctional; in the outside-in mode of signaling, the integrins detect and transduce signals that regulate a variety of cellular processes. Simultaneously, in the inside-out mode of signaling, the integrins can modulate the composition of the local microenvironment. Ideally, the bioengineering paradigm will develop strategies to exploit this unique class of receptors to direct tissue reconstruction, modulate the wound healing process, and promote more complete tissue regeneration during recovery from acute and chronic injuries. It may be possible to develop physiologically relevant tissue-engineering scaffolds that selectively direct cell migration, cell survival, and cell phenotype.

Intellectual Property Management

Michael Blakeney

Director, Queen Mary Intellectual Property Research Institute, University of London,
London, U.K.

INTELLECTUAL PROPERTY AND RESEARCH

Intellectual Property is a broad term for the various rights, which the law gives for the protection of economic investment in creative effort. These rights may be conferred by statute or as a consequence of the development of legal principles in the courts. Intellectual property legislation may be obliged as a result of international agreement, such as the World Trade Organization Agreement on Trade-Related aspects of Intellectual Property Rights (TRIPS) or, in the case of U.S.A., as a consequence of its membership of the North America Free Trade Association (NAFTA). The principal categories of intellectual property, which are going to be relevant to research institutes are patents, industrial designs, plant variety rights, trademarks, confidential information, copyright, and database rights.

Patents

A patent is a statutory privilege granted by a government to an inventor and to other persons deriving their rights from the inventor, for a fixed period of years, to exclude other persons from manufacturing, using, or selling a patented product or from using a patented method or process. Patent rights are conferred by statute as a matter of right to the person who is entitled to apply for it and who fulfils the prescribed registration requirements. The protection secured by the registration of a patent is usually limited in time. For example, under the TRIPS Agreement, which sets the basic minimum standard for intellectual property protection, the term of patent protection is 20 yr. In some countries, there may be opportunities for extensions of protection for particular categories of invention such as for pharmaceutical processes. At the end of the period of protection, the patented invention is said to be within the public domain that is available for anyone to exploit. As will be discussed below, this means that patent information in the public domain is a valuable source of data for research institutes.

An invention is usually defined as an idea, which permits the solution of a specific problem in a field of technology. The applicant for the protection of an invention is usually the inventor or his/her successor in

title. For an invention to be protected by a patent it must (i) be new; (ii) involve an inventive step; (iii) be industrially applicable; and (iv) not be a category of excluded invention.

Invention

A distinction is often drawn between inventions and discoveries, as the latter are not considered patentable. Scientific theories without a practical application are not patentable either because as discoveries they are not inventions, or because in their restriction to the province of theory, they cannot easily be characterized as methods of manufacture.^[1] Thus a computer program comprising no more than a mathematical algorithm is not patentable,^[2] whereas the application of an algorithm for some practical purpose, such as for the production of images in computer display graphics, has been characterized as a method of manufacture.^[3] Similarly, a computer program, which permitted a word processor to assemble text in Chinese characters, was held to be patentable.^[4] It is possible for legislation to decree that something considered as a discovery is deemed to be an invention. For example, the European Parliament in its Biotechnology Directive provides that biological material, which is isolated from its natural environment or produced by means of a technical process, is deemed to be an invention even if this material previously occurred in nature. The U.S. Supreme Court took a similar position in *Diamond vs. Chakrabarty*^[5] in ruling that a bacterium genetically engineered to degrade crude oil was an invention.

Novelty

An invention is considered to be new “if it does not form part of the state of the art.” The state of the art is taken to comprise all matter (whether a product, a process, information about either, or anything else), which has been disclosed to the public by prior publication in a tangible form, by oral disclosure, or by use in any way prior to the filing of the patent application. Disclosure may also have occurred through scholarly publication, through a public address or lecture, being placed on the Internet, or through the use of a product

or process embodying the invention. Given that the right to patent an invention can be lost through premature disclosure, it may be incumbent upon an agricultural research institute to institute a system for the management of the publication activities of its researchers.

Inventive step

An invention is said to involve an “inventive step” if, having regard to the prior art, it would not have been obvious to a person having an ordinary skill in the art. In other words, the invention must involve a creative advance on existing knowledge. Researchers from public research institutes will often be requested to provide expert testimony in patents cases as to the current state of the technological art.

Industrial applicability

The requirement that an invention be industrially applicable, or useful, excludes from patent protection purely theoretical inventions, which cannot be carried out in practice. The notion of an applicability, which is “industrial,” connotes a commercial scale of application.

Exclusions from patentability

The TRIPS Agreement envisages the exclusion from patentability of (i) inventions the publication or exploitation of which could broadly be considered to encourage immoral behavior or (ii) “any variety of animal or plant or any essentially biological process for the production of animal or plants, not being a micro-biological process or the product of such process.”

The registration procedure

To obtain a patent, an application is filed with a Patent Office. The application will contain, among other things, a description of the invention, with any drawings referred to in the description and the claims made for the invention. The description must disclose the invention in a manner sufficiently clear and complete for it to be carried out by a person skilled in the art. The disclosure of the invention has to present the invention in the context of the state of the art. To be patentable, the invention must offer a novel solution to a technical problem and the description has to relate the invention to the background art. The function of the claim is to define the scope of the protection, which is sought. A patent application is examined by the Patents Office to ensure that the application meets the

formal registration requirements. The application may then proceed to examination as to substance. For example, the registration authority may institute a search of the patent documents of other nations and of significant technical journals and other publications to ensure that an applicant’s invention has not been previously disclosed. Some countries permit the registration of patents for inventions, which have only been partially disclosed in prior art. Some countries confine relevant prior art to national disclosure, or to prior use and prior oral disclosure.

The application may be published or laid open for public inspection before a patent is granted. An opportunity may be given for third parties to oppose the grant of protection. After the examination of the application as to form and to substance and after the consideration of any opposition, the registration authority will decide on whether to grant a patent. The fact of the granting of the patent will be published in an official gazette.

Patents are national rights. The Patent Cooperation Treaty provides for some procedural efficiencies, for example in having a single application designating a number of countries and having a single state-of-the-art search report available for each national office. In some countries, patent protection is not available for all inventions. For reasons of national interest, some countries withhold patent protection from inventions pertaining to agriculture, food, medical and pharmaceutical products, and nuclear and computer technology. Because patent protection extends only to inventions of a technological nature, protection is withheld from advances relating to methods of business, including financial and accounting techniques, as well as from medical treatments, plant varieties, and animal breeds.

Most countries have compulsory licensing provisions whereby if a patent is not “worked” within a stipulated period of time, the patent holder may be obliged to license the patent right to another person in return for compensation. Compulsory licensing has become a particularly controversial subject. Granting authorities, on one hand, are concerned to prevent patents being used as a means of preventing market entry. Patentees, on the other hand, seek to extend the categories of justification for non-working.

Patent documents as a source of research information

Patent documents are an easily accessible source of research information because they have a fairly uniform structure throughout the world. Patent documents contain both bibliographic and technical information and a search report.

Bibliographic information is presented on the first page of a patent document and includes the following:

1. Dates, names, and addresses of the persons involved in the patent, such as the inventor, the owner of the patent right, and the representative of the owner, or patent agent, as well as particulars of the issuing authority.
2. Classification symbols of the International Patent Classification (IPC), and in some cases, also the national patent classification.
3. Title of the invention, abstract of the description, and a representative drawing or a chemical formula.

Each of the bibliographic data items on the first page of a patent document is identified by a two-digit numeric code, which is universally adopted and facilitates the understanding of the names, dates, addresses, and classification symbols, even without any knowledge of the language in which the patent documentation is published.

The technical information contained in a patent document usually includes:

1. A short description of the state of the art of technology as known to the inventor.
2. The detailed description of the invention in such a manner that a technician skilled in the art is able to work the invention.
3. Drawings or chemical formulae illustrating the invention.
4. The claims, which define the scope of the invention.

The length of a patent document will vary according to the field of technology, but they usually average between 10 and 15 pages.

The search report is established by the patent examiner in the Patent Office. It will contain references to all patent documents, which describe similar or identical technical solutions as the purported invention.

A number of advantages have been identified with the use of patent documents as a source of technological information:

1. Current patent documents contain the latest information. Because of the loss of novelty through publication in academic journals, patent documents will often be the first place where an invention is disclosed, e.g., the Hollerith punch card, Baird television, and Whittle jet engine were disclosed in patent documents a number of years prior to their discussion in the academic literature.

2. Patent documents contain information, which would not otherwise be disclosed, e.g., studies in U.K. and U.S.A. indicate that less than 20% of technical solutions published in patent documents were later published in other scientific journals.
3. Patent documents have a uniform structure, using classification symbols, which simplifies the access to information.
4. Patent documents identify the commercial application of inventions.
5. Patent documents indicate the name and address of the applicant, the patentee, and the inventor. This assists the identification of the source of licensing opportunities.

Typically, adopting the formalities prescribed under the Patents Cooperation Treaty (PCT), an application will contain a request, a description, claims, and an abstract. Occasionally, drawings may be required. The request will identify the applicant and will seek protection for a named invention. The description will contain the disclosure of the invention, identifying the technical field to which the invention relates, a description of the state of the art, together with a bibliography, and the disclosure of the invention with sufficient clarity and completeness to enable it to be understood by a person having ordinary skill in the art. The description will also identify the novelty in the invention by reference to the preexisting art. Finally, the description will indicate the way in which the invention will be industrially applied. The claims, which are made for an invention will define the scope of protection, which is offered. A tension will exist between the width of the claims, which are made by an applicant and the limitation to those claims, which may be considered to be supported by the description and also having account of matters, which are considered already to be part of the state of the art or which are considered to be obvious. Failure to satisfy the disclosure requirements may result from insufficiency of the description or from ambiguity in the claims. Disclosure must be sufficient to permit an informed reader with reasonable skill in the trade to perform the invention. Read with the knowledge of that reader, claims must clearly and succinctly delineate the invention. Finally, the claims must be fairly based on the material revealed in the specification.

Industrial Designs

An industrial design is the ornamental or esthetic aspect of a useful article. Industrial designs are protected through registration. As with patents, most countries require novelty. The standard of novelty varies between universal and national novelty. A difficult issue

in designs protection is the extent to which a design must differ from an earlier design to be considered novel. Minor variations are usually inadequate. A desirable test is whether the design claimed is subjectively new in the sense that it is not an imitation of designs already known to the creator. The critical feature of industrial applicability is that the design is repeatable in commercial quantities. Thus items of artistic craftsmanship are outside the scope of design protection and are more properly protectable under copyright laws.

Industrial designs are protected against unauthorized copying or imitation for 15 yr, dated from the end of the calendar year in which the design was first recorded in a design document or an article was first made to the design, whichever occurred first.

Trademarks

A trademark is usually defined as a sign capable of being represented graphically, which is capable of distinguishing goods or services of one undertaking from those of other undertakings. Originally trademarks were protected for use in relation to goods, but in recent years, the marks used in relation to services have been embraced by this style of protection.

To be registered as a trademark, a sign must be represented in a visible form. In some countries, audible or olfactory signs may be registered if they can be recorded in an appropriate manner. Visible signs typically include names, invented or existing words, letters, numbers, pictures and symbols, or combinations of these signs. Under most trademark laws, the shape of goods or their containers, or the design of their labels or fabrics can be registered as marks. The marks, which are excepted from registration, are those that are not distinctive, or deceptively similar to existing marks and marks, which violate public order or morality.

Most trademark laws allow separate registrations for a mark in respect of each of the 42 categories of goods and services laid down in the International Classification of Goods and Services, which was established in accordance with the Nice Agreement of 1957 and its subsequent revisions. Registration may be permitted with the disclaimer of some elements of a mark. For example, in a word mark, there may be disclaimer of those words, which would be common to the relevant trade.

The application process usually requires an examination by the granting office to ensure compliance with the formal registration requirements, as well as with the substantive requirement of distinctiveness. There also has to be a check as to whether a mark is in conflict with prior rights. After the publication of an

application, most countries provide for an opposition process whereby an interested third party may protest the registration of a mark, usually on the grounds of prior rights or deceptive similarity with another mark.

Upon acceptance of a mark, registration is conferred for a term of between 10 and 20 yr, with a possibility for renewal. A mark will expire if a renewal is not sought. Expungement of a mark may also be sought where its use becomes deceptive or where the mark becomes generic of goods or services. For example, the marks "Vaseline" and "gramophone" are two examples of marks, which became generic descriptions of the type of goods to which they were appended.

A controversial requirement of some trade mark laws is that registration of a trademark is contingent upon its use or a bona fide intention to use upon or in close association with the classes of goods or services in respect of which it is registered. A similar requirement provides for the removal of the registration after a prescribed period of non-use. Protection without registration may be extended to "well-known marks," i.e., those with a significant reputation in a country. Such marks invariably have a substantial international reputation through advertising and use.

Registration of a mark confers protection against emulation by traders using identical or substantially similar marks. Most systems of registration permit assignment or licensure. A system of registered user may be provided to record trademark licenses.

In the event of infringement of a registered mark, a trademark proprietor may seek relief in the form of injunction, compensation orders, and seizure of infringing goods.

The use of a trademark is a warranty of the quality of the goods or services supplied under that mark. The name, acronym, or logo of a research institute is often a warranty of the quality of the services supplied by that institute. Its designation is worthy of protection, particularly because unauthorized traders may falsely represent an affiliation with the institute. Similarly, the products, which are produced by an agricultural research institute may also be worthy of protection, e.g., the IRRI prefix for rice types developed at that institute.

A new form of trademark style protection is registration of an Internet domain name. Imitation of a trademark by an Internet domain name is a trademark infringement and the unauthorized registration of another's name as an Internet domain name is also actionable.

Confidential Information (Including Trade Secrets)

Intellectual property rights, such as patents, trademarks, and industrial designs, which arise as a result of

registration may be contrasted with the rights, which arise under know-how agreements. In the latter case, know-how, which is also described as trade secrets, is protected by the law of confidential information. This is judge-made law (i.e., arising without legislation) in contrast with the various intellectual property rights, which arise as a result of legislation.

The statutory rights, such as patents, trademarks, and copyright are conferred in respect of specific acts of artistic or technological creativity, whereas know-how agreements tend to involve the more general application of technology in a commercial situation. The commercialization of intellectual property through a manufacturing enterprise will typically involve the following: (i) preinvestment studies, including the preparation of a feasibility study and project report; (ii) engineering, including preparation of machinery specifications, plant design, and factory layout; (iii) selection of equipment, plant construction, erection and installation of machinery, and start-up of plant; (iv) acquisition of manufacturing technology; and (v) technical assistance during postinstallation period, including training programs and management assistance.^[6] In other words, intellectual property rights cannot be effectively utilized without the deployment of substantial quantities of know-how. However, unlike for intellectual property rights, there is no system of registration for know-how, and it will be protected only if it is regarded as confidential or if a restriction is placed upon its unauthorized communication.

In the case of employee contracts, most common law systems imply a contractual term obliging employees not to divulge information, which is considered to be the property of an employer. This information will include much of the information relevant to the commercialization of intellectual property listed above such as plant and equipment design, production methods, and customer lists. This contractual term is enforceable only against an employee. To prevent a third party from wrongfully acquiring and using a person's trade secrets, the courts have fashioned rights in equity and tort against third parties. In determining whether information is protectable as a trade secret, the courts have regard to: (i) the extent to which the information is known by employees and by persons outside the relevant business; (ii) the extent of measures made to guard its secrecy; (iii) the value of the information to the business and to competitors; (iv) the amount of effort or money expended in developing the information; and (v) the ease or difficulty with which the information could be properly acquired or duplicated by others.^[7]

The research data and test results assembled by a research institute may form part of the corpus of its confidential information or trade secrets and be protectable under the law.

Biotechnological Rights and Plant Varieties

Biotechnological invention, particularly through the practice of genetic engineering, has become increasingly important for agriculture and for the treatment of disease. Historically, the question of the patentability of "animate" substances proceeded down a separate legal channel to that concerning the patentability of plant varieties. Originally, it was considered that discoveries involving living organisms and material were not inventions for the purposes of most patent statutes. Exceptions to this principle were made for microorganisms used in fermentation and in antibiotics. However, in 1969, the Supreme Court of the Federal Republic of Germany ruled that animal breeding techniques were patentable, provided that the technique was repeatable.^[8] In U.S.A., the courts had consistently rejected claims for the patentability of animate matter until the 1980 decision of the Supreme Court in *Diamond vs. Chakrabarty*.^[9] In that case, the Court ruled that a genetically engineered bacterium capable of breaking down the components of crude oil was patentable. It recognized that the touchstone of patentability was not whether an invention involved living or inanimate subject matter, but whether it involved a man-made invention.

As an alternative to the protection of plant varieties under patent laws, plant varieties may be protected under plant breeder's rights (PBR) laws modeled on the Union for the Protection of New Varieties of Plants (UPOV) Convention International Convention for the Protection of New Varieties of Plants. Generally, under this legislation, the plant breeder is conferred an exclusive right to perform or to license the following acts in relation to propagating material of the variety:

- Produce or reproduce the material.
- Condition the material for the purpose of propagation.
- Offer the material for sale.
- Sell the material.
- Import the material.
- Export the material.
- Stock the material for the purposes described above.

The general duration of PBR under the UPOV Convention is 25 yr in the case of trees and vines and 20 yr for any other variety.

As with patents, PBRs are established after a registration process. A plant variety is considered to be registrable, if it has a breeder, is distinct, uniform, stable, and has not been or has only recently been exploited. A plant variety is considered distinct if it is clearly distinguishable from any other variety whose existence is a matter of common knowledge. It is

uniform if, subject to the variation, which may be expected from the particular features of its propagation, it is uniform in its relevant characteristics on propagation. A plant variety is stable if its relevant characteristics remain unchanged after repeated propagation. A plant variety is taken not to have been exploited if it or propagating material has not been sold to another person by or with the consent of the breeder. The test of no commercial exploitation is easier to satisfy than the test for novelty under patent law, and the choice between the two forms of intellectual property right is a matter to be considered by a research institute.

A similar disclosure of the technology to that required under patent law is required under the Plant Varieties Act 1983. Thus documents, which are published by the various plant variety registries, will provide a valuable source of research data.

Copyright

Copyright law is concerned with the protection and exploitation of the expression of ideas in a tangible form. The central right, which the law confers is to prevent unauthorized persons from copying a work. To be protected as copyright, ideas have to be expressed in an original way; that is they must have their origin in the labor of the creator. Works are protected irrespective of their quality.

Subject matter of protection

Originally, the subject matter of copyright protection was printed in literary artistic and literary works. As reprographic technology has improved, protection has been extended to technical drawings, maps, paintings, three-dimensional works such as sculptures and architectural works, and to photographs and cinematographic works. More recently, copyright protection has been extended to computer programs, Internet web sites, and to databases.

Rights comprised in copyright

The owner of a copyrighted work may exclude others from using it without authorization. The acts, which require the authorization of the copyright owner are usually the following: (i) copying or reproducing the work; (ii) performing the work in public; (iii) making a sound recording of the work; (iv) making a motion picture of the work; (v) broadcasting a work through the electromagnetic spectrum or through cable diffusion; and (vi) translating or adapting the work.

In addition to these rights, certain “moral rights” have been recognized by the Berne Convention for the

Protection of Literary and Artistic Works.^[10] These include the right to claim authorship of a work and the right to object to any distortion, mutilation, or other modification of, or other derogatory action in relation to a work, which would be prejudicial to an author’s honor or reputation. These moral rights usually remain with an author, even after the transfer of the various economic rights mentioned above.

Neighboring rights

Three kinds of rights neighbor upon copyright protection. These are: (i) the rights of performing artists in their performances; (ii) the rights of producers of phonograms; and (iii) the rights of broadcasting organizations in their radio and television programs.

Copyright and research institutes

Obviously protected by copyright law are the publications, which emanate from research institutes. A sometimes-difficult question concerns the ownership of the scholarly articles and papers of researchers within an institute. Strictly speaking, if produced in the course of their employment, the copyright in this scholarship is owned by the research institute. However, as a matter of practice, these ownership rights are conventionally waived, as it is often considered to be antithetical to the research ethos of an institute to insist upon these rights. On the other hand, where this scholarly output forms part of the teaching materials produced by an institute, a clarification of the ownership of this material is counseled. The moral rights of researchers in their scholarly publications will carry across to teaching materials that incorporate those publications and this has to be borne in mind in the way in which editorial work is affected.

Obviously a research institute must monitor the use of the copyright work of others in its own publications and teaching materials. This will include online works, which are incorporated into any online materials or web sites.

Database rights

The European Database Directive, which was implemented in U.K. in the Copyright and Rights in Databases Regulations, 1997, provides for the protection of material contained in databases against unauthorized extraction or reutilization. A “database” is defined as “a collection of independent works, data, or other materials arranged in a systematic or methodical way and individually accessible by electronic or other means.” Much of the data assembled by

teams and researchers in a research institute will fall within this definition. Also protected are “the materials necessary for the operation or consultation of certain databases such as thesaurus and indexation systems.” Thus bibliographic tools maintained by research libraries may fall within this protective regime. The duration of the right to prevent unauthorized extraction is 15 yr. The regulations also provide that if a database is made by an employee in the course of employment, the employer shall be regarded as the maker, subject to any agreement to the contrary. This will be an import issue for research institutes.

In U.S.A., databases are protected, where some effort has been applied for their development.

OWNERSHIP OF INTELLECTUAL PROPERTY BY RESEARCH INSTITUTES

Accountability

Much of the funding received by university research institutes is obtained from public sources such as governments, international organizations, or charitable foundations. Consequently, institutional accountability is needed for the intellectual property emerging from its research; institutes may take the view that their research results are freely available to all. However, an unauthorized person may seek to register a patent arising from that research, thereby preventing its use as a public good. This may have to be preempted by the institute seeking its own intellectual property protection. Patent or plant variety rights, thus obtained, can be licensed to users on a non-exclusive basis.

As owner of the intellectual property, the institute can apply quality assurance procedures to its evaluation, protection, development, and exploitation through administrative procedures dedicated to this task. It can also assist innovators in the commercialization of the intellectual property by concentrating the expertise in an area available to all research teams.

The purpose of intellectual property ownership by a research institute is invariably to promote the fundamental research mission of the institute, to protect its integrity and welfare, to provide a resource for industry, to obtain appropriate return for the use of facilities, resources, and services provided by the institution, to encourage the growth, progress, and success of the research institute through ventures with industry, seeking commercial returns, to provide fair and reasonable reward (and incentive) to staff and students who apply their intellectual activity, to increase the acumen and accountability for management and use of public funds, and to foster

the identity of the research institute and an esprit de corps.

Enhancing Public/Private Cooperation

Much research carried out at university research institutes is conducted with industry collaboration. Industry operates in an environment, which uses intellectual property rights to protect the value of its products and the money expended on R&D. Many corporations will not invest in, or transfer technology to, countries, which do not have an intellectual property infrastructure, so corporations are increasingly beginning to insist that research institutes have an equivalent infrastructure. Where collaborative research is to be conducted, the private collaborator will insist that the fruits of the research, often representing a significant investment by it, are not appropriated by some unauthorized third party. Sometimes the research will involve an elaboration of a piece of intellectual property contributed from the private sector, and the contributor may insist that the research institute has an appropriate intellectual property regime.

Ownership of Intellectual Property

As a general rule, a research institute will own all the intellectual property generated by its staff (and research students). This is, at least, on the basis that the intellectual property has been created in the course of employment or that research institute resources and services have contributed, including, often, preexisting intellectual property belonging, or licensed by the research institute. The question of intellectual property ownership is also clarified through the adoption of an intellectual property statute, particularly one, which provides for the insertion of an intellectual property clause in the contract of employment.

Most institutions deal with the ownership issue in their contracts of employment or staff policies.

MANAGING THE INTELLECTUAL PROPERTY OF A RESEARCH INSTITUTE

Intellectual Property Policy

In the modern world of biomaterials and bio-engineering, it is imperative for a research institute to formulate an intellectual property policy, both to protect the assets created by the institute and to comply with any contractual obligations concerning third party intellectual property used by an institute. Invariably, a considerable amount of investment will underpin the activities of a research institute, and a

failure to secure the ownership of any intellectual property assets, which are generated by the institute can represent a squandering of that investment. The failure to manage third party intellectual property rights may also have financial repercussions, if the institute is held liable for breach of contract in relation to proprietary rights made available for limited purposes.

Compliance by an institute's researchers with an institute's intellectual property policy can be built into the contracts of employment issued by an institute. In any event, an effective intellectual property policy will be one, which is expressed to be in support of an institute's research mission. For example, intellectual property assets, which are generated can be traded for third party intellectual property rights, which are necessary to the research of the institute.

Providing for a central point of expertise to manage intellectual property is one way to assist university research institutes to deal with the complexities of the legal protection of intellectual property rights and commercial arrangements needed for the acquisition and the exploitation of those rights. Additionally, some research may depend upon the acquisition of a third party's intellectual property rights. For example, a private company may wish to contribute a patented gene. This may be on the basis that it is exclusively for the use of the institute or on condition that any improvements or applications are jointly patented. This will also be more conveniently managed centrally. Given that the right to patent an invention can be lost through premature disclosure, it may be incumbent upon an agricultural research institute to institute a system for the management of the publication activities of its researchers.

The research institute may choose between a specially dedicated research liaison office (RLO) and an official within the institute with intellectual property responsibilities. The decision will usually be made on the basis of funds available to pay salaries and to house relevant staff. A critical factor will be the expected revenues, which is expected to be generated from intellectual property by the research institute. Where the research institute is associated with a university, it will usually be able to avail itself of the services of a central university institution. Where a research institute is not able to avail itself of the facilities offered by an associated university or government body, it will probably be advised to deploy one of its officers to perform the intellectual property coordination function.

The RLO may decide not to exploit ownership for certain intellectual property, in which case, the rights will be released to the innovator(s), usually subject to a non-exclusive license to use the intellectual property for research in the research institute. In those cases where the RLO forms the view that the research institute should be involved in the exploitation of the

intellectual property, it will work with the innovator(s) in market evaluation and in finding commercial collaborators to exploit their intellectual property. Each case differs, and an appropriate strategy must be devised in conjunction with the research staff involved. The RLO will be responsible for securing professional assistance under appropriate conditions of secrecy. The ultimate vehicle for commercialization may be the research institute, through the RLO, or through the institute's commercial arm. The RLO will ensure the coordination of commercialization activities and prevent conflicts of interest.

To enable the RLO to evaluate the commercial potential of inventions and discoveries, researchers should be obliged to divulge their research activities in an appropriate form. This form will capture all preliminary information required for initial evaluation. Initial evaluation will involve assessing the invention's patentability (or other intellectual property protection) and commercial potential, and fulfilling any obligations to research sponsors. For example, companies supporting specific research projects may have in the relevant research agreement the first right to negotiate licenses for any inventions resulting from that research. Non-profit research sponsors may also have certain rights under previously negotiated research agreements. These rights and obligations must be fully defined and resolved before the invention can be made available for licensing.

The time needed to complete initial evaluation varies greatly for each invention. For example, efforts to determine commercial interest may need to await receipt of further research data or resolution of outstanding sponsor obligations.

Owing to the high cost of prosecuting and then maintaining patents, the RLO will usually have to delay filing of patent applications until strong commercial potential interest in technologies has been confirmed. In many cases, initial filing is authorized only when companies commit to inventions through letter or option agreements. During the course of the patenting and licensing process, multiple patent applications may be filed to maximize patent coverage for a given technology and cover developments made during the preparation period. Applications also may well be filed in foreign countries. Again, the commercial potential of the invention must be considered when making subsequent decisions to file or maintain patents.

Where commercialization of intellectual property rights is decided upon, the RLO will approach the most appropriate firms from a list prepared in conjunction with the innovators. The RLO will prepare executive summaries of inventions and submits these to relevant publications and databases. Marketing packages can be targeted to potential licensees identified

through discussions with inventors and the use of various internal and external resource lists. The RLO will negotiate agreements in conjunction with the innovators to ensure conformity with the role and mission of the research institute.

Once potential licensees have been identified, negotiations proceed in a variety of ways. Short-term letter agreements may be used to confirm company interest in technologies and establish their commitment to pay patent costs during an evaluation and negotiation period. Option agreements define each party's rights and responsibilities of the two parties and grant licensees the right to utilize the institute's intellectual property.

Depending on the nature of individual technologies and the estimated resources necessary for development and commercialization, the research institute may grant licensees exclusive rights, rights exclusive for a particular field of use, or non-exclusive rights. For example, most inventions in the health-care field require very large investments of time and resources to develop and commercialize. Companies will often only make the necessary investment within the context of an exclusive license agreement. In contrast, plant varieties would have already been tested and are ready for commercialization, thus they are licensed (typically) non-exclusively to multiple companies.

CONCLUSIONS

The principal objective of the intellectual property management policy of a research institute is to further the research mission of the institution. This is achieved by creating a fruitful climate for innovation and invention, and facilitating the establishment of strategic linkages with researchers in other research institutes and with the private sector. The management of

an institute's intellectual property resources may be through a specially established RLO or by utilizing the intellectual property services, which may be offered by an equivalent office within an associated institution such as a university. Through its RLO, a better understanding of the rights, which the law gives for the protection of creative effort, will be communicated to researchers and funding will be secured through collaborative research and development agreements. The RLO will be responsible for protecting and maintaining the intellectual property assets of the research institute and assist in developing an awareness and appreciation of the use of patent documents and registered plant variety data as research resources.

Interpenetrating Polymeric Networks

Nicholas A. Peppas

Jing Zhang

Departments of Chemical and Biomedical Engineering and Division of Pharmaceutics,
University of Texas at Austin, Austin, Texas, U.S.A.

INTRODUCTION

Interpenetrating polymer networks (IPNs) are combinations of two or more polymers in network form, with at least one of them polymerized and/or crosslinked in the immediate presence of the other. Usually two networks are involved in an IPN system. The IPNs may have similar characteristics to polymer blends, more specifically a combined property that can be achieved from the interpenetration of the two networks. The interpenetration of two dissimilar networks may result in immiscible phases or phase separation in the IPN system. However, interpenetration of networks does not change the properties of each network. The proportion and properties of each polymer can be varied independently. Usually, network interpenetration increases the number of physical crosslinks in the system to achieve higher apparent crosslinking density and to strengthen the mechanical behavior of the system.

From a topological point of view, IPNs are closely related to polymer blends, block, graft, and crosslinked copolymers.^[1,2] An IPN can be distinguished from other multipolymer systems in three ways: 1) an IPN swells, but does not dissolve in solvents; 2) creep and flow are suppressed because of the interlocked crosslinks in the IPN; and 3) IPNs can exhibit characteristic morphologies because of mutual incompatibility.^[1]

Research on biomedical IPNs has been focused on the studies of IPN synthesis,^[1,2] morphological behavior,^[3-9] properties and industrial applications.^[1,10-12] Sperling,^[1,4,13] Klempner,^[10,14] Frisch,^[12] Lipatov,^[8,15] and their associates have contributed significantly to the area of IPNs.

BACKGROUND

Depending on the preparation method, IPNs can be classified^[1] as follows:

Sequential IPN: In sequential IPNs, the polymer network I is synthesized first. Monomer II plus a crosslinking agent and an initiator are swollen into network I and polymerized in situ.

Simultaneous interpenetrating network: The monomers and/or prepolymers plus a crosslinking agent and

initiators of both networks are mixed, followed by simultaneous polymerization via noninterfering reactions.

Latex IPN: The polymers are made in the form of lattices. Thus, each particle constitutes a micro-IPN. Usually, a core-shell structure develops in latex IPNs.

Gradient IPN: In gradient IPNs, the overall composition or crosslinking density of the material varies from location to location on the macroscopic level. One way of preparing these materials involves partial swelling of polymer network I by monomer II, followed by rapid polymerization before diffusional equilibrium takes place. Thus, a film can be made with polymer network I predominantly on one surface and polymer network II on the other surface, with a gradient composition throughout the interior.

Thermoplastic IPN: These materials utilize physical crosslinks, which may involve chain entanglements and a crystalline region. As thermoplastics, they may flow at elevated temperatures.

PHASE SEPARATION AND MECHANICAL BEHAVIOR OF IPNs

As neither of the two polymers is 100% miscible, IPNs polymer can be phase separated at some specific composition and temperature range. This is because of the low entropy of mixing caused by the low compatibility of the two components, which can lead to a negative Gibbs free energy change, as shown in Eq. (1).

$$\Delta G_{\text{mix}} = \Delta H_{\text{mix}} - T\Delta S_{\text{mix}} \quad (1)$$

Thus, several phase diagrams are possible for polymer/polymer IPN systems.^[1] For the phase separated IPNs, phase continuity, phase size, and shape all contribute to the mechanical behavior of the system.^[1] Glass transition temperatures may be broadened or shifted by greater or lesser mixing. Of course, in the limit of compatibility, only one transition will be observed. The morphology of IPNs is usually investigated by scanning electron microscopy (SEM).

Because in IPNs there is no chemical bonding between the two networks involved in the system, each network should retain its properties. Thus, the IPN

behavior should be the combination of the two networks, and the IPN property can be tuned by simply changing the composition of each component. The molecular interpenetration results in physical entanglements in the IPNs, which increase the apparent crosslinking density and further lead to higher mechanical strength of the material.

IPNs made from conventional polymers have been used as ion-exchange resins, sound and vibration damping materials, sheet molding compounds, and tough plastics^[10] depending on the homopolymers used.

Recently, IPNs made of biocompatible polymers have been proposed for applications as membranes, drug delivery carriers, artificial teeth, and artificial tissues. Environmentally sensitive biocompatible hydrogels have also been used to make IPNs^[16–19] especially for medical applications.

HYDROGELS AS IPNs

IPN hydrogels are crosslinked polymeric networks, which are able to absorb large amounts of water and swell up to equilibrium. These networks may be physically or chemically crosslinked to maintain their structural integrity.

IPN hydrogels are used in a variety of applications especially in the biomedical field. Because of the high water content of these materials, gel IPNs are very similar to natural tissue and often exhibit good biocompatibility.^[20] These characteristics allow hydrogels to be used in drug delivery systems, biosensors, contact lenses, superabsorbents, and artificial tissue. Also, because of their water content, hydrogels are good candidates for membrane applications in which the water allows for solute diffusion through the gels.^[21–26]

IPN hydrogels can be classified as neutral and ionic hydrogels depending on the type of repeating units and side chains on the polymer backbone. For example, a neutral hydrogel used in an IPN, such as poly(vinyl alcohol), does not have ionizable groups on the polymer backbone or side chain. Thus, its swelling ratio is independent of pH or ionic strength. Ionic hydrogels, on the contrary, are hydrogels with ionizable functional groups. They can be further classified as anionic and cationic hydrogels depending on the nature of ionizable moieties on their backbones.

Anionic gels contain acidic groups, which ionize when the pH of the surrounding medium rises above their pK_a . Anionic IPN gels swell at high pH values and collapse at low pH values. In the unionized state, the hydrogen of the carboxylic group might be donated to a nearby electron-rich group to form hydrogen bonding which leads to the formation of polymer complexes.

Poly(acrylic acid) (PAA) and poly(methacrylic acid) (PMAA) are typical examples of anionic hydrogels

utilized in IPNs. Similarly, copolymers of PMAA and PAA with poly(ethylene glycol)^[27,28] and poly(2-hydroxyethyl methacrylate)^[29] have been used in IPNs as drug release carriers. Copolymers of PMAA with poly(*N*-isopropyl acrylamide) (PNIPAAm) show interesting coupling of pH and temperature-sensitive swelling behavior and have been proposed for drug delivery and biomedical applications.^[30,31]

Cationic gels usually contain amino groups which form $-NH_3^+$ when the pH of the surrounding medium decreases below pK_a . Dimethylaminoethyl methacrylate and diethylaminoethyl methacrylate (DEAEM) are the typical cationic monomers used in IPNs. Cationic hydrogels swell at low pH and collapse at high pH. Thus, they can be used in insulin delivery.^[32,33]

ENVIRONMENTALLY SENSITIVE POLYMERS IN HYDROGELS

Environmentally sensitive hydrogels can be used as IPN components. They are gels whose properties, most notably their swelling ratio, change in response to specific environmental stimuli, such as temperature, pH, electric field, solvent quality, light, pressure, and ionic strength.^[34] Among these, pH-sensitive and temperature-sensitive hydrogels have been investigated extensively.^[35–42]

Polymers of methacrylic acid (MAA) display sharp sensitivity to external pH^[43,44] with capability of controlling solute permeation by the corresponding changes in swelling behavior. At high pH values, the carboxylic acid side groups become ionized, creating a repulsive force, which expands crosslinked PMAA networks. In acidic solutions, the carboxylic groups maintain the $-COOH$ structure, and the polymer remains in a collapsed state. Fig. 1 illustrates how the polymer networks response to the environmental pH.

Temperature influence on the swelling ratio in IPNs varies according to the dependence and sensitivity of a given hydrogel. Hydrogels with positive thermosensitivity experience increased swelling with increasing

Fig. 1 The effect of pH on pure PMAA hydrogel in aqueous solution.

Fig. 2 The effect of temperature on the poly(*N*-isopropyl acrylamide) hydrogel in aqueous solution.

temperature. Those with negative thermosensitivity experience decreased swelling with increasing temperature as shown in Fig. 2. The affinity between solvent and the monomer units in a gel greatly affects the type of transition. Positive thermosensitive gels contain mostly hydrophilic monomers. On the other hand, negative thermosensitive gels are composed of monomers such as *N*-methylacrylamide, *N,N*-dimethylacrylamide, and *N*-isopropyl acrylamide, containing hydrophobic substituents.^[45]

Since the first report by Tanaka,^[46] crosslinked PNIPAAm have been the most studied temperature-sensitive hydrogels, especially in IPN applications. Such a swelling behavior of PNIPAAm is characterized by a lower critical solution temperature (LCST).

The LCST can be defined as the critical temperature at which a polymer solution undergoes phase transition from a soluble to an insoluble state when the temperature is raised. In the case of crosslinked hydrogels, LCST represents the volume-phase transition temperature of swelling/deswelling process. Pure PNIPAAm gels have an LCST of 32°C swelling at temperatures lower than 32°C and collapsing at temperatures higher than 32°C. The LCST of PNIPAAm can be modified by copolymerization with acrylamide, acrylic acid (AA), and alkyl methacrylates.^[47–49] However, when PNIPAAm is modified by grafting or conjugation^[50] or by interpenetrating with a second network,^[49,51–53] the LCST remained almost constant. This is significant for biomedical applications.

Many theories have been proposed to explain the LCST phenomenon in PNIPAAm single chains and gels, as summarized by Schild.^[54] In the discussion of PNIPAAm single chain theory, Heskins and Guillet^[55] noted that the water is often “ice-like” (more ordered) near the hydrophobic groups (the *N*-isopropyl) and that the ordering may be because of the hydrogen bondings between the hydrophilic group (amide) and water. They speculated that both these effects, hydrophobic interaction and hydrogen bonding, might contribute to the LCST transition. There has been much debate on whether the “hydrophobic effects” or “hydrogen bonding effects” are dominant in the

transition process. Otake et al.^[56] proposed that the driving force is entirely by “hydrophobic interactions,” while on the other extreme, Prausnitz and coworkers^[57] attributed the LCST entirely to hydrogen bonding.

The earliest prediction of the PNIPAAm behavior was by Hirotsu et al.^[58] They incorporated the Flory–Huggins mixing term and ideal elasticity into the free energy expression. However, this theory could not predict the discontinuous transitions for nonionic gels.

Prausnitz and coworkers^[57] developed a theory based on hydrogen bonding in a lattice thus overcoming the deficiencies of the Flory–Huggins theory. This theory predicts the discontinuous transition for nonionic gels and fits with Tanaka’s data, but not with Prausnitz group’s own observation. Cussler and coworkers^[59,60] defined a parameter for an interaction energy from the various cohesive energy densities in the system which fitted the experimental results but overpredicted the pressure effect on gel swelling. By assuming the mixing term as a virial expansion and assuming that the entire interaction term is derived from hydrophobic crosslinks, Saito and coworkers^[61] predicted continuous transitions that become discontinuous upon ionization.

With such diverse theories on PNIPAAm single chains and gels, it is clear that the theoretical explanation of the LCST is far from complete, especially when these networks are used in IPNs. In general, it is accepted that there is a delicate hydrophilic/hydrophobic balance (both hydrophobic interaction and hydrogen bonding are being considered) at the LCST of PNIPAAm. At temperatures above the LCST, this balance is broken by the increased mobility of both PNIPAAm chains and solvent, which lead to the collapse of the PNIPAAm chains.

APPLICATIONS OF TEMPERATURE-SENSITIVE IPN HYDROGELS

Because of their temperature responsive characteristics, temperature-sensitive hydrogels used as components in IPNs have been proposed for applications in separation, biosensors, drug delivery systems, and surface modified biomaterials.

PNIPAAm has been used in size-selective solvent extraction.^[62] Dry PNIPAAm gels can be swollen in aqueous solutions with different size molecules as solutes. When the gels swell, small size solutes enter the networks while the larger solutes are excluded from entering the gels because of size limitations of the gel mesh. Therefore, when the gels are removed, the solution with the higher molecular weight solute is concentrated. On the other hand, by raising the temperature higher than LCST, solvent with a higher concentration of the smaller molecule will be extracted from the gel.

Temperature-sensitive IPN gels have also been proposed for use in mechanical valves, where the polymer can control the extent to which a valve opens by its degree of swelling.

There are also numerous reports of using temperature-sensitive hydrogels in drug delivery applications. Okano, Bae, Kim, Hoffman, Peppas, and their coworkers have made significant contributions in this area.^[16,20,48,49,51,53,63–69]

Okano's group has also applied the temperature-sensitive PNIPAAm to prepare surface modified biomaterials and devices. By introducing PNIPAAm grafts onto surfaces with regulated morphology, the surface hydrophilicity can be modulated by external signals. Kikuchi and Okano^[70] used the surface hydrophilic/hydrophobic alteration property to create cell culture systems.

Okano et al.^[66] prepared copolymers of NIPAAm and butylmethacrylate (BMA) and IPNs of PNIPAAm and poly(tetramethylene ether glycol) (PTMEG). The shrinking behavior for disk-shaped gels with increasing temperature was dependent on the gel composition and the fabrication techniques used.

An important observation in these studies was that the initial shrinkage of the gels occurred at the surface of the membranes. The consequence of this phenomenon was that the outer surface formed a denser structure, which regulated water and subsequently the solute transport. For example, the release of indomethacin from these gels was studied, and it was shown that at low temperatures in the range of 20°C, indomethacin followed pseudo-zero-order or first-order release kinetics depending on the networks formed, while at higher temperatures of approximately 30°C, indomethacin could not diffuse out of the gels. This "on-off" release in response to temperature could be explained by the drastic surface response to the temperature rather than the bulk swelling change.

The effect of copolymerization of NIPAAm with BMA and interpenetration of PNIPAAm with PTMEG on the thermosensitivity of swelling showed that the LCST of the copolymer decreased because of the incorporation of hydrophobic BMA, while the LCST of the IPNs was not changed by the incorporation of the hydrophobic PTMEG.

Temperature- and pH-sensitive IPNs containing silicone rubber domains within copolymers of NIPAAm and AA were also synthesized by Dong et al.^[71] These gels contained macropores so that they could swell and collapse much faster than homopolymers of NIPAAm. Biocatalyst immobilization was studied.^[71] Copolymer of NIPAAm and MAA was also studied by Dong and Hoffman.^[47] P(NIPAAm-co-MAA) exhibited both pH and temperature sensitivity, and the gels showed higher swelling ratios in the swollen state because of the hydrophilicity of the MAA group.

In an effort to obtain superior biomedical IPNs, we^[30,72] synthesized copolymers of NIPAAm and MAA. These gels displayed both temperature and pH sensitivity with sharp transition regions that were functions of environmental conditions and polymer composition. The mesh space available for diffusion in the gels changed greatly between the collapsed and swollen states. This change was shown to control streptokinase release in a pulsatile pattern with respect to small changes in external pH and temperature.

When subjected to changes in temperature and pH at the same time, the swelling ratio responded more quickly and to a greater degree than when only one condition was changed. In subsequent work in our laboratory, Vakkalanka et al.^[31] showed that terpolymers of NIPAAm, AA, and 2-hydroxyethyl methacrylate (HEMA) could be prepared and used to add mechanical strength and integrity to the hydrogels. Pulsatile pH- and temperature-dependent swelling studies were performed to determine the extent and rate of gel swelling in response to changing conditions. Results showed that increasing the NIPAAm concentration in the terpolymers resulted in a higher degree of temperature-sensitive swelling. The terpolymers also exhibited an improved temperature sensitivity compared to the copolymers at a relatively low NIPAAm concentration. Poly(NIPAAm-co-BMA-DEAEMA) were also synthesized by Feil et al.^[73] with BMA as a hydrophobic component to increase the mechanical stability and DEAEMA (DEAEM) as the pH-sensitive component.

IPN gels composed of poly(ethylene oxide–dimethyl siloxane–ethylene oxide) triblock copolymers and PNIPAAm were synthesized by Mukae et al.^[52] Transmission electron microscopy and differential scanning calorimetry (DSC) studies of bulk IPNs showed phase separation with partial phase mixing between the two chemically independent networks. Aqueous equilibrium swelling behavior was examined as a function of temperature. DSC thermograms of the swollen IPNs indicated the same swelling transition temperature as that of the PNIPAAm gels. This was in sharp contrast with the random copolymer of NIPAAm in which the transition was affected by the presence of comonomer. The swelling/deswelling kinetics of IPNs was also controlled by gel compositions and applied temperatures.

Temperature-sensitive semi-IPNs of crosslinked PNIPAAm and linear poly[ether(urethane-urea)] (Biomer[®]) were prepared by Gutowska et al.^[51] The results indicated that the semi-IPNs exhibited LCST transitions. The incorporation of Biomer strongly influenced the mechanical strength, equilibrium swelling properties, and the deswelling kinetics of the semi-IPN gels. Compared to the PNIPAAm gels, the mechanical strength increased after the incorporation of hydrophobic Biomer because of the increased apparent

effective crosslinking densities and lower swelling levels. Swelling studies showed that the incorporation of Biomer did not affect the LCST but resulted in decreased thermosensitivity and lower swelling ratios. Semi-IPNs with relatively higher Biomer concentrations exhibited faster deswelling rate because of the presence of Biomer[®] which prevented the formation of the skin-type layer on the gel surface which in turn increased the deswelling rate. Loading and release of heparin was studied as a function of temperature and Biomer content in the semi-IPNs. The partition coefficients of heparin within the networks decreased with increasing temperature and Biomer content. The release of heparin was decreased by the formation of a skin layer in the hydrogels with lower Biomer content.

Lim et al.^[17] synthesized IPNs of PNIPAAm and polyurethane (PU) and IPNs of PNIPAAm and PAA. As expected, the urethane network in PNIPAAm/PU IPNs improved the mechanical strength but reduced the swelling and drug release rates because of the hydrophobic characteristics of PU. Again, the LCST was little affected by the incorporation of PU. The drug releasing ability at 28°C was controlled competitively by both PAA and PNIPAAm components. However, at 37°C, the release was controlled mostly by the PAA because of the collapse of PNIPAAm which inhibited the swelling ability of PAA network.

Research has also been conducted on temperature-sensitive IPNs based on other *N*-alkylacrylamide materials. IPNs composed of PAA and poly(acrylamide-co-butyl methacrylate) and IPNs composed of poly(acrylamide) and PAA were synthesized by Katono et al.^[16] Positive temperature sensitivity was observed in these IPNs which was attributed to the continuity of hydrogen-bonded polymer complexes between PAA and poly(acrylamide), or the so-called chain-chain zipper effect. This phenomenon was not shown in PNIPAAm-based IPNs because of the steric hindrance of the *N*-isopropyl group.

In our laboratory, IPNs composed of the temperature-sensitive PNIPAAm and the pH-sensitive PMAA were prepared by a sequential UV polymerization method.^[74-77] The IPN hydrogels were characterized for their temperature- and pH-responsive behavior by equilibrium swelling studies, oscillatory swelling studies, and DSC. The equilibrium swelling behavior as a function of temperature and pH is shown in Fig. 3 for PMAA/PNIPAAm IPNs containing 70 mol% of PNIPAAm. Fig. 4 shows the significant effect that the ionic strength has on the swelling of the same networks. The oscillatory swelling behavior as a function of time and temperature at pH values of 7.4 and 4.0 (Fig. 5) shows the versatility that these IPNs have in medical applications, as they can act as actuators or valves.

The permeability of these IPNs was investigated under various pH and temperature conditions. The

Fig. 3 Equilibrium swelling behavior as a function of temperature at pH 4.06 (○) and pH 6.16 (□) for PMAA/PNIPAAm IPNs containing 70 mol% of PNIPAAm.

results showed that these hydrogels exhibited a combined pH and temperature sensitivity at a temperature range of 31–32°C and a pH value of approximately 5.5. Permeation study results indicated a significant size exclusion behavior while model drugs with different sizes permeate through the IPN membranes. The permeability of the IPN membrane could be significantly affected by varying the pH and temperature conditions.

Fig. 4 Equilibrium swelling behavior as a function of ionic strength at pH 7.0, 22°C for PMAA/PNIPAAm IPN containing 70 mol% of PNIPAAm (○), PMAA (□), and PNIPAAm (Δ).

Fig. 5 Oscillatory swelling behavior as a function of time and temperature at pH 7.4 and 4.0 for PMAA/PNIPAAm IPN samples containing 70 mol% of PNIPAAm.

The morphology of these IPNs was investigated by the SEM and atomic force microscopy.^[75,77] The environmental conditions induced morphological changes for these dual sensitive IPN hydrogels which were studied by cryogenic SEM, when the gels were analyzed in their wet state. The results showed that the porous

Fig. 6 Scanning electron micrograph of a PMAA/PNIPAAm IPN sample prepared from 40 vol% of MAA methanolic solution (for the primary network) and 0.2 g/ml NIPAAm methanolic solution (for the secondary network), with 1 wt% of initiator, DMPA, and 1 mol% of crosslinking agent, tetraethylene glycol dimethacrylate (TEGDMA), for each solution. Sample was dried first in air for two days and then in vacuum oven for five days and was fractured after liquid nitrogen quenching. The bar indicates 10 μm .

size (see also Fig. 6) in the IPN was strongly influenced by the environmental pH and temperature. Decrease in pH and increase in temperature resulted in significant pore size decrease for the swollen IPNs hydrogels.

CONCLUSIONS

In recent years considerable research attention has been focused on IPN hydrogels that are able to alter their volume and properties in response to environmental stimuli such as pH, temperature, ionic strength, and electric field. Because of their drastic swelling and syneresis in response to environmental stimuli, these polymeric hydrogels have been investigated for many biomedical and pharmaceutical applications, including controlled drug delivery, molecular separation, tissue culture substrates, enzyme activity controlling systems, and materials for improved biocompatibility. By chain interpenetration, we may attain combination of properties from these two polymer networks. As there is no chemical bonding between the two component networks, each network may retain its own property while the proportion of each network can be varied independently. Interpenetration of the two networks may also lead to a much higher mechanical strength with respect to the homopolymer network.

INTRODUCTION

Intravascular ultrasound (IVUS) is an established imaging modality used to visualize vascular pathology and morphology in real time. IVUS is a catheter-based imaging system using small ultrasound transducer(s) to image from inside a blood vessel. The two types of IVUS catheters are a 64-element circumferential array transducer and a single-element rotating (element or mirror) transducer. Images produced from IVUS are cross-sections of the artery perpendicular to the flow direction in the vessel. IVUS has several advantages over other imaging modalities. It provides real-time ultrasound images from inside the vessel at very high resolution with large penetration depths. Furthermore, IVUS enables not only anatomical imaging of vessels and plaques but also functional imaging. Currently, the primary disadvantages of IVUS include being minimally invasive (the catheter is placed inside the vasculature via the femoral artery), imaging only one cross-section of the vessel at a time, and requiring additional time and cost in the catheterization lab for the procedure. Overall, IVUS has been shown to change clinical outcomes by aiding clinicians in better diagnosing plaque composition, quantifying the degree of stenosis, determining the appropriate interventional therapy, and evaluating interventional results. Future developments in IVUS could further increase its role in the catheterization laboratory with such applications as molecular imaging, a forward-viewing array, quantitative flow imaging, and an integrated balloon ultrasound catheter guiding interventions in real time.

CLINICAL PROBLEM

Before IVUS technology and applications are discussed, it is important to understand the clinical

problem it was designed to address. Cardiovascular disease remains the primary cause of death in the United States, leading to nearly one million deaths a year. The American Heart Association estimates that nearly 60 million Americans have some form of cardiovascular disease, and the total economic burden of hospitalization, treatment, and lost time from work amounts to \$330 billion per year.^[1]

The most dangerous form of cardiovascular disease is atherosclerotic coronary artery disease, which leads to narrowing and stiffening of arteries that supply blood to the heart. Atherosclerosis results from repeated injury, subsequent inflammation, and repair of the vascular wall. Endothelial cell injury leads to an inflammatory response and lipid accumulation mostly from low-density lipoprotein cholesterol in the bloodstream. Endothelial cells, along with macrophages, promote rapid accumulation of lipids leading to fatty streaks or foam cells. At this stage, atherosclerosis is considered to be reversible with appropriate changes to risk factors (smoking, exercise, healthy diet, etc.). If atherosclerosis continues, a plaque (atheroma) forms around a lipid core. A stable plaque (fibroatheroma) is characterized by a thick fibrous cap composed of smooth muscle cells and a small lipid core. In contrast, a plaque susceptible to rupture is characterized by a large lipid core and a thin fibrous cap. They are also referred to as vulnerable plaques. Note that the lipid core is highly thrombolytic. Upon rupture, lipids interact with the blood to induce thrombosis (blood clot formation), artery blockage, and ultimately myocardial infarction (heart attack). If the atheroma stabilizes, smooth muscle cell proliferation can prevent rupture but still lead to calcification and severe fibrosis. Continued plaque growth can lead to severe stenosis (vessel occlusion) and ischemia (lack of oxygenated blood). In the past, conventional wisdom in cardiovascular research assumed that most myocardial

infarctions and strokes were caused by artery occlusion due to plaque growth.^[2] Recent studies have shown that plaque rupture, not vessel occlusion, is the leading cause of these acute events.^[3]

CLINICAL TREATMENTS

To effectively treat atherosclerosis, several interventions have been developed and are currently used in the clinic. The most common interventional procedure is percutaneous transluminal coronary angioplasty (PTCA). In PTCA, a balloon catheter is inserted into the arterial vasculature via the femoral artery over a smaller guide wire. Once the balloon catheter arrives at the coronary lesion to be dilated, the balloon is pressurized with fluid to expand the arterial lumen. The first balloon angioplasty procedure was performed in 1977 by Dr. Grüntzig in Zurich, Switzerland.^[4] The procedure is most effective for softer plaques. Although angioplasty proved effective in many cases, restenosis (subsequent occlusion of the artery lumen after the procedure) rates can still be 20–30%, based on follow-up studies performed about six months after the procedure.^[5,6]

Due to the limited success of PTCA procedures, stents were developed to be placed inside the vessel to maintain lumen diameter after the balloon intervention. Stents are meshed scaffold tubes delivered over an angioplasty balloon. As the angioplasty balloon is inflated, the stent expands and is implanted inside the vessel lumen. Since gaining FDA approval in 1994, stents have become the primary interventional procedure accounting for a majority of angioplasty procedures in catheterization laboratories.^[7] Stents effectively prop open the occluded vessel by pushing on the plaque and arterial wall to expand the lumen diameter. Clinical complications related to stent deployment are underdeployment and overdeployment. Underdeployment can lead to stent collapse if it is not in complete contact with the vessel lumen. Furthermore, blood can collect in the gap between the arterial tissue and the underdeployed stent leading to thrombosis.

To avoid these complications, stents are usually overdeployed or overpressurized. While preventing stent collapse, overpressurizing the stent can lead to vessel rupture, edge dissections of the vessel, or distal embolism. Furthermore, stent overdeployment leads to restenosis as balloon overpressurization triggers an injury response from the vessel. The inflammatory response due to endothelial cell damage results in neointimal hyperplasia (smooth muscle cell proliferation into the lumen leading to restenosis) in the very vessel the stent was intended to open. Most recently, drug-coated stents have been developed to deliver

chemicals inhibiting neointimal proliferation. The recent study by Sousa et al.^[8] shows promising initial results in human patients with no in-stent, edge restenosis, or major clinical events eight months after a stent procedure. Although more recent studies with a larger number of patients and longer follow-up evaluation have yielded less promising results,^[9] drug-coated stents appear to significantly reduce restenosis rates.

Other common interventional procedures include atherectomy, brachytherapy, and coronary bypass surgery. Atherectomy uses a small rotating blade on the tip of a catheter to cut away the plaque and collect debris with a suction tube. This procedure is usually reserved for calcified plaques resistant to angioplasty or stent procedures,^[10] but it has the risk of vessel rupture or injury. Another interventional treatment for coronary artery disease is brachytherapy. This procedure involves delivering focused radiation at the lesion site using a catheter. By delivering localized radiation to the lesion, the goal is to kill unhealthy plaque cells. In more severe cases, when angioplasty or stent procedures go awry or do not significantly change the lumen diameter of the coronary artery for the long term, coronary bypass surgery is required. Vessels are usually grafted from extremities to provide collateral flow around occluded areas in the coronary vasculature. This surgical procedure generally requires cracking the sternum and opening the rib cage to gain access to the heart.

For all of the therapies mentioned above, pharmaceuticals plays a significant and ever growing role in the treatment of cardiovascular disease. During the procedure, anticoagulants such as heparin are usually delivered immediately after the procedure to help minimize thrombosis in the treated artery. Furthermore, cholesterol-lowering drugs have been shown to be valuable adjuvants to lifestyle changes (stopping smoking, regular exercise, and healthy diet) to help manage coronary artery disease.^[11,12] Research is also being carried out to study the effects of anti-inflammatory drugs to minimize the inflammatory response in the treated region. Also, chemicals that inhibit vascular endothelial growth factor (VEGF) are used in drug-coated stents.^[8,13]

IVUS IMAGING

To help diagnose and treat cardiovascular disease, IVUS imaging was developed to help the clinician visualize arterial pathologies from inside the vessel. IVUS uses small ultrasound transducer(s) integrated into an intraluminal catheter. Brightness mode (B-mode) cross-sectional images of the vessel are acquired and displayed in real time for the clinician, as

Fig. 1 B-mode IVUS image (left) of an occluded artery. A plaque filling nearly the entire lumen is easily differentiated from the vascular wall. Simultaneous B-mode and flow image highlighting the open lumen within a partially occluded vessel is shown on the right. The flow region is delineated in white (print version) or shown in red (online version). Flow images are produced using a non-Doppler decorrelation method. (Reprinted with permission from Ref. [20]. © 1997 IEEE.)

illustrated in the left panel of Fig. 1. The typical IVUS catheter is only about 1 mm in diameter and is inserted into the patient's vasculature via the femoral artery. The two most common IVUS catheters are a 64-element circumferential array transducer and a single-element rotating (element or mirror) transducer. A drawing illustrating both designs is shown in Fig. 2. The single element catheter operates at a center frequency of 30 MHz at frame rates up to 50 Hz. This catheter can produce image artifacts due to nonuniform rotational distortion, a result of frictional forces when the catheter is inside the vessel.^[10] The solid-state circumferential array transducer operates at a center frequency of 20 MHz using synthetic aperture processing to form images at frame rates of about 30 Hz. The advantages of this transducer are that there are no mechanical parts, elements are controlled electronically, and its smaller footprint allows it to be integrated into combined devices, as discussed subsequently.

Intravascular ultrasound is primarily used as a diagnostic tool to measure lumen diameter and degree of stenosis pre- and postintervention (angioplasty or stent deployment). In addition, IVUS is also used to

Fig. 2 Two types of IVUS catheters. The top drawing is a single rotating ultrasound element transducer and the lower drawing is of a solid-state ultrasound array transducer. (Reprinted with permission from Ref. [20]. © 1997 IEEE.)

measure blood flow to determine if normal physiological flow has been restored after an interventional procedure.

Intravascular ultrasound provides real-time, high-resolution (50–75 μm) images with large penetration depths of 5–8 mm. By imaging from inside the vessel, IVUS allows for both anatomical and functional imaging to help diagnose and treat cardiovascular diseases. The primary disadvantages of IVUS include being minimally invasive and imaging only one cross-section of the vessel at a time. Furthermore, IVUS often increases both the time and cost of interventional procedures.

OTHER IMAGING MODALITIES

To better understand IVUS, it is important to compare it to other imaging modalities used for cardiovascular imaging. X-ray angiography remains the gold standard for coronary arteries. Its main advantages are high spatial resolution (150 μm) and relatively low cost compared to other modalities.^[14] The main drawbacks are the radiation exposure for the patient during an intervention procedure as multiple injections of radioactive contrast agent are delivered. In general, contrast agents can be radioactive (usually for X-ray, computed tomography (CT), and nuclear imaging) or nonradioactive (usually for magnetic resonance imaging (MRI) and ultrasound), and their purpose is to enhance image quality by highlighting certain tissues or features. Another drawback to X-ray angiography is that planar X-ray imaging captures only a projection of the vasculature and can often misdiagnose asymmetric lesions.^[14]

Computed tomography is an extension angiography. X-ray CT is an imaging tool that uses a ring of X-ray detectors opposed to the X-ray transmitter. The main advantage of CT is its noninvasive, cross-sectional imaging of vessels to diagnose vascular occlusions and atherosclerotic calcified lesions. In addition, fast multislice CT allows for three-dimensional (3-D) volume data acquisition and slice images can be reconstructed with an in-plane resolution of 600 $\mu\text{m} \times 600 \mu\text{m}$ and a slice thickness of 1 mm. CT can also be used to image vessels after an interventional procedure and during noninvasive follow-up studies. Unfortunately, CT, like X-ray angiography, exposes the patient to radioactive iodinated contrast agents often used during the procedure.

Another noninvasive imaging modality is MRI. MRI uses a high-field whole-body magnet and radio-frequency coils to manipulate nuclear spins in the body for functional and anatomical imaging.^[15] MRI has the advantage of being able to identify large lipid regions in a plaque, which is useful for identifying vulnerable

plaques. Furthermore, like CT, MRI collects a 3-D volume of data and allows for any slice to be viewed after the data acquisition. The resolution for magnetic resonance angiography images is typically about $1000\ \mu\text{m} \times 1000\ \mu\text{m}$ (or $1\ \text{mm} \times 1\ \text{mm}$) with a frame rate of about 5 Hz. MRI slice thickness can range from 1 to 10 mm, depending on frame rate. In MRI, paramagnetic contrast agents can be used to enhance images. The drawbacks of MRI are the long data acquisition times and the tradeoffs of higher resolution images for lower frame rates.

Nuclear imaging uses radiopharmaceuticals injected into the patient intravenously in small doses to study physiological parameters (as opposed to imaging anatomical features) by collecting images over time. As different regions of the body selectively absorb these radioactive materials, gamma rays are emitted and detected. Although nuclear imaging provides important functional information, both spatial and temporal resolutions are lower than with other modalities, and the patient must be injected with radioactive isotopes to achieve contrast.

Optical coherence tomography (OCT) imaging is a relatively new modality developed by Fujimoto in 1991.^[16] OCT operates much like a single-element ultrasound transducer but uses optics to transmit and receive one-dimensional signals, which are then combined to form an image. Its primary advantage is high resolution (about $10\ \mu\text{m}$) at a frame rate around 10 Hz. This resolution is on the order of histological images and can help characterize plaques and image inside a vessel. The major obstacle to vascular imaging with OCT is that the transmitted light is highly scattered by blood.^[17]

CLINICAL APPLICATIONS

Conventional IVUS images show the vessel cross-section to a depth of 5–8 mm from the catheter. Quantitative lumen measurements are made from these images to diagnose vessel stenosis. With the development of vascular interventional procedures such as angioplasties and stents, comparing pre- and post-procedure lumen measurements is especially useful in evaluating an intervention. Thus, a clinician can immediately determine if further interventions are necessary.

In addition to visualizing lumen morphology, IVUS images can also assess coronary blood flow during diagnostic or posttherapeutic interventions, as illustrated in the right panel of Fig. 1. One of the challenges to measuring flow with IVUS is that blood flows normal to the side-looking imaging plane (vessel cross-section). Therefore, Doppler processing cannot be used to image the flow field. Recent developments in

IVUS technology have allowed for real-time blood speed imaging with IVUS using a filter bank approach.^[18] With quantitative flow measurements, clinicians can evaluate the degree of stenosis before and after an intervention and validate the procedure before pulling back the catheter.

FUTURE DIRECTIONS

Intravascular ultrasound technology is continually being improved to create high-resolution images (through smaller high-frequency ultrasound elements) and smaller catheters. In addition to these advances in the catheter itself, several promising new applications and IVUS designs could lead to a more significant role for IVUS in diagnosing and treating cardiovascular disease.

Due to the increase in cardiovascular diseases, there has been a growing interest in measuring mechanical properties of arterial tissues and pathologies using strain imaging and IVUS.^[19–21] If vulnerable plaques can be identified and their mechanical properties quantitatively measured, they can help guide interventional procedures and plaque rupture could be better understood. IVUS images can be used to produce strain and elasticity images (with deformations applied by a balloon catheter or the cardiac pulse) to differentiate soft (lipid) and hard (fibrotic) regions of a plaque. Figure 3 shows a thrombus located inside a rabbit thoracic aorta that is hard to distinguish from the vessel in the B-mode image on the left but clearly visible in the strain image on the right. Tissue displacements can be accurately measured with speckle-tracking algorithms by imaging from inside a balloon

Fig. 3 IVUS images of an excised rabbit thoracic aorta with a thrombus imaged from inside a balloon catheter placed in a water tank. The left image is the B-mode and the right is the strain image. The B-mode image is displayed over a 40-dB log scale and strains are displayed over a truncated range of 10% (black) to 35% (white). The strain image highlights the soft thrombus inside the aorta that is not clearly visible in the B-mode image alone. (Reprinted with permission from Ref. [25]. © 2002 IEEE.)

Fig. 4 Forward-viewing IVUS array drawing and simulated images. The forward-viewing IVUS array enables 3-D imaging and imaging of the C-mode plane denoted by the dark gray disk and the simulated image on the right. The B-mode image in this geometry is orthogonal to the C-mode plane, as shown on the left.

catheter as a deformation is applied to the artery or lesion. Displacement data are accumulated and processed to create strain and elasticity images of vascular tissues and pathologies. Clinical evidence has shown that distensibility of atherosclerotic coronary lesions may vary widely, from undilatable hard lesions to soft highly compliant ones.^[22] In particular, the elastic moduli of a normal arterial wall and a coronary plaque can vary by over an order of magnitude.^[23]

Another exciting future direction for IVUS is a forward-viewing catheter to image areas of the vessel in front of the device.^[24] Using a ring-annular array of ultrasound elements, 3-D data can be acquired to image tissue and flow in front of the catheter. Multi-view images, as shown in Fig. 4, would allow the clinician to accurately guide the IVUS catheter to the lesion of interest and view the plaque without disturbing it. The C-mode image in this geometry is similar to the conventional B-mode image in the side-looking IVUS catheter and images the vessel cross-section. The B-mode image in this geometry is orthogonal to this plane and can image along the length of the vessel. Using this forward-viewing B-mode image, Doppler flow measurements would be possible in the region distal to the IVUS array. This forward-viewing array can be fabricated by modifying the current solid-state IVUS catheter to image in both the side-viewing (conventional) and forward-viewing modes to allow for imaging at the location of the catheter as well as the region in front of it.

Conventional IVUS imaging can be extended to provide 3-D images by acquiring a series of real-time cross-sectional images and using image segmentation and rendering to allow the clinician to view the vessel and pathology from any angle. The physician could rotate the 3-D image and also view different imaging planes (or slices) to obtain a better view of the plaque and vessel morphology. Three-dimensional

IVUS images would be particularly useful for unusual vessel or plaque shapes, suspicious plaques, and regions near vessel branches.

Perhaps the greatest clinical limitation in balloon angioplasty and stent deployment procedures is the lack of image guidance and quantitative feedback during the procedure. Even preprocedure estimates of lumen diameter and occlusion can lead to significant errors due to planar projections obtained by X-ray angiography.^[14] Due to the lack of image guidance, stents are often underdeployed, leading to thrombosis or stent collapse, or overdeployed, resulting in greater intimal injury and higher restenosis rates. However, current uses of IVUS are still limited to imaging before and after the procedure but not *during* it. Furthermore, imaging pre- and postprocedure requires the use of additional catheters and lengthens the total intervention time. Both of these factors can significantly add to the total cost for patient treatment.

To address these important clinical problems, an integrated balloon ultrasound catheter has been proposed to combine IVUS imaging and therapy in realtime during an interventional procedure.^[19,25] Figure 5 shows a drawing of the integrated device along with a photo. The clinical opportunities and the significance of an integrated device are numerous. First, imaging from inside a balloon catheter enables strain imaging of arterial pathologies to characterize tissues and guide interventions. By imaging in real time as the balloon probes the tissue, lesions could be characterized before a complete angioplasty procedure is carried out. Even during stent procedures, strain imaging could prevent overdeployment. For balloon procedures such as angioplasty and stent deployment, the integrated balloon ultrasound catheter could

Fig. 5 Integrated balloon ultrasound catheter. The top is a drawing with the IVUS array shown inside the balloon catheter. Below the drawing is a photo of an integrated balloon ultrasound catheter prototype. (Reprinted with permission from Ref. [25]. © 2002 IEEE.)

provide both real-time image guidance and quantitative feedback during the interventional procedures. Both visual and quantitative feedback would help clinicians achieve optimal stent deployment. After a procedure is performed, the balloon can be deflated and moved in pullback mode along the length of the lesion to verify that the stent has been fully deployed. Last, the current limitations of IVUS can be overcome by providing a single catheter device for balloon interventions and reducing total intervention time, at the same time providing significant feedback during the procedure and allowing for a more controlled and reliable intervention.

The ultimate goal of an integrated device is to significantly change clinical outcomes by reducing intimal injury and subsequent restenosis rates. By verifying stent deployment with the same integrated balloon ultrasound catheter after the procedure, complete deployment can be easily validated in pullback mode. If any regions are underdeployed, the balloon can easily be realigned and reinflated using the same metric and real-time image guidance. Ultimately, the integrated balloon ultrasound catheter could transform cardiovascular interventions into a single catheter procedure. By reducing the number of catheters used, the total procedure time would decrease for the patient and lead to increased patient throughput for a catheterization laboratory.

In addition to exploring these potential advancements in IVUS technology, several research groups are currently investigating ultrasound-mediated gene therapy and molecular imaging applications with high-frequency ultrasound. Recent work by one research group has explored ligand-targeted contrast agents using microbubbles for IVUS.^[26,27] The potential benefits of molecular imaging are the ability to detect, monitor, and treat different pathologies. Other groups are studying the effects of IVUS therapy to enhance transgenic expression^[28] and reduce neointimal hyperplasia.

CONCLUSION

Intravascular ultrasound is a valuable imaging modality in the catheterization laboratory used to diagnose cardiovascular diseases. Recent developments and current research show promise for IVUS gaining a larger role in guiding interventional procedures. With the development of a forward-viewing IVUS array and an integrated balloon ultrasound catheter, IVUS can be used as a single interventional device to not only diagnose but also guide therapies and provide real-time feedback to the clinician. In addition, further advances in IVUS catheter fabrication will lead to higher-resolution images and smaller catheters. Last,

emerging applications such as 3-D rendering, strain processing, and molecular imaging will continue to make IVUS an important imaging tool in treating cardiovascular disease.

In Vivo Cardiovascular Models

B. H. Walpoth

Department of Cardiovascular Surgery, University Hospital, Geneva, Switzerland

O. M. Hess

Swiss Cardiovascular Center, University Hospital, Bern, Switzerland

INTRODUCTION

Synthetic vascular grafts are increasingly used for replacement of medium and large arteries. However, synthetic grafts have failed as vascular conduits in small arteries (<6 mm) such as coronary and peripheral vessels.^[1,2] Various attempts have been made to overcome this problem by using autologous material (vein, artery, pericardium, umbilical cord, etc.) with satisfactory long-term results.^[3-6] However, in the case of diseased autologous material or previous surgery, homologous or, eventually, heterologous or synthetic material have to be used, but results are less satisfactory.^[7-10] Tissue engineering, as a new promising technique, has gained a lot of interest for improving long-term patency of small synthetic vascular grafts by seeding endothelial and/or smooth muscle cells.^[11-16] Animal models are, therefore, essential for preclinical assessment of novel synthetic or tissue-engineered vascular grafts.^[17-19]

The main goal of these animal models is:

- To test new synthetic or biological materials (non-degradable or degradable).
- To study blood and tissue compatibility.
- To assess rejection and healing processes.
- To evaluate genetically modified auto-/allo- or xenografts.

MODELS

Application of new devices for implantation in humans requires thorough in-vitro testing for physical characteristics (compliance and tensile strength) and tissue reactions in cell culture models. As a next step, in vivo models should be used to test for vascular pathophysiology and several conditions have to be taken into consideration for the testing of vascular prostheses, low and high pressure systems; pulsatile and non-pulsatile flow; conduit or capacitance vessels; presence or absence of endothelium; and normal or arteriosclerotic vessels (inflammation).^[20-24]

Animal Models

Multiple factors must be considered for animal models, such as animal species, circulation models, implantation sites, and concomitant treatment.^[25-40]

Rodents (mice and rats) have several advantages, such as availability and cost effectiveness, but operations and follow-up tests are usually difficult and results are less applicable to humans.^[28,29] The rabbit model is often chosen for its ability to replicate human arteriosclerotic lesions after cholesterol-rich feeding.^[39] Pigs and primates are used for preclinical studies, especially when similar devices as in humans have to be used, such as stents, valve prostheses, etc.^[40] A few questions can be answered by using acute experiments such as feasibility studies for graft suturing or early blood thrombogenicity testing. Mostly, chronic experiments are applied in order to assess changes over time (mainly in small animals) and long-term patency, etc. In larger animals, these changes can be assessed repetitively using newer, sophisticated, noninvasive and invasive methods such as echo-doppler, MRI imaging and flow studies, quantitative angiography, and/or intravascular ultrasound (IVUS).^[41-43]

Site of Implantation

Major differences are found after vascular implantation in a low-pressure (venous side) or a high-pressure (arterial side) system. Furthermore, results will be influenced by the size of the prosthesis, the native flow, and peripheral resistance of the vessel being tested.^[44] In general, coronary arteries show a high flow rate compared to their size and, thus, better results than distal peripheral artery replacements of comparable sizes.

Different surgical techniques can be employed such as end-to-end or end-to-side bypass anastomosis or even a looped vascular graft.^[45-47] Furthermore, animal treatment (such as antithrombotic agents) will vary according to the species used.^[48] As a general rule, vascular replacement of the infrarenal aorta typically shows a good long-term patency without any drug therapy in the rat model. In contrast, carotid artery

replacements in the pig model with 3–4 mm synthetic vascular grafts require antithrombotic long-term therapy to yield a satisfactory patency rate.^[38,49]

Graft Material

During the last 20 years, innumerable tests have been carried out with various synthetic and biological grafts to overcome the bad patency rates in small-caliber vascular prostheses.^[11–16,50–55]

The best clinical results for arterial and venous replacement are obtained with autologous materials such as saphenous vein, internal mammary artery-free transplants, or in situ, or radial, artery.^[3–6] Clinically, an off-the-shelf vascular graft with all diameters and lengths comparable to autologous material would be the surgeon's dream. However, even the best clinical long-term results for small vascular prostheses are unsatisfactory. For large arterial replacements such as aortic aneurysms, Dacron and expanded-polytetrafluoroethylene (ePTFE) prostheses have been used with good long-term results due to the large size and high-flow situation.^[18] For peripheral vascular surgery, synthetic ePTFE grafts have a certain role, but patency is limited. These grafts can be improved by surface coatings such as heparin bonding, bi-layer surface treatment, etc.^[49,56–59] Others have tested biological replacement grafts such as homografts (cryopreserved) or xenografts such as glutaraldehyde-denatured bovine carotid arteries or uvine ureters.^[9,10] More recent studies have explored autologous endothelial cell seeding on synthetic ePTFE grafts with promising results.^[11,14] The technique, however, is time- and cost-intensive and cannot be used for emergency surgery because the grafts have to be prepared with autologous culture-expanded cells.

Vascular tissue engineering using nondegradable or degradable synthetic grafts or grafts produced from recombinant human proteins have been used successfully as scaffolds for cell growth.^[60–62] Potential cells to be used in such scaffolds are autologous endothelial cells, smooth muscle cells, or progenitor stem cells.^[63–65] Experimental and clinical data on autologous cell seeding techniques on nondegradable vascular grafts have shown reasonably good results.^[11,66] However, regardless of the method (direct seeding or culture expansion), the rate of surface coverage after implantation is still incomplete (about 50–75%).^[67] One of the explanations for this observation is the high shear stress in the arterial circulation.^[23] The use of progenitor or even embryonic stem cells has not yet passed the experimental stage. Progenitor cells have to be harvested and enriched before graft seeding. More recently, several groups have been working with the

concept of using blood-borne endothelial progenitor cells to attach to the inner graft surface in vivo (statins and/or growth factors).^[68–70] Ultimately, a three-dimensional biodegradable vascular scaffold made out of synthetic or, better yet, of human recombinant proteins with embryonic or progenitor cell seeding (either in vitro or in vivo), may be the solution for the future.^[71,72]

Functional Assessment

A variety of functional tests are available in animal models. The larger the animal, the easier the use of these techniques, which normally include flow, pressure, and resistance measurements. Most commonly the transit time Doppler flow technique is used (CardioMed, Norway). This technique represents a fast and cost-effective method that yields excellent accuracy and reproducibility.^[73,74] Other techniques include Duplex sonograph or angiographic examinations. These methods combine a morphological image with some information about blood flow and flow distribution. The assessment of compliance is difficult under in-vivo conditions but comparisons with normal vessels may give important information on long-term patency.^[44–46] After explantation of the vessels, vasomotion can be tested with the vascular ring technique. This technique, however, can be applied only to autologous or possibly tissue-engineered neovessels.^[75]

Morphological Assessment

On completion of a study, an in situ pressure-fixation with glutaraldehyde is recommended in order to preserve all anatomical details of the anastomosis and the vascular prosthesis because any fixation will create a shrinkage of the vessel wall. After explantation several parameters can be determined: Macroscopically, the in-growth of the prosthesis into the adjacent tissue is thought to have a beneficial effect on patency (due to adventitial neovessels promoting endothelial coverage) and may represent some protection against possible graft infections.^[76] Certainly such tissue ingrowth may induce fibrosis with a reduction in vascular compliance leading possibly to accelerated intimal hyperplasia reaction and graft occlusion.^[77] Microscopically, patency, luminal surface, intimal hyperplasia, and tissue reaction, as well as prosthesis in-growth, can also be studied. Intimal hyperplasia formation is normally assessed quantitatively with micrometry on vascular longitudinal or cross sections. Normally the intimal hyperplasia thickness as well as the ratio of stenosis to the normal vessel is calculated.^[49] In the case of biological or degradable grafts, degradation rate and

foreign body reaction can be assessed.^[78] Scanning electron microscopy (SEM) is the method of choice to examine the inner surface.^[79] An evaluation of cellular and platelet deposition and microthrombus formation is indicative of blood compatibility.^[80–82] Further studies such as immunohistochemistry, molecular analysis, or gene expression may be used to evaluate molecular adaptation of these vascular prostheses to the surrounding tissue.^[33,83]

Description of Some Currently Used In-Vivo Cardiovascular Models

Blood thrombogenicity in the acute pig model

Early blood thrombogenicity may be tested in a femorofemoral arteriovenous shunt model. A specific canula is placed in the femoral artery and connected to a similar canula in the femoral vein. The vascular grafts (normally pieces of about 3–5 cm length with various diameters) are placed between these two canulae. Blood is then circulated for varying time intervals. Normally morphological and structural changes are assessed after 3, 9, and 30 minutes. These tests are performed under constant flow and pressure. A typical study protocol includes the following two steps: perfusion without heparin followed by perfusion with systemic heparinization of the animal.

Morphological examination of the vascular grafts is done on the explanted pieces after pressure fixation using scanning electron microscopy. Figures 1 and 2

Fig. 1 Scanning electron microscopy (SEM) picture of the inner surface of the ePTFE (control) graft after 9 minutes blood perfusion (arteriovenous shunt model in the pig). Note the moderate cellular (WBC [↓]) deposition and the severe platelet deposition [↑] with some micro-thrombi formation [X].

Fig. 2 SEM picture of the inner surface of the ePTFE-coated graft with PPS-PEG dry after 9 minutes of blood perfusion. Note the striking difference from Fig. 1 with only little white blood cell deposition and no platelets or microthrombi.

show the same ePTFE graft (control vs. coating) after 9 minutes of perfusion without heparin. Note the significant cellular and platelet deposition in Fig. 1 (control) as compared to Fig. 2 using polypropylene sulfide and poly-ethylene glycol (PPS-PEG) coating.^[84] Thrombogenicity is normally evaluated by the amount of cellular deposition and especially the deposition of platelets and microthrombi.

Fig. 3 Histological cross section of a poly(glycolic acid) (PGA) graft manufactured by electrospinning after 2 weeks of subcutaneous implantation. Note the early degradation of the material (loosening of the material) and mild cellular ingrowth as well as tissue reaction of the perivascular tissue.

Fig. 4 Histological cross section of a poly(lactic acid) (PLA) graft, manufactured by electrospinning after 2 weeks of subcutaneous implantation. Note the advanced degradation of the graft material with a more pronounced tissue reaction of the perivascular tissue compared to Fig. 3.

Degradation and tissue reaction in the rat model

Subcutaneous implantation of pieces of vascular grafts is used, e.g., for testing new degradable synthetic or biological graft material. Advantages of this technique are the simple surgery and the fact that several materials can be compared in the same animal. In addition, material calcification can be easily studied in this model before using costly long-term survival experience as, for example, when studying new cell-seeded or tissue-engineered valves or grafts. Besides histological staining, a high resolution radiography will clearly

show microcalcification in the material.^[29,85] After subcutaneous implantation animals are sacrificed at 2, 4, 8, or 12 weeks and morphological assessments are performed as mentioned. Figures 3 and 4 are examples of degradable synthetic grafts after two weeks of implantation. Note the slight degradation with mild cellular in-growth and tissue reaction of the perivascular tissue in Fig. 3 poly(glycolic acid) (PGA) as compared to Fig. 4 polylactic acid (PLA) showing an advanced degradation of the graft with more tissue reaction than in Fig. 3.

Vascular graft replacement in the small animal

Following subcutaneous implantation of the grafts, the vascular prostheses with degradation rate ranging between 4 and 8 weeks with little tissue reaction are implanted in a small animal for assessment of graft patency and intimal hyperplasia formation.^[49] This implies microvascular surgery using magnifying loops or an operative microscope with specialized instruments and trained personnel. Due to the small sample size, noninvasive follow-up examinations are difficult and normally animals will be euthanized for morphological assessment in the rat model. Adequate information is normally obtained after 4 weeks of implantation. However, long-term implantation up to 6 or 12 months is advisable for assessing intimal hyperplasia, calcification, and aneurysm formation. Figure 5 shows a polyurethane graft at infrarenal aortic implantation in the rat (left panel) and at sacrifice after 4 weeks of implantation (middle panel). The right panel shows an histological longitudinal section with graft anastomosis.

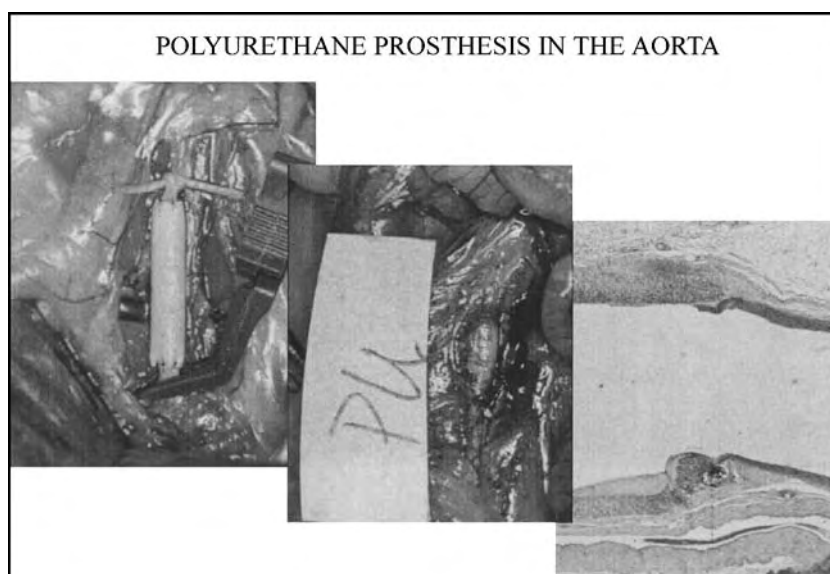

Fig. 5 The polyurethane graft upon implantation at infrarenal aortic position in the rat (left panel) and at sacrifice after 4 weeks of implantation (middle panel). The right panel shows a histological longitudinal section with graft anastomosis. Towards the left, the graft structure is clearly seen covered by about ten layers thickness of neointimal cells. In the middle, some tissue reaction is visible mainly due to the surgical anastomosis, and on the right side, the normal arterial wall structure is recognizable.

Pig carotid bypass

Fig. 6 Carotid artery flow measurement using the transit time technique (left) and an ePTFE carotid artery end-to-end replacement (right).

Vascular graft replacement in the atherosclerotic (cholesterol-rich diet) rabbit

The majority of experimental studies are performed in healthy juvenile vessels. In clinical situations, vascular replacement, however, is performed most often in patients with advanced atherosclerotic disease. Thus, the animal models may not be appropriate to answer clinical questions and requirements.^[39] The high cholesterol-fed rabbit model is well established and induces severe arteromatous vascular lesions that are similar to the early changes seen in human arteriosclerosis.^[39]

These changes appear in the rabbit after 4–6 weeks, but lack calcification and plaque ulcerations. Nevertheless, it is the model of choice for testing new anti-proliferative drugs such as statins or rapamycin or taxol.^[83,86]

Bilateral carotid artery replacement in the pig

This animal model has several advantages compared to studies based on rodents. In the past, such experiments have been performed with mongrel or dogs bred for experimental use with good results. An advantage of the canine model is the large size and good surgical accessibility of not only the carotid vessels but also femoral arteries.^[57,59] However, for ethical reasons, most studies with dogs have been discontinued. In the porcine model, vascular anatomy and morphology of the heart and great vessels are similar to humans. Furthermore, the advantage of using a bilateral carotid artery replacement is that each animal can serve as its own control, reducing interanimal variability.^[31,38,87] Of equal importance is the small size of the carotid artery in the pig; such a vessel diameter (3–4 mm internal diameter), would be appropriate for human coronary bypass vessels. Furthermore, clinically available invasive and noninvasive methods can be used repetitively for assessing long-term patency and intimal hyperplasia formation. Figure 6 shows a carotid artery flow measurement using the transit time

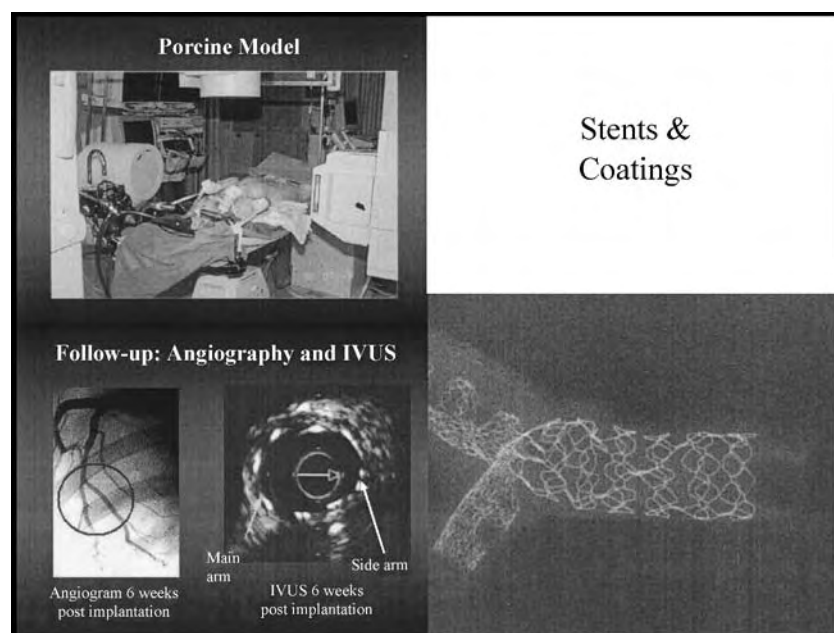

Fig. 7 Animal at follow-up during selective coronary angiography and intravascular Doppler flow measurement 6 weeks after implantation of a bifurcation stent (left). The angiogram shows a widely patent stented bifurcation, which is confirmed by IVUS. The right panel shows an ex-vivo high-resolution radiograph of the stent structure.

Fig. 8 Cross sections of coronary arteries of the pig, either native (A), or after 6 weeks of stent implantation (B,C,D). Note the severe intimal formation (near occlusion) in the control stents as compared to the stents coated with TiNOX 1 or 2. (Reproduced from Ref. [93] with permission from Circulation.)

technique (left) and an ePTFE carotid artery end-to-end replacement (right).

Porcine coronary artery overstretch model and stent implantation

The porcine coronary anatomy is similar to humans, especially with regard to collateralization.^[88] Therefore, this model is often used for preclinical testing of vascular implants. The Achilles heel of percutaneous

transluminal coronary angioplasty (PTCA) is restenosis due to excessive neointimal hyperplasia with negative vascular remodeling.^[89] Intracoronary stents have reduced restenosis but in-stent restenosis (constrictive vascular remodeling) remains a major problem. Thus, new stent designs with passive or active surface coatings with or without drug elution are often tested in the porcine overstretch model.^[90-92] (See Fig. 7.)

The effect of novel stent coatings on coronary artery remodelling has been studied in 12 pigs, each instrumented with three stainless steel stents (15 mm length, 2.5–3.0 mm diameter), and a control and two TiNOX-coated (titanium-nitrid-oxide) stents (TiNOX 1 = ceramic; TiNOX 2 = metallic coating). After 6 weeks of survival, animals were euthanized and histological specimens of the stented segments were performed by digital morphometry. Largest neointimal hyperplasia (expressed as surface area) was found in uncoated (2.6 mm²) followed by TiNOX 1-coated (1.5 mm²) and TiNOX 2-coated (1.4 mm²) stent (Fig. 8). Thus, restenosis rate was reduced by 40% in TiNOX-coated stents.^[93]

In a similar study, the effect of poly(propylene sulfide)-poly(ethylene glycol) PPS-PEG and gold coating was tested (Fig. 9). The results show a significantly lesser degree of intimal proliferation in the PPS-PEG-coated stents compared to control or gold-coated stents.^[94]

Despite a large variety of in-vitro tests and new diagnostic procedures including molecular and genetic analysis, in-vivo testing of cardiovascular devices and vascular prostheses remains important before clinical implantation. Several models have been described above, each of which having certain advantages. A stepwise progression from acute to small chronic implantations followed by chronic long-term testing in the large animals is recommended.

Fig. 9 Side-by-side histological cross sections (low- and high-magnification) after 6 weeks of implantation for (left) control: uncoated stented vessel; (center) PPS-PEG coated stented vessel; and (right) gold-coated stented vessel.

INTRODUCTION

Artificial kidneys or hemodialyzers play an important role in saving the life of patients with kidney failures. The reported incident rates of patients with end-stage renal disease (ESRD) worldwide have increased steadily since 1989, and the U.S.A. continues to have the highest incident rates according to the U.S. Renal Data System 2000 Annual Data Report. The number of ESRD patients in the U.S.A. had increased significantly over the past 20 years, and it is projected to grow exponentially over the next 10 years. This number is projected to increase to 661,330 in 2010, an increase of 78% compared to 372,407 in 2000. Among these ESRD patients, those undergoing dialysis therapy are projected to increase to 520,240 in 2010 with an increase of 85% compared to 281,355 in 2000. In addition, the total annual cost of Medicare for ESRD patients in the U.S.A. is projected to be \$28.3 billion in 2010, an increase of 99% compared to \$14.2 billion in 2000.

In this article, we will discuss the fundamentals of artificial kidneys from the engineering perspective. We will first discuss the basic functions of human kidneys, classification of uremic solutes, basic designs and classification of artificial kidneys, property and classification of dialysis membranes, mass transfers in artificial kidneys, parameters used to characterize performance of artificial kidneys, and finally different forms of renal replacement therapies for acute renal failure (ARF). Because it is spatially impossible to discuss in depth the topic of artificial kidneys in solely one article, we encourage the readers to refer to the "Articles of Further Interest," "References," and "Bibliography" cited at the end of this article for further readings.

HUMAN KIDNEYS

Kidneys (Fig. 1) remove uremic solutes and excess plasma water from our blood and excrete them as urine. Healthy kidneys process about 190 L of blood per hour and produce approximately 1–2 L of urine per day.^[1] In addition to excretion of metabolic wastes and water, kidneys also regulate the acid–base balance in our blood and release three important hormones: erythropoietin, renin, and calcitriol. Erythropoietin stimulates our bones to generate red blood cells. Renin regulates our blood pressure. Calcitriol stimulates calcium reabsorption at the tubule and hence helps maintain a proper calcium level in our body.

There are three types of kidney failures: acute, chronic, and end-stage renal failures. End-stage renal failure is commonly called ESRD. Acute renal failure (ARF) is a sudden drop of the renal function caused by a sudden injury to the kidneys such as trauma and drugs or alcohol poisoning. The ARF may be counteracted if the kidneys are not seriously damaged. Chronic renal failure, on the other hand, is a gradual irreversible loss of the renal function. The ESRD is the final stage of kidney failure.

Kidney failure is said to occur when the kidneys lost 80–90% of their renal function. Most people remain healthy after having lost 50% of their renal function.^[1] Kidney failure, if untreated, the accumulation of uremic solutes in the blood can cause uremia and eventually lead to death; therefore, all kidney-failure patients must receive either renal replacement therapy or kidney transplantation to survive. An excellent discussion on the human kidneys and their diseases can be found in Refs. [2–6].

Fig. 1 The structure of human kidneys. Each kidney contains about one million nephrons where blood purification takes place. The excess plasma water and metabolic wastes are filtered from the blood-carrying capillaries in the nephrons and are sent to the bladder as urine through the ureters.

CLASSIFICATION OF UREMIC SOLUTES

Uremic solutes can be divided into four groups^[7] based on their molecular weights. The so-called “small solutes” have molecular weights less than 300 Daltons (Da), “middle molecules” have molecular-weights between 500 and 5000 Da, “low molecular weight protein” have molecular weights between 5000 and 50,000 Da, and “large proteins” have molecular weights greater than 50,000 Da. A Dalton is a unit of molecular weight. Examples of small solutes are urea (60 Da) and creatinine (113 Da), which are byproducts of protein metabolism and are commonly measured to estimate kidney health; low molecular-weight proteins are β_2 -microglobulin (11,818 Da) and parathyroid hormone (9425 Da); and large protein is albumin (66,000 Da). This classification scheme will be used throughout this article.

History Perspective of Uremic Solutes

In the 1960s, the retention of small solutes in the human blood was believed to be the main cause of uremic syndrome. At that time, conventional hemodialysis mediated by diffusive transport of small solutes was claimed to be adequate for treating kidney-failure patients. In addition, some researchers^[8,9] claimed that larger solutes are unimportant to uremic syndrome, and they therefore emphasized on the clearance of small solutes as the measurement of

adequacy of hemodialysis. In contrast, other researchers^[10,11] found discrepancy between urea (small solute) clearance and uremic syndrome.

In the early 1970s, the Middle Molecule hypothesis^[12,13] was proposed, and it resulted in the classification “middle molecule.” The Middle Molecule hypothesis states that uremic syndrome is at least in part caused by the retention of middle molecules in the blood.

In the 1980s, the discrepancy between urea clearance and uremic syndrome, and the Middle Molecule hypothesis, however, were ignored when experimental results from the National Cooperative Dialysis Study (NCDS) showed that the removal of urea was correlated to the morbidity and mortality of hemodialysis patients.^[14,15] Despite the NCDS results, Rockel et al.^[16,17] found elevated concentration of low molecular-weight proteins, which normally undergo catabolism in the kidneys, in chronic hemodialysis patients. Gejyo et al.^[18] and Gorevic et al.^[19,20] discovered that the elevated concentration of β_2 -microglobulin, a middle molecule, leads to systemic amyloidosis in long-time hemodialysis patients. The β_2 -microglobulin is the first middle molecule to be linked to a specific clinical syndrome occurring exclusively in hemodialysis patients.^[21]

In the 1990s, Vanholder et al.^[22] revisited the Middle Molecule hypothesis and confirmed that the uremic syndrome is at least in part caused by the retention of middle molecules in the human blood. In addition, Anderstam et al.^[23] showed evidence that suggests that

the retention of middle molecules in the blood causes uremic appetite suppression, where they found that the middle molecules isolated from the uremic ultrafiltrate inhibit ingestive behavior in rats. All these findings have shown the importance of the middle molecules in uremic syndrome.

Most recently, a more sophisticated classification scheme of uremic solute has been proposed by the European Uremic Toxicity Working Group, which was initiated by the European Society for Artificial Organs in 1999. Details of that classification scheme can be found in Refs. [24,25]. A review on the pathophysiologic effects of uremic solutes has been done by Vanholder and De Smet.^[26]

ARTIFICIAL KIDNEYS

Artificial kidneys or hemodialyzers are used in extracorporeal renal therapies for the removal of uremic solutes and excess plasma water from the blood of patients with kidney failure. The terms *artificial kidney* and *hemodialyzer* will be used interchangeably throughout this article.

Historical Perspective of Artificial Kidneys

The first scientific description of hemodialysis principle was published by Graham^[27] in 1854, and the first prototype hemodialyzer (Fig. 2) was developed by

Fig. 2 The first prototype hemodialyzer developed by Abel et al. in 1914. (From Ref. [28].)

Abel, Rowntree, and Turner^[29] in 1913. The hemodialyzer was cylindrical in shape with an inner diameter of 10 cm and a length of 50 cm. It contained 30 collodion tube membranes with an inner diameter of 8 mm, with hirudin as the anticoagulant and saline as the dialysate. Abel et al. performed the first historical *in vivo* hemodialysis on a dog and succeeded in removing sodium salicylate administered to the dog from its body fluid. They referred to the process as *vividiffusion*.

The first hemodialyzer used on human was reported by Haas^[30] in 1923. Haas also used collodion tube membranes. He used hirudin as anticoagulant but later

Fig. 3 The rotating-drum artificial kidney developed by William J. Kolff that, for the first time, succeeded in treating a patient with ARF in 1945. (From Ref. [33].)

switched to heparin and built several models and sizes of hemodialyzers. None of Haas' patients, however, survived.

In 1945, Kolff^[31,32] developed the rotating-drum artificial kidney (Fig. 3) and succeeded in treating a patient with ARF for the first time. Kolff spirally wrapped a 30-m cellophane tube with an inner diameter of 25 mm around a wooden drum. The drum was rotated and half immersed in a 100-L stationary dialysate bath. Kolff^[34] later improved his rotating-drum artificial kidney by developing a twin-coil disposable artificial kidney (Fig. 4) in 1956.

In 1960, a plate-and-frame hemodialyzer called the Kiil dialyzer was developed by Kiil.^[35] It was made of multiple flat sheets of cellophanes sandwiched between plastic boards having multiple grooves. The Kiil dialyzer has a total membrane surface area of 1.8 m² and extracorporeal volume of 700 mL.

In 1964, the hollow-fiber hemodialyzer called the capillary kidney was first proposed by Stewart, Cerny, and Mahon.^[36] The capillary kidney was very similar to the prototype hemodialyzer developed by Abel, Rowntree, and Turner^[29] except that it has a much smaller inner diameter of hollow-fiber membrane. Hollow-fiber hemodialyzers are the most widely used hemodialyzers today.

Fig. 4 A twin-coil disposable artificial kidney developed by William J. Kolff in 1956 (From Ref. [28].)

Hollow-Fiber Artificial Kidneys

A typical hollow-fiber hemodialyzer contains between 6000 and 12,000 hollow fibers, depending on the size of the hemodialyzer. These hollow fibers have an inner diameter of about 200 μm and a wall thickness between 15 and 50 μm . These hollow fibers are made of semi-permeable membranes, and they act as a semipermeable barrier for the mass transfer of uremic solutes and excess plasma water from the blood to the dialysate. These hollow fibers are potted with either polyurethane or epoxy at both ends of the hemodialyzer to form tubesheets. Hollow-fiber hemodialyzers are available in different sizes (about 2–5 cm in diameter and 15–30 cm in length), and the choice of the size of hemodialyzer depends upon the size of the dialysis patient, where a large dialysis patient requires a large hemodialyzer.

From an engineering perspective, a hollow-fiber hemodialyzer is a countercurrent mass exchanger. The hollow-fiber design is preferred because it has a higher surface area per unit blood volume, thereby maximizing the overall mass-transfer surface area compared with other designs such as flat sheet and spiral wound. A hollow-fiber hemodialyzer has two compartments: blood and dialysate compartments. Its engineering design (Fig. 5) is very similar to a shell-and-tube heat exchanger. The tube side (inside the lumen of hollow fibers) is called the blood compartment, and the shell side (outside the lumen of hollow fibers) is called the dialysate compartment. The blood and dialysate are introduced countercurrently through the hemodialyzer to optimize the mass transfer of solutes by enhancing their concentration difference across the hollow-fiber membrane. The typical blood flow rates used in the clinical settings are between 200 and 400 mL/min, and the dialysate flow rates are between 500 and 800 mL/min, depending upon the size and physical conditions of the dialysis patient and the type of renal replacement therapy.

The geometrical designs of hemodialyzers play a critical role in regulating the flow distributions in the blood and dialysate compartments, and hence in determining their performance in removing uremic solutes. Ideally, the flow distributions in both the blood and dialysate compartments should be spatially uniform to ensure optimal removal of uremic solutes from the blood to the dialysate. Any mismatch of the blood and dialysate flows or the presence of shunt flow in either compartment can impair the removal efficacy of uremic solutes. In practice, it is very difficult to introduce uniform flow distribution throughout the dialysate compartment because of the presence of thousands of hollow fibers that create a complex pathway for the dialysate. We have studied the flow distribution in hollow-fiber hemodialyzers extensively using magnetic resonance imaging.^[37–41] Fig. 6 shows

Fig. 5 A general schematic drawing of an artificial kidney. The shape and size of an artificial kidney vary from different manufacturers.

an example of dialysate flow distribution at the middle cross-section of a polyamide hemodialyzer^[39] containing 10,000 hollow fibers, each with an inner diameter of 215 μm and a wall thickness of 50 μm . The velocity was imaged in the axial direction, and the dialysate flow rate was 600 mL/min. The dialysate flow distribution of this hemodialyzer was nonuniform where channeling flows occurred at the periphery. The channeling flows were caused by the uneven spacing of hollow fibers in the hemodialyzer. We have also shown that the design of flow baffle in the dialysate compartment affects significantly the dialysate flow distribution.^[40] Fig. 7 shows the designs of two different

flow baffles, and Fig. 8 shows their corresponding dialysate flow distributions near the inlet and the outlet of dialysate ports at dialysate flow rates between 200 and 1000 mL/min.

CLASSIFICATION OF ARTIFICIAL KIDNEYS

Artificial kidneys can be classified based upon the transport property of their membranes or their uses in dialysis therapy. The classification schema, nevertheless, remain somewhat debatable. Some researchers classify hemodialyzers based on their water

POLYAMIDE HEMODIALYZER Dialysate Compartment

Flow Rate: 600 mL/min

Fig. 6 Dialysate-side velocity distribution at the middle cross-section of a polyamide hemodialyzer containing 10,000 hollow fibers. (From Ref. [39].)

Fig. 7 Pictorial representation of two different flow baffles in hemodialyzers A and B. (From Ref. [40].)

permeabilities, while others classify hemodialyzers based on their solute permeabilities. The terms *low flux*, *high flux*, and *high efficiency* are most widely used in the literature. In the most general sense, we may associate *low flux* with hemodialyzers that remove small solutes, *high flux* with hemodialyzers that remove middle molecules and low molecular-weight proteins, and *high efficiency* with hemodialyzers that either require short dialysis treatment time or have a large membrane area.

Low Flux and High Flux

Some researchers classify hemodialyzers based on their water permeabilities, where low and high fluxes are associated with low and high ultrafiltration coefficients, respectively; whereas, other researchers classify hemodialyzers based on their solute permeabilities, where low and high fluxes are associated with low and high solute permeabilities, respectively. The classification scheme based on ultrafiltration coefficient has also been reported, and it remains debatable^[42] because different sizes of hemodialyzers made from the same membrane can be classified as either low or high flux depending on the total surface area of their membranes; for instance, for a given type of membrane and transmembrane pressure, a hemodialyzer with a large membrane area has a higher ultrafiltration

coefficient and hence a higher ultrafiltration rate compared with a hemodialyzer with a small membrane area. This classification scheme would be more useful in comparing hemodialyzers if we normalized the ultrafiltration coefficient with respect to the membrane area.

Subsequently, in 1991, the Center for Disease Control and Prevention (CDC) defined a high-flux hemodialyzer^[43] as having an ultrafiltration coefficient per unit membrane area equal to or greater than $20 \text{ mL/hr/mmHg/m}^2$. In 1995, the Hemodialysis (HEMO) Study,^[42,44] nonetheless, defined low-flux and high-flux hemodialyzers as having β_2 -microglobulin clearance less than 10 and greater than 20 mL/min , respectively. A classification of high-flux hemodialyzers as having hydrophobic membrane, high mass-transfer-area coefficient k_0A of urea, and ultrafiltration coefficient per unit membrane area greater than $10 \text{ mL/hr/mmHg/m}^2$ has also been reported in the literature.^[45]

Despite the above classifications, the only classification scheme recognized by the U.S. Food and Drug Administration is based on the water permeability,^[46] with low permeability hemodialyzers having ultrafiltration coefficients of less than 8 mL/hr/mmHg and high permeability hemodialyzers having ultrafiltration coefficients of equal to or greater than 8 mL/hr/mmHg .

We would also like to point out that the water permeability of dialysis membrane is not necessarily correlated to its solute permeability.^[46] Consider two different membranes A and B of equal area and porosity. Membrane A has a large number of small pores, and B has a small number of large pores. Although the diffusive transport properties of small solutes through these membranes would be equal, hence equal permeability of small solutes, because of equal porosity; the water permeability in membrane B would be greater than that in A because the ultrafiltrate flow, hence water permeability, is proportional to the fourth power of the membrane's pore radius.^[47]

High Efficiency

The term *high efficiency* is first used by Keshaviah et al.^[48] during the 1980s to describe the type of dialysis therapy rather than the type of hemodialyzer. These researchers showed that a significant reduction in treatment time with a high clearance of urea is possible by using a high blood flow rate and a cellulose-acetate hemodialyzer with a large membrane area. Subsequently, others have started using the term *high efficiency* in the literature with reference to hemodialyzers having a short dialysis treatment time or a large membrane area.

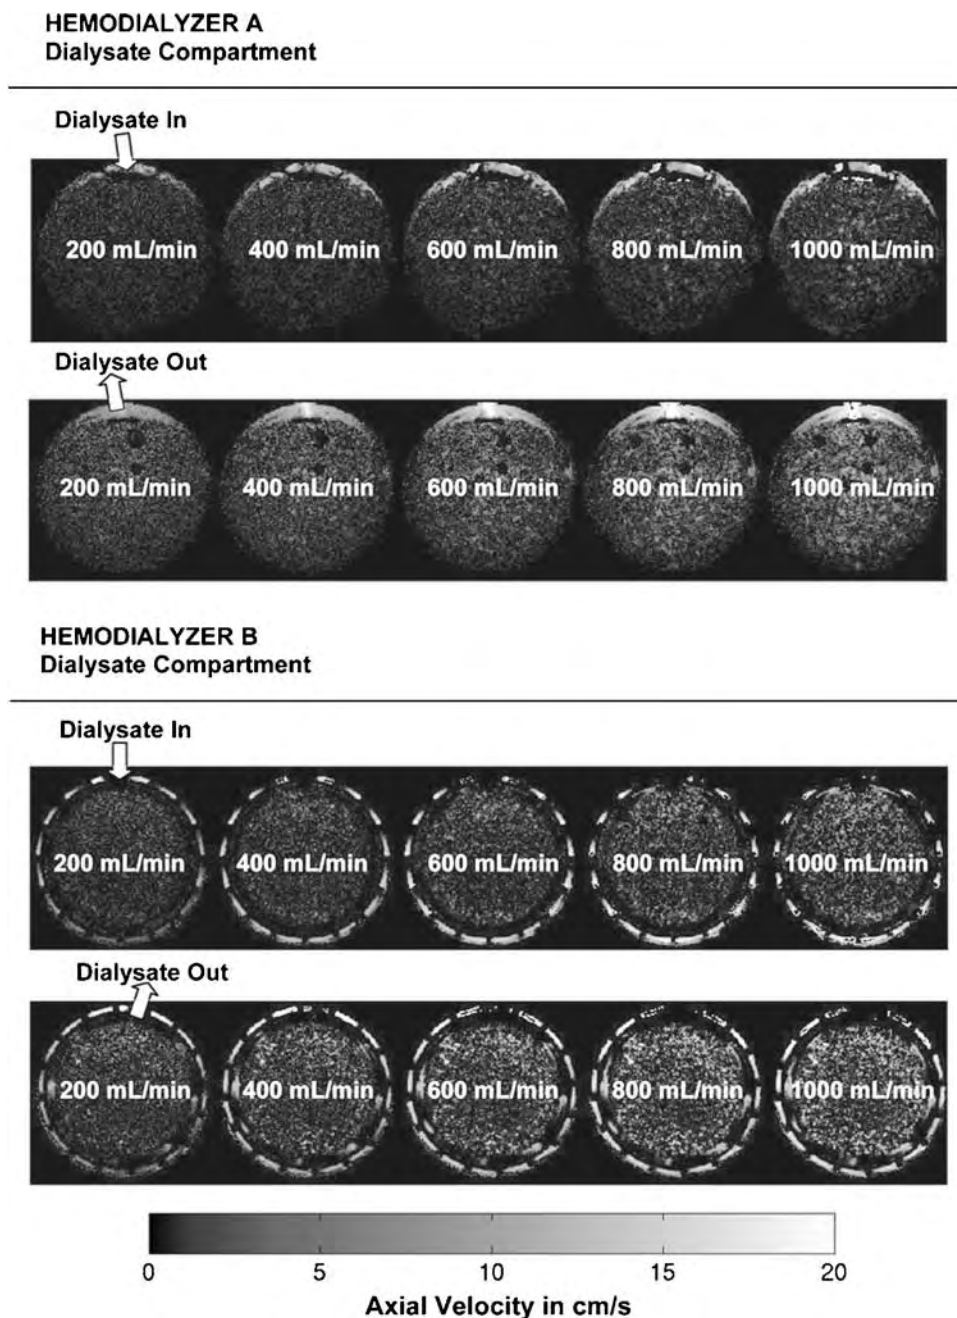

Fig. 8 Dialysate-side velocity distributions at the dialysate ports of hemodialyzers A and B, each with different designs of flow baffles. (From Ref. [40].)

A high-efficiency hemodialyzer^[45] was also referred to as having either an urea clearance greater than 150 mL/min or an urea clearance greater than 200 mL/min and a mass-transfer-area coefficient k_0A of urea greater than 450 mL/min. Other researchers have defined a high-efficiency hemodialyzer based on urea clearance per body weight^[49] and on urea clearance per distribution volume.^[50]

In 1991, the CDC defined a high-efficiency hemodialyzer^[43] as having an ultrafiltration coefficient

between 10 and 19 mL/hr/mmHg. This definition distinguishes a hemodialyzer that needs an ultrafiltration control system from the one that does not.

The term *high efficiency*, however, has subsequently become less apparent in the literature because the current goal of dialysis treatment^[45] has shifted from shortening treatment time to optimizing solute clearances of middle molecules and low molecular-weight proteins. Retrospective data have shown that mortality increases in dialysis patients with treatment time less

than 3.5 hr.^[51] A longer dialysis time is also claimed to improve blood pressure regulation in dialysis patients.^[52]

Another interesting classification scheme, which is notably mentioned, has subsequently been proposed by Akizawa, Kinugasa, and Ideura.^[53] They classify hemodialyzers by performance into five types: standard low flux, high flux, highly permeable, adsorptive, and high performance. They claimed that many other proposals and discussions are required before determining the final classification.

DIALYSIS MEMBRANES

Dialysis membranes act as a semipermeable barrier for the removal of uremic solutes and excess plasma water from the blood to the dialysate. Dialysis membranes vary in morphology and chemical composition. The morphology determines the transport properties of uremic solutes, while the chemical composition determines the biocompatibility of the membrane. An ideal dialysis membrane should be capable of selectively removing a broad range of uremic solutes comparable to those removed by the native kidneys and should not induce any adverse reactions between the membrane and the blood or any administered drugs during dialysis therapy. Equally important, the physicochemical properties of an ideal dialysis membrane should be resistant to change under different operating conditions and during sterilization.

Biocompatibility

The discovery that pulmonary leukostasis may have been resulted from the complement activation by cellulosic membranes in the 1970s^[54] has opened a new dimension to the concept of biocompatibility in dialysis membranes. Complement activation is the sequential activation of serum components C1 through C9, initiated by either an erythrocyte-antibody complex or microbial polysaccharides owing to the presence of microbes or other foreign materials in the blood, resulting in an inflammatory response. The complement system, once activated, fires in a cascade-like fashion in which one component activates the next, and it is an adjunct to the antibody system. The extent of complement activation depends on the membrane material and is used as a parameter for the assessment of membrane biocompatibility,^[55] for instance, the plasma concentration of terminal C5b-9 complement complex can be used for the quantification of complement activation and hence as a marker of biocompatibility of the membrane.^[56,57]

Another important biocompatibility aspect of the dialysis membrane is the adsorption of proteins on the membrane surface, also known as protein fouling. The adsorption of proteins increases the transmembrane resistance to fluid and solute transport, and hence decreases the water and solute permeabilities of the membrane. Protein adsorption is usually seen on the surface of hydrophobic membrane.^[58] Morti and Zydney^[59,60] have shown that the protein layer has a significant effect on the clearance of uremic solutes with molecular weights greater than 10,000 Da in cellulose-triacetate, polyacrylonitrile, and polysulfone hemodialyzers. They have also shown that the thickness of the protein layer increases with increasing dialysis time, ranging from 0.25 μm after 40 min to 0.86 μm after 180 min. Although protein adsorption on the membrane surface has an adverse effect on its water and solute permeabilities, the ability of a membrane to adsorb specific proteins can be advantageous for removing harmful low molecular-weight proteins such as β_2 -microglobulin from the blood, which will be discussed later.

CLASSIFICATION OF DIALYSIS MEMBRANES

We can classify dialysis membrane into three categories based on their polymeric compositions and preparation processes: regenerated cellulosic, modified cellulosic, and synthetic membranes. The effect of membrane composition and structure on the solute removal and biocompatibility in hemodialysis has been discussed by Clark, Hamburger, and Lysaght.^[46]

Regenerated Cellulosic Membranes

Regenerated cellulosic membranes are the first generation of dialysis membranes with low water and solute permeabilities (small pore size) and a relative thin wall thickness (5–15 μm). They are made from cellulose, a naturally occurring substance, and are structurally symmetric. These membranes are highly hydrophilic because of the presence of a large number of free hydroxyl groups on their cellulose monomers. The hydrophilic nature of these membranes promotes complement activation in dialysis patients because of the interaction of complement cascade products with the hydroxyl groups found in the membranes.^[46,61]

Apart from complement activation, regenerated cellulosic membranes offer great permeabilities on small solutes, but poor permeabilities on middle molecules and low molecular-weight proteins. An example of regenerated cellulosic membrane is Cuprophane[®] (Membrana GmbH, Wuppertal, Germany). Cuprophane is still being used in more than 50% of all

hemodialyzers throughout the world.^[62] In the U.S.A., however, the use of Cuprophane in hemodialyzers had declined from approximately 65% in 1990 to less than 20% in 1997.^[63] The popularity of Cuprophane has decreased over the past years because of its lack of biocompatibility and poor clearances on middle molecules and low molecular-weight proteins.

Modified Cellulosic Membranes

In an effort to improve the biocompatibility by decreasing the degree of complement activation in cellulosic membranes, modified cellulosic membranes were introduced in the 1980s. Modified cellulosic membranes are also made from cellulose. They are sometimes called substituted cellulosic membranes because parts or all of the hydroxyl groups on the cellulose monomers have been substituted by chemical groups such as the acetyl and benzyl groups. They have greater permeabilities of water and middle molecules (larger pore size) compared with the regenerated cellulosic membranes, but poor permeabilities of low molecular-weight proteins.

Examples of substituted cellulosic membrane modified by acetylation are cellulose acetate (substituted by one acetyl group), cellulose diacetate (substituted by two acetyl groups), and cellulose triacetate (substituted by three acetyl groups). These substituted cellulosic membranes have symmetric structure and relatively thin wall thickness. As opposed to the hydroxyl group, the acetyl group does not bind avidly to the C3 molecule to initiate activation of the complement cascade,^[64] consequently, complement activation and leukopenic response are attenuated.

Hemophan[®] (Membrana GmbH, Wuppertal, Germany) is another commonly used substituted cellulosic membrane. The diethylaminoethyl (DEAE) groups are used as the substituent on the cellulose monomers, and only a small percentage (less than 5%) of the hydroxyl groups are substituted^[64] in Hemophan. The DEAE groups are bulky and effective in shielding the hydroxyl groups through steric hindrance, hence attenuating the degree of complement activation and leukopenic response.

SMC[®] (synthetically modified cellulose), on the other hand, is made from cellulose where parts of the hydroxyl group on the cellulose monomer are substituted by etherification with the benzyl group. They are marketed under the name SMC (Membrana GmbH, Wuppertal, Germany).

The Hemophan membrane has been shown experimentally to be more biocompatible than the cellulose acetate, followed by the Cuprophane.^[65] The SMC membrane has been shown experimentally to be more biocompatible than the Cuprophane.^[66]

Synthetic Membranes

Synthetic membranes are new generation of membranes that are still under development. These membranes are developed in response to the pronounced complement activation and poor removal of middle molecules and low molecular-weight proteins associated with unmodified cellulosic membranes. Synthetic membranes are made from polymers such as polyacrylonitrile, polyamide, polymethylmethacrylate, polysulfone, and polyethersulfone. The use of polysulfone membranes in hemodialyzers in the U.S.A. had increased significantly from approximately 25% in 1990 to approximately 75% in 1997.^[63]

Synthetic membranes have different morphologies and various pore sizes depending on their manufacturing processes and polymeric compositions. Synthetic membranes have greater wall thickness (at least 20 μm) compared with cellulosic membranes and may be structurally symmetric or asymmetric. Asymmetric synthetic membranes usually have two or more layers with different porosities and pore-size distributions. The thin layer has small nominal pore size and acts as an active filtering layer; the thick layer has large nominal pore size and acts as a porous support layer for the thin layer. In addition, the porous support layer sometimes acts as an adsorption site to remove certain uremic solutes that are not removed by the thin layer.^[67] An example of a cross section of a synthetic hollow fiber^[41] is shown in Fig. 9. This hollow fiber has an asymmetric finger-like cross-sectional structure with three distinct layers combined with a microdomain structure at the inner surface. The outer and inner layers have a thickness of 0.1 and 0.5 μm , respectively.

Fig. 9 Scanning electron micrographs of a polyamide hollow fiber at (A) 2000 \times and (B) 200 \times magnifications. These micrographs show the unique morphology of the hollow fiber. (From Ref. [41].)

The intermediate finger-like structure has a thickness of 45–50 μm . The microdomain inner surface is created by inserting hydrophilic areas into the hydrophobic polymer to create a balanced combination of hydrophilicity and hydrophobicity. A balanced hydrophilic–hydrophobic membrane has an excellent biocompatibility for use in hemodialyzers as discussed below.

In general, hydrophilic membranes promote complement activation as discussed earlier, and hydrophobic membranes promote adsorption of proteins on their surfaces. Conventional synthetic membranes made from polyamide, polysulfone, and polyethersulfone are highly hydrophobic, and thereby their solute permeabilities are highly affected by the adsorption of proteins on their membrane surfaces. A hydrophilic additive, polyvinylpyrrolidone, is added during the manufacturing process to create a balance between hydrophilicity, hydrophobicity and hence a balance between complement activation and proteins adsorption in these membranes. A balance between complement activation and proteins adsorption improves the overall biocompatibility of these membranes. The discussion on the biocompatibility advantage of membranes having a balanced combination of hydrophilicity and hydrophobicity can be found in Refs.^[66,68] Hakim et al.^[69] have demonstrated that the relative risk of mortality of patients dialyzed with synthetic or substituted cellulosic membranes was at least 25% less than that of the patients dialyzed with unsubstituted cellulosic membranes. Vitamin E-bonded dialysis membranes with improved biocompatibility have also been reported in the literature.^[70–80]

HOLLOW-FIBER MEMBRANES

Although clear differences exist among different types of membrane, a number of common features are evident in hollow-fiber membranes. These hollow fibers typically have inner diameter between 180 and 220 μm , wall thickness between 15 and 50 μm , and length between 15 and 30 cm. The dimensions of hollow fibers are dictated by the operating conditions required during dialysis therapy and are result of a compromise between opposing forces.^[64] A small inner diameter of hollow fiber, on one hand, is preferred because it provides a short diffusive distance for removal of uremic solutes. For a given blood flow rate, a smaller inner diameter also provides a larger shear rate that results in greater attenuation of the effect of blood-side boundary layer.^[81] A small inner diameter, on the other hand, has an undesirable effect that induces large resistance to the blood flow as discussed below. We can model hollow fibers as nonporous cylindrical tubes, and the blood flow inside them is governed by the

Hagen–Poiseuille equation^[82]

$$Q_B = \frac{N\pi r^4 \Delta P}{8\mu L} \quad (1)$$

where Q_B is the blood flow rate, N is the number of hollow fibers, r is the radius of hollow fibers, ΔP is the axial pressure drop, μ is the blood viscosity, and L is the length of hollow fibers. We can rearrange Eq. (1) into

$$Q_B = \frac{N\Delta P}{R} \quad \text{where } R = \frac{8\mu L}{\pi r^4} \quad (2)$$

R is the resistance to the blood flow. Eq. (2) shows that R is inversely proportional to the fourth power of r ; hence, a small decrease in inner diameter of hollow fibers causes a large increase in resistance to the blood flow. Eq. (2) also shows that an increase either in hollow-fiber length or hematocrit level (increasing hematocrit level increases blood viscosity) increases the resistance to the blood flow. To maintain the blood flow rate with increasing resistance to the blood flow for a given number of hollow fibers, the axial pressure drop increases, as seen from Eq. (2), and causes significant backfiltration of dialysate under normal operating conditions.^[83] Backfiltration increases the likelihood of transfer of cytokine-inducing substances from contaminated dialysate to the blood.^[84]

MEMBRANE PORE AND PORE-SIZE DISTRIBUTION

As an approximation, we can view the membrane as having straight cylindrical pores perpendicular to the membrane surface^[85] as shown in Fig. 10. We assume all pores have the same radius R_p , which is larger than the stoke radius R_s of a hypothetical solute. The ultrafiltrate (convective) flow through these straight cylindrical pores is governed by the Hagen–Poiseuille equation [Eq. (1)] and is proportional to the fourth power of the pore radius; hence, although the ultrafiltrate flow (water permeability) is affected by the number of pores, it is affected strongly by the pore size. The diffusive flow, on the other hand, is also affected strongly by the membrane pore size in addition to the membrane thickness; but not as strong as the ultrafiltrate flow. The diffusive flow is proportional to the second power of the pore radius [Eqs. (6) and (7)].

The actual membranes used in hemodialyzers have distribution of pore sizes, and the pores are non-cylindrical in shape (Fig. 9). Fig. 11 shows the pore-size distributions and the corresponding sieving coefficient profiles of three hypothetical dialysis membranes.^[67] Membrane 1 has a large number of small pores

Fig. 10 Pictorial representation of an idealized membrane model with an equal pore radius R_p , which is larger than the stoke radius R_s of a hypothetical solute (lower panel); and the associated relationship between pore radius and solute permeability (upper panel). (From Ref. [85].)

(nominal diameter: 15 Å), and 2 has a large number of large pores (nominal diameter: 30 Å). Because of their narrow pore-size distributions, membranes 1 and 2 have sharp molecular-weight cutoffs of 10 and 60 kDa, respectively, which are favorable in dialysis membranes. Additionally, both membranes have favorable diffusive transport properties because of their large number of pores. Membrane 3, on the other hand, has an unfavorable pore-size distribution. The broad pore-size distribution explains the early drop-off in the sieving coefficient at low molecular-weight and the “tail” effect at high molecular-weight. The “tail” effect is highly undesirable because it may lead to albumin loss during dialysis treatment. Membrane 3 also has poor diffusive transport properties because of its small number of pores.

MASS TRANSFERS IN ARTIFICIAL KIDNEYS

The removal of uremic solutes in artificial kidneys is governed by three basic mass-transfer mechanisms: diffusion, convection, and adsorption. Diffusion and convection depend in part on the molecular size of

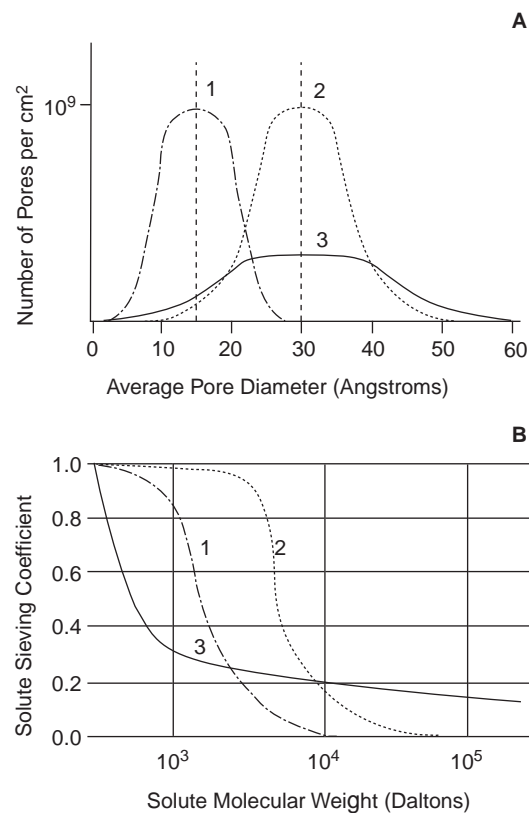

Fig. 11 Pore-size distributions and solute sieving coefficient profiles of three hypothetical dialysis membranes 1, 2, and 3. (A) The number of pores as a function of average pore diameter. (B) The solute sieving coefficient as a function of molecular weight. (From Ref. [67].)

uremic solutes and pore size of dialysis membranes, while adsorption depends on the physicochemical properties of uremic solutes and dialysis membranes (and the electrochemical properties for charged dialysis membranes).

Small solutes are predominantly removed by diffusion, and low molecular-weight proteins are removed by convection and occasionally by adsorption. Middle molecules are generally removed by diffusion and convection in high-flux and low-flux hemodialyzers, respectively, and the removal of middle molecules can be significantly enhanced by convection in high-flux hemodialyzers.

Diffusion

Diffusion is a statistical transport of solutes across a membrane by a difference in solute concentration, where solutes diffuse from the region of high concentration to the region of low concentration. Additionally, diffusion is strongly dependent on the solute molecular weight (large molecular weight corresponds to large molecular size and vice versa) and the

membrane morphology as will be discussed later. Diffusion was the primary transport mechanism of uremic solutes in the earlier development of hemodialyzers.

Diffusion of uremic solutes across the membrane, in the simplest sense, is governed by Fick's first law^[86]

$$J_{D,s} = -D_s \frac{dC}{dx} \quad (3)$$

where $J_{D,s}$ is the diffusive mass flux of a solute (mass removal rate per unit membrane area) across the membrane, D_s is the diffusion coefficient of a solute, and dC/dx is the solute concentration gradient in the x direction across the membrane. D_s is an intrinsic property of the membrane for a given solute. From Fick's first law [Eq. (3)], we can see that for a given concentration gradient across the membrane, the diffusive flux is proportional to the diffusion coefficient of the solute and is inversely proportional to the thickness of membrane. The negative sign on the right-hand side of Eq. (3) indicates that the net solute flux diffuses in the direction of negative concentration gradient, i.e., in the direction of decreasing solute concentration. We would like to point out, however, that Fick's first law is a simple phenomenological model that neglects the physicochemical details of the membrane and uremic solutes, and hence it provides no information on the relationship between the solute diffusive flux and the physicochemical natures of the membrane and uremic solutes.

When experimental data are unavailable, we can estimate the diffusion coefficient of a solute from the Stokes–Einstein equation^[87]

$$D_s = \frac{\kappa T}{6\pi r_s \mu} \quad (4)$$

where κ is Boltzmann's constant, T is the absolute temperature, r_s is the Stokes radius of the solute, and μ is the solution viscosity. We can estimate the Stokes radius of a solute from the following equation

$$r_s = \frac{3M_s}{4\pi\rho N_A} \quad (5)$$

M_s is the molecular weight of the solute, ρ is the hydrated density of the solute, and N_A is the Avogadro's number. Eqs. (4) and (5) show that diffusion is relatively favorable for low Molecular-weight solutes because of the inverse relationship between solute diffusion coefficient and MW. Eq. (4) also shows that, phenomenologically, the diffusive solute transport is dependent on the solution viscosity and temperature in addition to the solute molecular size. Stokes–Einstein equation has been reported to overestimating the

actual solute diffusion coefficient by 10% for solutes with molecular weights greater than several thousands.^[81] This equation is only applicable for laboratory experiments, where aqueous solutions with low solute concentration are used instead of human blood. The real transport of uremic solutes in human blood across the dialysis membrane is more complex than that in aqueous solution because of the coupling effect of blood, dialysate, and uremic solutes.

A common misconception among researchers is to relate the solute diffusion rate to the pore size of the membrane without taking into consideration the porosity of the membrane. Consider a membrane with n cylindrical straight pores with equal radius r perpendicular to the membrane surface, we can express the diffusive mass flux as^[47]

$$J_{D,s} = \frac{D_s \lambda \phi \Delta C}{x} \quad (6)$$

where λ is the solute partition coefficient ($\lambda=1$ for small solutes such as urea and creatinine, and less than one for larger solutes), ϕ is the membrane porosity, ΔC is the solute concentration difference across the membrane, and x is the membrane thickness. The membrane porosity is a function of pore size and pore number, and is given by

$$\phi = \frac{n\pi r^2}{A} \quad (7)$$

where A is the membrane area. Eq. (6) shows that solute diffusion is not only dependent on the membrane pore size, but also on porosity. Larger porosity allows greater access of small solutes to the membrane pores, and hence greater diffusion rate, provided the pore is relatively larger than the solute. Now, if we have two different membranes with equal surface area and thickness that are subjected to the same solute and solute concentration difference; one membrane with large pore and low porosity and another membrane with small pore and high porosity can have equivalent solute diffusion rates provided their pores are larger than the solute of interest.

Convection

Convection is the movement of fluid and solutes across a membrane by a difference in pressure. The uremic solutes are removed by the movement of fluid or solvent drag across the membrane. The pressure in the blood compartment of a hemodialyzer is made higher than that in the dialysate compartment and forces the uremic solutes to travel along with the moving fluid from the blood to the dialysate. Convection is

dependent on both the transport properties and dynamic characteristics of the moving fluid.

Convection was initially used to remove excess plasma water from the blood. With the advent of membrane technology, new high-flux dialysis membranes with improved solute transport properties of middle molecules and low molecular-weight proteins have been developed; and, to date, convection has been used to remove these uremic solutes in high-flux hemodialyzers in addition to the removal of excess plasma water.

It is worthwhile pointing out that even though convection is the main transport mechanism for the removal of middle molecules and low molecular-weight proteins in high-flux hemodialyzers, it does function in low-flux hemodialyzers as ultrafiltration for the removal of excess plasma water from the blood.

The convective volumetric rate of water from the blood to the dialysate, better known as the ultrafiltration rate Q_{UF} , is given by

$$Q_{UF} = K_{UF}\Delta P \quad (8)$$

where K_{UF} is the ultrafiltration coefficient, an intrinsic transport property of the membrane; and ΔP is the transmembrane pressure across the membrane. The transmembrane pressure is limited by the mechanical properties of the membrane. The ultrafiltration rate increases linearly with the applied transmembrane pressure until the maximum transmembrane pressure sustainable by the membrane; further increase in transmembrane pressure across the membrane beyond the maximum transmembrane pressure will cause the membrane to lose its mechanical strength and break.

The convective mass flux of a solute $J_{C,s}$, on the other hand, is given by^[88]

$$J_{C,s} = (1 - \sigma)J_{UF}C_m \quad (9)$$

where σ is the reflection coefficient (a measure of solute rejection by the membrane), J_{UF} is the ultrafiltrate flux (ultrafiltration rate per unit membrane area), and C_m is the mean intramembrane solute concentration (the average of the blood-side and dialysate-side solute concentrations, but the blood-side solute concentration is determined from the submembranous concentration rather than the bulk phase concentration). We can view the quantity $(1-\sigma)$ as the membrane resistance to convective flow, where $\sigma=1$ implies no convective flow, and $\sigma=0$ implies no resistance to the convective flow. Eq. (9) shows that the convective solute flux is dependent on the ultrafiltrate flux and hence on the transmembrane pressure, where it increases with increasing transmembrane pressure. The convective solute flux is also dependent on the solute molecular size and membrane physical properties. For a given

high-flux membrane and transmembrane pressure, the convective solute flux is independent of its molecular size for small solutes and some middle molecules ($\sigma=0$), and is strongly dependent on its molecular size for large molecules such as myoglobin and albumin ($\sigma>0$). The convective solute flux increases with decreasing solute molecular size. For a given solute and transmembrane pressure, on the other hand, the convective solute flux is highly dependent on the solute permeability of the membrane. The convective solute flux increases with increasing solute permeability of the membrane. The convective solute flux is also dependent on the solute charge, if any, and surface charge of the membrane.

Adsorption

Adsorption is the binding of uremic solutes onto the surface of a membrane. Adsorption plays a significant role in removing certain low molecular-weight proteins such as β_2 -microglobulin.^[89-91] Adsorption primarily occurs inside the internal structure of synthetic membranes rather than on the surface; thereby, the adsorption of low molecular-weight proteins greatly depends on the accessibility of these proteins to the membrane's internal structure.^[92] Consequently, adsorption of low molecular-weight proteins inside low-flux membranes is expected to be clinically insignificant compared with that occurs inside high-flux membranes with open structure. The adsorption affinity of low molecular-weight proteins on certain high-flux hydrophobic synthetic membranes is relatively high compared with hydrophilic cellulosic membranes.^[93] Ronco et al.^[94] have shown that adsorption accounts for more than 90% of the β_2 -microglobulin removal in a hydrophobic polysulfone hemodialyzer.

Adsorption also prevents the transfer of cytokine-inducing substances (CIS) from contaminated dialysate to the blood.^[95] Lonnemann and Koch^[96] and Li et al.^[97] have demonstrated that certain high-flux synthetic membranes attenuate either significantly or totally in vitro transfer of CIS from highly contaminated dialysate to the blood. This attenuation is attributed to the adsorptive removal of CIS by the membrane's internal structure via nonspecific hydrophobic interactions.

PERFORMANCE PARAMETERS OF ARTIFICIAL KIDNEYS

Clearance

One of the most frequently used parameters to evaluate the performance of hemodialyzers is clearance.

Clearance describes the ability of a hemodialyzer in removing a given solute in a single pass and is defined as the ratio of the solute mass removal rate to the solute concentration at the blood inlet of a hemodialyzer. From the engineering perspective, nonetheless, clearance provides little information on the understanding of mass transfer in hemodialyzers, but it is of practical importance for comparing the performance of different hemodialyzers and is often used in the medical community.

From the mass balance of a solute in a hemodialyzer with countercurrent blood-dialysate flow, assuming no adsorption occurs, we have

$$Q_{Bi}C_{Bi} - Q_{Bo}C_{Bo} = Q_{Do}C_{Do} - Q_{Di}C_{Di} \quad (10)$$

where Q_B , Q_D , C_B , and C_D are the blood flow rate, dialysate flow rate, blood solute concentration, and dialysate solute concentration, respectively. Subscripts *i* and *o* denote the inlet and the outlet, respectively. Dividing the left-hand side of Eq. (10) by C_{Bi} , we have the blood-side clearance K_B as

$$K_B = \frac{Q_{Bi}C_{Bi} - Q_{Bo}C_{Bo}}{C_{Bi}} \quad (11)$$

Because ultrafiltration rate Q_{UF} is given as

$$Q_{UF} = Q_{Bi} - Q_{Bo} \quad (12)$$

We can rearrange Eq. (11) as

$$K_B = \frac{Q_{Bo}(C_{Bi} - C_{Bo})}{C_{Bi}} + Q_{UF} \quad (13)$$

In the case of zero ultrafiltration, where $Q_{Bi} = Q_{Bo}$, Eq. (13) reduces to Eq. (11).

The blood-side clearance is also known as the whole blood clearance. It substantially overestimates the true solute clearance of a hemodialyzer^[98] because the actual water volumetric rate at which the solute is cleared is less than the blood volumetric rate used in the calculation.

We can reduce the overestimation of the blood-side clearance by measuring the blood water clearance. The blood water flow rate Q_{BW} , which accounts for the hematocrit-dependent effects on the effective solute distribution volume, is given by^[98]

$$Q_{BW} = 0.93Q_B [1 - \text{Hct} + K_{RBC}(1 - e^{-\alpha t})\text{Hct}] \quad (14)$$

where *Hct* is the hematocrit level, K_{RBC} is the partition coefficient between the red blood cell and plasma water for a given solute, α is the transcellular rate constant, and t is the characteristic hemodialyzer residence time. Estimates for these parameters can be found in

Shinaberger, Miller, and Gardner.^[99] We can then determine the blood water clearance K_{BW} by substituting Q_{BW} for Q_B in either Eq. (11) or (13). Eq. (13) shows that the blood-side clearance increases with increasing blood flow rate and ultrafiltration rate.

Similarly, dividing the right-hand side of Eq. (10) by C_{Bi} , we have the dialysate-side clearance K_D as

$$K_D = \frac{Q_{Do}C_{Do} - Q_{Di}C_{Di}}{C_{Bi}} \quad (15)$$

In the laboratory, C_{Di} is equal to zero because the dialysate is usually prepared to be free of the solute of interest; hence, we can further reduce Eq. (15) to

$$K_D = \frac{Q_{Do}C_{Do}}{C_{Bi}} \quad (16)$$

The dialysate-side clearance provides more accurate result and is considered the “gold standard” for evaluating hemodialyzers because there are no hematocrit-dependent effects on the effective solute distribution volume.^[83] The major drawback of the dialysate-side clearance is the difficulty in assaying solutes of very low concentrations in the dialysate. An example of the in-vitro clearances of a Gambro Polyflux 170H hemodialyzer^[100] at different blood flow rates is shown in Fig. 12.

Sieving Coefficient

Another performance parameter commonly seen in the literature is the sieving coefficient. Sieving coefficient is used to evaluate the convective removal capability of a

Fig. 12 In-vitro clearances of a Gambro Polyflux 170H hemodialyzer. (Data adapted from Ref. [100].)

hemodialyzer for a given solute. It is a dimensionless parameter that determines the extent of a solute permeating through the membrane. The sieving coefficient of a hemodialyzer can be determined experimentally by operating the hemodialyzer on a hemofiltration mode with a specific ultrafiltration rate, where no dialysate is used; and the inlet of the dialysate compartment is closed. The equation for determining the sieving coefficient SC is

$$SC = \frac{2C_{D_o}}{C_{B_i} + C_{B_o}} \quad (17)$$

where C_{B_i} and C_{B_o} are the solute concentrations at the inlet and outlet of the blood compartment, respectively; and C_{D_o} is the solute concentration at the outlet of the dialysate compartment.

Sieving coefficient depends strongly on the membrane pore size and is a function of ultrafiltration rate. The sieving coefficient depends also on the membrane charge, if any. The sieving coefficient increases with increasing ultrafiltration rate, up to an asymptotic value, and further increasing the ultrafiltration rate will cause the membrane to lose its mechanical strength and break. A sieving coefficient value of one indicates that 100% of the solute is permeating through the membrane, and a value of zero indicates that none of the solute is permeating.

All current hemodialyzers, irrespective of membrane type, have a sieving coefficient value of one for small solutes and less than one for middle molecules and low molecular-weight proteins. We can get an immediate appreciation of the permeability properties of a dialysis membrane by studying its sieving coefficient profile (sieving coefficients of solutes at different molecular weights). The sieving coefficient profiles of three hypothetical dialysis membranes with different pore-size distributions have been shown in Fig. 11. An example of an in-vitro sieving coefficient profile of a Gambro Polyflux R hemodialyzer^[101] is shown in Fig. 13.

RENAL REPLACEMENT THERAPIES IN ARF

The most serious forms of ARF are found with patients in the intensive care unit, which have the highest morbidity and mortality.^[102] There are several renal replacement therapies available for critically ill patients with ARF, and they can be grouped into intermittent renal replacement therapy (IRRT) and continuous renal replacement therapy (CRRT). Theoretically, CRRT is advantageous over IRRT because CRRT, which performs uremic filtration continuously, mimics the kidneys most closely and is hemodynamically more stable than IRRT, which performs uremic filtration

Fig. 13 An in-vitro sieving coefficient profile of a Gambro Polyflux R hemodialyzer. Q_B , Q_{UF} , and MW represent the blood flow rate, ultrafiltration rate, and molecular weight, respectively. (From Ref. [101].)

intermittently. The clinical advantage of CRRT over IRRT, however, remains controversial.^[103]

IRRT

Intermittent hemodialysis (IHD) has been the classic form of IRRT. It is the most used modality to treat ARF patients in the U.S.A.^[104] IHD is usually performed thrice weekly and lasts for 3–4 hr per session. A moderate blood flow rate between 200 and 250 mL/min and a dialysate flow rate of 500 mL/min are used.

Among advantages of IHD are rapid removal of solutes and fluids that results in rapid correction of electrolyte imbalance and removal of drugs or other substances in fatal intoxications.^[105] IHD requires less anticoagulation compared with CRRT because of its faster blood flow rate and shorter therapy duration.

One major drawback of IHD is hemodynamic instability caused by the rapid removal of solutes and fluids. Many patients develop hypotension^[106] during IHD that exacerbates renal injury and delays recovery.^[107] Rapid removal of solutes from the intravascular space can cause cerebral edema and increased intracranial pressure.^[108] ARF patients with head trauma or hepatic encephalopathy are at risk of brain edema and herniation.^[109] The cellulosic membranes commonly used in IHD have also been reported to have adverse effect on renal recovery by inducing activation of various inflammatory mediators and cascades.^[110,111]

Continuous Renal Replacement Therapy

CRRT is performed at a slower rate but continuously compared with IRRT, and hence provides better hemodynamic stability. There are several CRRT

modalities available. The first CRRT was developed by Kramer et al.^[112] called the arteriovenous hemofiltration, now called the continuous arteriovenous hemofiltration (CAVH) to treat diuretic-unresponsive fluid overload in critically ill patients with ARF. CAVH is the simplest form of CRRT. Blood is drawn from the femoral artery, flowed through a hemofilter under the influence of arterial pressure alone, and returned to the patient through the femoral vein. The blood flow rate is between 90 and 150 mL/min.^[113] The transmembrane pressure is generated from the arterial pressure, and CAVH filters between 10 and 15 L of plasma water per day. Substitution fluid is used to replace lost fluid during ultrafiltration.

Since then, various forms of CRRT have evolved that differ in the blood access and mass-transfer mode. Continuous arteriovenous hemodialysis (CAVHD) is very similar to CAVH, except that the uremic solutes are removed by diffusion instead of convection, and dialysate is used instead of substitution fluid compared with CAVH. In continuous arteriovenous hemodiafiltration (CAVHDF), on the other hand, the combination of diffusion and convection is used to remove uremic solutes. Several disadvantages of these arteriovenous therapies include the dependence of blood flow rate and ultrafiltration rate on the arterial pressure; low blood flow rate decreases the efficiency of the hemofilter and encourages blood clotting; and the arterial cannulation causes vascular complications such as ischemia, bleeding, and pseudoaneurysm.^[114]

Subsequently, the continuous arteriovenous therapies have been replaced by continuous venovenous therapies, which include continuous venovenous hemofiltration (CVVH), continuous venovenous hemodialysis (CVVHD), and continuous venovenous hemodiafiltration (CVVHDF). In these therapies, blood is drawn from either the femoral, internal jugular, or subclavian vein through a dual-lumen catheter; pumped through a hemofilter or hemodialyzer; and returned to the patient through the dual-lumen catheter inserted at the vein. Pumps are used to control the blood flow rate and

ultrafiltration rate, and hence to ensure adequate solute clearance and ultrafiltration rate. The substitution fluid is administered either before (predilution) or after (postdilution) the hemofilter in CVVH and CVVHDF. The predilution requires 15% more ultrafiltrate volume and offers enhanced solute removal along with diminished anticoagulation requirements.^[115] Table 1 lists the advantages of CRRT,^[116] Table 2 shows the comparison between different CRRTs,^[113] and Table 3 shows the comparison between the characteristics of IHD and CRRT. Detailed reviews and discussions on the above CRRT can be found in Refs.^[113,118–121]

Another rarely used CRRT in ARF is peritoneal dialysis. Peritoneal dialysis uses the peritoneal membrane to remove uremic solutes and excess plasma water from the blood. It is rarely used in ARF because it provides inadequate solute clearance in critically ill catabolic patients, increases the risk of peritonitis, compromises respiratory function by impeding diaphragmatic excursion, and is contraindicated in patients with recent abdominal surgery or abdominal sepsis.^[122] Detailed discussion on peritoneal dialysis has been presented by Daugirdas, Blake, and Ing.^[123]

Table 1 Advantages of CRRT

Hemodynamically well tolerated; minimal change in plasma osmolality
Better control of azotemia and electrolyte and acid–base balance; corrects abnormalities as they evolve; steady-state chemistries
Highly effective in removing fluid (postsurgery, pulmonary edema, and acute respiratory distress syndrome)
Facilitates administration of parenteral nutrition and obligatory intravenous medications (i.e., pressor, inotropic drugs) by creating unlimited “space” by virtue of continuous ultrafiltration
Recent efforts to make procedure user-friendly

(From Ref. [116].)

Table 2 Comparison between different CRRTs

Modality	Blood pump	Dialysate (D) or substitution fluid (SF)	Urea clearance (L/day)	Urea clearance (mL/min)	Middle molecules clearance	Simplicity
CVVH	Yes	SF	22–24	15–17	+++	++
CAVHD	No	D	24–30	17–21	n/a	+
CVVHD	Yes	D	24–30	17–21	n/a	++
CAVHDF	No	SF + D	36–38	25–26	+++	+++
CVVHDF	Yes	SF + D	36–38	25–26	+++	+++

Symbols: +, most simple; ++, moderate difficult; +++, most difficult. (From Ref. [113].)

Table 3 Comparison between IHD and CRRT

Intermittent hemodialysis	Continuous renal replacement therapy
Mainly diffusive	Mainly convective
Low-flux membrane	High-flux membrane
High dialysate flow	Low dialysate flow
On-line dialysate production	Industrially manufactured substitution fluid
A few hours per day	In theory, continuously
Technically demanding	Technically less demanding
Less labor intensive	Labor intensive

(From Ref. [117].)

Sustained Low-Efficiency Dialysis

Sustained low-efficiency dialysis (SLED)^[124,125] is a fairly new renal replacement therapy that combines the advantages of IHD and CRRT. SLED is performed at low blood and dialysate flow rates of 200 and 100 mL/min, respectively, for 6–12 hr/day. It provides hemodynamic stability, improved correction of hypervolemia, and superior solute removal compared with IHD. It uses the conventional hemodialysis machine and hence costs less than CRRT that requires expensive machine. SLED can be done intermittently based on the need of the patient; hence, the interruption of therapy for various diagnostics and therapeutic procedures can be avoided.

Only few data have been reported on SLED, and the clinical reliability and efficacy of SLED remain to be seen. We have used kinetic modeling to compare the effective doses delivered by CVVH, daily hemodialysis, and SLED.^[126] We used a modified equivalent renal clearance (EKR) to account for the unsteady initial stage of dialysis. We found that small solute EKR in CVVH is 8% and 60% higher than those in SLED and daily hemodialysis, respectively. The differences in EKR are more pronounced for middle and large solutes, where their EKR in CVVH are approximately twofold and fourfold larger than their corresponding values in daily hemodialysis and SLED, respectively. The superior removal of middle and large solutes in CVVH is caused by the powerful combination of convection and continuous operation in CVVH.

CONCLUSIONS

We have scratched the surface of the topic of artificial kidneys from the engineering perspective, where we have discussed the basic functions of human kidneys, classification of uremic solutes, basic designs and

classification of artificial kidneys, property and classification of dialysis membranes, mass transfers in artificial kidneys, parameters used to characterize performance of artificial kidneys, and different forms of renal replacement therapies for ARF.

The topic *artificial kidneys* encompasses a vast area of subjects, and it is spatially infeasible to discuss them all in purely one article; we thereby highly encourage the readers to refer to the “Article of Further Interest”, “References”, and “Bibliography” cited at the end of this article to further satisfy their quest for knowledge of artificial kidneys.

We hope that this fundamental entry provides the necessary momentum to further enhance the readers’ interest in artificial kidneys, and we wish the readers all the best for their endeavors in the research of artificial kidneys and in improving the quality of life of patients with kidney failures.

Knee Joint: Overuse Injuries

INTRODUCTION

Athletic activities and recreational exercises are the phenomenon of modern civilized societies. The Olympic logo “Citius, Altius, Fortius” may serve us better nowadays as “Even faster, even higher, even stronger.” As exercise continues to proliferate, so do the concomitant injuries, especially damage to the locomotor system. Damage of the locomotor system is the result of a series of repetitive microtraumas that overwhelm the tissue’s ability to repair itself. Therefore, many authors view it as one of the microtraumatic illnesses, but etiologically and pathogenetically, it would be better to term it as an overuse injury. The knee is a frequently injured joint in athletic and recreational activities. Overuse injuries are also frequent in the knee joint, the reason for this is that the knee joint participates in all sports activities (running, jumping, kicking, etc.) and that this joint area is characterized by numerous attachment sites for muscles and their tendons as well as by numerous bursae. It is also else to the nature of the specific joint between the patella and the femur (patellofemoral joint) that constitutes a part of the knee joint. These reasons amply explain why as much as 40% of all overuse injuries occurring in runners develop in the knee joint area. Speaking in general terms, all overuse injuries around the knee joint can be differentiated, depending on their anatomical localization into four groups (see Table 1).

As indicated in Table 1, there are numerous possible reasons for anterior knee pain. Note, however, that Table 1 primarily consists of chronic causes that lead to the development of anterior knee pain. Based on the anatomical localization (see Table 1), this entry will provide basic information on epidemiology, diagnostics, and treatment of overuse injuries around the knee joint.

PATELLOFEMORAL PAIN SYNDROME

There are numerous possible reasons for patellofemoral pain syndrome. Irregularities in the course of the patella and malalignment of the extensor system of the knee are

all described when discussing pain in the patellofemoral syndrome. Therefore, we feel it is imperative to clearly define the terms patellar malalignment, chondromalacia of the patella, and anterior knee pain.^[1]

Patellar Malalignment

Perhaps, the easiest way to define patellar malalignment is to say that malalignment of the extensor system of the knee entails changes in the architecture of the patellofemoral joint, which in turn change the relationship between the patellar stabilizers, leading to excessive tightness in some and insufficiency in others. Patellar malalignment also leads to an incorrect distribution of strain in the patellofemoral joint, resulting in increased pressure in certain areas of patellofemoral contact (see Fig. 1).

Patellar malalignment is a translational or rotational deviation of the patella relative to any axis, and it can be a major component of patellar pain. There are two theories to explain the origin of pain: the neural theory and the mechanical theory, but it should be noted that malalignment of the knee extensor system is not always accompanied by pain in the patellofemoral joint. During clinical examination of the patient who exhibits symptomatology characteristic of the patellofemoral joint, the physician should direct attention to defining the underlying causative factors that have led to the development of malalignment of the extensor system. There are several clinical tests to assess patellar mobility but these tests have fair and poor reliability. Radiographs (axial view, CT) and especially MR imaging (kinematic and dynamic axial imaging), as a noninvasive and nonionizing modality, have made significant contribution to the understanding of patellofemoral malalignment (see Fig. 2). The basic principle of therapy consists of correcting the underlying causative factors of patellar malalignment.

Chondromalacia of the Patella

The term was introduced into the medical literature by Konig in 1924. Chondromalacia, the word that has

Table 1 Overuse injuries of the knee joint

Anterior aspect	Medial aspect
Patellofemoral pain syndrome	Breaststroker's knee
Jumper's knee	Pes anserinus tendinitis/bursitis
Osgood-Schlatter disease	Plica syndrome
Sinding-Larsen-Johansson disease	Semimembranosus tendinitis
Stress fracture of the patella	Medial retinaculitis
Fat pad syndrome	
Posterior aspect	Lateral aspect
Fabellitis	Iliotibial band friction syndrome
Gastrocnemius strain	Popliteal tendinitis
	Bicipital tendinitis

defined the field of patellar pain during the last century, is now mostly a source of confusion and should be abandoned. The presence of soft cartilage (the literal translation of the term chondromalacia) is not strongly correlated with patellar pain. The confusion is further compounded by the use of poorly defined grades (for example, grade III chondromalacia). These types of lesions should be termed chondral or cartilage lesions, and they should be described qualitatively (for example, as blistering or fissuring) and quantitatively (in terms of size, location, and depth). The term chondromalacia patellae should not be used to diagnose patellofemoral pain but, rather, to describe lesions of articular cartilage. The term chondromalacia patellae, although once used as an all-inclusive term for anterior knee pain, is now widely accepted as a term used to describe pathological lesions of the patellar articular cartilage found at arthroscopy. Numerous different categorization systems of chondromalacia of the patella are found in the medical literature, depending on the state and characteristics of the change in the cartilage

**Fig. 1** Schematic representation of the tilt of the patella.**Fig. 2** Magnetic resonance imaging of the patellofemoral joint at (A) 15° and (B) 0° of the flexion.

of the patellofemoral joint and the size and location of the changes. Outerbridge's classification is most frequently used, as well as the arthroscopic categorization by Joensen. Hungerford differentiates among closed chondromalacia, open chondromalacia, chondrosclerosis, surface changes in the cartilage, and development of tufts.

Anterior Knee Pain

The term anterior knee pain is suggested to encompass all pain-related problems, excluding anterior knee pain due to intraarticular pathology. Anterior knee pain is a common complaint in the orthopedic clinic. The differential diagnosis is wide and the principal goal of initial assessment is to detect remediable causes. A clear understanding of the pathophysiology of anterior knee pain is inhibited by the use of imprecise, poorly defined, and often interchanged words, such as malalignment, patellar alignment, maltracking, subluxation, dislocation, and congruence. Although, some physicians compare the diagnosis of anterior knee pain to a "large wastepaper basket," these physicians still agree that it is better to begin treatment, even with this "provisory" diagnosis, and try to determine the precise location of the injury and/or damaged area while monitoring the development of the syndrome. Ireland recognizes mechanical, inflammatory, and mixed causes of pain. According to Fulkerson, use of the term anterior knee pain will underline the need to search further for a specific cause of pain in each patient, remembering that there is not always a correlation between articular lesions and pain.^[2] Anterior knee pain caused by overactivity in an athletic or military population is described by many authors. As we pointed out in the beginning of this entry, a synergistic effect and definite correlation exist among malalignment of the knee extensor system, instability of the

patella, chondromalacia of the patella, and anterior knee pain, and this is the reason why it is better to call all these disturbances according to symptomatology, patellofemoral pain syndrome. The complexity related to the patellofemoral pain syndrome explains the complexity present when treating this syndrome. After a precise diagnosis, the physician should prescribe treatment of the cause of the pain, which can be either nonoperative or operative. If, for example, the primary cause of pain is excessive pressure on the lateral part of the patella caused by malalignment, then the physician can attempt to correct this malalignment with electrostimulation of the vastus medialis muscle and/or by having the patient wear a brace designed for stabilizing the patella. Surgically, treatment consists of full arthroscopic stabilization of the patella.^[3] The same principle is considered for the other causes of the patellofemoral pain syndrome.

PATELLAR TENDINITIS/TENDINOSIS (JUMPER'S KNEE)

Patellar tendinitis/tendinosis is characterized by pathological changes in the quadriceps tendon and its insertion to the proximal pole of the patella, and the patellar tendon (patellar ligament) and its proximal insertion to the apex of the patella or distal insertion to the tibial tubercle. Other terms are also found in the medical literature that are frequently used to describe the same syndrome: patellar apicitis, enthesitis apicis patellae, jumper's knee, volleyball's knee, and basketball's knee. Jumper's knee is a clinical entity most commonly found in athletes who, during their athletic activities, habitually place excessive strain on the extensory system of their knees with numerous jumps or a long period of running. Kujala et al. reported in their retrospective study that during a 5 yr interval in a test sample of 2672 ambulatory patients with various knee injuries, fully 26.4% suffered from complications related to jumper's knee.^[4] Repeated mechanical excessive strain is, without doubt, the basic prerequisite for the development of this syndrome. An analysis of training methods and procedures has indicated that the type of training method used has no significant bearing on the development of jumper's knee. A much more important causative factor was found to be the amount of training (both the amount of time and the amount of mechanical strain placed on the knee) that the athlete habitually carries out. The development of jumper's knee, to a large degree, also depends on the somatic characteristics of the athlete, of which the best known and most intensively studied are the anatomic features of the lower extremities. Although, most of the studies carried out to date have been less interested in the external factors causing jumper's knee, it is quite

certain that excessive strain caused by training and exercising on hard surfaces contributes significantly to the development of this syndrome. With regard to the group of anatomical changes of the lower extremity, the unequal lower extremities and patella alta are causative factors for the development of jumper's knee. We feel confident in concluding that the underlying causes of patellar tendinosis are based on the mechanical characteristics of the tendon and the area of insertion of the tendon into the bone (its elasticity and its ability to stretch). The basic etiopathogenetic course of events leading to the development of overuse syndrome of the quadriceps tendon and the patellar tendon, i.e., jumper's knee, can be defined as the state that arises when mechanical overstrain overcomes the adaptive ability of the excessively strained tissue. Today, it is believed that insertional tendinopathy along with changes in the tendon microstructure (tendinosis) is the mainstay of this condition. We performed an investigation to document pathological changes in bone, the bone–tendon junction, and the patellar ligament in 34 athletes treated surgically.^[1] Pathological changes in the bone were found in one-third of the operated patients, on the bone–tendon junction in two-thirds of patients, and in the patellar ligament pathological changes were found in all operated patients. Pathohistological changes included cellular proliferation within the tendinous tissue accompanied by a prominence of capillary proliferation, chronic inflammatory cell infiltration, hyaline degeneration, mucoid degeneration, microtears of the tendinous tissues, neovascularisation, and tenocyte infiltration, etc. Polarization microscopy showed loss of clear demarcation of collagen bundles accompanied by loss of the normal dense, homogenous polarization pattern. On the basis of our histopathological examinations we support the opinion of the majority of authors that the time has come to change the name of this overuse injury colloquially named, jumper's knee, from patellar tendinitis to patellar tendinosis.

The clinical picture of jumper's knee is characterized by the presence of pain as the basic symptom and a decreased functional ability of the afflicted lower extremity. The pain can appear either in the area of the upper or lower pole of the patella, or in the area of the tibial tuberosity. Pećina and Bojanić reported the appearance of pain on the upper pole of the patella in 10% of their patients, in the area of tibial tuberosity also in 10% of patients, and at the tip of the patella in 80% of athletes suffering from jumper's knee.^[5] The main features of this pain consist of sharpness of varying intensity that gradually evolves and whose appearance is not connected with evident trauma. Some authors have suggested the categorization of jumper's knee into different stages (three or five), based on the prevalence of the main clinical symptoms—pain

Table 2 Classification of jumper's knee according to the main clinical symptoms

Stage 1	Pain only after sports activity
Stage 2	Pain at the beginning of sports activity, disappearing after warm-up and reappearing after activity
Stage 3	Pain at the beginning, during, and after sports activity
Stage 4	Constant pain at rest and during activity Inability to participate in sports
Stage 5	Complete rupture of patellar tendon

and loss of function in the extremity. We prefer categorization or classification in five stages (see Table 2).

Radiographic analysis may reveal bony changes on the poles of the patella and the tibial tuberosity, as well as ossification in the tendon structure. The diagnosis of jumper's knee is facilitated by the use of ultrasound examination of the quadriceps tendon and the patellar ligament.^[6] Some authors have recommended an ultrasound classification of jumper's knee, again in three or five stages (see Fig. 3). To date, there have been a number of reports concerning the success of MR imaging diagnostics of jumper's knee. The authors feel that based on these results they are better able to objectively prescribe the most suitable therapy.

Although jumper's knee is relatively easy to diagnose, its treatment is more difficult. Of the numerous nonoperative treatments available (cryotherapy, anti-inflammatory drugs, stretching exercises and strengthening of the extensor muscle system of the knee, stretching of the hamstring muscles, strengthening of

Fig. 3 Longitudinal ultrasound showing focal hypoechoic area (arrow) in the substance of the proximal tendon.

Fig. 4 Schematic representation of arthroscopic patellar apicotomy.

the extensor system of the knee by concentric and eccentric exercises) specific physiotherapy and correction of technical errors are often efficient. Surgical treatment is indicated only if a prolonged and well-supervised conservative treatment program fails. Surgical excision of irreversible lesions, demonstrated on ultrasonography or MR images, are logical procedures, which provide good results.^[7] There are numerous different operative approaches and we prefer the surgical procedure known as arthroscopically assisted approach or fully arthroscopic technique (see Fig. 4), taking into consideration the localization of the pain, knee extensor mechanism alignment, ultrasound, MR imaging, and arthroscopic intraoperative findings.^[1]

ILIOTIBIAL BAND FRICTION SYNDROME

Iliotibial band friction syndrome (ITBFS) results from activity comprising many repetitive flexion and extension movements of the knee, during which rubbing of the band against the lateral femoral epicondyle occurs. This produces irritation and inflammatory reaction within the iliotibial band or the underlying bursa (see Fig. 5).

Iliotibial band friction syndrome is one of the most common overuse injuries in professional runners and also in recreational joggers. The term iliotibial band friction syndrome was introduced by Renne in 1975.^[8] Orava diagnosed ITBFS in 6.4% athletes with overuse

Fig. 5 Mechanism of development of ITBFS.

injuries, and some other authors found a 4.7% frequency of ITBFS in 4173 injured runners.^[1,9] Also it is noted that there is a higher incidence of ITBFS in long-distance runners than in middle-distance runners and sprinters. The iliotibial band (TIB) or tract is a thickened band of fascia extending from the iliac crest down the lateral side of the thigh to its attachment on the lateral tibial condyle (Gerdy's tubercle). With the knee in the extended position, the ITB lies anterior to the lateral femoral epicondyle; in knee flexion of 30° it lies behind the lateral femoral epicondyle. The friction (or impingement) occurs near footstrike, predominantly in the foot contact phase at or slightly below 30° of the flexion, between the posterior edge of the iliotibial band and the underlying lateral femoral epicondyle. The activities entailing many repetitive flexion and extension movements of the knee produce irritation and subsequent inflammatory reactions within the ITB or formation of underlying bursae and secondary inflammation. Most commonly, the ITBFS is a result

of training errors and anatomical malalignment, of the lower extremity. Malalignment conditions of forefoot varus and/or subtalar varus, tibia vara, and genu varum lead to excessive and/or prolonged forefoot pronation during the support phase of the running cycle and this causes ITBFS in more than 50% of cases. Other predisposing factors to ITBFS have been cited: poor ITB flexibility, leg length discrepancies, increased prominence of the lateral femoral epicondyle, hard and/or uneven running surface, and inadequate workout shoes. The patients with ITBFS experience pain at the lateral side of the knee. Pain is stinging in nature, and is located at the lateral femoral condyle 2 cm above the joint line, but it may radiate downward along the iliotibial band, or upward along the lateral side of the thigh. Initially, the pain appears immediately after engagement in activity and usually disappears following a few hours of rest. The next phase is characterized by pain at the very beginning of the activity, its disappearance after warming up, and appearance again on completion of the activity. It is common that the athlete does not seek medical attention in that time and it results in progressive development of the syndrome. In the final stage, the pain impairs even normal walking. The clinical history data are of great importance in the diagnosis of ITBFS, but also various provocative tests for ITBFS have been described. During Noble's test the patient lies in a supine position and the knee is flexed to 90° (see Fig. 6). The examiner holds the ankle of the affected leg in one hand and presses on the lateral femoral epicondyle with the thumb of the other hand. While maintaining constant pressure, the examiner slowly extends the leg. Pain appears when the knee is flexed to 30°, and the patient usually reports that it is the kind of pain experienced when running. Modification of this test according to Pecina consists of putting the lower leg in varus position when performing knee extension. Ober's test is used to diagnose flexibility of the ITB

Fig. 6 Provocation of pain in ITBFS (Noble's test).

Fig. 7 Ober's test.

(see Fig. 7). Ultrasonographic and MR examinations may depict some abnormalities in patients with ITBFS. As a part of differential diagnosis several other conditions should be taken in to consideration: popliteal tendinitis, rupture of the lateral knee joint capsule and/or lateral meniscus, cyst of the lateral meniscus, lesion of the lateral collateral ligament, lateral patellar compression syndrome, but most often the differential diagnosis should be made between the ITBFS and popliteal tendinitis.

The treatment of ITBFS is usually nonoperative: correction of predisposing factors, short-term cessation or modification of athletic activities, ITB stretching exercises, ice massage of the painful area, analgesic/nonsteroidal anti-inflammatory drugs, although infiltration of steroids combined with local anesthetic into the site of the most intense pain is recommended by some authors. When formation of a bursa has been confirmed, the application of steroids injection is also indicated. Surgery is recommended in resistant cases: a transverse cut is made in the 2 cm-long posterior portion of the ITB at the level of the lateral femoral epicondyle and in this way, a V-shaped defect is obtained preventing friction between ITB and lateral femoral epicondyle.

BREASTSTROKER'S KNEE

A high percentage of breaststroke swimmers complained of pain in the medial part of the knee joint. This condition has been termed breaststroker's knee, although further studies showed that breaststroker's knee was diagnosed in swimmers who used the free-style, backstroke, or butterfly stroke. Kennedy and Hawkins believed that a tibial collateral ligament strain on the proximal femoral origin of the ligament, resulting from repeated stretching of the origin during

breaststroke swimming, was the primary disorder leading to breaststroker's knee.^[10] The stretching of the ligament origin is caused by extension of the knee during the "whip kick" phase of breaststroke swimming, accompanied by an excessive valgus stress on the knee joint and the outward rotation of the leg in the final phase of the stroke (see Fig. 8).

In most cases the pain is localized in the lower area of the medial facet of the patella. The inflammation, thickening, and fibrosis of the medial parapatellar plica as potential causes of breaststroker's knee pain are described and arthroscopically confirmed. Arthroscopic findings range from localized medial synovitis of the knee to generalized synovitis and chondromalatic changes on the medial facet of the patella. Slow-motion analysis of the mechanics of the breaststroke showed that the primary cause of breaststroker's knee was the incorrect technique during the "whip kick" phase. Breaststroker's knee symptoms usually appear after 3 yr of competitive swimming. In most cases, both knees are affected and in the beginning the area of the greatest tenderness is localized in the proximal origin of the medial collateral ligament. The later phase is characterized by pain in the lower medial patellar facet area. As with other overuse injuries, the ideal treatment of breaststroker's knee is prevention. Identifying the mechanism of injury and prescribing appropriate management is not easy, unless one has a thorough understanding of proper technique of the four competitive strokes. Proper warm-up exercise, local application of ice, and ultrasound can be helpful. Stretching exercises of the hamstring muscles and strengthening exercises for the medial vastus muscle should be performed as well. Surgical treatment is rarely indicated.

Fig. 8 Biomechanical explanation of the causes leading to the development of breaststroker's knee. Note the stretching of the medial collateral ligament (black arrow) and external rotation of the legs (grey arrows).

OSGOOD–SCHLATTER DISEASE

The most often encountered overuse injuries in children and adolescents are the traction apophysitises, among which the most common and best known is Osgood–Schlatter disease, that is, traction apophysitis of the tibial tubercle. Traction apophysitis of the tibial tubercle develops during the adolescent growth spurt, most often at 11 yr of age in girls and at 13 yr of age in boys. It occurs slightly more often in boys. The clinical picture consists of pain localized to the area of tibial tubercle. The tubercle may be swollen and hypertrophied. Most authors agree that rapid adolescent skeletal growth leads to relative “tightness” of the soft tissues, as skeletal growth is faster than the elongation of the muscle–tendon units. This in turn creates increased tensile forces on the muscles, tendons, and their attachment sites (the apophyses), which cause avulsion fractures of the bony part of the traction apophysis on the tibial tubercle. Physical examination reveals pain during palpation of the tibial tubercle. Resisted extension of the knee from the 90° flexed position will usually reproduce pain, but resisted straight-leg rising is usually painless. The lateral radiograph generally shows the characteristic picture of prominent tibial tubercle with irregularly fragmented ossific nucleus, or a free bony fragment proximal to the tubercle (see Fig. 9).

Nonoperative treatment of Osgood–Schlatter disease, as with other traction apophysites, is based on the

Fig. 9 Osgood–Schlatter disease in a young basketball player.

same principles that apply to all overuse injuries. Today, there is no need for total immobilization or for totally refraining from athletic activities. Corticosteroid injections are not indicated because the condition is not primarily inflammatory and because of the numerous unwanted side effects. Of vital importance is that the physician informs the parents, the coach, and the child athlete of the natural course of Osgood–Schlatter disease. The symptoms of Osgood–Schlatter disease will generally decline and disappear in most patients if nonoperative treatment is carried out long enough, especially after bone growth is terminated. In athletes or physically active young people surgical treatment gives good results in chronic unresolved cases.^[11]

SINDING–LARSEN–JOHANSSON DISEASE

This is a traction apophysitis of the inferior pole of the patella (in rare cases it affects the superior pole as well) and this entity is similar to Osgood–Schlatter disease. Sinding–Larsen–Johansson disease is more common in boys, generally between the ages of 10–15 yr, and is characterized by tenderness of the knee and limping. Clinical examination reveals localized tenderness and swelling over the distal pole of the patella. Lateral radiograph reveals delayed ossification of the inferior pole of the patella. Ultrasound examination gives complete information about the involvement of bone, cartilage, and patellar tendon. The lower pole of the patella appears irregular, fragmented, with swelling of the cartilage and thickening at the insertion of patellar tendon. Treatment is the same as with Osgood–Schlatter disease.

FAT PAD SYNDROME (HOFFA DISEASE)

The primary cause of fat pad syndrome is repeated traumatization of the infrapatellar fatty pad (corpus adiposum Hoffa) during activities that require constant repetition of maximal extension in the knee. It is necessary to distinguish two phases, acute and chronic. Fat pad syndrome is characterized by contact tenderness of the fatty pad, as well as during palpation along the edge of the patellar ligament. Fat pad syndrome is further characterized by the appearance of pain during hyperextension of the knee, the so-called Smillie’s sign (appearance of pain during sudden passive hyperextension of the knee), by the appearance of blockades that are hard to differentiate from meniscal blockades. Magnetic resonance imaging is a useful tool in the study of Hoffa’s fat pad, whose local and systemic involvement is an often ignored cause of anterior knee pain.^[12] In addition, the infrapatellar fat pad may be involved secondary from intrinsic and

extrinsic processes: intracapsular chondroma, localized nodular synovitis, postarthroscopy and postsurgery fibrosis, meniscal and ganglion cyst, Cyclops lesion, etc. In most cases, treatment is nonoperative, but it includes elevation of the heels of the shoes, which reduces, and in some cases completely disables, hyperextension of the knee. In persistent cases arthroscopic resection of the fat pad is performed.

PLICA SYNDROME

Plicae synoviales are normal synovial structures of the knee joint cavity. They are remnants of the mesenchymal tissue that occupies the space between the distal femoral and proximal tibial epiphyses in the 8-week embryo. Incomplete resorption leaves synovial pleats in most of the knee. The infrapatellar plica is the most constant and is also called the mucosum ligament. The suprapatellar plica partially divides the suprapatellar recessus from the knee joint, and the medial plica, which can in some cases be joined to the suprapatellar plica, projects along the anteromedial part of the knee joint to the infrapatellar fatty pad.^[13] The infrapatellar plica was found to be thickened and fibrotic and to have lost in normal elasticity and consequently to be impinged at the intercondylar notch and trochlea, blocking further extension beyond 25° of knee flexion. Arthroscopy allows a very precise assessment of the plica including dynamic examination, in plica syndrome the symptoms are, in most cases, caused by a chronically changed (fibrotic, enlarged, and sometimes calcified) medial (also called mediopatellar) plica. While bending the knee, the affected plica strikes the medial facet of the patella; while extending the knee, it is in contact with the anteromedial part of the femoral condyle (see Fig. 10).

Fig. 10 Arthroscopic view of the symptomatic plica synovialis.

Anamnestic data of repeated audible effects described as explosive snaps and occasional blockades help in diagnosing the plica syndrome. Clinical examination sometimes reveals the plica during palpation, but in most cases the only symptom is tenderness to palpation of the medial facet of the patella and medial femoral condyle. Ultrasound, MR imaging, and arthroscopy are very reliable diagnostic tools. Non-operative treatment includes wearing of special knee braces. Arthroscopic excision of a painful medial plica provides satisfactory relief of symptoms.

SEMIMEMBRANOSUS TENDINITIS

Semimembranosus tendinitis is often an overlooked cause of posteromedial knee pain. The main symptom is pain located at the very posteromedial corner of the knee just below the joint line. During physical examination, pain is produced by applying pressure to the anterior medial tendon of the semimembranosus muscle, immediately below the knee joint, and at the insertion of the posterior medial tendon on the posterior part of the tibial medial condyle. Tenderness is amplified if the knee is in 90° flexion and the lower leg in maximum outward rotation. Differential diagnosis includes ruling out the possibility of medial collateral ligament bursitis, and injury of the medial meniscus. The pes anserinus tendons should also be palpated to rule out the possibility of enthesitis of those tendons and, in some cases, the inflammation of the pes anserinus bursae. In most cases, treatment is non-operative and surgical intervention is rarely indicated consisting of surgical exploration, drilling of the insertion site, and semimembranosus tendon transfer.

PES ANSERINUS TENDINITIS AND BURSITIS

The tendon of the sartorius, semimembranosus, and gracilis muscles insert on the medial plane of the tibia, just below the condyle, forming the pes anserinus (goose foot). Pes anserinus syndrome is frequently found in long-distance runners. Predisposing factors for the development of this syndrome include incorrect training techniques, excessive tightness of the hamstring muscles, valgus alignment of the knee, and excessive rotation of the lower leg in the outward direction.^[14] Bursitis is more frequent and presents fewer problems, both in diagnostics and in treatment. A slight swelling is usually found on the medial side of the knee joint. Ultrasound and MR imaging facilitate correct diagnosis of bursitis. Diagnosing tendinitis (enthesitis) presents more problems, especially regarding differential diagnosis of an internal derangement of the medial compartment of the knee. Magnetic

resonance imaging can be useful in diagnosing pes anserinus tendinitis, and in some cases, scintigraphy is performed to rule out the possibility of stress fracture of the tibia. Treatment is usually nonoperative. Local injection of corticosteroid plus anesthetic is more effective than noninjection therapy.

POPLITEAL TENDINITIS

Popliteal tendinitis is characterized by localized tenderness in the area above the origin of the popliteal muscle on the lateral part of the lateral femoral condyle.^[15] Excessive and/or extended pronation of the foot during running is considered to be a predisposing factor in developing this syndrome. Popliteal tendinitis or popliteal tenosynovitis is one of the many injuries to the knee joint that are characterized by tenderness in the lateral area of the knee. To localize the exact area of greatest tenderness, the affected leg is placed in the so-called figure of 4 position where the popliteus muscle tendon and the lateral collateral ligament are extended and thus accessible to palpation (see Fig. 11). Pain is produced by applying pressure with a finger to the area of the insertion of the popliteus muscle located slightly anteriorly and distally from the origin of the lateral collateral ligament. Treatment is usually nonoperative and carried out according to the principles

Fig. 11 Figure of 4—diagnostic test for popliteal tendinitis.

set down for treating enthesitis. Surgical treatment is rarely performed.

FABELLA SYNDROME (FABELLITIS)

The fabella is a sesamoid bone located on the posterior side of the lateral femoral condyle in the lateral head of the gastrocnemius muscle. It is present in 10–18% of the population. Injuries to the fabella can cause tenderness and sensation of radiating pain in the lower leg. Although fracture and dislocation of the fabella is described in athletes, fabella syndrome is mostly the direct result of long-lasting microtraumas.^[16] Clinical manifestations are characterized by the gradual onset of pain that radiates into the lower leg, specifically the peroneus communis nerve dermatoma. The pain is usually moderate in intensity and associated with knee movements, either because of extension of the muscles during hyperextension of the knee or because of direct pressure on the fabella, e.g., when sitting with legs crossed. The fabella syndrome appears to be unique to late adolescence, that is 15–17 yr of age. Differential diagnosis must rule out the possibility of rupture of the posterior horn of the lateral meniscus and also tendinitis of the lateral head of the gastrocnemius muscle, the biceps femoris, and the popliteus muscle. If the usual nonoperative treatment, including infiltration of anesthetics with corticosteroids, does not produce improvement, surgical treatment, consisting of extirpation of the fabella is indicated.

CONCLUSIONS

Because of its exceptional vulnerability, and its extremely complex anatomic and biomechanical structure, the knee joint, like no other joint in the human body, poses great challenges to a treating physician. The knee joint is a frequently injured joint in athletic and recreational activities, and according to some statistics, one-half, or possibly even more, of all sports-related injuries are incurred in the knee joint. Although most of the injuries of the knee joint are acute ones, such as meniscal or anterior cruciate ligament ruptures, overuse injuries are becoming more and more present in overall knee pathology. The reasons for this are that the knee joint participates in all sports activities (running, jumping, kicking, etc.), and also the joint area is characterized by numerous attachment sites for muscles and their tendons as well as by numerous bursae. It is also because the specific joint between the patella and the femur (articulatio femoropatellaris) constitutes a part of the knee joint. Overuse injuries of the knee joint deserve special attention because, though very common, they are complex in

terms of their detection and differential diagnosis. Thorough knowledge of epidemiology, etiology, pathophysiology and diagnostic modalities is crucial to diagnose these injuries correctly. As with most of the overuse injuries, the treatment is usually conservative and the concept is known as “relative rest.” If the conservative treatment fails, numerous surgical options, including minimally invasive procedures such as arthroscopy and endoscopy, are available to the treating physician.

INTRODUCTION

Total knee replacement (TKR) has been around in some form for over fifty years. The complexities of the knee joint began to be understood only thirty years ago. Because of this, TKR was initially not as successful as Sir John Charnley's artificial hip. However, over the last twenty years, dramatic advancements in the knowledge of knee mechanics have led to modifications of the design of the artificial knee, which appear to be durable. As with most techniques in modern medicine, the envelope is constantly expanding so that increasing numbers of patients are receiving the benefits of knee arthroplasty.

Knee joint replacement is a safe operation with good success rates. To date, cemented fixation has been the gold standard for TKR with excellent long-term results. Medium- and long-term results from cementless TKR have proven to be satisfactory. The effectiveness of bioactive coatings in augmenting TKR fixation has achieved positive early results, and bioactive coatings may be an alternative to cement in achieving long-term durability.

HISTORY

In the 1860s Fergusson reported performing a resection arthroplasty of the knee for arthritis, and Verneuil is thought to have performed the first interposition arthroplasty using joint capsule. Other substances were subsequently tried including skin, muscle, fascia, fat, and pig bladder.

The first artificial implants were tried in the 1940s as molds fitted to the femoral condyles (following similar designs in the hip). In the next decade tibial replacement was also attempted but both designs led to problems with loosening and persistent pain. Combined femoral and tibial articular surface replacements appeared in the 1950s as simple hinges. These implants failed to account for the complexities of knee motion and consequently had high failure rates.

In 1971, Gunston^[1] importantly recognized that the knee does not rotate on a single axis like a hinge.

Gunston showed that the femoral condyles roll and glide on the tibia with multiple instant centers of rotation. His polycentric knee replacement had early success with its improved kinematics over hinged implants, but failed because of inadequate fixation of the prosthesis to bone.

The highly conforming and constrained Geomedic knee arthroplasty,^[2] introduced in 1973 at the Mayo Clinic, ignored Gunston's work and gave rise to a kinematic conflict. Knee prosthesis designs since then have either followed Gunston's principle in attempting to reproduce normal knee kinematics, or have provided a more conforming articulation to govern knee motion.

A variety of condylar prostheses have since been designed. The Total Condylar prosthesis designed by Insall in 1973^[3] was one of these. This prosthesis concentrated on mechanics and did not try to reproduce normal knee motion. Ranawat et al.^[4] reported 94% survivorship at 15-year follow-up, which is the most impressive reported to date; however, range of motion was not recorded. The component was subsequently redesigned to more closely reproduce the normal kinematics of the knee and to improve range of motion of the component. At the same time, a prosthesis with more natural kinematics was developed at the Hospital for Special Surgery, relying on the retained cruciate ligaments to provide knee motion.

The argument as to whether the posterior cruciate ligament should be preserved or sacrificed goes on to this day. Long-term follow-up studies do not show any significant differences, although gait has been shown to be more normal, especially when walking up and down stairs, if ligaments are preserved.^[5] One approach to incorporating normal kinematics and maximal conformity is with mobile tibial bearings. Long-term follow-up of these prostheses has so far shown encouraging results with predictable long-term survival.^[6]

DEFINITION OF PROBLEM

Patients with painful, deformed, and unstable knees secondary to degenerative or inflammatory conditions need a prosthesis that will provide reproducible relief

of pain and improvement in function. Morbidity and complications from the procedure should be minimal. The complexities of a normal knee joint however, are not easily reproduced with modern techniques and patients should understand that the prosthesis will not be a normal knee. The prosthesis should be durable, requiring patients to undergo only one definitive procedure in their lifetime, although in younger patients, this may be unrealistic. Revision procedures should always be contemplated, and bone preservation is mandatory in the initial procedure.

Indications for Surgery

The primary indication for TKR is to relieve pain caused by severe arthritis. Correction of significant deformity is an important indication, but is rarely used as the primary indication for surgery. Before surgery is considered, all conservative treatment measures should have been exhausted.

Knee replacement has a finite expected survival that is adversely affected by activity level. It is generally indicated in older patients with more modest activity levels, but is also clearly indicated in younger patients who have limited function because of systemic arthritis with multiple joint involvement. Young patients requesting knee replacement, especially those with post-traumatic arthritis, are not excluded by age but must be significantly disabled and must understand the inherent longevity of joint replacement. Rarely, severe patellofemoral arthritis may justify arthroplasty because the expected outcome of arthroplasty is superior to patellectomy. Deformity can sometimes become the principal indication for knee replacement in patients with moderate arthritis when flexion contracture or varus or valgus laxity is significant.

Contraindications

Absolute contraindications to TKR include knee sepsis including previous osteomyelitis, a remote source of ongoing infection, extensor mechanism dysfunction, severe vascular disease, recurvatum deformity secondary to muscular weakness, and the presence of a well-functioning knee arthrodesis. Relative contraindications include medical conditions that preclude safe anesthesia, the demands of surgery and rehabilitation, a neuropathic joint, obesity, or skin conditions within the field of surgery such as psoriasis.

RELEVANT ANATOMY

Movement of the knee joint can be classified into six degrees of freedom—three translations (anterior/

posterior, medial/lateral, and inferior/superior) and three rotations (flexion/extension, internal/external, and abduction/adduction). The movements of the knee joint are determined by the shape of the articulating surfaces of the tibia and femur and the orientation of the four major ligaments of the knee joint (the anterior and posterior cruciate ligaments and the medial and lateral collateral ligaments). The two cruciate ligaments create a four-bar linkage system that maintains a fixed femoral and tibial relationship throughout flexion.

Knee flexion and extension involves a combination of rolling and sliding, termed femoral rollback, an ingenious way of allowing increased ranges of flexion. Because of asymmetry between the lateral and medial femoral condyles, the lateral condyle rolls a greater distance than the medial condyle during 20 degrees of knee flexion. This causes a coupled external rotation of the tibia, which is described as the screw-home mechanism that locks the knee into extension.

The primary function of the medial collateral ligament is to restrain valgus rotation of the knee joint, with secondary function being control of external rotation. The lateral collateral ligament restrains against varus rotation and resists internal rotation.

The primary function of the anterior cruciate ligament (ACL) is to resist anterior displacement of the tibia on the femur when the knee is flexed, and to control the screw-home mechanism of the tibia in terminal extension of the knee. A secondary function of the ACL is to resist varus or valgus rotation of the tibia, especially in the absence of the collateral ligaments. The ACL also resists internal rotation of the tibia. The main function of the posterior cruciate ligament (PCL) is to allow femoral rollback in flexion and to resist posterior translation of the tibia relative to the femur. The PCL also controls external rotation of the tibia with increasing knee flexion. Retention of the PCL in TKR has been shown biomechanically to provide a more normal kinematic rollback of the femur on the tibia. This is also important for improving the lever arm of the quadriceps mechanism with flexion of the knee.

The movement of the patellofemoral joint can be characterized as rotating, gliding, and sliding. During flexion of the knee, the patella moves distally on the femur. This movement is governed by its attachments to the quadriceps tendon, ligamentum patellae, and the anterior aspects of the femoral condyles. The muscles and ligaments of the patellofemoral joint are responsible for producing extension of the knee. The patella acts as a pulley in transmitting the force developed by the quadriceps muscles to the femur and the patellar ligament. It also increases the mechanical advantage of the quadriceps muscle relative to the instant center of rotation of the knee.

The mechanical axis of the lower limb is an imaginary line through which the weight of the body passes. It runs from the center of the hip to the center of the ankle through the middle of the knee. This is altered in the presence of deformity and must be reconstituted at surgery. This allows normalization of gait and protects the prosthesis from eccentric loading and early failure.

PROSTHETIC DESIGN FACTORS

A typical total knee replacement has four components (Fig. 1). These include a femoral component (usually cobalt–chromium alloy); a tibial component (either titanium or cobalt–chromium alloy); a meniscal insert (polyethylene), which can be fixed or mobile; and a patella-resurfacing component (polyethylene). The design and material used in each component are important when attempting to recreate the kinematics of a normal knee joint. Cobalt-based alloy (CoCrMo) is said to be a reliable material that meets the prerequisites of biocompatibility and durability that make it suitable for use in joint prostheses of the knee, hip, and shoulder.^[7,8]

Femoral and Tibial Component Design Factors

A functional design that also reproduces the kinematics of a normal knee joint is the goal of all prosthetic designs. In order to do this, the femoral component must recreate the correct anatomical sizes and shapes of the femur. If the PCL is to be retained, adequate replacement of the resected femoral condyles and tibial cuts is required to maintain full flexion and femoral rollback (Fig. 2). Excessive or insufficient thickness may result in loss of flexion and absence of rollback. Andriacchi et al.^[5] compared the kinematic characteristics of five different designs of knee replacement and found that all resulted in abnormalities during gait, although the cruciate-retaining designs produced a more normal range of motion during stair climbing. Abnormalities

Fig. 1 Location of the (A) femoral and (B) tibial beaded component surfaces.

Fig. 2 Flexion obtained in a TKR with a fixed bearing.

during knee motion following TKR are also the result of interactions of surrounding soft tissue structures and efforts to achieve a suitable balance.

The decision to conserve or sacrifice the PCL has important consequences when considering component design and patient function outcome. Advantages of keeping the PCL include preservation of proprioception, maintenance of femoral rollback, prevention of posterior subluxation, and greater reproduction of the kinematics of a normal knee. Disadvantages include joint looseness or tightness and decreased meniscal insert conformity resulting in increased contact stresses due to femoral rolling and sliding. Advantages of sacrificing the PCL include a technically easier operation, increased conformity of the articular surface resulting in increased anterior-posterior stability, and no sliding. Disadvantages are reduced range of motion due to absence of rollback; increased constraint related to conformity of the meniscal insert, which increases stress at the fixation interface on the tibia; and altered kinematics and proprioception of the knee.

Tibial component design is also important, especially as concerns fixation. Tibial loosening is a major cause of failure in total knee arthroplasty due to tibial lift-off and subsequent subsidence. Many factors influence the initial stability of an uncemented tibial tray, including implant design, geometry of the bearing surfaces, quality of the underlying cancellous bone, and surgical technique. In an uncemented knee arthroplasty, stable initial fixation is a prerequisite of successful bone ingrowth and long-term fixation (Fig. 3). To allow successful osseointegration, screw fixation must elicit less than 100 μm initial motion,^[9–11] with best fixation occurring with the use of four screws. Other designs of tibial components incorporate stems and cement in order to further enhance fixation and prevent lift-off and shear. In fact, it has been shown that short or long stems do not enhance fixation with cemented or

Fig. 3 Machine setup for testing tibial plate micromotion with four-screw fixation.

uncemented arthroplasty,^[12] and that use of a stem results in reduced metaphyseal bone density.^[13]

Cortical coverage is important when designing and implanting the tibial component. Subsidence can occur when inadequate cortical coverage is achieved due to an undersized tibial component, especially in the uncemented knee. A broad variety of sizes should be available to allow adequate cortical coverage without affecting the congruence of femoral component articulation.

Meniscal Insert Material and Design Properties

The function of the meniscal insert is to provide effortless articulation between the femur and tibia and to allow for correct anatomical function of the joint. Meniscal insert failure is the primary reason for total knee replacement failure.^[14] The metal femoral component is 100 to 200 times stiffer than the plastic meniscal insert, and hence it acts like a rigid indenter, deforming the plastic.^[15] Consequently, the design of the meniscal insert is critical to the longevity and success of the prosthesis. The choice of material and manufacturing processes used, as well as the geometry of the meniscal insert, are the key design factors in reducing stress in the component, hence increasing its lifetime.

The principle reasons for failure of meniscal inserts are delamination and pitting.^[16] Delamination is caused by tiny cracks forming under the articulating

Fig. 4 Meniscal inserts demonstrating delamination.

surface. These cracks start to propagate, running parallel to the surface and resulting in sheets of the material laminating away.^[17] Pitting is a similar mechanism, where the cracks start at the surface and propagate inward. Both types of failure—especially delamination due to excessive amounts of material breaking away at one time—are detrimental to the function of the joint (Fig. 4). Failure can lead to infection in the joint (because of the biological reaction to debris particles) and loosening of the prosthesis.^[18] To increase the longevity of the meniscal insert, stresses in the component must be reduced and manufacturing processes refined to reduce defects in the material that may predispose it to failure.

The standard material currently used for the meniscal insert is medical-grade, ultra-high, molecular-weight polyethylene (UHMWPE). UHMWPE is a biocompatible material with excellent wear-resistant characteristics and a very low coefficient of friction with cobalt–chromium alloy, commonly used for the femoral component. The coefficient of friction between UHMWPE and cobalt–chromium alloy has been reported at between 0.03 and 0.16 with excellent wear rates.^[19] Other polymeric materials have been tried in the past to increase the strength of the articulating component, but UHMWPE has surpassed other materials with excellent wear rates and fatigue resistance.^[19] More recently, the strengthening of UHMWPE by cross-linking has been studied to achieve a stronger material with higher wear resistance. Although high wear resistance has been achieved, cross-linking produces a more brittle material, detrimental to fatigue resistance properties and hence lowering longevity.^[20]

The manufacturing and sterilization processes used to make meniscal inserts also affect the longevity of the component. UHMWPE meniscal inserts were originally manufactured by heat pressing, a process that heats the material under compression and allows it to flow into all cavities of the mold, where it then cools.

This process produces inconsistent cooling of the material. Significant grain boundaries are consequently formed that are weak points in the material.^[21] These imperfections are key regions where the delamination process can initiate. More successful is the recent use of machining UHMWPE from ram-extruded or compression-molded rods to manufacture the components. This process produces material with minimal evidence of grain boundaries and consequently higher fatigue resistance.^[21] Two main types of sterilization are used for medical purposes. The most common is gamma irradiation. This process has been shown to oxidate the material, which degrades the density of UHMWPE over time.^[22] Because this is detrimental to the fatigue resistance of UHMWPE,^[23] ethylene oxide sterilization is now preferred as an alternative.

The geometry of the meniscal insert is critical to not only the function of the joint, but also to the stresses produced in the component and consequently to the longevity of the prostheses. Two key design factors concerning the geometry of the component are the thickness of the meniscal insert and its conformity with the femoral component. Studies have shown that greater meniscal insert thickness results in lower stresses, with minimum thicknesses below 6 mm causing excessive stresses. The problem with increasing meniscal insert thickness is maintaining anatomically correct joint space, accomplished by sacrificing proximal tibial bone.^[15] A balance must therefore be achieved to maximize meniscal thickness, reduce bone loss, and maintain joint space. Increasing conformity of meniscal insert to femoral component increases contact area and consequently reduces contact stresses.^[18] Because the kinematics of the knee joint is very complex, more conforming designs will likely restrict the natural movement and function of the joint. Again, balance must be attained made between conformity and function of the knee joint.

Mobile-Bearing Insert

The mobile-bearing insert in total knee arthroplasty is designed to move freely in the joint during knee motion. There are generally two types of mobile bearing: the semiconstraining, rotating platform has a central peg that allows rotation but no translations; the other, less constraining, self-centering mobile bearing allows both rotation and translation. Both types sit on a polished tibial surface and are highly conforming to the femoral component (Fig. 5). The potential benefits of mobile meniscal-bearing total knee prostheses are good mobility, low contact stress, and low shear stress on the components, thus reducing polyethylene wear and implant failure.^[24-29]

Fig. 5 Polished meniscal-bearing tibial plates.

The perceived advantages of meniscal-bearing TKRs are the potential for reduced polyethylene wear while allowing unrestrained tibiofemoral movement^[28,30,31] and increased range of movement (Fig. 6) compared to similar designs with fixed bearing. Mobile-bearing TKRs have significantly reduced upper- and lower-surface stresses compared with fixed-bearing components.^[32] The mean rate of polyethylene penetration of congruent meniscal bearings is less than that of fixed bearings and has been estimated in vitro to be as low as 0.05 mm^[33] to 0.01 mm^[28] per year.

By allowing completely unconstrained motion with a mobile-bearing system, as compared to central peg systems and systems where the bearings are constrained by tracks, high-shear stresses in the polyethylene and at the bone/component interface are avoided. However, there is an increased possibility for subluxation of the meniscal insert with these designs, although the incidence of this is very low.^[29] Knees undergoing replacement are diseased and their individual kinematics

Fig. 6 Flexion obtained in a TKR with meniscal bearing. (Note femoral rollback.)

is impossible to forecast. As a result, it is essential that the mobile bearing be allowed to find its own place and range of motion to suit the knee in which it has been implanted. In order to achieve this, the bearing should be self-centering. It is essential to have equal flexion and extension gaps when using mobile bearings.

Femoral Morphology and Component Rotation

Femoral morphology is commonly assumed to be relatively consistent when performing total knee arthroplasty.^[34] However, recent work has demonstrated three distinct shapes of the distal femur: ectomorphic, mesomorphic, and endomorphic.^[35] This variation in morphology affects the choice of femoral components. To avoid undersizing the prosthesis, prosthesis kits in the future may offer narrow as well as wide femoral components, to accommodate the variation in femoral morphology.

Bone cuts are made to prepare the distal femur to accept the femoral component using anatomical landmarks for reference. Correct varus–valgus alignment is usually achieved with either an intramedullary guide against the anatomical axis or an extramedullary guide to demonstrate the mechanical axis. Femoral component rotation is also dependent on the shape of the distal femur.

Accurate rotation of the femoral component in total knee arthroplasty is important for normal patella tracking, symmetrical patellofemoral joint contact, neutral varus–valgus positioning in flexion, correct rotational alignment of the tibia in extension, and avoidance of anterior femoral notching.^[36,37] Internal rotation of the femoral component causes a shift into valgus alignment with flexion and an increase in the quadriceps angle (commonly known as the Q-angle) with harmful effects on patella tracking. Internal rotation of the femoral component also causes differences in the flexion and extension gaps by altering the relative dimensions of the posterior condyles in flexion. Flexion then causes asymmetrical tension across the prosthesis and gapping on the lateral side.^[36]

COMPONENT FIXATION

Cemented and Cementless Fixation in TKR

There has been much debate in recent years regarding the optimal method of fixation in TKR. The consensus generally accepts cement fixation as the ideal, with randomized studies revealing longer survival rates with few complications.^[4,38–43] However, more recent studies comparing cemented and cementless techniques have revealed few differences, if any.^[39,44–47] Unlike with the

hip, early use in TKR of a cementless technique was unsuccessful, with high failure rates due to inadequate fixation and failure of bone ingrowth onto porous surfaces. A poor prosthetic design rationale and use of metal-backed patellae also resulted in the cementless prosthesis being associated with high rates of failure, raising concerns over use of such prostheses.

The long-term survival of TKR fixation using polymethylmethacrylate (PMMA) cement is well-published with excellent results confirming satisfactory functional scores and prosthesis survival greater than ninety % after more than 10 years.^[4,38–43] Many surgeons choose to use a cemented fixation due to its decreased technical difficulty with implantation and reliable long-term results. Cement, however, has been indicated as a major factor in prosthetic loosening due to its limited fatigue life, poor stress properties, and association with osteolysis. The presence of cement disease has been reported with hip replacements where, in younger patients, cement can be implicated as the major cause of aseptic loosening due to its unnatural biomaterial properties.^[48] The question thus arises whether there is a need to use cement or not.

Porous coated prostheses were first used in the 1980s as an alternative to cemented components in an attempt to overcome the problem of aseptic loosening. Ingrowth of the prosthesis occurs when the porous coated surface of the prosthesis is applied to a living bone surface with an initially stable interface with minimal micromotion. The porous surface is penetrated with hematoma and inflammatory cells following implantation. As early as 4 weeks postimplant, the porous surface is replaced with early bone structures, and by 6 months postimplant, mature bone formation occurs.^[34]

Medium- and long-term results from cementless TKR have proven satisfactory.^[39,49,50] Theoretically, cementless fixation has the advantages of less third-body wear, decreased maintenance, better restoration of bone stock, and safer implantation after bacterial arthritis. Long-term studies reveal little difference in survival rates between cemented and cementless designs, leading to an increase in the popularity of cementless fixation.^[26,46,51] Comparable results with cemented and cementless design, theoretically longer and more durable outcomes, and the long-term efficacy of calcium phosphates (i.e., hydroxyapatite) that enhance fixation have led to the continuing increase in the use of cementless knee arthroplasty prostheses.

Hydroxyapatite (HA) in TKR

Over the last decade simple press-fit total knee prostheses have not demonstrated enough intrinsic stability, and ingrowth into porous coated implants has been inconsistent, possibly because of inexact bone

Fig. 7 Evidence of osseointegration achieved with hydroxyapatite (HA) coating.

cuts. The problem with some early cementless designs was that they allowed inadequate tibial cortical coverage; the tibial inserts therefore often sank. Preliminary reports,^[40,52–54] suggested that HA-coated implants could improve stability and fixation of cementless TKR.

The effectiveness of hydroxyapatite (HA) in augmenting TKR fixation has been proven.^[55–57] The presence of HA has been shown to encourage bone growth onto the porous coated prostheses (Fig. 7), as indicated by the reduction of lucent lines when compared to similar uncemented prostheses.^[58] Hydroxyapatite coating has been shown to enhance fixation in total hip replacement,^[59,60] however, its role in TKR has only recently been demonstrated. Early results with bioactive coatings on prosthetic interfaces have been encouraging. Growing concern over cement fixation and so-called cement disease has led to increased use of cementless fixation in TKR.

FUNCTION AFTER TKR

Many knee replacement systems have demonstrated adequate functional results and range of motion at middle- to long-term follow-up. Most follow-up studies' functional scoring systems use pain, ability to walk, ability to ascend and descend stairs, and use of a walking aid as measures of outcome.^[61,62] Kneeling ability is usually not considered, although some scoring systems, derived from patient questionnaires, have included kneeling as a measure of knee function.^[61,63,64]

The kneeling position is important in many activities of daily living and is important in some vocations.^[65,66] The kneeling position has been shown to be a predisposing factor for osteoarthritis of the knee, and so preselects patients who will need to kneel after TKR. Kneeling has also been shown to be an important

intermediate body position by which older adults rise from the floor or garden.^[67] Many patients ask questions about kneeling ability before TKR surgery. It is difficult to answer this inquiry because of the dearth of studies on the subject.^[68,69] One study reveals that 70% of patients were able to kneel with minimal discomfort following surgery.^[69]

A number of reports in the literature indicate that up to 56% of patients return to sports after total hip replacement.^[70,71] There are only a few studies on patients returning to sports after TKR, even though knee replacement rates approach those of hip replacement. One study^[72] reports up to 77% of patients able to return to sports following TKR. With increasing implant survivorship, patient expectation of a good, functional result will also rise.

CONCLUSION

The majority of patients are satisfied with their knee replacements. If relief of pain is the main indication for surgery, then this should indeed be the case. Good knee function is usually restored after TKR, and the majority of patients are able to return to low-impact sporting activity. Long-term studies confirm satisfactory functional scores, and show 91–96% prosthesis survival at 14–15-year follow-up. The ideal prosthesis will eventually be cementless with minimal friction because of highly polished surfaces, mobile bearing, and minimal bone resection, giving rise to a normal range of motion and the kinematics of a normal joint.

Laboratory Animals: Ethics and Regulations for Care and Use

Kathy E. Laber

M. Michael Swindle

Department of Comparative Medicine, Medical University of South Carolina, Charleston, South Carolina, U.S.A.

INTRODUCTION

This article reviews common ethical arguments used both for and against the use of animals as biomedical research models, thereby providing information which will aid the investigator who either volunteers or is unwittingly engaged in discussing the use of animals in biomedical research. It also provides a summary of the laws and regulations, which govern the use of animals in research in the U.S.A. A working understanding of these laws and regulations is critical for those individuals who choose to utilize animals in their efforts to advance biomedical research. It is important to also recognize that although many of the European countries and Canada share in common the ethical arguments and parallel the animal use principles presented in this article, many of these countries have their own unique sets of laws regulating the use of animals. If animal work is to be conducted in collaboration with foreign countries, further resources specific to that country should be consulted.

ETHICS

The use of animals for biomedical research is a controversial and complex moral issue. Medical professionals and their patients clearly depend upon the advances made through the use of animals in research on a daily basis, but that unavoidable dependency does not eliminate the moral quandary, i.e., “whether it is ‘right’ to take the life of animal in pursuit of scientific knowledge and advancing medical treatment.” The emphasis and interest in this moral dilemma has increased in recent years as our society has continued to move away from its agricultural base. In western society the only interaction that many individuals have with animals is the emotion-based relationship of a pet-owner.^[1]

Moral values are primarily imprinted by religious followings, and many religions support the concept that human life is more valuable than animal life. Most religions support the animal’s position as a food and

work source, but religious teachings generally condemn cruelty toward animals. Religions tend to encourage individuals to act as responsible animal guardians. The major religions such as Christianity, Judaism, and Islam generally support the use of animals in research with the significant caveats being that animal pain and distress is minimized and that the research is likely to lead to the saving of human life or the relief of human suffering.^[2]

Philosophers have purported the concept that humans have greater “moral standing” than animals as humans have vastly superior sensory and cognitive abilities. For example, humans are more aware of pain and pleasure, thereby making the lesser-evolved animal species the more humane choice for research studies. After an evaluation of the level of moral standing an animal possesses and a determination that the animal has lesser moral standing than humans, the issue then debated is whether it is acceptable to utilize that animal *because* it has lesser moral standing than humans. This philosophical concept has created great angst over the use of nonhuman primates, particularly great apes, as they are felt to have a moral standing more closely related to man’s as evidenced by sensory and cognitive abilities that include language and self-consciousness. Other philosophers have argued that there is not a difference in “degrees” of moral standing and the acknowledgement of moral standing comes with the simple possession of life, the ability to feel pain and consciousness, and the possession of beliefs and desires. Clearly, if one adopts these tenets many animals used for science would be considered as having moral standing equal to man; therefore the use of animals in basic research is comparable to the use of humans in basic research. The mass embracement of this philosophical ideal would unmistakably bring biomedical research to a halt.^[3]

The utilitarian approach to the animal use debate is used quite eloquently by both scientists and animal activists, i.e., the greatest good for the greatest number justifies the means. Scientists argue that animal research is justified because it brings benefits to humans that outweigh the harm to animals. Antivivisectionists

argue in turn that the suffering of laboratory animals is marked, and the benefits are too limited to warrant this suffering. Both of these arguments beg the question of “how much does an animal suffer?” In its natural habitat a mouse ranges through wide areas and avoids human contact. Does something as simple as putting a mouse into a cage with frequent human contact cause a level of suffering that outweighs the benefit achieved from that animal? Does that mouse suffer more or less than a rabbit placed into a cage? Do all animals experience pain to the same degree? Clearly, because of the large variety of species used in research in combination with the lack of objective data on what constitutes distress or even pain for each individual species, we cannot cleanly define how much an animal suffers in any given experiment. Therefore the utilitarian approach to the use of animals in research provides logical arguments that support both sides of the debate.^[4]

The advent of transgenic technology has created a new era in animal research with additional ethical issues requiring thoughtful deliberation. Modifying the genetic endowment that defines a living being is felt by some to be intrinsically immoral. The process of inserting a foreign genetic material has the potential to create pain and distress in animals. The insertion of DNA occurs randomly in the genome creating the potential for gross mutations, severe disease, and mortality. Counter to that argument is the fact that transgenic technology has decreased the use of larger, potentially more sentient animals and has allowed for the rapid advancement of medical therapies targeted at the gene level.^[5]

The intense emotional response that is evoked in individuals about the topic of animal use for research has resulted in the organization of extremist groups such as People for the Ethical Treatment of Animals and the Animal Liberation Front. These groups are adept at presenting information within media campaigns to negatively sway public opinion against animals in research. They have also been very effective at presenting these views throughout the primary school systems. Extremists have, with increased frequency, resorted to terrorist tactics to “liberate” animals housed in research facilities, vandalize laboratories, and intimidate investigators and their families. The governments of the U.S.A. and several other nations have worked to develop legislation which prosecutes these activities; however such campaigns have effectively diminished the private business research sector from growing in places such as the U.K. Historically, scientists have not aggressively combated the animal activist movement; although in recent years the National Association for Biomedical Research (www.nabr.org) has lobbied for legislation that protects the research enterprise. The affiliated Foundation

for Biomedical Research (www.fbresearch.org) has worked to educate individuals about the benefits of biomedical research. Of potential future concern is the growing number of law schools that are expanding their curriculum to study the legal rights of animals. This could lead to the legal stance that humans are not “owners” of animals but rather their guardians. The adoption of this philosophy at a grass root level would clearly add monumental barriers to the use of animals in research.

At present, the general populace in the U.S.A. support the idea that research is important, that animals deserve some level of moral standing in our society, and that research on animals can be justified under certain conditions. This support, however, is dependent in part upon the species being used and the type of research being performed. For example, there is more support for the use of mice in cancer research than the use of rabbits for cosmetic testing. The use of pet species such as dogs and cats and nonhuman primates generates more concern from the public than rodent species.^[6] The concerns that the public has about the use of animals in research have led to adoption of a variety of guiding principles and laws which ensure the public that certain ethical considerations are being given to the use of animals in research.

ANIMAL WELFARE ACT

Although animals have been utilized in biomedical research for centuries, the first law in the U.S.A. impacting on biomedical research was the *Laboratory Animal Welfare Act of 1966* [later renamed the *Animal Welfare Act* (AWA) <http://www.nal.usda.gov/awic/pubs/awicdocs.htm>]. The public outcry that leads to the creation of this law was the result of the media publicizing that dogs and cats were being stolen and used for research, or housed by animal dealers in inappropriate ways prior to being sold to research institutions.^[7] The law implemented licensing requirements for animal dealers in addition to detailing transportation, husbandry, and veterinary care requirements for certain species animals used in biomedical research.

The AWA has been amended several times over the years, with each amendment resulting in additional regulations; however, it was the 1985 amendment to the AWA that broke new ground resulting in a very significant impact on the use of animals in biomedical research. One of the major changes pursuant to this amendment was the requirement that institutions appoint an Institutional Animal Care and Use Committee (IACUC). This committee, with its required specified membership inclusive of scientists, was, by law, assigned the responsibility for the animal care and

use program in coordination with the attending veterinarian. Historically, the weight of ensuring compliance with the AWA had been placed primarily on the back of the attending veterinarian. This arrangement often created a state of conflict between the attending veterinarian who was enforcing the AWA and the investigators who were focused on completing their research in the most efficient manner irrespective of the laws and regulations, thereby creating the potential for a dysfunctional research environment. Key to empowerment of the IACUC was its legal ability to suspend the use of animals on a project if the animal use was not being conducted in a manner consistent with the AWA principles or consistent with the scientific plan that the IACUC was to review and approve. The IACUC now became responsible for reviewing facilities where animals were held as well as the program for animal care and use twice yearly with a report of their activities forwarded to an individual who had to have the authority and resources to correct any issues the committee identified. Deficiencies in either the program or the facilities had to be corrected within a specified time frame, or the deficiency then had to be reported to the U.S. Department of Agriculture (USDA). The IACUC was also charged with reviewing the scientific plan for the animals to ensure that: 1) procedures were carried out by an individual adequately trained to conduct them; 2) procedures would avoid or minimize pain and distress, and be conducted with appropriate anesthetics and analgesics; 3) appropriate perioperative surgical care would be provided; 4) multiple survival surgery would be scientifically justified; 5) alternatives to the use of animals had been considered and documented; 6) a qualified veterinarian was consulted in the planning of the project; and 7) euthanasia would be conducted in an acceptable manner. In addition to the husbandry and veterinary care standards that were present in the original law, the amendment required that attention be given to the psychological well-being of nonhuman primates and that dogs received exercise and socialization.^[8]

Compliance with the AWA is monitored by trained veterinarians through unannounced visits employed by the USDA. The visits vary in frequency and length dependent in part on the size of the program, the species utilized, and the history of compliance. Deviations from the law are cited and the institution has the opportunity to either respond with corrections or contest the findings. Uncorrected or repeat deficiencies often result in significant fines being levied on the institution. In addition, information that the USDA collects in its inspection reports is accessible to the public through the *Freedom of Information Act* which has been used by animal rights activists to miscommunicate the findings to news media.

Of particular note is the fact that the AWA specifically *excludes* certain animals in its coverage: farm animals used for agricultural purposes, cold blooded animals, birds, and the majority of animals that are used for research—rats and mice.

HEALTH RESEARCH EXTENSION ACT

Concurrent with the Animal Welfare Amendment of 1985 was the enactment of Public Law 99-158 known as the *Health Research Extension Act*. This Act, in broad brush strokes, defined principles that institutions receiving support from the *Public Health Service* (PHS) were required to follow.^[9] The principles were expanded in the publication *Public Health Service Policy on Humane Care and Use of Laboratory Animals* (PHS Policy), enforced by the Office of Laboratory Animal Welfare—OLAW (<http://grants.nih.gov/grants/olaw/olaw.htm>).^[10] The principles required that each institution which received National Institutes of Health (NIH) funding submit an assurance describing their animal care and use program, which must then be approved for compliance with the Policy by OLAW prior to the release of funds from NIH. The Policy is a less voluminous document when compared to the AWA; however within its pages is the requirement that institutions use the *Guide for the Care and Use of Laboratory Animals* (Guide) as a basis for developing and implementing an institutional program for activities involving animals.^[11] The Guide, in turn, is a complex document which defines the operations of an animal care program in much greater detail (see below). The Policy expands the needed IACUC membership from three, as stated in the AWA, to five. It also increases well beyond the scope of the AWA the circumstances which are reportable to OLAW. The AWA only requires that the IACUC report suspension of activities, whereas the Policy requires that the IACUC report serious or continuing noncompliance with the Policy or serious deviations from the provisions of the Guide to OLAW. The OLAW, in turn, expects that institutions will be able to self correct the deficiencies that are identified and notified OLAW accordingly (Table 1).

Although OLAW, the organization responsible for enforcing the PHS Policy, rarely conducts unannounced inspections, they have investigated institutions for cause with the ramifications of negative finding being much more financially significant than the fines imposed by the USDA for noncompliance. The OLAW has the ability to withhold or restrict PHS animal welfare assurances which will eliminate or restrict funding from PHS agencies such as the NIH or the Food and Drug Administration (FDA). The OLAW has an additional

Table 1 Requirements of PHS policy/NIH guide and Animal Welfare Act

Requirement	PHS policy/NIH guide	Animal Welfare Act
IACUC membership	Five members: one nonscientific community, one scientist, one veterinarian	Three members: one community representative, one scientist, one veterinarian
IACUC duties	Review protocols, semi annual inspection, report suspended activities, report serious deviation from the Guide, report serious or continuing noncompliance	Review protocols, semiannual inspection, report suspension of an activity
Annual report	IACUC through the Institutional Official (IO) to OLAW annually	IO to APHIS prior to December 1 reporting fiscal year (October 1–September 30)
Suspensions/noncompliance	IACUC through the IO to OLAW	IACUC through the IO to APHIS
Species covered	All vertebrates	Includes mammalian species. Excludes rats, mice, birds, farm animals used for food and fiber research and cold blooded animals
Registration	PHS approved assurance required for federal funding. Approved for up to five years	Required registration when using covered species. Updated every three years
Training requirements	All personnel	All personnel
Inspections	Potentially OLAW	USDA at least annually
Shipping regulations	None	Specific for covered species
Exercise and socialization	General guidelines	Specific for dogs
Psychological well being	General guidelines for enrichment	Specific for primates
Husbandry standards	Specific standards	Specific for covered species
Surgical standards	Facility, personnel, anesthesia/analgesia, sterile technique, postoperative care. Multiple survival surgery requires scientific justification	Appropriate anesthesia/analgesia, no paralytic agents without anesthesia. Multiple survival surgery requires scientific justification
Construction standards	Specific	General
Veterinary consultation and care	Required	Required
Alternatives to animals for invasive procedures	Literature search required	Literature search required and use of National Agricultural Library should be encouraged
Sanitation standards	Specific	General

mission of being both an educator and a resource for the biomedical research community. They frequently cohost didactic lectures across the U.S.A. providing information on best practices for IACUC function in addition to helping to fund educational materials on research techniques related to animals.

AAALAC INTERNATIONAL ACCREDITATION

During the post-World War II science boom, leading veterinarians and researchers recognized the need for

an independent organization to encourage high standards for humane animal care and use in science. A committee called the Animal Facilities Accreditation Board was formed, and in 1963 they drafted the first *Guide for Laboratory Animal Facilities and Care*. In 1964, this group conducted 26 site visits of institutions using animals in research using this Guide on a trial basis. At the same time, the committee requested financial assistance from various biomedical associations who were committed to humane treatment of animals in research. The concept was well received by the biomedical research community, and in 1965, a

permanent organization called the American Association for the Accreditation of Laboratory Animal Care (AAALAC; www.aaalac.org) was formed. The organization was established to be operated by a Council of expert veterinarians, scientists, and administrators well versed in complexities of animal research. The organization reported then to a Board of Trustees that represented the scientific community. The mission of AAALAC, as defined by the Board of Trustees, was to enhance life sciences by promoting the responsible treatment of animals used in research, teaching and testing through voluntary accreditation and assessment programs. In 1996, AAALAC changed its name to the Association for the Assessment and Accreditation of Laboratory Animal Care, International to reflect its expansion outside the U.S.A. Today, more than 670 institutions are accredited in 25 different countries. Unlike reviews conducted by either the USDA or the OLAW, AAALAC site visits are completely *voluntary*, and the results are completely *confidential*. The site visits are conducted as peer-review assessments evaluating performance-based outcomes. The guidelines by which programs are evaluated include the "Guide" and certain widely accepted peer-reviewed reference resources such as the *American Veterinary Medical Association (AVMA) Panel on Euthanasia*,^[12] the *Guide for the Care and Use of Agricultural Animals in Agricultural Research and Teaching*,^[13] and the *Guidelines for the Care and Use of Mammals in Neuroscience and Behavioral Research*.^[14] Countries outside the U.S.A. which participate in the AAALAC process are also evaluated by laws and regulations specific to that country such as the European Union's *Council Directive on the Approximation of Laws, Regulations and Administrative Provisions of the Member States Regarding the Protection of Animals Used for Experimental and Other Scientific Purposes (EEC 86/609)*,^[15] or the Council of Europe's *European Convention for the Protection of Vertebrate Animals Used for Experimental and Other Scientific Purposes (Convention ETS 123)*^[16] or the Canadian Council for Animal Care's *Guide to the Care and Use of Experimental Animals*.^[17] A listing of Council approved reference resources that AAALAC utilizes to evaluate programs can be found on their web site. The outcome of the visit decided by a vote of Council can be: 1) full accreditation; 2) deferred accreditation which indicates that some relatively easily correctable deficiencies were present; 3) probation which indicates that some serious deficiencies requiring intensive programmatic adjustments were present; or 4) revocation of accreditation which must be approved by the Board of Trustees.

Site visits occur every three years, but annual reports are required. In addition, deficiencies cited by or self-reported to the USDA or OLAW must be

forwarded to AAALAC. Certain funding agencies require AAALAC accreditation (i.e., American Heart Association), and achieving full accreditation helps tremendously in streamlining the application for a PHS assurance as required to receive NIH funding. In addition, accreditation signals to both the general public and the scientific community that the institution has a commitment to maintaining a high quality animal care and use program.

THE GUIDE FOR CARE AND USE OF LABORATORY ANIMALS

Any discussion of laws and regulations would be remiss without further explanation given to the Guide, the cornerstone of both the PHS policy and the AAALAC accreditation process. As mentioned above, the first version of the Guide was published in 1963 by a group of dedicated professionals who formed a committee within the American Association of Laboratory Animal Science organization. The next revision of the Guide followed rapidly in 1965, published by the National Research Council through the Institute of Laboratory Animal Resources. The AWA and the Guide presented the very first guidelines and laws to impact on the biomedical research community at about the same time. All future revisions of the Guide have occurred through the National Research Council. The last revision of the Guide occurred in 1996, at which time the concept of performance vs. engineering standards was introduced. The Guide now in many areas defines what the outcome should be, but leaves it up to professional judgment to determine how to best achieve that outcome. Previous versions of the Guide were much more prescriptive in their requirements for husbandry standards. The newest version of the Guide also put increased emphasis on behavioral management for all animals. Enrichment should be provided for animals in terms of conspecific contact for social animals, exercise opportunities, and structural cage enrichments such as nesting material for rodents and "play" items for larger species such as pigs and goats.

The Guide is one of the most detailed documents instructing institutions about how to conduct an animal care and use program. Its scope encompasses all vertebrate animals. It has four chapters that discuss institutional policies and responsibilities, the necessary animal environment, housing and animal oversight, the depth of veterinary medical care, and the physical plant requirements. The research leadership at the vast majority of U.S. institutions which use animals in research is intimately familiar with the guidelines and recommendations found within this document, and use

them as the framework on which to base their animal care and use program.

ENDANGERED SPECIES ACT

The Endangered Species Act^[18] was enacted in 1973. Relative to animals, this act was designed to provide a means whereby threatened species may be conserved. It therefore prohibits transport and commerce of endangered species and prohibits the import of primates except for research purposes. The endangered animals that existed within the U.S.A. prior to 1973 are exempt from the act. The regulatory authority for this act is vested with the U.S. Department of the Interior (USDI), and implemented by the USDI's Fish and Wildlife Service.

GOOD LABORATORY PRACTICES ACT

The Good Laboratory Practices (GLP) Act^[19] was enacted in 1978 to provide standards for the conduction of preclinical trials in animals. The act requires that institutions, which are mainly pharmaceutical companies, follow all applicable laws and regulations. In addition, the GLP provide for intensive documentation of all procedures that are performed. It includes complete postmortem examinations of animals undergoing the testing procedures. GLP standards are of such intensity that offices which specifically monitor the procedures and maintain the paperwork are a practical necessity. Thus, most of the GLP trials are conducted by biomedical corporations and contract research laboratories. The law is regulated by the FDA which periodically conducts compliance inspections of the institutions.

OTHER REGULATIONS

In addition to the federal laws there are a number of other regulations that apply to animals in research. Notably the Veterans Administration (VA) has requirements that include mandatory AAALAC accreditation of their research facilities. The VA also has a protocol review process and position statements that are more in depth than the requirements of most academic institutions. The Department of Defense (DOD) also has specific policies, procedures, and responsibilities detailing the use of animals that are supported by DOD funding.

Professional societies also publish guidelines for performing research in specific fields. In particular, the AVMA publishes the *AVMA Guidelines for Euthanasia* which is utilized as the standard for which OLAW, the

USDA, and AAALAC expect institutions to meet. Many other professional societies such as the Society of Neurosciences also publish guidelines for conducting experiments which are within their field of interest.

CONCLUSIONS

The responsible conduct of research utilizing animals requires both a thorough understanding of the laws and regulations applicable to their use as well as an appreciation for the ethical dilemma that many who work with animals experience.

The wise researcher is aware of the negative public perception of animal research that often prevails and realizes that the biomedical research community as a whole could vastly benefit from proactive vs. reactive public education. Ongoing efforts by the researcher to refine and replace the use of animals in research are both a legal requirement and a moral one. Science could not advance without the use of animals, but their use in research must be executed with a solid balance of compassion for both the humans receiving the benefits and the animals whose lives are being sacrificed.

Laser-Tissue Interaction

E. Duco Jansen

Department of Biomedical Engineering, Vanderbilt University, Nashville, Tennessee, U.S.A.

INTRODUCTION

When applying laser light to biological tissue, a variety of complex interactions may occur (Fig. 1). A comprehensive discussion of all aspects of laser-tissue interaction is clearly beyond the scope and page limits of this article, so we will limit our discussion to the most important concepts. Specific tissue characteristics as well as laser parameters contribute to this diversity. Most important among optical tissue properties are the refractive index and the wavelength-dependent coefficients of absorption, and scattering. Together they determine the distribution of light and total transmission of the tissue at a certain wavelength. This initial distribution of light lies at the very heart of all ensuing effects, whether they are therapeutic or diagnostic. On the other hand, the following parameters are given by the laser radiation itself: wavelength, exposure time, laser power, applied energy, spot size, radiant exposure (energy/unit area), and irradiance (power/unit area). Among these, the exposure time is a crucial parameter when selecting the type of interaction, as we will find shortly.

TISSUE OPTICS

In describing the optical properties and light propagation in tissues, light is treated as photons. The primary reason for this approach is that biological tissue is an inhomogeneous mix of compounds, many with unknown properties. Hence, analytical solutions to Maxwell's equations in this medium pose an intractable mathematical problem. The representation of light as photons presents the opportunity to apply probabilistic approaches that lend themselves particularly well to numerical solutions that are tractable in computer simulations. Photons in a turbid medium such as tissue can move randomly in all directions and may be scattered (described by its scattering coefficient μ_s [m^{-1}]) or absorbed (described by its absorption coefficient μ_a [m^{-1}]). These coefficients along with anisotropy (i.e., the direction in which a photon is scattered) and index of refraction are referred to as the

optical properties of a material. If photons impinge on tissue several things can happen:

1. Some photons will reflect off the surface of the material (similar to what happens to glass and other materials—Fresnel's equations hold for tissue as well).
2. The majority of the photons will enter the tissue, upon which the following can happen:
 - a) The photon is absorbed (and can be converted to heat, trigger a chemical reaction, or cause fluorescence emission).
 - b) The photon is scattered (bumps into a particle and changes direction, but continues to exist).
 - c) Some photons can make it through the entire slab without running into anything. They are neither scattered nor absorbed and will emerge on the other side—these are called ballistic photons.

Absorption

We will first consider the case when only light is absorbed. In tissue optics, absorption of photons is a crucial event:

- Absorption is the primary event that allows a laser or other light source to cause a potentially therapeutic (or damaging) effect on a tissue. Without absorption, there is no energy transfer to the tissue and the tissue is left unaffected by the light.
- Absorption of light can provide diagnostic information by providing a clue as to the chemical composition of a tissue, and serve as a mechanism of optical contrast during imaging. Absorption is used in both spectroscopic and imaging applications.

Molecules that absorb light are called chromophores. Some examples of chromophores are water, blood (hemoglobin), melanin, amino acids, proteins, and fatty acids.

- In the UV: Tissue absorption is high due to protein, amino acid, fatty acid, and DNA absorption.
- In the visible: Whole blood (hemoglobin) is a strong absorber for some wavelengths (blue/green), but its

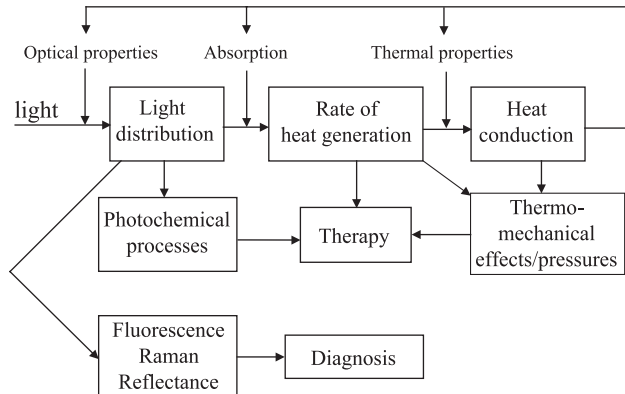

Fig. 1 Schematic of laser-tissue interactions.

effect is limited since the fraction of blood in tissue is small, unless one considers highly perfused tissues or the vasculature itself. Melanin is a strong absorber, again providing a small fraction of tissue on average except when considering areas with strong pigmentation such as the skin or retina.

- In the IR: Tissue absorption is dominated by water absorption.

The absorption of light can be characterized using Beer's Law, which predicts that the light intensity in a material decays exponentially with depth:

$$E(z) = E_0 e^{-c\xi(\lambda)z} \quad (1)$$

where E_0 is the incident irradiance [W/m^2], $E(z)$ is the irradiance through some distance z of the medium, c is the concentration of absorbing molecules in the medium, and $\xi(\lambda)$ is the molecular absorption coefficient (also known as the molar extinction coefficient), which is a function of the wavelength.

Often, c and $\xi(\lambda)$ are not known for tissue. Instead the two are lumped together and defined in a probability approach. We then replace $(c\xi(\lambda))$ with the absorption coefficient ($\mu_a(\lambda)$) and rewrite Beer's Law as:

$$E(z) = E_0 e^{-\mu_a(\lambda)z} \quad (2)$$

The absorption coefficient is defined as follows: When a photon travels over an infinitesimal distance Δz , the probability for absorption is given by $\mu_a \Delta z$ where μ_a is defined as the absorption coefficient (m^{-1}) (i.e., $1/\mu_a$ is the mean free path a photon travels before an absorption event takes place).^[1]

A related and useful parameter is the penetration depth, defined as the depth in the medium at which the energy or irradiance is reduced to $1/e$ times ($\sim 37\%$) the incident irradiance at the surface. Per definition, the penetration depth equals $1/\mu_a$ in cases where there is no scattering.

We have defined the irradiance (sometimes referred to as intensity) as power per unit area [W/m^2]. Thus, the irradiance gives us information about how much light made it to a certain point in the tissue. However, it does not tell us how much of that light is absorbed at that point. We define a new term called the heat source term or rate of heat generation, S , as the number of photons absorbed per unit volume [W/m^3]. Note that number of photons absorbed can be related to amount of heat generated, i.e., heat source. Mathematically, heat source can be written as the product of the irradiance at some point in the tissue and the probability of absorption of that light at that point:

$$S(z) = \mu_a E_0 e^{-\mu_a z} = \mu_a E(z) \quad (3)$$

Scattering

Scattering of light occurs in media that contain spatial fluctuations in the refractive index, n , whether such fluctuations are discrete particles or more continuous variations in n .

In biomedical optics, scattering of photons is an important event:

- Scattering provides feedback during therapy. For example, during laser coagulation of tissues, the onset of scattering is an observable endpoint that signals a desired therapeutic goal. Scattering also strongly affects the dosimetry of light during therapeutic procedures that depend on absorption. The scattering affects where the light goes and thus where absorption will occur.
- Scattering has diagnostic value. Scattering depends on the microstructure of a tissue, e.g., the density of lipid membranes in the cells, the size of nuclei, the presence of collagen fibers, the status of hydration in the tissue, etc. Scattering is used for both spectroscopic and imaging applications.

The scattering coefficient is defined as follows: When a photon travels over an infinitesimal distance Δz , the probability for scattering is given by $\mu_s \Delta z$ where μ_s is defined as the scattering coefficient (m^{-1}). The mean free path of scattering is $1/\mu_s$.^[1] Although the scattering coefficient tells us something about the likelihood that scattering occurs, it says nothing about the direction in which the light is scattered if scattering occurs. This scattering direction is described by the phase function $p(s, s')$, which represents the probability that a photon will scatter from direction s to direction s' . Light scattering in tissue is not isotropic, but strongly forward directed. A measure of the degree of anisotropy in scattering is given by the anisotropy factor, g , which is defined as the average cosine of the

scattering angle, θ . With this, it should be easy to understand that: total forward scattering: $g=1$; isotropic scattering: $g=0$; total backscattering: $g=-1$. For tissues in the visible and near-IR wavelengths, $g \approx 0.7-0.95$. With knowledge about both the probability of scattering and the scattering direction, we can define a few new useful parameters, known as the reduced optical properties:

- Reduced scattering coefficient: $\mu_s' = \mu_s(1-g)$
- Reduced attenuation coefficient: $\mu_t = \mu_a + \mu_s'$
- Effective attenuation coefficient:

$$\mu_{eff} = \sqrt{3\mu_a(\mu_a + \mu_s')}$$
- Penetration depth = mean free path = $1/\mu_t$
- Effective penetration depth: $\delta_{eff} = 1/\mu_{eff}$

Light scattered from the collimated beam undergoes multiple scattering events as it propagates through tissue. The transport theory is used to describe the transfer of energy through tissue. This theory is based on a statistical approximation of photon particle transport in a multiple scattering medium. The light transport equation relates the gradient of radiance at position r in direction s to losses due to absorption and scattering and gain due to scattering from all other directions s' into s .^[1]

$$\frac{dL(r, \hat{s})}{ds} = -\mu_a L(r, \hat{s}) - \mu_s L(r, \hat{s}) + S(r, \hat{s}) + \mu_s \int_{4\pi} p(\hat{s}, \hat{s}') L(r, \hat{s}') d\omega' \quad (4)$$

where dL/ds = change in radiance at r in the direction s , $L(r, s)$ = radiance defined as the propagation of photon power, $\mu_a L(r, \hat{s})$ = losses due to absorption, $\mu_s L(r, \hat{s})$ = losses due to scattering, $\mu_s \int_{4\pi} p(\hat{s}, \hat{s}') L(r, \hat{s}') d\omega'$ - gain due to scattering from all s' into s where $p(s, s')$ is the phase function, and $S(r, s)$ = source of power generated at r in the direction s .

The light transport equation is a complicated differential equation that has no analytical solution except for a few special cases. In most problems involving light scattering, different models can be used to solve the light transport equation. These include the Adding-Doubling method, Delta-Eddington method, Kubelka-Munk or two-flux theory, diffusion approximation method, and Monte Carlo simulations.^[1]

LIGHT-TISSUE INTERACTIONS

During the first decades after invention of the laser by Maiman in 1960, many studies have been conducted, investigating potential interaction effects by using all types of laser systems and tissue targets. Although the

number of possible combinations for the experimental parameters is unlimited, mainly three different types of interaction mechanisms are classified today: photochemical, photothermal, and photomechanical. Each of these interaction mechanisms will be discussed in detail in the following sections. In particular, the physical principles governing these interactions are reviewed.

Before going into detail, an interesting observation deserves to be stated. All these seemingly different interaction types share a common property: the characteristic radiant exposure [J/cm^2] ranges from approximately $1 \text{ J}/\text{cm}^2$ to $1000 \text{ J}/\text{cm}^2$. This is surprising since the irradiance itself varies over more than 15 orders of magnitude. Thus, a single parameter distinguishes and primarily controls these processes: the duration of the laser exposure, which is largely similar to the interaction time itself.^[2]

A log-log plot of irradiance versus pulse duration with the basic interaction mechanisms is shown in Fig. 2. In this figure, the photomechanical mechanisms are separated into three subcategories: photoablation, plasma-induced ablation, and photodisruption. In the graphs, the two diagonals show constant radiant exposures at $1 \text{ J}/\text{cm}^2$ and $1000 \text{ J}/\text{cm}^2$, respectively. According to this graph, the timescale can roughly be divided into three major sections: continuous wave or exposure times $>1 \text{ s}$ for photochemical interactions, 100 s down to $1 \mu\text{s}$ for photothermal interactions, and $1 \mu\text{s}$ and shorter for photomechanical interactions. It should be clear, however, that these boundaries are not strict, and adjacent interaction types cannot always be separated. Thus, overlap in these main regions does exist. For example, in the range of $1 \mu\text{s}$ to several

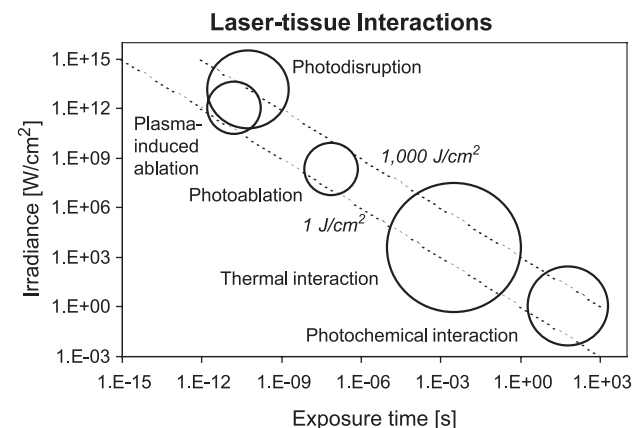

Fig. 2 Laser-tissue interaction regimes. Note that despite the fact that the irradiance varies over more than 15 orders of magnitude, the characteristic radiant exposure [J/cm^2] ranges from approximately $1 \text{ J}/\text{cm}^2$ to $1000 \text{ J}/\text{cm}^2$. (Figure adapted from Ref. [2].)

hundreds of μs , the interaction mechanisms typically have photothermal as well as photomechanical components to them, while many photochemical interactions also exhibit photothermal components. Finally, there is the possibility that multiple pulses of a particular interaction type collectively contribute to another interaction type. For example, even pulses of a duration of 100 ps, each of which has negligible thermal interactions, may add up to a measurable temperature increase if applied at repetition rates of 20 Hz or higher, depending on the laser. We will now consider each of the main interaction mechanisms in some more detail.

PHOTOCHEMICAL INTERACTIONS

We will only briefly discuss photochemical interactions. An excellent overview of mechanisms and some applications can be found in chapter 3 of Niemz's book on laser-tissue interaction.^[2] In brief, the group of photochemical interactions is based on the fact that light can induce chemical effects and reactions within macromolecules or tissues. The most obvious example of this is created by nature itself—photosynthesis. In the field of medical laser applications, photochemical interaction mechanisms play a role during photodynamic therapy (PDT).^[3] Frequently, biostimulation is also attributed to photochemical interactions, although this is not scientifically ascertained.

Photochemical interactions take place at very low irradiances (typically 1 W/cm^2) and long exposure times ranging from seconds to tens of minutes. Careful selection of laser parameters (most notably wavelength) yields a radiation distribution inside the tissue that is primarily determined by scattering. In most cases, wavelengths in the red and near-infrared part of the spectrum (600–900 nm) are used because of their low absorption and resulting deep penetration in tissue.

During PDT, chromophores (called photosensitizers) are injected in the body. Monochromatic light may then trigger selective photochemical reactions. The end result of a significant amount of complicated reactive species chemistry is that the activated photosensitizer, acting as a catalyst, causes highly cytotoxic compounds to be released, causing an irreversible oxidation of essential cell structures. Applications of PDT have traditionally focused on treatment of tumor although recently, excellent results have been reported in nononcological applications such as treatment of age-related macular degeneration (AMD).^[4]

Another type of photochemical laser-tissue interaction is molecular bond breaking. The absorbed photon excites the molecule to a higher electronic, vibrational, or rotational state. If the photon energy is

large enough to excite the molecule to an electronic state that is not bound, the molecule dissociates. Then it may form radicals or it may break. Clearly, the prerequisite for such a mechanism is ample supply of high-energy (short wavelength, UV) photons, because only those photons possess sufficient energy to overcome the molecular bond strength of organic molecules.

Recent and exciting developments that rely on photochemical interactions include experimental applications in the field of gene therapy where light may be used to activate caged DNA.^[5] In this scenario, therapeutic DNA is synthesized and linked to an inactivating group (a caged compound). Upon light exposure, cleavage of the DNA from its cage is achieved, rendering the active, translatable form of the therapeutic DNA only where light exposure is activated. Similarly, light-induced sense or antisense therapy may hold significant promise in this field.

Summary of Photochemical Interactions

- Main idea: Using photosensitizer acting as catalyst (PDT); optical activation/modulation of certain biochemical pathways (Biostimulation).
- Observations: No macroscopic observations.
- Typical lasers: Red dye lasers, diode lasers.
- Typical pulse durations: 1 second to CW.
- Typical irradiances: $0.01\text{--}50 \text{ W/cm}^2$.
- Special applications: PDT, biostimulation, gene therapy (?).

PHOTOTHERMAL INTERACTIONS

Photothermal interactions include a large group of interaction types resulting from the transformation of absorbed light energy to heat, leading to a local temperature increase. Thermal effects can be induced by either continuous wave (CW) or pulsed laser radiation. While photochemical processes are often governed by a specific reaction pathway, photothermal effects generally tend to be nonspecific and are mediated primarily by absorption of optical energy and secondly, governed by fundamental principles of heat transport. Depending on the duration and peak value of the temperature achieved, different effects like coagulation, vaporization, melting, or carbonization may be distinguished. An excellent overview of these interaction regimes can be found.^[6] It is essential to emphasize that thermal interactions in tissue are typically governed by rate processes, i.e., not just the temperature plays a role, but the duration for which the tissue is exposed to a particular temperature is also a parameter of major importance.

Once deposited in tissue and given sufficient time, the traditional mechanism of heat transfer applies to laser-irradiated biological tissues. Heat flows in biological tissue whenever a temperature difference exists. The transfer of thermal energy is governed by the laws of thermodynamics: 1) energy is conserved; 2) heat flows from areas of high temperature to areas of low temperature. The primary mechanisms of heat transfer to consider include: conduction, convection, and radiation.^[7] In addition, the following processes may have important effects on the overall temperature field of the laser-irradiated tissue: metabolic heat, perfusion, and evaporation.

Ablation

The word ablation comes from the latin *ablatus*, which means to remove. There are two meanings of the word ablation. In a physics/engineering sense, it refers to the physical removal of material (tissue), while in the medical/biological sense, it refers to the physiological removal of tissue (i.e., causing the tissue to stop performing the processes needed for survival of the tissue, that is, killing the cells, but not necessarily physically removing them). The disciplines in medicine where laser ablation has received the most attention are:

- Cardiology—angioplasty, arrhythmia treatment, TMR.
- Ophthalmology—corneal reshaping (LASIK), cataract surgery.
- Orthopedic surgery—cartilage, bone ablation (knees, joints, herniated discs).
- Dentistry—drilling cavities, soft tissue (gums).
- Dermatology—burn eschar debridement, skin resurfacing, hair removal.

Generally, below the boiling point of water, thermal interactions are dominated by protein denaturation and tissue coagulation, resulting in many cases in cell apoptosis or necrosis. Several medical applications use this type of interaction to achieve the clinical endpoint. For example, during interstitial hyperthermia, relatively weakly absorbed wavelengths are used, combined with long exposure times (minutes), to slowly coagulate or cook a mass of tissue such as a tumor using fiber-optic delivery of laser light.

Around 100°C, the thermal interactions become dominated by evaporation of water and we typically operate in the regime where physical material removal occurs. In this case, the goal is usually to remove or ablate the target tissue while minimizing the damage to the tissue left behind. Some notable exceptions to this paradigm include those applications where, in addition to cutting with the laser, some coagulation is desirable,

for instance, when the target tissue is highly vascularized. The amount of collateral thermal damage is largely determined by the amount of heat that can diffuse out of the irradiated tissue prior to the ejection of this material. We will now look at the process of ablation in some more detail.

The chronicle of ablation with a continuous wave laser generally follows the following sequence:

1. Light interaction with tissue (governed by tissue optical properties).
2. Conversion of optical energy to thermal energy (heat generation).
3. Tissue temperature rise (heat source and conduction).
4. Denaturation and dehydration of the tissue (this may affect the thermal and optical properties of the tissue).
5. Increase of subsurface pressure.
6. Explosion resulting in the expulsion of heated tissue fragments—this removes energy.
7. Exposure of cooler subsurface layers to light energy (then going back to 1).
8. At some point, all the tissue water has been evaporated and carbonization/pyrolysis of tissue will occur.

During tissue vaporization, the position of the tissue surface, where tissue and air meet, moves deeper into the tissue. The velocity at which the ablation front moves into the tissue is called the ablation velocity. By using a moderate irradiance and measuring surface temperatures with an IR thermal camera, it is possible to document the initial surface heating and explosive ejection of tissue. The onset of ablation occurs above 100°C due to subsurface superheating. As hot tissue is removed, a cooler layer is exposed to the laser irradiation. The temperature of the exposed layer remains at approximately 100°C while continued irradiation dehydrates the tissue. The removal of water decreases the local thermal conductivity, reducing heat conduction to the surrounding area. Continued radiation rapidly increases the tissue temperature until it reaches about 350 to 450°C; the tissue burns and carbonizes.

At, or just above 100°C, water vapor is generated volumetrically, the equilibrium is pushed toward the vapor phase, and, for sufficiently high laser fluence rates (irradiances), more vapor is produced than can escape by simple diffusion. The excess vapor is trapped in the tissue layers, forming vacuoles. The superheated vapor contained in the vacuoles will expand quickly, compressing the surrounding, rapidly drying tissues that form the vacuolar walls. As the vacuoles expand, the wall separating the vapor pockets from each other or the tissue surface become thin. The walls rupture as the force of the increasing pressures of expanding

vapor overcomes the mechanical strength of the tissue. In most applications of lasers as ablative devices, the goal is to remove the target tissue while minimizing collateral damage to adjacent tissue layers. Based on the very nature of the interaction of laser radiation with tissue, as we have seen, the damage mechanisms may be thermal or mechanical.^[6] In brief, mechanical damage is caused by subsurface explosion of heated tissue material (in particular, in cases where the absorption coefficient is relatively small), whereas thermal damage is caused by two sources: 1) thermal diffusion (from heated tissue to surrounding cooler tissue); and 2) direct deposition of heat in layers beyond the point where the energy density was sufficient for ablation, i.e., below threshold. The irony is that reducing the pulse duration will minimize the amount of heat diffusion that can take place before heated material is ejected. However, this same reduction of the duration of the pulse will cause the ablation process to be even more explosive and violent, thus increasing the collateral mechanical damage to the tissue.

It should be obvious that by choosing wavelengths that are highly absorbed (i.e., large absorption coefficient) in tissue, the energy is confined to a smaller volume and thus, the irradiance or radiant exposure necessary to achieve ablation will be less. In addition, the extent of the zone of tissue that is heated to subablative energy densities will be greatly reduced in this case.

Pulsed Laser Ablation

The question we now need to ask ourselves is: When is a laser a pulsed laser? Whereas there are certainly good answers and clear definitions from a laser physics point of view (i.e., how the machine works), we will look at it with a laser-tissue interaction mindset. As we have seen, laser ablation appears to be a trade-off between causing thermal damage with long pulses and mechanical damage with short pulses. First, when considering thermal diffusion, when the laser penetration depth is less than the laser spot radius, the thermal diffusion time, τ_{th} , can be defined as:

$$\tau_{th} = \frac{\delta^2}{4\alpha} \quad (5)$$

where δ is the penetration depth of laser light in tissue with thermal diffusivity, $\alpha = 0.15 \text{ m}^2/\text{s}$ for water at 37°C . For laser pulses shorter than the thermal diffusion time, the distribution of thermal energy is determined by the laser light distribution. This situation is known as thermal confinement. If the laser pulse duration is larger than the thermal diffusion time, the

thermal energy propagates into the tissue during the laser pulse. The criterion for thermal confinement is:

$$\tau_{pulse} < \tau_{th} \quad (6)$$

Next, we need to consider mechanical effects. A major photomechanical interaction during most tissue ablation events is tissue water vaporization, resulting in explosive removal of tissue structures, which has been described as the popcorn effect for CW lasers. Note that in this scheme, the explosiveness of the process may be severe enough to eject liquid or solid tissue fragments. As such, the energy needed to accomplish a certain crater size may be significantly less than expected based on calculations that assume true vaporization of the tissue. This ejection process is driven by the fact that water when converted to steam has a volumetric expansion of approximately 1620 at 1 atm. A superb and comprehensive overview of the physics of pulsed laser ablation of tissue has been published by Vogel and Venugopalan.^[8]

Summary of Photothermal Interactions

- Main idea: Achieving a certain temperature that leads to the desired thermal effect.
- Observations: Either coagulation, vaporization, melting, or carbonization.
- Typical lasers: CO_2 , Nd:YAG, Ho:YAG, Er:YAG, Argon ion, diode lasers.
- Typical pulse durations: 1 μs – minutes.
- Typical irradiances: $10\text{--}10^6 \text{ W/cm}^2$.
- Special applications: Coagulation, vaporization, melting, thermal decomposition, treatment of retinal detachment, Port-wine stain, retinal photocoagulation, interstitial hyperthermia.

PHOTOMECHANICAL INTERACTION

Photomechanical interaction includes mechanisms associated with photoablation, explosive vaporization, plasma-induced ablation, and effects of laser-induced acoustic (shock waves). Note that even though we discuss them separately, photothermal and photomechanical events are closely intertwined. Photomechanical mechanisms can be caused by the thermoelastic expansion of tissue due to extremely rapid heating of the target tissue by the pulsed laser light and recoil caused by ejection of ablated material. These photomechanical interactions cause stress waves, which propagate with the speed of sound or faster. If the laser pulse length is shorter than the time it takes the stress wave to propagate out of the irradiated tissue volume, large peak stresses can be

reached. These stresses may contribute to the ablation mechanism and may inflict damage to adjacent tissue.

Laser-Induced Acoustics

In addition to the explosion and material ejection, a second mechanical effect is the formation of pressure and shock waves. These pressure waves can be caused by the thermoelastic expansion of tissue or due to recoil caused by the ejection of ablation material. Thermoelastic expansion describes the event that due to heating of a material, the material expands (due to an on average larger molecular spacing). If the heating is rapid enough, significant expansion of the material may take place, leading to pressure waves that are formed in the heated volume and will propagate in the tissue outside the heated volume.

The instantaneous pressure rise is proportional to the temperature rise and can be calculated:^[14]

$$\Delta P = \frac{1}{\gamma} \frac{\Delta V}{V} = \frac{1}{\gamma} \beta \Delta T \quad (7)$$

where:

$$\gamma = \frac{1}{\rho \sigma^2} \frac{c_v}{c_p} [Pa^{-1}] \quad (8)$$

γ = coefficient of isothermal compressibility [Pa^{-1}],
 β = volumetric expansion coefficient [K^{-1}], c_v = specific heat at constant volume [J/kg K], c_p = specific heat at constant pressure [J/kg K].

Thus, we can write ΔP as:

$$\Delta P(z) = \beta \rho \sigma^2 \frac{c_v}{c_p} \Delta T(z) = \frac{\beta \sigma^2}{c_p} \mu_a H_0 e^{-\mu_{eff} z} \quad (9)$$

where $\beta \sigma^2 / c_p$ is known as the Gruneisen coefficient, Γ (dimensionless). This simplifies the expression for the pressure rise to:

$$\Delta P(z) = \Gamma \mu_a H_0 e^{-\mu_{eff} z} \quad (10)$$

The Gruneisen coefficient is a temperature-dependent parameter, approximately 0.11 for water at 20°C. It can be seen from Eq. 10 that the pressure as a function of depth of the acoustic wave will be proportional to (and thus exactly follow) the temperature distribution as a function of depth. This in turn means it will exactly mimic the light distribution in tissue. Hence, for an absorption-dominated case where the light distribution follows a Beer's law, exponential distribution, the shape of the pressure wave, will also be an exponential decay with depth.

These photomechanical interactions (thermoelastic expansion, ablative recoil, and explosive vaporization)

cause stress waves, which propagate with the speed of sound, $\sigma = 1500$ m/s, or even faster as in the case of shockwaves. Analogous to heat diffusion, we can define a stress diffusion time:

$$\tau_{str} = \frac{\delta}{\sigma} \quad (11)$$

where τ_{str} is the stress confinement time, δ is the penetration depth of the light in the tissue, and σ is the speed of sound in the medium. If the laser pulse length, τ_p , is shorter than the time it takes the stress wave to propagate out of the irradiated volume, large peak stresses can be reached. These stresses may contribute to the ablation mechanism and may inflict damage to adjacent tissues, even far away from the irradiated zone. The criterion for so-called stress confinement is given by:

$$\tau_{pulse} < \tau_{str} \quad (12)$$

Confinement (and with it the determination if the effect of the laser is considered pulsed or not) depends on the laser pulse length and the optical penetration depth (i.e., absorption coefficient). In Fig. 3, the pulse length versus penetration depth is shown; marked in it are various common lasers with their characteristic pulse durations and optical penetration depths (recall that these depend on the wavelength). For example, from this figure, it follows that the interaction of both the XeCl excimer and the Holmium:YAG laser are thermally confined, but not stress confined.

Explosive Surface Evaporation and Phase Explosion

Regardless of whether conditions of stress confinement are met (and hence thermoelastic expansion-induced pressure waves are created), short laser pulses when

Fig. 3 Confinement regimes for laser-tissue interactions. (Figure adapted from Ref. [16].)

containing sufficient energy can cause the explosive phase change of water. This explosive surface vaporization or phase explosion results in the forceful ejection of debris. In turn, the conservation of momentum dictates that the force of the ejected debris must be compensated by an equal force in the opposite direction. The net result is that if explosive ablation occurs, a second source of pressure wave generation, namely the ablative recoil force, causes forceful compressive stress waves into the tissue. The amplitude of these pressure waves scales with the laser radiant exposure.

Plasma-Induced Ablation

A last regime of laser-tissue interactions involves the use of ultrashort (ps and fs) lasers. Using these type of laser devices, the peak irradiances are so high ($>10^{12}$ W/cm²) that the electric field of the light permeating the medium is capable of ionizing the material, a process known as plasma formation or dielectric breakdown. This can occur even when the linear absorption of the wavelength used is negligible. The result is the generation of a small cloud of free electrons and positively charged ions, known as a plasma. In turn, once formed, the plasma becomes self-absorbing, causing the remaining laser energy to be efficiently coupled in the growing plasma. Prerequisites for the occurrence of a plasma are: 1) a very short laser pulse (in order to increase the power, even when only small pulse energies are used); and 2) a small spot size (the irradiance scales with the inverse of the spot radius squared. The resulting plasma typically involves small volumes (several microns), but may in this microscopic volume reach local temperatures exceeding thousands of degrees. In the moments immediately following the laser pulse, the plasma energy diffuses to the surrounding tissue (water). The result is virtually always the formation of a pressure or shock wave and the rapid vaporization of tissue water, resulting in an explosive ablation process. Notable medical applications of this technology include the use of Q-switched Nd:YAG lasers (few ns, 1064 nm) in cataract surgery and more recently, the use of a fs laser for the creation of bladeless corneal flaps in LASIK surgery.^[9] In the latter case, the near-IR laser is focused inside the corneal stroma at the desired depth and each fs pulse generates a rapidly expanding and collapsing microbubble of approximately 3 μ m in diameter, which separates corneal layers. The laser beam is scanned over the cornea at 20 kHz and adjacent voids together create a clean hinged flap. Other exciting applications of plasma-induced microevents have been reported in cellular manipulation and subcellular microsurgery.^[15] A detailed

discussion of the physics of laser-induced plasma formation and photodisruption is beyond the scope of this article and the reader is referred to.^[2]

BIOLOGICAL EFFECTS

Regardless of the source of damage (thermal, mechanical, or even photochemical), biological tissue typically responds to lethal damage with either a necrotic or apoptotic response. The exact decision of whether a cell will move down the necrotic or apoptotic pathway in response to laser-induced damage is largely unknown. Some evidence exists that oxidative stress, as generated, for example, in photodynamic therapy, shows a marked upregulation of apoptotic markers.^[10] Similar sublethal damage has been shown to upregulate the expression of molecular chaperones such as the heat shock protein family, in particular hsp70.^[11,12] In many lethal thermal damage scenarios, the biological response can be classified as a coagulation necrosis, followed by a normal wound healing response that includes formation of granulation tissue, scar formation, and scar remodeling.^[13] The promise of lasers to substantially increase wound healing speed or cosmetic appearance of scars has thus far remained elusive.

SUMMARY

Long pulses cause collateral thermal damage to tissue adjacent to the ablation crater while short pulses cause collateral mechanical damage. Thermal damage can be the result of thermal diffusion or direct irradiation of tissue at subthreshold levels. Mechanical damage can be the result of explosive vaporization or laser-induced pressure transients. The latter can originate by thermoelastic expansion, ablative recoil, or as a side effect of rapid explosive vaporization. The pulse duration and depth of penetration determine whether the interaction of the laser pulse with tissue is thermally confined and/or mechanically confined.

Laser Transmyocardial Revascularization

James W. Jones
Nancy A. Crigger
Bruce W. Richman

Baylor College of Medicine, Houston, Texas, U.S.A.

INTRODUCTION

Evidence continues to mount that Transmyocardial Laser Revascularization (TMR) is a safe and effective treatment for angina, as more and more patients have had their angioplasties and coronary artery bypass grafts experience failure over time. Important questions about TMR nevertheless remain unanswered. TMR appears to relieve the symptoms without affecting the underlying atherosclerotic disease, and its method of action has not been established. Like angioplasty and coronary bypass, TMR is in fact a palliative therapy rather than a cure for atherosclerotic heart disease. The most plausible current formulations of TMR's therapeutic mechanism posit a reconfiguration of the microcirculation, with blood shunted from epicardial to endocardial areas. These unresolved issues notwithstanding, TMR benefits patients with end-stage coronary disease and represents a pioneering effort to remodel the microcirculation of patients with arteriosclerotic occlusive disease.

BACKGROUND

Beck attempted the first direct surgical treatment of ischemic heart disease in 1934 when he tried to improve the microcirculation by suturing the left greater pectoral muscle onto the surface of a poorly perfused heart.^[1] Others continued the effort using creative but unscientific methods, and with varying degrees of success.^[1] Vineburg's procedure showed the best results in externally augmenting the microcirculation,^[2] but this was soon rendered obsolete by the advent of coronary artery bypass to treat macro-circulatory obstructions. TMR is a return to direct treatment of the microcirculation. The approach has several theoretical advantages for treating all patients with ischemic heart disease, because suitable target arteries needed for bypass or balloon angioplasty procedures are not required. This will become more important in coming years, because an increasing number of bypassed and angioplastied patients have exhausted their target vessels and are no longer candidates for conventional procedures.

The concept of TMR emerged from an erroneous hypothesis that the human heart contained sinusoids connecting the ventricular chamber with the myocardium. This concept stimulated mechanical attempts to create additional ventricular chamber connections,^[3] but the idea was discredited when it was observed that the new passages degenerated into scar tissue and closed. The advent of surgical lasers suggested the possibility that better channels might remain open and patent as new blood conduits.^[4] In 1984, after 15 years of preparation, Mirhoseini used a relatively low-powered CO₂ laser to create channels through areas he could not bypass during myocardial revascularization procedures.^[2] He had excellent clinical results in 12 patients, and reported channels on postoperative ventriculograms. These early results, coupled with the development of a high-power 850-watt CO₂ laser, encouraged several prestigious surgical groups to begin transmyocardial laser revascularization as an independent beating heart procedure.^[5,6] These pioneering efforts were anchored in the belief that new channels immediately improved myocardial blood flow by allowing seepage of oxygenated blood in the ventricular chamber into the myocardial wall.

Animal studies in dogs, originally intended to compare healing properties of different lasers, showed that scar tissue developed in every instance, not an artificially created sinusoid.^[7,8] The hearts of patients who underwent TMR but succumbed to noncardiac causes were histologically examined with no evidence of patency in any of more than 200 laser channels.^[8] Sophisticated blood flow studies using microspheres showed closure within minutes.^[9] A therapy with an unproven hypothesis had proven effective in reducing angina, but the putative mechanism of action upon which the therapy had been based was completely discredited. TMR was and still is an empirical therapy in search of a therapeutic mechanism.

Current Hypotheses on Mechanism of Action

The most prominent currently favored hypotheses of TMR's mechanism of action include angiogenesis and denervation. Denervation is suggested by the

conspicuous absence of angina immediately upon postoperative emergence from anesthesia.^[5,6,10] Al-Sheikh compared PET scans before and after TMR in eight patients, finding evidence for sympathetic denervation in all.^[11] Reports of both denervation and nondenervation in dog hearts following TMR were confused by other variables in two recently published studies.^[12-14] Denervation would be an explanation consistent with the clinical course, effective in reducing angina, but unsatisfactory as a therapeutic modality. There are less expensive and less invasive means of accomplishing the same goal. The real danger of cardiac denervation in ischemic heart disease is elimination of the early warning function of angina, producing potentially deadly silent ischemia. We reviewed exercise tolerance tests before and after both TMR and percutaneous myocardial revascularization (PMR) and found that silent ischemic changes were no more frequent than in the preoperative studies.^[15] The additional time patients were able to spend on the treadmill was not attributable to the absence of angina; from lack of angina, the percentage of people showing electrocardiographic evidence of ischemia without symptoms was the same pre- and postoperatively.

Angiogenesis is an evident part of the histopathology of healing from the laser injuries in every study.^[16-21] This neovascularization is clearly visible on photomicrographs, with open channels communicating to intramyocardial vessels in humans.^[18] In an ischemic canine model, no differences were seen in blood flow either acutely or two months after TMR in resting animals. When stressed at the two-month interval, however, the animals with TMR averaged 40% greater blood flow than control animals,^[22] indicating that functional connections were allowing blood to reach the endocardial areas. The cardiac microcirculatory anatomy determined by corrosion scanning electron microscopy runs in cable-like bundles surrounding myocyte layers with extensive connections longitudinally, but not from superficial to deep.^[23] Combining these findings, the likely effect of TMR is injury-induced angiogenesis facilitating redistribution of flow to areas of marginal perfusion during periods of greater demand. A recent study used magnetic resonance imaging and found a more modest but important benefit. Both the perfusion and global performance of the heart were unchanged, but the lasered areas were prevented from scarring, as indicated by the absence of fixed perfusion defects in the TMR patients.^[24]

THE PROCEDURE

Between October 1996 and December 2002, we performed 125 transmyocardial revascularization operations

using the Holmium-YAG laser. 115 male patients with an average age of 62 years and an average ejection fraction of 0.37 received TMR laser surgery. At the time of surgery, patients were prescribed an average of five cardiac-related medications and had 4.5 failed conventional revascularization attempts; all had at least one previous coronary bypass procedure. Eighty-seven had one or more serious comorbid conditions, including prior stroke, COPD with steroids, morbid obesity with sleep apnea, renal failure, leukemia, Lupus Erythematosus, or peripheral vascular disease requiring amputation.

Initially, a Holmium-YAG laser (CardioGenesis Corporation, Sunnyvale, California), gated to the electrocardiographic R wave, firing in triple 2-Joule bursts, was used. Later in the series, a non-gated Holmium-YAG laser manufactured by Eclipse was used. The change in lasers occurred following the merger of manufacturer Eclipse with CardioGenesis. The merged companies maintained the CardioGenesis name.

The candidate for transmyocardial revascularization surgery must receive complete disclosure of all potential risks and complications and understand that this procedure has a currently unknown mechanism of action. The patient's emotional status must also be evaluated preoperatively. Many are at the end-stage of their heart disease and may have psychological sequelae to multiple failed operations, catheter interventions, and other therapies. Qualified patients should be provided with appropriate reassurance, sedatives, and/or anxiolytics to avoid increased stress and its deleterious effect on the heart.

Candidates for transmyocardial revascularization surgery are almost always high risk patients with severe heart disease. They nevertheless vary considerably in their mortality risk. Highest-risk patients have severe triple-vessel disease without any directly perfused areas.^[25] Their inflow is severely limited, consistent with the concept of redistributed blood flow, and is compatible with the redistribution of blood flow mechanism concept. Such patients may have operative mortality rates as high as 25%,^[25] an excessive price for symptom relief. Patients with congestive heart failure (CHF) are high risk^[6] because they lack myocardial reserve. Poor early appreciation of how TMR initially injured the heart without creating an immediate new source of blood flow resulted in inappropriate application of TMR therapy with sometimes disastrous results. Uncompensated CHF has since been recognized as a contraindication for TMR. Patients with well-compensated CHF did not have a significantly higher operative mortality, but a greater number died during a six-month follow-up period.^[26] An ejection fraction of at least 25% has now been incorporated into the standard guidelines for

determining patient suitability for TMR therapy. Using TMR or conventional bypass grafting on patients with unstable coronary syndromes increases risk. In one sizable study, patients with unmanageable angina for acute syndromes had a five-fold increase in operative mortality.^[27] Others confirmed the increased mortality in severely unstable patients.^[26] A stabilizing period of several weeks after such episodes has been recommended before TMR is attempted. We have administered TMR in desperation to ten such patients who could not be stabilized with medical therapy; all survived.^[28] This is not to recommend TMR in acutely unstable patients, but to confirm that TMR can achieve good results in carefully selected clinical situations.

Specific operative steps can be taken to minimize the potential complications associated with this complex surgical group. As suggested by Horvath,^[5] insertion of an epidural catheter and the tranquil induction of anesthesia reduces pain and limits coronary artery spasms. Operating time is decreased and the procedure made much easier by the insertion of a double lumen or Univent endotracheal tube collapsing the left lung to provide adequate exposure. Radial and femoral arterial lines, a Swan-Ganz catheter, I.V. lines, and a Foley catheter are all standard. Initially, we placed access lines in the femoral veins in the event of an intraoperative emergency, but have thus far had no occasion to use them and have stopped placing them. The femoral arterial line is started to provide a consistently reliable arterial pressure and ready access should it become necessary to insert an intraaortic balloon pump (IABP) during surgery. We have had to insert the IABP postoperatively in two patients. Five patients were taken to the operating room with IABPs in place.

Transesophageal echocardiography (TEE) is available for intraoperative cardiac monitoring and to observe the appearance of intraventricular bubbles during laser application as an indication that we have entered the ventricular chamber. TEE was very useful as a monitor of cardiac function, providing early detection of transient myocardial ischemia in the early stages of the procedure's development. We have contained operative costs by not using TEE in our last 75 patients, with no discernable adverse effects. When monitoring intraventricular bubbles to determine chamber entry, TEE is operator-dependent and less reliable than the surgeon's ability to visualize pulsatile blood flow from the new channel. Transient intraoperative ischemia can nevertheless be detected early by monitoring ST-segment elevation. A signal from the anesthesiologist gives the surgeon an opportunity to rest the heart. Channeling too quickly can destabilize cardiac homeostasis.

After induction of anesthesia, the patient is placed in the left lateral decubitus position at an angle

thirty degrees from perpendicular to the operating table. Proper positioning presents the anterior area of the chest as a flat surface and provides the most direct access and exposure to the heart. The left side of the thorax, the anterior half of the abdomen, and the left groin area are all prepped in the sterile field. The entire area is circumscribed with towels and a thyroidectomy drape is placed to the anterior midline just below the left nipple and slanted upward toward the axilla.

The skin is infiltrated with 1% lidocaine without epinephrine prior to incision. Anterior, lateral, or muscle-sparing posterolateral thoracotomies all provide equally satisfactory access. It is our impression that patients in whom the anterior approach is used have less postoperative pain and recover more rapidly than those treated with other incisions.

A 4-inch or smaller incision is made over either the fourth or fifth interspace. The fifth interspace can be used to provide direct exposure of the heart's inferior surface when it is the only area to be treated, but may not be adequate for ready access to the base of anterior and lateral areas. An incision in the fourth interspace is recommended for entry to all other divisions of the left ventricle, either alone or in combination with the inferior region. Others have used the fifth and sixth interspaces satisfactorily.

We have arbitrarily divided the left ventricle into three main regions as served by the principal coronary arteries: anterior (anterior descending), lateral (Circumflex), and inferior (right coronary). These zones are further divided into a total of seven sections (anterior, anterior-lateral, lateral-anterior, lateral, lateral-inferior, inferior-lateral, and inferior), facilitating localization of channel placement. These are in the geometric form of roughly 1-centimeter-wide strips oriented longitudinally, the total encompassing the entire area of left ventricular surface. If one does not use a ruler initially for perspective, it is possible to "overchannel." The newly created laser channels are 1-millimeter vaporized tracts surrounded by a 1–2-millimeter zone of necrosis and varying radii of edema. Overchanneling can create a significant area of dead heart muscle.

After skin incision we use two Gelpy retractors to gain exposure and insert a Toufier retractor when the intercostal space is entered. The retractor is opened slowly and division between the intercostal muscles is extended as tension develops. The pectoralis muscles and the latissimus dorsi muscle are preferably undermined rather than divided. In most patients this permits access to the entire left ventricle, although exposure is limited to one region at a time. When this technique is inadequate to permit satisfactory exposure, the upper rib is "shingled" laterally with a rib shear. When wound closure is begun the rib is

reapproximated with a single No. 5 wire suture, as are any unintended rib fractures.

Upon entering the thorax one may find numerous adhesions of the pleura to the anterior cardiac surface. Adhesions containing vascular structures are ligated with either clips or suture and not cauterized. Electrocautery should be limited to structures that are away from the phrenic nerve, and this practice is best instituted before the nerve is visualized, since its course can vary considerably in patients who have had previous cardiac surgery. From the midpoint of its pericardial course the phrenic nerve travels slightly anteriorly. Therefore, the safest dissection either keeps it continuously in sight or, if that becomes difficult, turns decidedly anterior as the apex of the heart is approached.

Once the pericardium is opened, the dissection proceeds parallel to and about 1 centimeter anterior to the phrenic nerve. This approach creates a small pocket inferiorly that maximizes exposure of the inferior and inferolateral areas of the heart, with limited traction on the phrenic nerve. Dissection of the pericardium off the heart is facilitated by placing traction sutures as exposure is developed. As the dissection continues, the anterior pericardium is opened from the center and folded back to expose the area for laser channeling. The separation of the pericardium is not usually difficult, even in patients who have undergone sternectomy and flap placement for sternal osteomyelitis after coronary bypass surgery, and this approach avoids the problem areas.

Upon completion of the dissection, the ventricular apex is directly facing the surgeon standing on the left side of the operating table. Maneuvering the heart within the dissected space can expose all of the left ventricle, one segment at a time. Exposure is carried anteriorly to the anterior descending artery, and inferiorly to the posterior descending artery, depending on the areas to be treated. A 1-inch malleable retractor covered by a 4-by-4 sponge tied in place has been most helpful in providing gently stabilized retraction in the limited available space.

The Holmium-YAG laser probe is placed on the epicardial surface and fired until the probe enters the ventricular chamber. The probe must not be forced, as this movement will allow entry without firing the laser; instead, the probe is advanced after each succeeding laser firing only until the ventricular chamber is reached. Since this procedure is performed on a beating heart, the surgeon must be able to control the probe to avoid inadvertent damage to normal myocardium. The probe can be stabilized either by using vascular forceps to grasp the epicardium, or by firing the laser once on the epicardial surface to create a small surface hollow. The probe itself can be held either directly in the hand or in an instrument designed

for the purpose. The probe holder used in this study is malleable and works well in reaching areas at the base of the anterior and lateral zones and the more apical inferior zone, but it requires too much space to easily position the laser to the base of the heart in the inferior area. That area is best reached by positioning the probe with two vascular forceps.

The conventional intent of laser surgery is formation of channels that enter the ventricular chamber perpendicular to the myocardial wall. Although the concept of primary conduit formation from the ventricular chamber is questionable, we hesitate to alter the empirical method that may or may not have contributed to the technique's clinical success. There are four indicators of laser entry into the ventricular chamber: 1) pulsatile spurting blood; 2) bubble formation as seen on transesophageal echocardiography; 3) a change in the sound of the laser; and 4) feeling the probe enter the ventricular chamber. Because the thickness of the ventricle decreases from the basal areas toward the apex of the heart, the closer one is to the apex the easier it becomes to penetrate to the ventricular chamber. The probe used in our study measured 17 mm in length and may not be long enough to traverse the ventricular wall in basal areas, especially in patients with hypertension-related cardiac hypertrophy.

Pulsatile blood flow is the best indicator of ventricular penetration. Bleeding stops with simple finger pressure in virtually all cases, and once stopped does not resume. This has been true in patients on aspirin, with low platelet counts, and with thinned ventricular walls. In rare cases when the procedure may be prolonged due to bleeding channels, slight pressure on a hemostatic pad placed over the channel is effective (Fig. 1).

The proper amount of myocardium to be treated varies among patients and among treating surgeons.

Fig. 1 Applying finger pressure to a Holmium-YAG laser channel in a patient.

L

Areas shown to be ischemic by thallium scan are typically treated with minimal extension onto adjacent normal myocardium. Arguments for directed rather than global treatment include the historically limited success of prophylactic surgical procedures. Most of these patients are quite ill and frail, and the surgical procedures to which they are subjected should impose the least possible physiological stress. The directed treatment strategy has shown good short-term results, and the procedure can be repeated in the event of recurrent angina. It is nevertheless essential that all ischemic areas be treated; directed treatment is unlikely to be successful otherwise.

The areas to be treated are determined preoperatively. We have had excellent correlation between angiographic anatomy and the reversible ischemia shown by thallium scan. Areas with nonreversible perfusion defects were not treated. We did see some discrepancy between the thallium scan reading and the anatomy, in that the distal inferior surface ischemia was often ischemia of the apical segment.

The patient's intraoperative clinical status must be controlled at all times. We have twice seen decreased regional wall motion on TEE associated with dramatic ST-T wave changes on the monitor screen and concomitant substantial rises in pulmonary pressures. In both cases, the deteriorating clinical status responded to suspension of surgical manipulation, removing the chest retractor, and allowing time for the anesthesiologist to intensify vasodilator therapy and increase the depth of anesthesia. Ischemic problems did not recur in these patients and there was no postoperative evidence of myocardial damage.

Perioperative arrhythmias are of considerable concern in this patient population. The operating room should be equipped with external sterile and unsterile defibrillator paddles and easily accessible internal paddles, though none of our patients has required defibrillation or displayed dysrhythmias during laser firing. In four patients, however, the initial positioning of the probe in preparation for firing the laser resulted in considerable ectopy. This was easily controlled by firing the laser in the target area, thus scoring and desensitizing the myocardium before the actual channeling began.

At the end of the procedure, all areas of dissection and laser treatment are inspected with irrigation and any accumulated clot is removed. The pericardium was left open in all cases.

Before reinflation of the left lung, intercostal blocks are placed under direct vision in the intercostal space of the incision and at least two interspaces above and below. The blocks are placed as far posterior as possible. A 3½-inch spinal needle is usually adequate, but in exceptionally large patients a 5-inch needle can be used. A mixture of 60 ml of .25% Marcaine

and 80 milligrams of Depo-Medrol usually provides one to three days of pain relief. A properly placed single 24 F chest tube is adequate and seems to be less painful than the larger tubes commonly used for other thoracic procedures. Intraoperative care to avoid damage to the left lung facilitates early chest tube removal.

Patients are typically extubated in the ICU shortly after arrival. A continuous nitroglycerin infusion is maintained at the maximum level tolerated by the patient's blood pressure. The propofol drip is discontinued and pain is controlled by the epidural. The anesthesiologists are responsible for epidural analgesia and treating the associated side effects of the epidural until its removal. About half of the patients require only oral analgesic supplementation, but for those requiring more pain control, PCA morphine sulfate is the preferred analgesic. When carbon dioxide retention is a short-term problem, intravenous ketorolac tromethamine is helpful.

If the chest tube drains less than 100 ml in the preceding 12 hours, it is removed the evening of surgery or on the first postoperative morning. In all our patients the chest tubes were removed in less than 24 hours. One patient required drainage of a recurrent pleural effusion. The nitroglycerin drips are slowly reduced (5 ml/30 minutes), and a nitroglycerin patch applied when the drip reaches 10 ml/hr. Those who tolerate discontinuation of the drips are transferred to the floor. Alert patients are allowed to administer their own previously prescribed home medications. Oral analgesics are ordered every three hours to avoid delays associated with prn requests.

Ambulation is begun on postoperative day one, with most discharges one to two days later. We have observed that post-TMR patients who are asymptomatic tend to reduce medications too rapidly and without appropriate medical consultations; their discharge instructions should strongly caution patients against medication reduction without medical supervision.

The beneficial results of TMR therapy are often dramatic, provided that perioperative risks can be minimized. Our approach stresses techniques that reduce pain and limit the chance of perioperative myocardial infarction. At 12-month follow-up these patients have shown significant angina class improvement when compared to both control patients and their own preoperative status.^[29] Likewise, average exercise tolerance with a Modified Bruce Protocol has been significantly better among TMR patients than among medication controls. Holmium-YAG laser channeling of the myocardium has been effective in reducing anginal pain and improving quality of life in ischemic heart disease patients who are without alternative therapeutic options.^[26,29-34]

CLINICAL RESULTS

Clinical outcomes determine the usefulness of medical therapies. At this time, TMR is a specialized therapy. Surgical therapy of ischemic heart disease began with attempts to manipulate the microcirculation and progressed to coronary bypass surgery as a macroscopic method of redirecting blood flow around circulatory obstructions. Percutaneous Transarterial Catheter Arterioplasty restored blood flow within the obstructed channels themselves.

Subjective Clinical Results

All of the studies published thus far have reported that angina pectoris is relieved to a significant extent by TMR. In longitudinal uncontrolled trials, the CO₂ laser^[5,30] and the newer Holmium-YAG laser^[33,34] showed clinical dramatic improvement. While this data stimulated further use and development of TMR, it did not fulfill the compelling need for evidence-based data to support wide implementation of a major new invasive treatment method. The proponents of this therapy started three controlled trials in the United States and one controlled trial in England, all of which were published in 1999.^[29-32] The results of all four studies showed highly significant differences in the percentage of TMR and control patients registering improvement of at least two scale angina classes 12 months after operation. Schofield and colleagues^[31] reported similar findings but did not consider the improvements to be clinically important. Other randomized trials showed improvement that doubled or tripled the magnitude of those results.^[29,30,32] When a blinded method of determining the patient's angina class was used, the scores were markedly lower than in the nonblinded ratings, but remained significantly better than those for the medically treated group.^[32] Patients in all four randomized studies reported higher quality of life scores, consistent with improving symptoms. During the 12-month follow-up, TMR patients required fewer hospitalizations for cardiac events.^[29-31] The symptoms, if not necessarily the process, of ischemic heart disease showed positive responses to TMR. The possibility of a surgical placebo effect exists, but is unlikely to account for these results. The treated population was effectively bedridden prior to operation, and most were able to resume normal lifestyles postoperatively. Surgical placebo effects typically persist for two to three months, and affect no more than 30% of patients.^[10]

Objective Clinical Results

Several investigators report evidence of increased perfusion on thallium scan,^[30,35,36] but other equally

well-conducted work reports no significant changes.^[37] One group^[30] showed a significant number (20%) of patients with better-perfused segments after TMR, but 26.4% of these study patients had incomplete follow-up and 19% of the patient evaluations could not be used, weakening the value of the overall report. One possible explanation for the differences in studies and the overall failure to show improvement in perfusion is the variability in thallium scans over time.^[37] In support of the improved perfusion concept, dobutamine stress echocardiography has shown improvement of global contractile reserve in a porcine model of chronic ischemia^[38] as well as in humans.^[30,39]

Exploring this apparent inconsistency, Frazier used PET scanning, the most sensitive test for myocardial perfusion, and reported that patients showed an increase in the relative perfusion of the subendocardial to epicardial areas after TMR.^[6] Most important, these findings were seen in patients who had no significant improvement in thallium scans. If these conflicting reports are accepted as fact, it is conceivable that the thallium scan lacks the necessary sensitivity, or that flow redistributes from areas of adequate perfusion to underperfused myocardium, such as epicardium and subendocardium, through new microvascular connections.

Clarification and enhancement of the mechanism of action of TMR holds promise as a forerunner of future therapies to treat vascular disease through remodeling the microcirculation. At present it illustrates that treatment of illness without treating the disease using empiric therapies remains a valuable staple of medicine.

INTRODUCTION

Ligament damage is a frequent sequel to joint trauma, and anyone experiencing pain and disability after a significant ligament injury will attest to the urgent need of finding new treatments to accelerate and promote improved healing. Damage to the anterior cruciate (ACL) and medial collateral (MCL) ligaments of the knee is particularly common. Once thought of as inert structures, ligaments are now seen to participate actively in joint function and homeostasis by means of complex mechanical, physiological, and cellular interactions. Ligament injuries that do not heal therefore result in abnormal loading of other joint structures, leading to degeneration and the development of osteoarthritis.

Joint trauma generally produces complex injuries involving multiple tissues. For research purposes, the use of animal models allows the degree and type of ligament injury to be isolated and controlled, and permits the application of analysis techniques that cannot be used in a clinical setting. This entry gives a brief overview of ligament structure, function, and response to injury, followed by a discussion of specific animal models of ligament injury, healing, and reconstruction. The application of new technology for the assessment of ligament healing and physiology is also discussed.

NORMAL LIGAMENT STRUCTURE AND FUNCTION

Anatomy, Structure, and Composition

Skeletal ligaments are dense, white, hypovascular tissues connected at both ends to bone. Some ligaments, such as the MCL of the knee, are distinct cord-like structures, but many consist of several discrete bands that merge into one another. These distinct bands can provide functional heterogeneity within otherwise homogeneous tissue. At their bony

attachments (insertions), ligaments show unique structural alterations, with varying cell shapes and fiber orientations and a gradual change in the composition and organization of the fibrous tissue that becomes calcified and merges into the bone surface.

Ligament tissue consists of closely spaced collagen fibers aligned predominantly along the long axis of the ligament. Under polarized light microscopy, the fibers show a regular sinusoidal pattern along their length that is termed “crimp.” Fiber crimping is thought to act as a mechanism for load damping. Collagen fibers within ligaments are organized parallel bundles or fascicles delineated by a cellular layer, the *endoligament*.^[1] Ligament cells comingle with the collagen fibers within a fascicle and are organized into rows that run along the long axis of the ligament. The ligament fascicles are encased in a cellular layer, the *epiligament*, which is populated by both nerves and blood vessels. Adjacent rows are interconnected by cytoplasmic processes joining one cell to the next via functional gap junctions. This arrangement produces a complex interconnected array of cells that is thought to extend from one end of the ligament to the other. This array has been termed the *cellular matrix*.

Ligament tissue is relatively hypovascular, with approximately 2% of its volume typically occupied by blood vessels.^[2] The majority of blood vessels are located in the *epiligament*, forming vascular plexuses with a random vessel orientation that show a typical branching pattern into small vascular channels. Deeper ligament tissue is less vascular, and the vessels are more linearly aligned with the long axis. These deep vessels run parallel to the collagen bundles in the ligament, and show infrequent anastomoses in the tissue substance. Blood vessels in ligaments are often associated with nerves showing a similar longitudinal organization.

The innervation of ligaments originates mainly from neighboring muscular, cutaneous, and articular nerve trunks.^[3] In the *epiligament*, nerve fibers and blood vessels form a rich plexus, sending branches that penetrate the ligament. Most nerve fibers do not enter

the ligament, but terminate as nerve endings on the surface. Myelinated sensory, unmyelinated sensory, and sympathetic nerve fiber types have been identified in ligament tissue. In addition to the classical neurotransmitters (acetylcholine, amines, amino acids, and nitric oxide), 10 or more slow-transmitting neuropeptides have recently been identified in ligaments: sensory neuropeptides (substance P and calcitonin gene-related peptide), opioid peptides, and sympathetic peptides (neuropeptide Y and vasoactive intestinal polypeptide).

Functions of Ligaments

Ligament function has been traditionally viewed as purely mechanical, stabilizing and controlling joint articulation to distribute forces and protect other tissues. More recent evidence suggests that ligaments also play a significant role in sensory feedback, and that the mechanical properties of ligament are influenced by neurovascular function.

Ligaments show nonlinear mechanical behavior, being relatively compliant under low-load conditions and showing increasing stiffness with increasing tensile load.^[4] The crimped structure and viscoelastic properties of collagen fibers both contribute to this behavior, which is also determined by age, gender, and loading history of the tissue. Recently, it has been suggested that ligaments function under repeated or sustained low loads in normal daily activity, and respond to this environment by the phenomenon of creep (elongation) rather than relaxation. Excessive ligament creep can result in significant joint laxity and subsequent tissue injury, and is therefore of particular clinical relevance.

Recent experiments showing that ligament viscoelastic properties are affected by tissue water content have brought the importance of understanding physiological processes in connective tissues into a new focus. Tissue water content is determined by a variety of factors under vasomotor control, and ligament creep behavior is dependent on the state of hydration. Increasing hydration leads to increased creep, while displacing tissue water with sucrose leads to decreased creep.^[5] The physiologic regulation of connective tissue water content is therefore crucial to the maintenance of mechanical function within normal parameters.

There is good evidence to suggest that the mechanoreceptors found in ligaments play a substantial role in motor control. Sensory input from ligament receptors appears to be important for normal balancing of muscle forces, inducing reflex joint stiffening in response to applied loads, and increasing tension in both flexor and extensor muscles. This stiffens and stabilizes the joint, thereby protecting the articular surfaces from mechanical damage.

The physiology of normal ligaments is complex with regard to cell-matrix structure, as well as heterogeneous with respect to neural and microvasculature elements; this has considerable implications for the normal regulation of these tissues.

MODELS OF LIGAMENT INJURY AND HEALING

Injury to ligaments occurs as a direct result of trauma, or subsequent to altered joint mechanics in unstable or osteoarthritic joints. The knee joint in particular has been the focus of numerous studies, partly owing to the frequency with which clinical injury occurs, and partly because the internal and external ligaments of the knee demonstrate significant differences in their response to injury: the MCL shows a healing response similar to other soft tissues and can regenerate its structure to closely resemble the original. Conversely, one of the major stabilizing ligaments of the knee, the ACL shows a very minor healing capability, and injury to this ligament generally results in joint instability and osteoarthritis. This has led to the development of models that create an injury to the ligament tissue while retaining mechanical stability of the joint. Ligament injury models fall into four main categories: ligament division (rupture or transection), joint laxity (micro-injury), reconstruction, and in vitro techniques. Models of ligament injury are illustrated in Figs. 1 and 2.

Rupture or Transection

Ligament injury results from tearing of the collagen bundles by varying degrees. Subject to sufficient force, collagen fibers are completely torn, and the entire ligament is severed. Early work on ligament injuries attempted to reproduce clinical trauma by the crude method of subjecting the joint to larger-than-normal forces, resulting in injuries of varying extent and location. Later studies focused more specifically on controlling the site of damage; for example, Frank et al. used a model of MCL injury where a braided steel suture was placed under the ligament and pulled upwards perpendicular to the joint to cause a midsubstance rupture.^[6] This model of ligament rupture is similar to a clinical injury in that the ends of the ligament are frayed, producing a characteristic “mop-end” appearance (Fig. 1A). However, because other structures in the joint and regions of the ligament remote from the actual injury site are also subjected to aberrant forces, interpretation of the results from these experiments is complex.

While rupture models of ligament injury may closely approximate clinical injuries, the degree and location of damage vary widely. To give better control over the

Fig. 1 Schematic showing surgical models of MCL injury and healing.

site and extent of ligament injury, surgical transection models were developed. Complete division of the MCL or ACL is easily achieved under surgical anesthesia using a scalpel, where the ligament is transected at its midpoint, and two uniform blunt ends are produced (Fig. 1B). Initially, frayed ends were thought to be prerequisite for normal MCL healing; however, it was shown that there was no difference in the mechanical or histological properties of a healing ligament whether the ends were initially frayed or cut.^[7]

During healing of the MCL, scar tissue forms that is thought to affect the mechanical properties of the ligament, showing disorganization of the collagen fiber structure and increased vascularity that reduces tensile strength of the tissue (see below for details of ligament healing responses). To assess the contribution of

scar tissue to the mechanical properties of healing ligaments, two further models of transection were developed in the rabbit MCL,^[8] one aimed at increasing the amount of scar tissue by separating the two cut ends of the ligament ("gap" injury, Fig. 1C), and one aimed at reducing the amount of scarring by maximizing the contact area of the cut ends ("Z-plasty," Fig. 1D). This study demonstrated that both gap and contact injuries healed with scar tissue, recovering their biomechanical viscoelastic behaviors to 68–92% of contralateral control ligaments by 14–40 weeks. However, "contact scars remodeled more quickly, recovered laxity more quickly, and were generally closer to contralateral control ligaments than gaps in terms of their structural strength, stiffness, and material behaviors after 40 weeks of healing."^[8] The

Fig. 2 Schematic showing surgical models of ACL injury, joint laxity, and osteoarthritis.

authors concluded that there were differences in the early rate and possibly in the later quality of ligament healing when cut rabbit MCL ends were in proximity.^[8] Other models of MCL injury such as tissue windows and partial sections have been developed for comparison with ACL injury models detailed below (Figs. 1 and 1F).

In contrast to the MCL, the ACL of the knee generally shows poor healing capacity in both clinical patients and animal models. In fact, it may be stated that for all intents and purposes, the transected ACL never heals.^[9,10]

It has proven quite useful to study the transected ACL in animal models (Fig. 2A) and compare its healing response with an extra-articular ligament such as the MCL that shows much better recovery after injury. Early attempts at severing the ACL used a stab incision to the anterior surface of the joint using a scalpel blade; however, the success of this model was very limited because of inconsistent injuries to the ACL and added damage to the cartilage and other joint structures. A more recently established and much more consistent approach to ACL transection is to open the joint cavity by a lateral capsulotomy, retract the fat pad, isolate the ACL with a hooked probe, and completely transect the ligament using a scalpel blade (Fig. 2A). Completeness of ACL transection is tested by drawing the tibia anteriorly relative to the femur, and the wound is sutured closed. This provides a consistent model of injury, where the ACL is completely transected while minimizing damage to other tissues.

A possible reason for poor healing of the ACL is the intra-articular location of the ligament, where the ACL provides the major mechanical resistance to anterior translation of the tibia. When the ACL is ruptured or cut (Fig. 2A), the biomechanics of the knee are significantly altered, and the motion of the tibia relative to the femur is greatly increased (“joint laxity”). Healing of the ACL may be impossible in this environment because of lack of apposition of the ligament ends. This hypothesis has led to the development of knee injury models that either physically reattach the cut ligament ends (suture repair, Fig. 2B), or attempt to induce the formation of scar tissue while retaining the mechanical integrity of the joint (tissue window and partial transactions, Figs. 2 and 2D). Histological, mechanical, and physiological measures of ACL healing can then be compared with control ACLs, or with the MCL to determine differences in the reaction to injury.

Joint Laxity and Osteoarthritis

In addition to studying the healing responses of the ACL itself, the ACL-deficient model of joint injury

(Fig. 2A) is also useful in two other areas of study: microtrauma to other joint structures as a consequence of joint laxity, and in the longer term, development of osteoarthritis in the joint.

Disruption of the ACL produces increased joint laxity and altered joint mechanics, and forces placed on the joint that would normally be resisted by the ACL are redistributed throughout the remaining connective tissues. The chronically abnormal biomechanical environment in an ACL-deficient knee induces a series of maladaptive physiological and mechanical alterations in secondary joint stabilizing structures that may in turn undergo injury as a result. Specific results of chronic instability are pain and inflammation, hyperemia, and angiogenesis in articular soft tissue, including ligaments. Assessing the function of the MCL in an ACL-deficient joint allows examination of the tissue response to an altered mechanical environment without inducing a direct injury to the MCL. This model has produced interesting results that are discussed below.

Long-term untreated joint laxity induces a cycle of recurring inflammation and progressively alters the tissue mechanics, and ultimately leads to the development of osteoarthritis in the joint. The ACL-deficient knee of several species has been used to study the mechanics, cartilage properties, and bone remodeling in osteoarthritis joints.

Ligament Reconstruction

In light of the poor healing potential of the ACL even when the ends of the injured ligament are apposed, alternative treatments involving replacement or reconstruction of the ligament have been developed and clinical ACL reconstruction has become almost standard practice.^[11] In animal models, replacement of the injured ACL with biologic or synthetic materials has been tested in a variety of species with significant success.

Autografting of the ligament with other tissues such as hamstring tendon, semitendinosus tendon, and patellar tendon from the same animal is common. This precludes graft rejection but causes morbidity of the donor site that may be problematic, especially in smaller species. As an alternative allografting of tissue from donor animals has been used, but there is increased risk of infection and graft rejection. Synthetic materials such as polyester ribbon can also be used to stabilize the joint; however, the viscoelastic properties of such materials are very different from biological tissue and can lead to difficulty in interpreting the results. Nonetheless, ACL reconstruction models, especially autografts, have provided a wealth of information on the relation between

joint laxity and the development of microinjury and osteoarthritis.

In Vitro Models

An alternative approach to in vivo models of ligament injury is the use of tissue explants or cell cultures to study the properties and migration of ligament fibroblasts and cellular responses to a variety of growth factors. While these models have received little attention in the past, recently developed culture techniques have shown differences in the responsiveness of cells from ACL and MCL tissues to cytokines and neuro-peptides.^[12] Medial collateral ligament fibroblasts derived from tissue explants show greater proliferation, migration, and collagen synthesis than ACL cells and are more responsive to externally applied factors such as tumor growth factor-B. These intrinsic differences in the properties of MCL and ACL fibroblasts may go some way to explaining the differential healing potentials of these two ligaments.

ANIMAL SPECIES IN LIGAMENT RESEARCH

In the clinical setting, joint trauma generally results in complex injuries involving several tissues, and it is therefore difficult to evaluate the contribution of the various structures to the injury response. The use of animal models allows specific types of ligament injury to be induced under controlled conditions where the degree of healing can be directly correlated to changes in biomechanics, joint physiology, and homeostasis. The choice of animal species is dependent on a number of variables, some of which are nonscientific factors such as ease of handling and housing costs. In general, larger species are used for studies of biomechanics, where the size and articulation of the joints more closely resembles human joints. Smaller species are more commonly used for histologic assessments of healing and innervation.

Sheep and Goats

These species have relatively large knee joints, and are well suited for studies of the ACL healing and reconstruction.^[13–15] The anatomy and flexion mechanics of sheep and goat knees more closely resemble that of humans than do smaller species, because of the stiffness of the stifle joint. Sheep are somewhat amenable to exercise training on a treadmill; however, the specialized housing needs of these animals may preclude their use at some institutions.

Dogs

Dogs were used in some of the earliest studies of ligament injury,^[16] and are still widely used, because they are easy to handle and can be trained in a variety of exercise protocols. There is also a large existing database on canine ligament healing from veterinary research. The disadvantages of the model are the relatively high costs of animal purchase and housing and restrictions placed on experimental protocols by institutions because of the companion nature of the species.

Rabbits

There is a large database on the biomechanics, histology, and physiology of ligament injuries in the rabbit.^[4,6] The New Zealand White rabbit is a commonly used strain because of its relatively low purchase cost, basic housing requirements, and ease of handling. In addition, adult rabbits weigh between 5 and 7 kg, and so the knee joint of these animals is large enough for meaningful mechanical testing to be done, yet small enough that histological sectioning of the entire joint is still feasible. Models of MCL injury, ACL injury (joint laxity), and ACL reconstruction have all been established in the rabbit model.

Rats

Rats have not traditionally been used for ligament studies, mainly because of the small size of their joints, and the fact that rats were thought to grow continually throughout their life so that bone and soft tissues are being continually remodeled. However, rodent models have recently been used successfully to study the innervation of joints, ligament, and tendon.^[3,17] In addition, we now know that although the epiphyseal plates of rats do not ossify, they do become dormant shortly after sexual maturity; so these animals may be more commonly used in studies of ligament biology because of the potential cost savings and the wealth of biological probes and techniques available for use in rat tissues.

LIGAMENT HEALING RESPONSES

The effectiveness of ligament healing depends upon a variety of factors, including location of the ligament, type and extent of injury, and the animal species used for the study. Ligament anatomy and healing has been assessed using a wide variety of techniques, including biomechanical assessment of tissue viscoelastic properties, histological and immunohistochemical studies

of structure and innervation, and functional indicators of vascular physiology such as perfusion imaging. In this section, a comparison of healing in the MCL and ACL is used to illustrate the application of some of these techniques.

Phases of Ligament Healing

The injury response of ligament tissue follows a similar pattern to other soft tissues, although the time taken for the process to occur is relatively long.^[18] Some ligaments such as the MCL show almost complete healing, while others such as the ACL demonstrate almost no injury response. In ligaments where an injury response occurs, healing can be divided into three phases: hemorrhage and inflammation, proliferation, and remodeling.

Initially, torn ligament ends are bridged by a blood clot that is absorbed as the injury site is infiltrated by cells; damaged material is degraded, and repair is initiated by cellular and vascular factors. Blood flow to the ligament is significantly increased and remains elevated for several weeks.^[2]

In the proliferative phase, infiltration by hypertrophic fibroblast cells produces “scar” tissue, a hypercellular collagen matrix that joins the torn ends of the ligament. This scar tissue is structurally disorganized and mechanically weak, and contains collagen fibers that are randomly oriented and of smaller diameter than normal ligament tissue. With time, collagen fibers and bundles are found to be realigned with the long axis of the ligament. Scar tissue is relatively vascular, and it has been suggested that the perforation of a normally highly organized tissue by myriad small, structurally weak blood vessels contributes significantly to the inferior mechanical properties of healing ligaments.

After a ligament injury, it takes months to years for tissue remodeling. Components of the scar tissue change their composition and orientation, and the cellularity and the vascularity gradually decrease, but the tissue remains mechanically weak. Some matrix components return to near-normal levels, but the remodeled tissue still contains different proteoglycans, collagen fiber types, and diameters that appear to create a new functional baseline. In the long term, the extent of recovery after a ligament injury depends on many factors including the degree of joint movement, apposition of the ligament ends, and neurovascular responses.

Biomechanics

Testing the material properties and mechanical behaviors of bone–ligament–bone complexes has been widely used to assess the recovery of ligament function

after injury. The major function of ligaments is to resist and distribute forces applied to the joint, and so the viscoelastic properties of the tissue have been extensively studied in a variety of injury models. For a detailed review of the biomechanics of knee ligaments see Ref. [4].

In comparing the mechanical properties of the MCL and the ACL, the most commonly used protocol is to leave the ligament attached to the femur and tibia, which are then clamped into the testing device. Using a bone–ligament–bone complex rather than the ligament alone eliminates the problems of securely gripping the tissue and the concern that the presence of clamp–tissue interfaces may affect the measurement of its properties. A bone–ligament–bone complex provides a structural unit to which load can be applied to determine mechanical behaviors such as stress, strain, and creep. The low-load viscoelastic properties of ligaments have recently received much attention, because it is now believed that these properties are most representative of ligament function under normal conditions.

The biomechanical properties of MCL scars are generally inferior to normal ligaments, demonstrating a slow recovery of many properties. During cyclic loading, or a single static load, the stress relaxation of scar tissue is more than normal and therefore relies more heavily on other tissues to compensate. The creep properties of the tissue are reduced, and scarred ligaments show twice as much creep when subjected to cyclic loads far below their failure strength. The length of the ligament is reestablished during later remodeling, but at 14 weeks after a “gap” injury, failure strength of the MCL complex in the rabbit is still only half of sham-operated controls.^[7,8]

Following complete transection of the ACL, there is generally insufficient scar formation to allow mechanical testing; the ligament stumps remain separated and may eventually be absorbed. However, models of ACL repair or replacement such as suture repair, partial injury, or reconstructions have been compared with control ACLs. One study in dogs showed that the failure and tensile strength of ACL reconstructions using patellar tendon autografts was initially only 10% of control values; these properties did improve over time, but never recovered to within normal range.^[11] Factors such as graft fixation, position, composition, and tension must be taken into consideration in the interpretation of such results.

Histology

Ligament structure, cellularity, and innervation have been characterized using a wide range of histological and immunohistochemical techniques. Simple techniques such as hematoxylin and eosin staining can

be used to study the appearance of ligament cells, blood vessels, and organization of the collagen fiber structure, providing a measure of the metabolic and mechanical status of the tissue. Recent ultrastructural studies have revealed ligament cellular organization and communication via gap junctions,^[1] while immunohistochemical staining for nerve fibers and vasoactive peptides has provided new information on the role of vasomotor reflexes and innervation in ligament function and healing.^[3,17,19]

Following injury to the MCL, there is significant inflammation followed by the formation of scar tissue that is highly cellular and vascular and shows a derangement of collagen fiber structure. During the remodeling phase, the fibers gradually realign themselves with the long axis of the ligament, and the cellular organization of the tissue is restored.^[18] In contrast, injuries to the ACL show almost no cellular response, even when the ligament ends are physically apposed. The MCL also shows a significant remodeling response in ACL-deficient knees, presumably in response to increased and aberrant forces in a lax joint. The ligament thickens along most of its length, demonstrating similarities in appearance to scar tissue formed after direct injury.

Immunohistochemistry has been used to detect nerve fibers and vasoactive neuropeptides in ligaments.^[3,19] Fig. 3 shows nerve fibers in the rabbit MCL

Fig. 3 Immunostaining of rabbit MCL for (A) the neuronal marker PGP9.5 and (B) the vasoactive peptide CGRP. Arrows indicate the longitudinal axis of the ligament, and in (B), is also aligned with an adjacent blood vessel.

immunostained for the neuronal marker protein gene product 9.5 (PGP 9.5) and the neuropeptide CGRP.^[3] Six weeks after gap injury in the MCL, calcitonin gene-related peptide (CGRP) immunoreactivity is increased in the scar tissue. The vasoactive and trophic properties of neuropeptides in injured ligaments likely contribute to their healing potential, affecting angiogenesis, inflammation, and scar tissue formation.

Vascular Physiology

The blood flow, vascularity, and water content of ligaments significantly affect their mechanical properties, and a vascular response after injury is crucial to tissue healing. The vasoactive responses of blood vessels in ligaments have remained largely unknown, because of a lack of accurate measures of normal tissue vascularity and vasomotor activity. A range of techniques have been used to measure ligament blood flow, beginning with vascular casting techniques in the late 1980s and progressing through colored

Fig. 4 Laser speckle perfusion images showing blood flow to the rabbit MCL in (A) control and (B) ACL-deficient joints. Areas of low flow are in blue, areas of moderate flow are in green and in yellow, and areas of high flow are in red. (From Ref. [17].)

microsphere infusion and laser Doppler imaging.^[2] Most recently, new technology for the real time assessment of tissue blood flow, laser speckle perfusion imaging (LSPI), allows visualization of ligament blood vessels and microcirculation in living tissue with minimal invasiveness. This enables physiologic studies of vasoregulatory processes under a variety of clinical and research conditions.^[20]

There is a clear difference in the vascular response of the MCL and the ACL after partial transection injuries in the rabbit, which almost certainly contributes to the lack of healing in the ACL. Using colored microsphere infusion, we have shown that the MCL responds to partial transection with a massive increase in blood flow and vascularity, peaking at six weeks after injury and returning toward control levels by 16 weeks.^[9] In contrast, blood flow to the ACL after partial transection was not significantly different from sham-operated animals at any time.

The application of LSPI to ligament injuries allows a more rapid and dynamic assessment of tissue vascular responses.^[21] Fig. 4A shows the blood supply to a normal rabbit MCL measured by LSPI. The perfusion image is color coded so that regions of low blood flow appear blue, regions of moderate flow appear green and yellow, and areas of high flow appear red. In Fig. 4A, individual blood vessels supplying the MCL appear green and yellow on a blue background. The larger epiligamentous vessels appear as a branching network over the surface of the ligament, while the capillary microcirculation is seen as background perfusion without distinct vessels. Fig. 4B shows the injury response of the MCL in a lax joint, six weeks after surgical transection of the ACL. Blood flow and vascularity of the MCL is significantly increased, especially in the areas of greatest tissue thickening.

Application of new techniques such as LSPI allows assessment of connective tissue vascular responses at high speed and high resolution.

CONCLUSIONS

The use of animal models in the study of ligament injury has allowed significant advances in the understanding of structural, mechanical, and physiological changes occurring during connective tissue healing. The use of these models in combination with advances in analysis techniques has the potential to establish new therapeutic regimens following traumatic joint injury.

INTRODUCTION

The liver is one of the most complex and metabolically active organs in the body and performs many detoxification and protein synthetic functions that are essential to life. Extracorporeal bioartificial liver (BAL) systems consisting of functioning, viable hepatocytes may provide temporary support for patients with acute hepatic failure and save the lives of patients awaiting orthotopic liver transplantation (OLT).

In the past few years, we have seen several clinical studies testing the efficacy of BAL devices. These preliminary studies have provided some promising results, although current-generation liver-assist devices have not yet demonstrated sufficient efficacy and reliability for routine use. Some of the issues that the field of BAL development continues to wrestle with are: 1) how to support a large cell mass without substrate limitations so that cells function with maximum efficiency; 2) how to maintain high levels of stable long-term liver-specific function in an artificial (and potentially inhospitable) environment; and 3) how to minimize the priming volume (or dead space) that must be filled by blood or plasma from the patient. It is becoming clearer every day that a more fundamental understanding of the effect of environmental parameters on hepatocellular function, as well as host-BAL interactions, is necessary before the concept of BAL becomes a reality available at reasonable cost. This article describes the tissue-engineering principles and critical technologies that are relevant to the design of BAL devices, and provides future directions for the development of the next generation of BAL support systems.

CLINICAL RELEVANCE

The Clinical Problem

Approximately 30,000 patients die each year from end-stage liver disease in the United States. About 80% of these patients have decompensated chronic liver disease, typically caused by alcoholism or chronic

hepatitic C infection, and less commonly by a genetic—hepatocellular or anatomic—defect of liver function, or cancer. The other 20% die of acute liver failure (without preexisting chronic liver disease), which has various etiologies, including ischemia-reperfusion injury during liver surgery, acetaminophen poisoning, viral hepatitis, severe sepsis, idiosyncratic drug reactions, etc. Acute liver failure symptoms develop over a period of 6 weeks to 6 months and lead to death in over 80% of the cases, usually from cerebral edema, complications due to coagulopathy, and renal dysfunction. A more severe form of acute liver failure—fulminant hepatic failure—is characterized by a more rapid evolution (2–6 wk).

Orthotopic liver transplantation is the only clinically proven effective treatment for patients with end-stage liver disease. Acute liver patients have the highest priority for donor livers; however, because acute liver failure is an uncommon condition, it only accounts for 12% of OLTs.^[1] The latest data from the United Network for Organ Sharing, the organization that keeps track of organ transplants in the United States, show that the number of liver transplants performed yearly has increased at a constant rate of 240/year since 1992, to reach 4950 in 2000 (Fig. 1). However, the number of patients dying while on the waiting list has increased exponentially at a rate of 16–17% per year. As of August 31, 2002, a staggering 17,436 patients were on the liver transplant waiting list. Currently, 90% of the donated livers are transplanted; thus, any significant increase in the donor supply can only be achieved through dramatic improvements in the methods of organ procurement, as well as expansion of donor criteria.

The majority of donor livers are obtained from brain-dead cadavers that still possess respiratory and circulatory functions at the time of organ retrieval. A large pool that remains largely untapped consists of nonheart-beating cadavers.^[2] In 2001, only 3% of the cadaveric livers were from nonheart-beating donors, although it is estimated that the potential may be on the order of 250,000 annually.^[3] Such livers, however, are prone to primary nonfunction posttransplantation, and much more research is needed to develop

Fig. 1 Evolution of the supply and demand for donor livers in the United States. (Data from Ref. [1].)

techniques that would recondition or repair these organs to make them acceptable donors. Living-related donor transplantation, which involves using a graft obtained by means of a partial hepatectomy from a living donor (usually a parent or relative), is another promising alternative. Nevertheless, split- and living-liver donor techniques represent only about 3% of the total number of transplants performed in the United States,^[4] and are inherently limited because this procedure represents a significant risk for the donor.

All the aforementioned approaches to expand the donor pool are being actively pursued, and have the advantage that they do not require extensive regulatory review, thus shortening the time from concept to practice. Nevertheless, the extent of the problem is such that other alternatives to OLT are desperately needed. Some of the recent and more innovative approaches currently being explored are: 1) xenotransplantation; 2) hepatocyte transplantation; and 3) temporary liver support.

Xeno (Cross-Species Transplantation)

The transplantation of pig or baboon livers into humans has had several failed attempts in the recent past. For this approach to succeed, patients must first overcome hyperacute rejection, a very rapid immune response (~1 hour) that is characteristic of xenotransplantations, and must actively develop

microchimerism, an interaction of two coexisting cell populations leading to the down regulation of both recipient and graft immune systems.^[5] Another major concern is the potential transmission of infectious agents across species.^[6] Recent advances in genetic engineering may allow the modification of the immune response, and sophisticated breeding programs may provide animal breeds devoid of zoonotic diseases. These advances may eventually make xenogeneic livers a viable option for use as a bridge to transplantation, or possibly even as a permanent graft.

Hepatocyte transplantation

Transplantation of liver parenchymal cells (hepatocytes) offers the possibility of treating several patients with one single donor liver. The survival and function of implanted hepatocytes can be improved by incorporating the cells into implantable devices such as microcarriers (beads 200–300 μm in diameter that the cells can attach to), hydrogels, and other polymeric matrices. The most suitable implantation sites appear to be those that provide a microenvironment resembling that of liver, i.e., with a substrate that promotes hepatocyte attachment and a venous blood supply network, such as the splenic pulp and the host liver itself. Furthermore, permanent incorporation may require that the liver have significant preexisting damage and that the transplanted cells have a competitive advantage (e.g., they proliferate faster) v. those in the host's liver.^[7] Studies so far suggest that the efficiency of engraftment is quite low and that a lag time (which may be as long as 48 hours) is necessary before any clinical benefit occurs.^[8] (A 48-hour lag time may be too long in a rapidly deteriorating patient.) On the other hand, this approach offers an attractive prospect for correcting nonemergency conditions such as inherited metabolic defects of the liver.

Other implantable devices, such as capsules and hollow fibers, have been used to protect hepatocytes from the immune system of the host. Some encouraging results have been obtained over a period of a few weeks after implantation, but not beyond, possibly due to deterioration of the biomaterial.^[9,10] A common recurrent problem is the presence of a foreign-body reaction against the capsule material itself, leading to the generation, over a period of days to weeks, of a fibrotic layer around it, compromising metabolite transport between the implanted cells and the surroundings. Besides improvements in the biocompatibility of the material, one avenue that may improve the function of these devices is the use of materials or factors that promote the growth of blood vessels near the surface of the capsule.

Temporary liver support

Temporary liver support is a logical option for patients with acute liver failure where the host's liver has the potential to fully recover, as well as for use as a bridge to transplantation. The concept of temporary liver support is best exemplified by results obtained with auxiliary partial liver transplantation (APLT). Auxiliary partial liver transplantation, currently the only reliable method of temporary liver support, consists of implanting a functioning liver without removing the host's native organ. Auxiliary partial liver transplantation has been used to treat specific inborn liver disorders as well as acute fulminant hepatic failure. In certain cases of hepatic failure, the native liver recovered and the auxiliary liver could be safely removed, hence eliminating the need for lifelong immunosuppression.^[11] Indeed, one of the greatest appeals of temporary liver support is the possibility of spontaneous recovery without the need for transplantation. This would free up donor livers as well as eliminate the need for lifelong immunosuppression that is required by all transplant recipients, translating into significant cost savings for the health care system. Temporary liver support may also be used to maintain the patient's life during the long wait for a donor, as well as prevent liver failure-related complications that may make the patient too ill to tolerate a liver transplantation procedure.

Auxiliary partial liver transplantation depends on the availability of donated livers; there is thus a need to develop an off-the-shelf device akin to the kidney dialysis machine. Early devices for temporary liver support contained no cells (i.e., charcoal adsorption columns), and could not demonstrate therapeutic effectiveness.^[12] Nevertheless, there remains an interest in improving this methodology. Because the liver provides a myriad of detoxifying as well as protein synthetic functions, efforts in this area are mostly dedicated to the development of bioartificial systems incorporating live liver cells.

CELL SOURCE AND THERAPEUTIC CELL MASS

What Is the Therapeutic Cell Mass?

The cell mass required to support a patient during acute liver failure has not been systematically determined. Devices that have undergone clinical testing have used 5×10^9 – 6×10^{10} porcine hepatocytes^[13,14] or 4×10^{10} human hepatoma cells.^[15] In a more recent study on humans with acute liver failure, intrasplenic and intraarterial injections of human hepatocytes ranging from 10^9 – 4×10^{10} per patient (i.e., 1–10% of the total liver mass) transiently improved brain

function and several blood chemistry parameters, but not survival.^[8] Results from animal studies also suggest that relatively few hepatocytes (between 2% and 10% of the host's liver) are needed to effect a therapeutic benefit. This may be due in part to the fact that the exogenously supplied hepatocytes may aid the regeneration of the native liver. Current consensus is that the minimum cell mass necessary to support a human undergoing acute liver failure is about 5–10% of the total liver weight, or about 10^{10} cells.

Cell Source and Replication of Hepatocytes in Culture

Primary (i.e., directly isolated from an organ) human hepatocytes are the natural choice for the BAL. However, they are scarce due to the competing demand for livers for OLT. Human hepatocyte lines have been generated by the spontaneous transformation of long-term cultures of adult hepatocytes, as well as by a reversible transformation strategy based on Cre-Lox recombination of the SV40T viral antigen.^[16] No one has yet achieved the goal of generating a safe and fully-functional yet clonal, immortalized, or genetically-engineered human cell that can be substituted for primary hepatocytes. Besides providing a sufficient number of cells for BALs, proliferating cells would have the advantage of being able to be genetically engineered to overexpress metabolically significant genes (e.g., glutamine synthetase, cytochrome P450s, etc.). Currently, the only way to permanently integrate transgenes into the cellular genome is to infect replicating cells with retroviruses.

Recent data suggest that there are stem cells in the liver that can differentiate into fully mature hepatocytes.^[17] Furthermore, studies in rats, mice, and humans have shown that bone marrow is a major extrahepatic source of stem cells that may contribute to liver regeneration after hepatic injury. Pending more research on the mechanisms of stem cell differentiation into hepatocytes, stem cells remain a potentially significant source of liver cells.

In BAL devices tested so far in the clinic, the only human cell used has been the hepatoma C3A line,^[15,18] which originated from a tumor and may have significantly lower detoxification activities than primary hepatocytes. Most current BAL concepts are based on the use of pig hepatocytes. These present no risk of transmitting malignancies to the patient, but pose the risks of hyperacute rejection,^[5] transmission of zoonoses,^[6] and potential mismatch with human liver functions. Specialized breeding of transgenic animals could address the first two concerns. Very little is known about the metabolic compatibility of liver functions across species. Xenotransplantation studies

may help provide useful information in that respect, once there is reliable success in overcoming hyperacute rejection and early death after clinical xenotransplantation.

Development and Optimization of Hepatocyte and Liver Preservation Techniques

The development of optimal preservation protocols for hepatocytes that enable the storage and ready availability of cells for BALs, has been the subject of several studies. Hepatocytes have been cryopreserved shortly after isolation as well as after culture for several days. Compared to isolated cells, cultured hepatocytes exhibit greater resistance to high concentrations of the cryoprotective agent dimethyl sulfoxide, as evidenced by preservation of cell viability, cytoskeleton, and function. Based on experimental and theoretical studies, cooling rates between 5 and 10°C/min caused no significant decrease in albumin secretion rate compared to control, unfrozen, cultures.^[19,20]

There have been attempts to store hepatocyte cultures in various solutions used for cold storage of whole donor livers. One study showed that cultured hepatocytes maintained at 4°C lose significant viability after a few hours of cold storage, but that addition of polyethylene glycol significantly extends functionality and survival.^[21] Interestingly, the use of the University of Wisconsin (UW) solution, currently the most widely-used solution for cold organ storage, has not performed better than leaving the cells in standard hepatocyte culture medium. It is conceivable that the UW solution mediates its effect by prolonging the survival of non-parenchymal cells. It is hoped that further improvements in preservation solutions will enable the storage of BAL systems, as well as lengthen the useful cold storage time of whole livers for transplantation.

ENGINEERING A BIOARTIFICIAL LIVER FUNCTIONAL UNIT

Hepatocyte Function and the Environment

The basic functional unit in the liver is the hepatic lobule (Fig. 2), where hepatocytes are organized into a radial network of plates that are one cell thick. On each side of the plate is a thin layer of extracellular matrix (ECM) material that is covered by vascular endothelial cells. Other cell types, such as fat-storing cells and macrophages are dispersed throughout the lobule. Epithelial cells form bile ductules that collect the bile secreted by the hepatocytes. In the lobule, blood flows from the periportal outer region toward the central hepatic vein through specialized porous capillaries

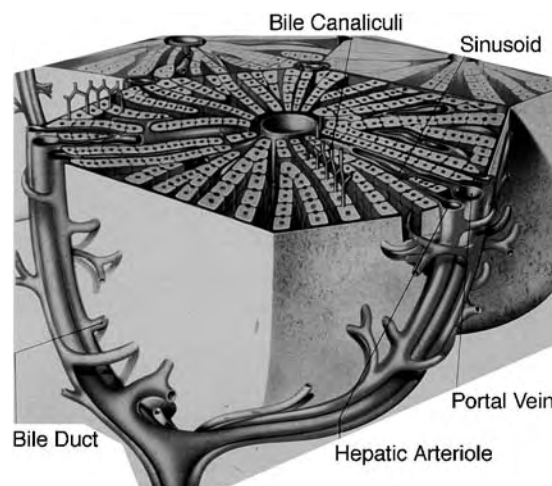

Fig. 2 Structure of the liver lobule. (Reproduced from Ref. [11] by permission of the publisher.)

called sinusoids. Hepatocytes in the periportal, intermediate or centrilobular, and perivenous zones exhibit different morphological and functional characteristics. For example, urea synthesis is a process with high capacity to metabolize ammonia and low affinity for the substrate, which occurs in the periportal and intermediate zones. In the perivenous zone, ammonia is removed by glutamine synthesis, a high-affinity but low-capacity process that removes traces of ammonia that cannot be metabolized by the urea cycle. Replicating the functional heterogeneity of hepatocytes in the lobule may be important to maximize the performance of the BAL.

The maintenance of functional heterogeneity in the liver is dependent on several factors, including gradients of hormones, substrates, oxygen, and ECM composition.^[22] In one study where hepatocytes were chronically exposed to increasing oxygen tensions within the physiological range of about 5 mm Hg (perivenous) to 85 mm Hg (periportal), urea synthesis increased about tenfold, whereas cytochrome P450-dependent detoxifying activity decreased slightly and albumin secretion was unchanged.^[23] These data suggest that by creating environmental conditions that emulate certain parts of the liver sinusoid, it is possible to modulate hepatocyte metabolism in a way that is consistent with in-vivo behavior, and to purposely upregulate or downregulate specific liver metabolic functions.

Biomaterials in Liver Tissue Engineering

Materials used in tissue engineering

Most of the natural ECM materials used for liver cell culture were obtained via solubilization of tissues by chemical processing. These protein solutions can often

be reconstituted into three-dimensional gels of any shape or form, and retain many chemical features of the ECM proteins, including bound growth factors, found *in vivo*. Commonly used reconstituted matrices include type I collagen, which is isolated from rat tail or bovine skin by mild acid treatment. The acid solution of collagen can be induced to form a gel upon restoring a physiological pH of 7.4, which causes the polymerization of collagen molecules into a large network of fibrils. The extent of cross-linking in this collagen is very low in comparison with that of the native tissue, but chemical cross-linking can be induced by either glutaraldehyde or dehydrothermal (vacuum and $\sim 100^\circ\text{C}$) treatment.

Naturally derived matrices provide good substrates for cell adhesion because cells express the adhesion receptors that specifically recognize and bind to ECM molecules that make up these matrices. Nevertheless, there have been considerable advances in the development of synthetic biocompatible polymers, which theoretically have an unparalleled range of physical and chemical properties. In practice, however, most studies have used relatively few synthetic materials, in part due to a reluctance to expend time and money to secure regulatory approval for clinical use of untested biomaterials.

Optimization of surface chemistry

Cells do not usually directly attach to artificial substrates, but rather to ECM proteins that are physically adsorbed (i.e., by virtue of hydrophobic and electrostatic interactions) or chemically (i.e., via covalent bonds) attached to the surface. Surface treatment, such as with ionized gas, is often used to favor protein adsorption. This process only modifies the surface of the material, and thus minimally affects its bulk mechanical properties. Surfaces have been coated with positively charged materials such as poly-L-lysine to promote cell adhesion by attractive electrostatic interactions with the cells. This is because the latter usually display a negative surface charge due to the presence of negative sialic acid residues on their surface glycocalyx.

Because physisorption is notoriously nonselective, covalent modification of substrates or chemisorption is used if necessary to provide more control over the type, density, and distribution of adhesive protein on the surface of the material. The first step involves using a reactive chemical that bonds to the surface and has a free functional group that easily reacts with free thiol, hydroxyl, carboxyl, or amine groups on proteins. This step often requires harsh chemical conditions, whereas the second step (which involves conjugation of the protein) can be accomplished under physiological conditions. This approach is also suitable to graft small

adhesive peptides (e.g., arginine-glycine-aspartic acid (RGD)-peptide) that otherwise would not stably bind to surfaces by physisorption.

Various ECM proteins, such as collagen and laminin, regulate the activities of transcription factors that control the expression of liver-specific genes such as albumin. It has been hypothesized that these factors bind ECM-responsive elements. It is important to realize that no matter what type of surface is used to seed the cells, over a period of several days of culture, cells will have secreted significant quantities of their own ECM onto the substrate, and the initial surface properties of the material will be dramatically altered. For example, cultured hepatocytes continually synthesize collagen, fibronectin, and laminin,^[24] and this secretion is important for the maintenance of long-term liver-specific protein secretion in hepatocytes cultured in collagen gels.

More chemically complex ECM, such as matrix extracted from Engelbroth-Holmes sarcoma (EHS) tumors grown in mice, whose composition more closely resembles basal lamina (it consists predominantly of type IV collagen, laminin, and heparan sulfate proteoglycan), induce the expression of liver-specific functions and phenotypic features typical of hepatocytes *in vivo*.^[25,26] There is evidence that the mechanochemical properties of such surfaces, whether they favor cell spreading, rounding, or aggregation, impact the responsiveness of the hepatocytes to growth and other trophic factors.^[27]

Extracellular matrix and cell polarity

Extracellular matrix geometry (or topology) affects hepatocyte morphology and function. The effect of matrix topology was investigated in a controlled fashion using a culture technique whereby cells cultured on a single surface were overlaid with a second layer of ECM, thereby creating a sandwich configuration around the cells. In the case of hepatocytes, the overlay establishes an ECM configuration that resembles that found in the liver (i.e., where hepatocytes are generally bounded by ECM at each of their opposite basolateral membrane domains). The result is that hepatocytes remain as a monolayer, but exhibit a dramatic increase in the expression of liver-specific functions compared to cultures on a single ECM-coated surface.^[24]

Rat hepatocytes cultured in the collagen sandwich, when compared to a single collagen gel substrate, have a dramatically altered organization and expression of cytoskeletal proteins. The collagen sandwich induces the formation of distinct apical and basolateral membrane domains, each expressing specific surface markers^[24] (Fig. 3). Cytoskeletal actin filaments are

Fig. 3 Morphology and localization of actin fibers in hepatocyte cultures on a single collagen gel (A and C) and in a collagen sandwich (B and D). A and B show the distribution of apical and basolateral membranes in relation to the localization of actin. C and D show actual immunofluorescence staining of actin filaments in rat hepatocytes. (C and D reproduced from Ezzell, R.M., et al., *Exp Cell Res* **1993**, *208*, 442–452, by permission of the publisher.)

concentrated under the plasma membrane in regions of contact with neighboring cells, forming the sheathing of a functional bile canalicular network. In contrast, hepatocytes cultured on a single gel exhibit actin-containing stress fibers on the ventral surface in contact with the substrate and no bile canaliculi, a pattern more typical of fibroblasts.

Controlling cell–cell interactions

In general, when cells are seeded on a substrate, they initially form a monolayer that is held together by both cell–substrate and cell–cell adhesions. If the substrate is only moderately adhesive, cell–cell adhesions may be stronger and the cells may spontaneously reorganize into compact aggregates that interact minimally with the surface. When hepatocytes are induced to form aggregates, they maintain viability and stable expression of liver-specific functions for several weeks. Furthermore, recent data show that hepatocytes in spheroids form functional bile canaliculi, which indicates that the cells exhibit distinct apical and basolateral membrane domains.^[28] Hepatocyte spheroids have been used as the basis for several BALs.^[29]

Approximately 20 years ago, it was discovered that hepatocytes could be cultured on feeder (or supportive) cells to maintain their viability and function.^[30] More recent studies showed that nonhepatic cells, even from

other species, may be used. In these culture systems, cell–cell interactions among hepatocytes and cells of another type (rat liver epithelial cells, liver sinusoidal endothelial cells, or mouse embryonic fibroblasts), or heterotypic interactions, are critical for the expression of hepatocellular functions. The disadvantages of coculture systems include the potential variability in the cell line used and the additional work needed to propagate that cell line and attend to the isolation of hepatocytes.

It may be desirable to optimize heterotypic cell–cell interactions in order to maximize the expression of liver-specific functions of the cocultures. Keeping in mind that cells cultured on surfaces do not usually layer onto each other (except for malignant cancer cell lines), random seeding using a low ratio of parenchymal cells to feeder cells will achieve this goal, but at the expense of using much of the available surface for fibroblasts, which do not provide the desired metabolic activity. On the other hand, micropatterning techniques enable the optimization of the seeding pattern of both cell types to ensure that each hepatocyte is near a feeder cell while minimizing the number of feeder cells.^[31] As a result, metabolic function per area of culture is increased and the ultimate size of a BAL with the required functional capacity is reduced. In prior studies using circular micropatterns, function per hepatocyte increased when the hepatocyte circle diameter decreased, and function per unit area of culture increased when the space occupied by fibroblasts in between the hepatocyte islands decreased (for a constant cell number ratio of the two cell types).

Various methods for patterning the deposition of ECM or other cell attachment factors onto surfaces have been developed.^[32] Photolithography involves spin-coating a surface (typically silicon or glass) with a layer approximately 1 μm thick of photoresist (a photo sensitive chemical resistant to acid), exposing the coated material to ultraviolet light through a mask that contains the pattern of interest, and treating the surface with a developer solution that dissolves only the exposed regions of photoresist (Fig. 4). This process leaves photoresist in previously unexposed areas of the substrate. The exposed areas of substrate can be chemically modified for attaching proteins, etc., or can be treated with hydrofluoric acid to etch the material. The etching time controls the depth of the channels created. Subsequently, the leftover photoresist is removed using an appropriate solvent, leaving a surface patterned with different molecules or grooves. A disadvantage of this method is that it uses chemicals that are toxic to cells, and generally harsh conditions that may denature proteins.

The etched surfaces produced by photolithography can be used to micromold various shapes in a polymer called poly(dimethylsiloxane) (PDMS). The PDMS cast faithfully reproduces the shape of the silicon or

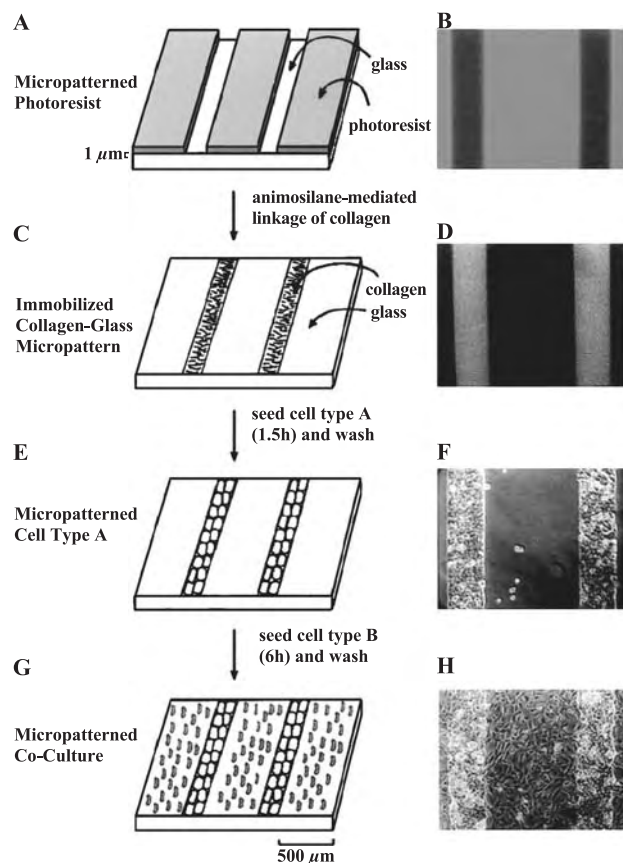

Fig. 4 Photolithographic technique for patterning cells on a glass surface. (Reproduced from Ref. [28] by permission of the publisher.)

glass mold to the μm scale, and can be used in various soft lithography techniques, including microstamping, microfluidic patterning, and stencil patterning. An infinite number of identical PDMS casts can be generated from a single master mold, which makes the technique very inexpensive. Soft lithography methods can be used on virtually any type of surface, including curved surfaces, owing to the flexibility of PDMS. In using these approaches, it is important that the base material be resistant to physisorption, or the selectivity of the adhesive groups may be significantly reduced *in vivo*. A successful approach to prevent adhesion to the base material is via covalent attachment of anti-adhesive factors on the remaining functional groups.

Porous three-dimensional matrices

Porous matrices with pore sizes in the range of 30–300 μm have been used to culture hepatocytes, and have been prepared by salt-leaching or freeze-drying techniques. The first method involves adding water-soluble crystals (e.g., NaCl) of size range similar to the desired pores in the melted base polymer

material. After solidification of the polymer, the salt crystals in the resulting solid are dissolved by exposure to aqueous solutions, leaving a pore in the place of every crystal. An alternative approach is to use supercritical carbon dioxide to create pores by the induction of microbubble formation within the polymer. The freeze-drying technique is based on the general principle that when freezing a solution, the solvent forms pure solid crystals while all solute materials are concentrated in the remaining unfrozen fraction. During the subsequent drying process, the solid crystals evaporate and leave pores. The morphology of the solid crystals is dependent on the physicochemical properties of the solution, the temperature gradient at the liquid–solid interface, and the velocity of that interface. Furthermore, the solid crystals tend to orient in the direction of the temperature gradient, so that the direction of the pores can be controlled as well. For practical applications, however, it is more typical to freeze solutions containing biomaterials in a bulk fashion. It is noteworthy that the rate of freezing and the temperature gradient are difficult to control and to maintain constant throughout the freezing process. Thus, porous materials made by this technique typically exhibit nonuniform pore sizes as one moves from the surface to the center.

Per unit volume, such porous materials have a large surface area; at least theoretically they can support the attachment of a large number of cells. This is in practice not the case because of the lack of efficient oxygen transport in porous matrices that lack a functional vascular system or other means to provide convective (i.e., flow-driven) delivery of nutrients. Pore size may affect whether the cells spread onto the substrate or invade the pores, in which case they tend to form three-dimensional aggregates. Such aggregates have been shown to express high levels of liver-specific function, presumably due to the formation of specialized cell–cell contacts among the hepatocytes.^[33]

Soluble Factors

Hepatocyte culture media

Certain hormonal additives have been found to be essential for the maintenance of long-term protein secretion and viability in cultured hepatocytes. For example, supplementation with corticosteroids such as hydrocortisone and dexamethasone is used to promote the expression of liver-specific functions in various hepatocyte culture configurations. Serum-free cultures do not benefit from the contribution of hormones and other metabolites found in the serum, and have more requirements in this respect. For example,

serum-free cultures of hepatocytes require exogenous insulin and proline.^[24] Insulin is an anabolic hormone, and proline is necessary for endogenous collagen synthesis. It is noteworthy that the expression of liver-specific genes in cultured liver slices is only slightly better in hormonally supplemented medium as opposed to basal medium. Further refinements in the composition of the ECM may thus relax some of the requirements for hormonal and other supplements in the culture medium.

Effect of plasma and blood

Rat hepatocytes that are seeded and maintained in standard hepatocyte culture medium and then exposed to either rat or human plasma become severely fatty within 24 hours, with a concomitant reduction in liver-specific functions. Plasma thus appears to be a rather inhospitable environment for hepatocytes, although it is clear that hepatocytes must be made to tolerate plasma for the concept of bioartificial liver to become reality. Supplementation of human anticoagulated plasma with hormones and amino acids (to bring those metabolites to levels similar to those found in standard hepatocyte culture medium) eliminates intracellular lipid accumulation and restores albumin and urea synthesis as well as P450-dependent detoxification.^[34,35] However, direct supplementation of plasma, especially with respect to the high levels of hormones used, is high in cost and potential health risk to the patient.

Hepatocytes are cultured in an artificial medium for several days prior to their use in a BAL, where they will contact plasma or blood from the patient. Culture media containing supraphysiological levels of hormones—and more specifically, insulin (used at about 10^4 times physiological concentration in standard hepatocyte culture medium)—predispose the hepatocytes to an abnormal response when subsequently exposed to plasma. In a recent study in our laboratory, we found that preconditioning hepatocytes in low insulin-containing medium reduced intracellular lipid accumulation during subsequent plasma exposure.^[36] Direct amino acid supplementation of plasma increased both urea and albumin secretion rates by the hepatocytes. We thus concluded that a combination of both preconditioning and plasma supplementation can be used to upregulate liver-specific functions of hepatocytes during plasma exposure.

BIOREACTORS

Transport Issues in Scale-up of Hepatocyte Cultures

In normal liver, no hepatocyte is farther than a few micrometers from circulating blood; thus, transport by

diffusion has to occur only over very short distances. Although oxygen diffusivity is an order of magnitude greater than that of many other small metabolites (e.g., glucose and amino acids), it has very low solubility in physiological fluids deprived of oxygen carriers. Thus, it is not possible to create large concentrations of gradients, which would provide the driving force for rapid oxygen transport over long distances. This, in addition to the fact that hepatocytes have a relatively high oxygen uptake rate, makes oxygen transport the most constraining parameter in the design of BAL devices.

Oxygen transport and uptake of hepatocytes have been extensively studied in the sandwich culture configuration in order to obtain the essential oxygen uptake parameters needed for the design of bioreactor configurations.^[37] The maximum oxygen uptake rate of cultured rat hepatocytes was measured to be about 13.5 pmol/s/ μg DNA, which is fairly stable after the first day in culture and continuing for up to 2 weeks. Interestingly, the oxygen uptake was about twice on the first day after cell seeding, presumably because of the increased energy required for cell attachment and spreading. Perhaps this should be taken into account when seeding hepatocytes into a BAL. Oxygen uptake was not sensitive to oxygen tension in the vicinity of the hepatocytes up to a lower limit of about 0.5 mm Hg. Below this, oxygen uptake decreased, suggesting that it becomes a limiting substrate for intracellular hepatocyte metabolism. Because oxygen is essential for hepatic adenosine triphosphate (ATP) synthesis, a reasonable design criterion would specify that oxygen tension remain above approximately 0.5 mm Hg.

Based on these parameters, it is possible to estimate oxygen concentration profiles in various bioreactor configurations based on a simple diffusion-reaction model that assumes that the process follows Michaelis–Menten kinetics. One can generally estimate that the maximum thickness of a static layer of aqueous medium on the surface of a confluent single hepatocyte layer is about 400 μm .^[38] Calculations of oxygen transport through hepatocyte aggregates suggest that even a relatively low density of cells (10^7 cells/ cm^3) cannot have a thickness exceeding about 300–500 μm . At cell densities of 10^8 cells/ cm^3 , which is similar to those found in normal liver, that thickness is only 100–200 μm .

Hollow-Fiber Systems

The hollow-fiber system has been the most widely used type of bioreactor in BAL development.^[39,40] The hollow-fiber cartridge consists of a shell traversed by a large number of small-diameter tubes. The cells may be placed within the fibers in the intracapillary space or

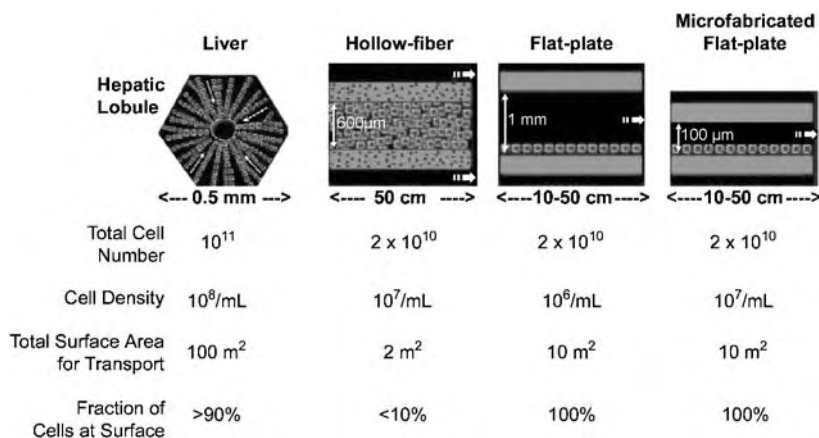

Fig. 5 Comparison among popular hepatocyte bioreactor configurations.

on the shell side in the extracapillary space. The compartment that does not contain the cells is generally perfused with culture medium or with the patient's plasma or blood. The fiber walls may provide the attaching surface for the cells or act as a barrier against the immune system of the host. Microcarriers have also been used as a means to establish an attachment surface for anchorage-dependent cells introduced in the shell side of hollow-fiber devices. Many studies have been conducted to determine optimal fiber dimensions, spacing, and reactor length based on oxygen transport considerations.^[41]

One difficulty with the hollow-fiber configuration is that interfiber distances (and consequently transport properties within the shell space) are not well controlled. Thus, it may be advantageous to place cells in the lumen of small fibers because the diffusional distance between the shell (where the nutrient supply would be) and the cells is essentially equal to the fiber diameter. In one configuration, hepatocytes have been suspended in a collagen solution and injected into the lumen of fibers where the collagen is allowed to gel. Contraction of the collagen lattice by the cells even creates a void in the intraluminal space, which can be perfused with hormonal supplements, etc., to enhance the cells' viability and function while the patient's plasma flows on the shell side. Because of the relatively large diameter of the fibers used as well as transport limitations associated with the fiber wall, these systems have been prone to substrate transport limitations. To improve oxygen delivery, additional fibers that carry oxygen straight into the device have been used.^[29,42]

Parallel Plate Systems

An alternative bioreactor configuration is based on a flat surface geometry^[37] where it is easier to control internal flow distribution and ensure that all cells are adequately perfused. The main drawback to this

configuration is that it is difficult to build a system that contains sufficient cell concentration (Fig. 5). For example, a 1 mm channel height would result in a 10-liter reactor to support 20×10^9 hepatocytes cultured on a surface 10 m^2 in area. For a liver failure patient who is probably hemodynamically unstable, it is generally accepted that the priming volume of the system not exceed 1 liter.

The volume of the device in the flat-plate geometry can be decreased by reducing the channel height (Fig. 5). However, this forces the fluid to move through a smaller gap, which rapidly increases the drag force (shear stress) imparted by the flow to the cells. Recent data suggest that hepatocyte function decreases significantly at shear stresses $>5 \text{ dy/cm}^2$.^[37] To reduce the deleterious effects of high shear, it may be possible to use grooved surfaces, wherein cells lodge and are less exposed to shear stress, allowing for faster flow without causing cell damage.

In an attempt to provide adequate oxygenation to cells and to protect them from shear in perfused bioreactors, gas-permeable membranes and membranes separating cells from plasma have been incorporated into the flat-plate geometry. A flat-plate microchannel bioreactor wherein cells directly contact the circulating medium has been developed.^[37] The channel is closed by a gas-permeable membrane on one surface, which decouples oxygen transport from the flow rate in the device. Comparing this with a similar flat-plate design wherein a nonpermeable glass surface is substituted to the membrane, internal membrane oxygenation removed the oxygen limitations that occur at low volumetric flow rates.

Monitoring the Performance of Bioartificial Livers

The performance of BALs is often assessed based on clinical parameters such as survival, grade of

encephalopathy, and blood and urine chemistry values. Because these parameters can vary from one patient to another depending on the severity of the disease, it is worthwhile to assess BAL function through other methods. Further insight into the function of the BAL can be obtained by measuring the change in metabolite levels across the BAL, including oxygen, CO₂, ammonia, urea, amino acids, and ketone bodies.

An enhanced perspective of metabolism and cellular function can be obtained with a mathematical modeling framework that considers the stoichiometric constraints of the intracellular reaction network of the cells in the BAL. One such methodology that is especially useful for the analysis of the metabolic function of organs and tissues is metabolic flux analysis. Metabolic flux analysis refers to the calculation of intracellular rates of metabolic reactions using steady-state metabolite balance models applied to measured rates of uptake and release of extracellular metabolites. This approach has been extensively used to study and improve strains of microorganisms (bacteria and yeasts) of significance in biotechnology, and has more recently been applied to mammalian cell systems, including perfused liver.^[43] Metabolic flux analysis, once validated for the particular case under study, is potentially very useful as it is noninvasive and cost effective.

CONCLUSION

The extracorporeal bioartificial liver is a promising technology for the treatment of liver failure, but significant technical challenges remain before systems with sufficient processing capacity and of manageable size can be developed. Most efforts to date have focused on device design and construction, and more recently on the development of methods to generate a continuous supply of human hepatocyte cell lines. New designs are not yet able to stably sustain the large cell populations needed for therapeutic purposes, and concerns about the safety of transformed cell lines remain. On the other hand, there have been fewer efforts to improve the specific functional capacity of the hepatocytes used in bioartificial livers. Increasing the efficiency of the cellular component of bioartificial livers would greatly facilitate their design. The functional capacity of cells used in bioartificial livers may be improved on at least three different levels: 1) by altering the internal machinery of individual cells to upregulate critical functions; 2) by judiciously controlling the spatial distribution of multiple cell populations with different specializations to emulate the organization of the liver acinus; and 3) by optimizing the overall treatment protocol, including the interval, duration, and number of treatment sessions.

INTRODUCTION

Artificial lungs currently used or in development are medical devices designed to take over or supplement the respiratory function of the lung, which is to oxygenate the blood and remove carbon dioxide. Current artificial lungs are also known as blood oxygenators and are simple passive modules composed of bundles of hollow fiber membranes through which blood is pumped. Blood oxygenators are used routinely in cardiopulmonary bypass for open-heart surgical procedures. Much less prevalent is the use of artificial lungs in treating respiratory insufficiencies or failures, in applications generally known as Extracorporeal Membrane Oxygenation (ECMO) or Extracorporeal Life Support (ECLS). However, the growing incidence of lung disease associated with our aging population, along with advances in biomaterials, has spurred significant recent development work toward next-generation artificial lungs that could be used to successfully treat patients with a variety of respiratory failures.

Acute and chronic diseases of the lung remain major healthcare problems. Each year nearly 350,000 Americans die of some form of lung disease.^[1] Overall, lung disease is America's number-three killer and is responsible for one in seven deaths. Adult respiratory distress syndrome (ARDS), only one form of acute lung failure, afflicts approximately 150,000 patients every year in the United States,^[2] and despite advances in critical care medicine, ARDS mortality remains between 40% and 50%.^[3,4] Most lung disease is chronic, and an estimated 30 million Americans are now living with chronic lung disease. Chronic obstructive pulmonary disease (COPD) includes emphysema and chronic bronchitis and afflicts over 16 million adults in the United States annually.^[5] COPD is the fourth leading cause of death and the second most common disability. Each year nearly 400,000 COPD patients will be hospitalized with acute exacerbations of their chronic condition, a rate that has risen nearly threefold in the last decade.^[6] Respiratory support for these patients is most often

maintained using mechanical ventilation, and although adequate gas exchange may be achieved, ventilatory support can lead to barotrauma, volutrauma, and other iatrogenic injuries, further exacerbating the acute respiratory insufficiency in many patients.^[7,8] Unlike mechanical ventilation, artificial lungs provide respiratory support independent of the lungs and allow a reversibly injured lung to rest and heal, thus offering the promise of improved treatment for acute respiratory insufficiencies or an effective bridge-to-lung transplant for chronic respiratory disease. Artificial lungs for longer-term respiratory support are likely far away, awaiting significant improvements in biomaterials and more efficient gas exchange strategies incorporated into their designs. Currently, lung transplantation remains the best treatment for chronic lung failures.

BACKGROUND

The natural lung represents a remarkable organ for gas exchange, and developing an artificial lung that approaches the gas exchange prowess of the natural lung is a significant engineering challenge. The alveoli of the lung, the tiny gas sacs at the termini of all the branching airways of the lung, offer intimate contact between inspired gas and blood flowing through capillaries in the lung (Fig. 1). The O₂ and CO₂ diffusing capacities of the lungs are proportional to the gas exchange area of the alveolar-capillary membrane and to the inverse of the diffusion distance across the alveolar-capillary membrane into blood.^[9] The substantial gas exchange capacity of the lung stems from an alveolar-capillary area comparable to a tennis court surface, 100–150 m², packaged compactly with a high surface area to blood volume ratio of approximately 300 cm⁻¹^[10] and a diffusion distance between gas and blood phases of no more than about 1–2 μm.^[11] The natural lung can provide gas exchange ranging from resting levels for both O₂ and CO₂ (about 200–250 ml/min in average adults) to 10–20 times that under exercise conditions,^[12] and it does so

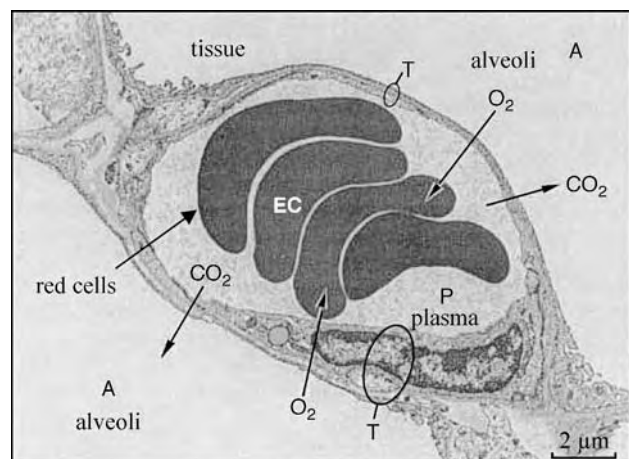

Fig. 1 The alveolar-capillary membrane in the natural lung showing intimate contact between inspired gas and blood in the lung. (Reprinted with written permission from Ref. [11], page 342, by Ewald R. Weibel/Harvard University Press.)

using room air as its oxygen supply gas. In contrast, current hollow fiber blood oxygenators, as used in cardiopulmonary bypass, have membrane areas ranging from 1 to 4 m² that are packaged much less compactly than in the natural lung, with a surface area to blood volume ratio 10 times less than in the natural lung (Fig. 2). The effective distance that gas diffuses between blood and gas flow pathways in artificial lungs is approximately 10–30 μm, an order of magnitude greater than in the natural lung.^[13] Thus, even with using 100% oxygen gas, artificial lungs currently used or under development aim at gas exchange levels that can support *resting* metabolic needs in patients. Artificial lungs that will allow patients any significant level of increased metabolic activity are not on the immediate horizon.

Fig. 2 Comparison of gas exchange parameters of the natural lung and current artificial lungs or blood oxygenators.

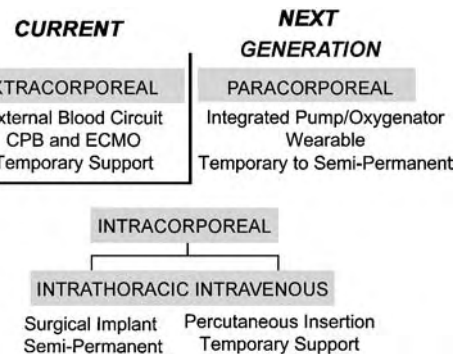

Fig. 3 Classification of artificial lung technology.

This article reviews artificial lung technology in terms of basic operational principles and present-day applications of standard blood oxygenators in cardiopulmonary bypass and ECMO/ECLS. Artificial lungs can be generally classified as extracorporeal, paracorporeal, intravascular, or intrathoracic (Fig. 3). The blood oxygenators used in cardiopulmonary bypass and ECMO/ECLS are extracorporeal artificial lungs incorporated into pump-containing external blood circuits. The companion article to this one (see Lung, Artificial: Current Research and Future Directions) will review research and development work on next-generation paracorporeal, intravascular, and intrathoracic artificial lungs. This review will not cover the interesting and significant work on past artificial lungs, devices which are no longer in use or in development, such as bubble oxygenators, disc-type oxygenators, or even the early work based on hollow fiber membranes. For information pertaining to these earlier efforts in artificial lung development, the interested reader is referred to several previous comprehensive review articles.^[13–15]

BASIC PRINCIPLES OF OPERATION

Hollow fiber membranes form the basic gas exchange units of contemporary artificial lungs and are small polymer tubes with microporous walls of 20 to 50 μm thickness and with outer diameters from 200 to 400 μm (Fig. 4). The wall pores have characteristic sizes typically below about 0.1 μm, and the porosity or volume fraction of the fiber wall can vary from about 30% to 50%.^[16] Hollow fiber membranes for artificial lungs are made from hydrophobic polymers (often polypropylene), so that the membrane wall pores remain gas-filled and respiratory gases can diffuse readily across it. In most artificial lung applications, an oxygen (O₂) “sweep gas” flows through the inside lumens of the hollow fibers, while blood flows outside the hollow fibers through the interstitial spaces in the hollow fiber bundle. Oxygen diffuses down its concentration gradient across

Fig. 4 Scanning electron micrograph of microporous hollow fiber membranes used in artificial lungs. The walls of the fibers (right) contain submicron pores where respiratory gases diffuse.

the fiber wall into blood, while carbon dioxide (CO_2) diffuses down its concentration gradient from the blood into the sweep gas flowing through the fibers and is removed when the sweep gas exits the device.

Determinants of Gas Exchange

The gas exchange permeance, K , of an artificial lung represents an overall mass transfer coefficient for either O_2 or CO_2 exchange.^[9] The overall O_2 exchange rate, \dot{V}_{O_2} , is related to the O_2 permeance according to

$$\dot{V}_{\text{O}_2} = K_{\text{O}_2} A (P_{\text{O}_{2g}} - P_{\text{O}_{2b}}) \quad (1)$$

where $P_{\text{O}_{2g}}$ and $P_{\text{O}_{2b}}$ are the average O_2 partial pressures in the sweep gas and blood phases, respectively, flowing through the artificial lung, and A is the total membrane area of the hollow fiber bundle. The gas exchange permeance for CO_2 removal can be related to the CO_2 exchange rate similarly using

$$\dot{V}_{\text{CO}_2} = K_{\text{CO}_2} A (P_{\text{CO}_{2b}} - P_{\text{CO}_{2g}}) \quad (2)$$

with the driving force for CO_2 exchange being the P_{CO_2} difference between blood and sweep gas. In artificial lungs the overall permeances for O_2 and CO_2 gas exchange are dictated by the diffusional resistances encountered as these gases diffuse between the sweep gas and blood flow pathways. Permeance is the inverse of a diffusional resistance, and the overall transfer resistance, in an artificial lung device has two principal components:

$$\frac{1}{K} = \frac{1}{K_m} + \frac{1}{K_b} \quad (3)$$

where K_m and K_b are the membrane and blood-side permeances for each gas (O_2 and CO_2). The term $1/K_m$

Fig. 5 Illustration of principal determinants of gas exchange in artificial lungs. $P_{\text{CO}_{2w}}$ represents the partial pressure of CO_2 at the membrane wall.

represents a diffusional resistance for the membrane itself, while $1/K_b$ represents a resistance for gas diffusing between the membrane and the flowing blood stream.

Figure 5 illustrates the membrane and blood-side diffusional resistances to gas exchange in artificial lungs by showing the general gradient in CO_2 partial pressure from the sweep gas to the blood pathway. Transfer resistance within the sweep gas pathway is negligible. Most of the diffusional resistance resides within a blood-side diffusional boundary layer, and secondarily within the membrane itself. The blood-side and membrane permeances dictate overall gas exchange in artificial lungs and represent serial transport processes whose resistances add directly to determine overall resistance, as in Eq. 3. As serial “resistors” the smallest permeance or largest resistance controls overall gas exchange in an artificial lung.

Membrane Permeance

Most artificial lungs, including standard blood oxygenators, use microporous hollow fiber membranes. Microporous hollow fibers have fixed submicron pores within the wall that are contiguous from outer to inner lumen, and gas exchange occurs by diffusion through these gas-filled pores. The polymer used does not dictate gas exchange through the membrane as much as the pore characteristics and the fiber wall porosity. In artificial lungs the hydrophobic nature of the polymers (e.g., polypropylene) used to make the fiber membranes prevents intrusion of blood plasma into the fiber pores under normal conditions. Most microporous hollow fiber membranes for artificial lungs are manufactured by Celgard (Charlotte, NC), Membrana (Germany), and Mitsubishi Rayon (Japan). Table 1 summarizes the properties of several commercially

Table 1 Properties of commercially available hollow fiber membranes

Fiber	OD/ID (microns)	Wall thickness (microns)	Pore size (width × length) (microns)	Porosity
Celgard x30–240	300/244	28	0.03 × 0.2	40%
Mitsubishi KPF-190	245/200	22	0.04 (width)	40–55%
Membrana PP 50/280	380/280	50	0.2	N/A
DIC	255/205	25	Nonporous coated	Nonporous coated

available microporous hollow fibers commonly used in artificial lung devices.

The membrane diffusional resistance of a microporous hollow fiber depends on the permeance, K_m , of the fiber membrane. Membrane permeance is not usually reported by fiber manufacturers because its effect on the overall gas exchange performance of artificial lungs is negligible compared to blood-side permeance. The K_m for microporous hollow fiber membranes can be estimated theoretically using simple diffusion principles, and doing so predicts membrane permeances of approximately 2×10^{-2} ml/cm²/s/cm Hg for O₂ and CO₂ gases in the Celgard X30-240 hollow fiber membrane.^[17] The K_m of microporous hollow fibers can be measured using gas–gas test systems (i.e., with the fibers immersed in a gas rather than a liquid), so that all the transfer resistance is associated with the membrane. Kamo et al.^[18] measured the oxygen permeance of the Mitsubishi KPF fiber as $K_m = 6.7 \times 10^{-2}$ ml/cm²/s/cm Hg. Lund^[16] determined K_m values of 1.72×10^{-2} and 1.47×10^{-2} ml/cm²/s/cm Hg for O₂ and CO₂, respectively, at room temperature for the Celgard X30-240 fiber. A membrane permeance of 10^{-2} ml/cm²/s/cm Hg for microporous hollow fibers represents a very large gas exchange capacity. For example, if membrane permeance dictated overall gas exchange, an artificial lung with 2 m² membrane area perfused with blood at a PCO₂ of 50 mm Hg would remove CO₂ at a theoretical rate of 60 liters per minute! The gas exchange rate of artificial lungs is much smaller than this because overall gas exchange is dictated by diffusional boundary layers that arise on fiber surfaces in the flowing blood stream. In practice, therefore, $K \cong K_b$ unless hollow fibers are coated with nonporous polymers (true membranes) to resist plasma wetting, as will now be described.

Membrane permeance can play an important role when coated or composite hollow fiber membranes are used to prevent plasma wetting in artificial lungs, a process in which blood plasma infiltrates the microporous walls of hollow fibers. Plasma wetting is a common problem when extracorporeal oxygenators are used in extended respiratory support and can lead to device failure within days.^[19,20] Plasma wetting results primarily from phospholipids, lipoproteins

and/or proteins in blood^[19] that adsorb onto the fiber polymer surfaces at the plasma interface, rendering the interface hydrophilic and allowing for wetting of the pores by either partial or complete plasma infiltration. Plasma infiltration markedly diminishes the membrane permeance, K_m , because relatively rapid gas phase diffusion is replaced by diffusion through stagnant plasma within fiber pores. The membrane permeance for a completely wetted hollow fiber is in the range of 10^{-7} ml/cm²/s/cm Hg for O₂, a 100,000-fold decrease compared with K_m for gas-filled pores.^[17] Thus even partial plasma infiltration into fiber membranes can significantly reduce membrane permeance and degrade artificial lung performance.

Composite hollow fibers incorporate a thin nonporous polymer layer as a true membrane or “skin” on the microporous fiber surface (Fig. 6). The true membrane blocks infiltration of plasma into pores and is a key functional requirement of artificial lungs for longer-term respiratory support. Composite hollow fiber membranes^[18,21,22] are made either by coating an existing microporous fiber with a thin nonporous polymer (a true composite hollow fiber) or by

**Fig. 6** SEMs of uncoated and coated hollow fiber membrane surfaces.

modifying the fabrication of the microporous fiber itself to seal off pores at the surface (an asymmetric hollow fiber). The nonporous polymer skin that prevents plasma wetting also diminishes membrane permeance because a nonporous polymer can present an impediment to gas diffusion. Indeed, the membrane permeance of a composite hollow fiber is essentially dominated by the nonporous polymer layer and is given by

$$K_m = \frac{\alpha_p D_p}{\delta} = \frac{P_m}{\delta} \quad (4)$$

where α_p and D_p are the solubility and diffusivity of the gas within the nonporous polymer and δ is the polymer layer thickness. Polymer manufacturers usually report the *product* of polymer solubility and diffusivity, the polymer permeability (P_m) to specific gases. The design of composite hollow fiber membranes for artificial lungs requires a K_m that does not significantly reduce overall gas exchange. As an example, if coated or composite fibers are to exert no more than a 5% reduction in overall gas exchange for a particular artificial lung design, then K_m needs to be greater than 20 times K_b . For this reason, composite hollow fiber membranes for artificial lungs require nonporous polymers with relatively high gas permeabilities (~ 100 Barriers or greater^a) that can be coated in a continuous layer of 1 μm thickness or less on microporous hollow fiber surfaces.^[21]

Diffusional Boundary Layers

The blood-side permeance of an artificial lung, K_b , accounts for gas movement through the diffusional boundary layers that exist adjacent to the fiber surfaces, where fluid velocity is reduced by drag forces. Gas molecules traverse the boundary layer by molecular diffusion before being exposed to sufficient convection by the blood flowing past fiber surfaces. The blood-side permeance can be expressed as

$$K_b = \frac{\alpha_b D_b}{\delta_{bl}} \quad (5)$$

where α_b and D_b are the effective solubility and diffusion coefficient of the diffusing gas in blood and δ_{bl} is an average boundary layer thickness. For O_2 and CO_2 the effective solubility accounts for increased solubility due to hemoglobin binding (for O_2) or carriage as bicarbonate ion (for CO_2).

^aA Barrier is a common unit of polymer permeability and is equal to 10^{-10} ml-cm/cm²/s/cm Hg.

The boundary layer thickness, δ_{bl} , depends on the local interaction between diffusional and velocity fields in the flowing blood phase subjacent to the fiber surfaces of the artificial lung. The nature of these diffusional boundary layers is complex, but the simple boundary layer paradigm of laminar flow past a flat membrane surface can be instructive (Fig. 7). Boundary layer thickness on a flat surface grows with distance along the surface in the direction of flow according to

$$\delta_{bl}(x) \approx \left(\frac{\nu}{D_b}\right)^{1/6} \sqrt{\frac{D_b}{V}} x \quad (6)$$

where ν is the kinematic viscosity, D_b is the species diffusion coefficient, and V is the bulk flow velocity past the surface.^[23] An important concept is that boundary layer thickness can be decreased by increasing the blood flow velocity past the fiber surfaces, and the resulting increase in gas exchange permeance (see Eqs. 5 and 6) varies as the square root of flow velocity. Furthermore, because boundary layers grow along the fiber surface, permeance and gas exchange are less with *longitudinal* flow, parallel to the fiber axes, than with *transverse* or *cross* flow, perpendicular to the fiber axes. The simple boundary layer paradigm predicts that K_b for transverse versus longitudinal flow would be $K_b^{tran}/K_b^{long} \approx \sqrt{L/d}$, where L and d are fiber length and diameter, respectively. Since L/d in hollow fiber bundles can vary from 100 to 1000, an appreciable mass transfer benefit exists for transverse compared to parallel blood flow through hollow fiber bundles.

Mass Transfer Correlations

The blood-side permeability, K_b , for artificial lungs can be estimated from mass transfer correlations obtained for flow through bundles of hollow fiber membranes.

Fig. 7 Classical diffusional boundary layer on a flat surface. P_w represents the species partial pressure at the membrane wall.

Convective mass transfer correlations have the general form^[24]

$$Sh = aRe^bSc^{1/3} \quad (7)$$

where Sh is the Sherwood number, $Sh = K_b d_h / \alpha D$; Re is the Reynolds number, $Re = V d_h / \nu$; and Sc is the Schmidt number, $Sc = \nu / D$. These correlations involve the hydraulic diameter, d_h , of the fiber bed; the average interstitial blood flow velocity, V ; the kinematic viscosity of blood, ν ; and the solubility, α , and diffusivity of the diffusing species in blood, D . Several studies^[25–29] have reported mass transfer correlations in water and blood for steady flow through various module geometries of packed hollow fiber membranes, over a range of bundle porosities and Reynolds numbers. The a and b parameters in these mass transfer correlations depend on the fabricated fiber module, its porosity, and the flow patterns through the bundle. For example, Yang and Cussler^[29] reported the correlation $Sh = 1.38Re^{0.34}Sc^{0.33}$ for flow through a 750-fiber bundle with a porosity of $\epsilon = 0.3$, and the correlation $Sh = 1.9Re^{0.4}Sc^{0.33}$ for cross flow through a 72-fiber bundle with a much greater porosity of $\epsilon = 0.93$. In the design of an implantable artificial lung, Vaslef et al.^[30] used a correlation of $Sh = 0.52Re^{0.29}Sc^{0.33}$ based on measurements in a Sarns Membrane Oxygenator. Hewitt and Federspiel^[24] averaged appropriate cross-flow correlations from the literature and used $Sh = 0.524Re^{0.523}Sc^{0.33}$ for model studies of gas exchange in an intravascular artificial lung. More complex correlations^[31] were proposed for blood flowing through modules of cross-laid fiber mats oriented at various angles to the direction of blood flow.

Vaslef et al.^[27] validated a useful method for using Sh versus Re correlations to relate O_2 exchange for water flow through an oxygenator bundle to that which would arise for blood flow through the same bundle. A dimensionless mass transfer correlation, $Sh = aRe^bSc^{1/3}$, determined for a fiber bundle applies to blood and water alike (with same a and b constants), but the diffusivity in Sc number must appropriately account for hemoglobin binding of O_2 in blood. The Schmidt number involves an effective diffusivity dependent on the slope of the oxyhemoglobin dissociation curve:^[24]

$$D_b^{eff} = \frac{D_b}{1 + C_{Hb} \frac{dS}{dP_{O_2}} \alpha_b^{-1}} \quad (8)$$

where C_{Hb} is hemoglobin concentration and S is hemoglobin saturation, while the Sherwood number involves the ordinary diffusivity of oxygen in blood, D_b . The permeance in blood depends on the blood P_{O_2} within the fiber bundle and can be 2–3 times that in

water near the steep portion of the oxyhemoglobin dissociation curve.^[24] The prediction of O_2 exchange in blood from water measurements worked well for several standard blood oxygenators,^[27] and while a similar approach could be developed for relating CO_2 exchange in blood and water, none has yet to be specifically proposed or validated.

THE BLOOD OXYGENATOR

Artificial lungs that are used currently are membrane blood oxygenators consisting of either microporous polypropylene hollow fiber membranes or, as in one design, silicone sheets. The general anatomy of the oxygenator is similar between the two types of devices despite the differing gas exchange surfaces. Blood enters the oxygenator through an inlet port and flows either along the outside of the hollow fibers or the outside of the silicone sheet. The blood is then collected in a manifolded region, flows through a heat exchanger, and then exits the device through an outlet port. The gas, which can be pure oxygen or a mixture of oxygen and room air, enters the oxygenator through a gas inlet port, flows through the inside of the hollow fibers/silicone sheets, and exits the device via an outlet port (Fig. 8). The key design considerations in blood oxygenators include minimizing the resistance to blood flow, reducing the priming volume, ensuring easy debubbling at setup, and minimizing blood activation and thrombogenicity.

Most current blood oxygenators (Fig. 9) have fiber membranes with outer diameters of 200–400 μm and wall thickness of 20–50 μm , total membrane surface area of 2–4 m^2 , and blood priming volume of 135–340 ml.^[17] The hollow fibers are wound or matted

Fig. 8 A modern artificial lung showing the various ports for blood and gas flows. The heat exchanger warms the blood using water at 37°C.

Fig. 9 Picture of currently used oxygenators. From left to right: Capiiox[®] SX from Terumo Cardiovascular Systems, Quadrox[®] from Jostra, and Affinity[®] from Medtronic.

within a hard plastic outer shell to produce fiber packing densities in the bundle of 40–60%, and the arrangement of the fiber bundle and blood flow patterns differ between devices.^[32] For example, fibers are helically wound in the Medtronic Affinity NT oxygenator. Blood enters the device through a central core channel and is then distributed radially through the fiber bundle. Fibers in the Jostra Quadrox oxygenator are aligned so that blood flow is perpendicular to the gas pathways. Hollow fiber oxygenators with intraluminal blood flow have been designed but are rarely used due to a generally unfavorable high resistance to blood flow.

The fabrication or wrapping of the fiber bundle in a blood oxygenator can be important as the geometry obtained impacts diffusional boundary layers, secondary flows, and gas exchange efficiency.^[33] A blood oxygenator is often characterized by its rated flow as a measure of the gas exchange capacity of the device. Rated flow (see Fig. 10) is the flow rate through the oxygenator at which an inlet blood saturation of 70% can be oxygenated to an outlet blood saturation of 95%.^[33] The rated flow can range from 1–1.8 l/min for a neonatal oxygenator and up to 7 l/min for an adult oxygenator (Table 2). A greater rated flow indicates an oxygenator with increased gas exchange capacity.

Silicone membrane oxygenators are often used in extracorporeal membrane oxygenation for respiratory

support since plasma leakage does not occur as it does in microporous hollow fiber oxygenators. Kolobow^[33] is generally credited with developing the first spiral-wound silicone membrane oxygenators in 1963. The oxygenator contains two silicone sheets sealed around the edges, which are wound around a polycarbonate core. Gas flows within the sealed sheets and blood flows countercurrently between the spiral wraps. The surface area of silicone membrane oxygenators ranges from 0.4 to 4.5 m² and the priming volumes range from 90 to 665 ml.^[33] Because diffusion occurs across a nonporous silicone sheet, the thickness of these sheets was reduced to 100–200 μm. Nevertheless, the gas exchange efficiency of silicone oxygenators is substantially below that of hollow fiber oxygenators. The AVECOR 0800 silicone oxygenator (a descendant of the Kolobow silicone oxygenator) has an O₂ transfer efficiency of 88 ml/min/m² compared to 150 ml/min/m² for the Affinity hollow fiber device.^[33] The resistance to blood flow is also higher in silicone sheet oxygenators compared with hollow fiber oxygenators, and debubbling the sheet oxygenators can be more difficult.

Oxygenators in Cardiopulmonary Bypass

Cardiopulmonary bypass (CPB) using an external flow circuit incorporating a blood oxygenator is used in

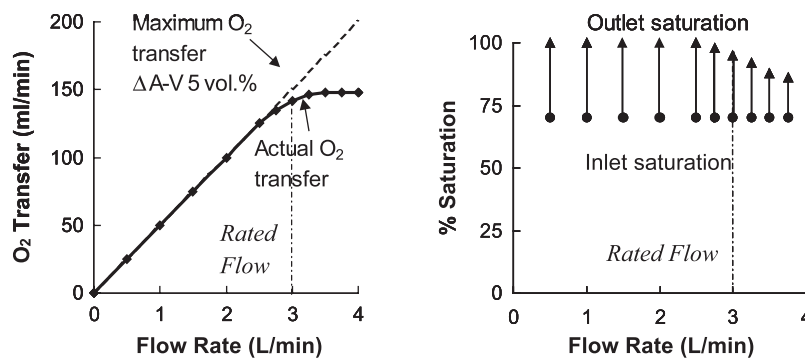

Fig. 10 The rated flow of a device is the maximum flow rate at which blood leaves the oxygenator at least 95% saturated. The rated flow depicted here is 3 l/min. (Adapted from Ref. [44].)

Table 2 Properties of blood oxygenators currently used clinically

	Membrane material ^a	Surface area (m ²)	Priming volume (ml)	Blood flow rate (l/min)	Rated blood flow (l/min)	Oxygen transfer (ml/min)

open-heart procedures to take over the function of both the heart and the lungs. Over 700,000 open-heart surgeries, including valve replacements, coronary artery bypass grafting, and heart transplants, were performed in the United States in 1999.^[34] In cardiopulmonary bypass, blood is drained by gravity from the inferior/superior vena cava or the right atrium into a venous reservoir and is then pumped through the oxygenator by either a roller or centrifugal pump back into the ascending aorta (Fig. 11). Blood flow during CBP is kept low (2–2.4 l/m²/min) to minimize bleeding.^[35] A heat exchanger is required to cool and rewarm the patient and is typically incorporated into the oxygenator. Oxygen, or a mixture of oxygen and carbon dioxide, is fed through flowmeters and blenders into the oxygenator at flow rates of 5–10 l/min, which is 2–3 times the flow rate of blood.^[36] The oxygenator must be capable of transferring up to 250 ml/min of oxygen and 200 ml/min of carbon dioxide during cardiopulmonary bypass in order to meet the

**Fig. 11** Schematic of cardiovascular bypass circuit.

metabolic needs of the patient.^[36] The bypass circuit also includes suction devices that are used to maintain a blood-free surgical field. The suctioned blood is collected and filtered in a cardiotomy reservoir and is then pumped into the venous reservoir. Other components of the bypass circuit include pressure and temperature monitors, sampling ports, filters, tubing, and cannulae.

A significant complication associated with oxygenators in cardiopulmonary bypass is activation of the coagulation cascades and thrombosis. Patients are anticoagulated with heparin to achieve an activated clotting time (ACT) of 480 seconds to prevent thrombosis-related oxygenator failures.^[37] Thrombus formation in the oxygenator can cause an increase in resistance to blood flow and a decrease in gas transfer. Thus, to reduce the risk of clot formation, oxygenators are designed to minimize regions of blood flow stasis, which typically promote thrombus formation. The high level of anticoagulation, however, can lead to an increased risk of bleeding. Oxygenators and the entire bypass circuit are now being coated with heparin in order to prevent clotting in the circuit while reducing the required amount of systemic anticoagulation. There are several different heparin coatings currently available on the market.^[38] The Carmeda Bioactive Surface has been used for more than a decade and utilizes a covalent end-point attachment of heparin to the surface. The BioLine Coating by Jostra first coats the surface with polypeptides and then with a low-molecular-weight heparin, Liquemin. The coating is available in two types, one for CBP and one for long-term use in extracorporeal membrane oxygenation. Other more recent coatings include AOThel by Artificial Organ Technology, Corline by Corline Systems AB, and the Trilium Bio-passive Surface by Avecor. Many studies have been performed on the efficacy of

the heparin coatings and the required level of systemic heparin with the coatings. Aldea et al.^[39] compared noncoated circuits and an ACT of 480 seconds with coated circuits and an ACT of 280 seconds. The heparin coating resulted in a 34% decrease in the need for blood products, 13.8% less bleeding, 43.6% shorter intubation time, 41.7% less time in the intensive care unit, and 17.8% less time in the hospital compared with noncoated circuits.

Extracorporeal Membrane Oxygenation

Extracorporeal membrane oxygenation (ECMO) uses blood oxygenators in pump-driven external circuits to provide respiratory support and lung rest and recovery for prolonged periods of time (1–30 days).^[40] ECMO is used in patients with severe lung failure who fail traditional mechanical ventilation. Similar to CPB circuits, the ECMO circuit contains a pump, a heat exchanger, and an oxygenator, but unlike CPB circuits, a venous reservoir and suctioning equipment is not used. In ECMO, the patient is continuously anticoagulated with heparin to achieve an ACT of 160–240 seconds, much less than that found in CPB.^[41] The required blood flow in ECMO is 120 ml/kg/min for neonates, 75 ml/kg/min for pediatric, and 50 ml/kg/min for adults.^[33] Extracorporeal membrane oxygenation is used to treat neonatal, pediatric, and adult patients with lung failure, and the effectiveness of ECMO differs in each of these groups. ECMO is most commonly used in neonates with a survival rate of 80%.^[42] Indications for neonatal ECMO include meconium aspiration syndrome, respiratory distress syndrome, persistent fetal circulation, persistent pulmonary hypertension, and hyaline membrane disease.^[43] Pediatric and adult patients have lower survival rates of 53% and 41%, respectively.^[42] Indications for ECMO in pediatric or adult patients are viral, bacterial, or aspiration pneumonia and acute respiratory distress syndrome (ARDS), which can be caused by trauma, pneumonia, or sepsis.^[44]

Three different cannulation techniques can be used in ECMO, including venovenous, venoarterial, and arteriovenous, referring to the locations of the blood drainage and return sites. Venovenous ECMO drains and returns to the venous system, venoarterial ECMO drains from the venous system and returns into the arterial system, and arteriovenous ECMO is the opposite. Venovenous (VV) ECMO was established in the 1960s and 1970s and is now the most commonly used cannulation technique.^[33,45] VV ECMO has several different sites for cannulation including the internal jugular, saphenous, or femoral veins or the right atrium. In neonates, VV ECMO can use a single dual-lumen cannula or two cannulae. The single

double-lumen cannula is used in the jugular vein, and the septum offset produces a larger channel for venous inflow into the ECMO circuit. The cannula must be designed to reduce recirculation of returned blood directly back into the ECMO circuit. Cardiac output, pump flow rate, cannula position, and right atrium size are all factors that can affect recirculation. Single double-lumen cannulation cannot be used in pediatric and adult ECMO due to inadequate venous inflow into the circuit and also high levels of hemolysis, recirculation, and pressure with flow rates greater than 600 ml/min.^[45]

Venoarterial (VA) ECMO was the original cannulation technique used in ECMO and is indicated when cardiac support is required in addition to respiratory support. In contrast, VV ECMO provides no cardiac support and is not used in patients with cardiac arrest, arrhythmias, or myocardial failure.^[45] The disadvantages of VA ECMO include cannulation of a major artery, lack of pulmonary perfusion, decreased cardiac output due to a higher afterload, and increased risk of neurological events. VV ECMO has several advantages over VA ECMO including preserving pulsatility and avoiding the cannulation of a major artery. Neurological events can also be reduced since thromboemboli from the circuit travel to the lungs instead of the brain. VV ECMO also prevents ischemic injury to the lungs since the lungs remain perfused with blood, but blood flow must be carefully regulated in order to prevent an imbalance in the central venous system.^[45] Given its advantages compared to VA ECMO, several institutions are now using VV ECMO and comparing results with VA ECMO. Knight et al.^[46] found an increased survival rate of 91% with VV ECMO compared to 80% with VA ECMO in neonates. Zahraa et al.^[47] performed a retrospective study from 1986–1997 comparing VV and VA ECMO in pediatric patients and found a trend for improved survival with VV ECMO with survival rates of 60% and 56%, respectively.

The inflammatory and thrombogenic complications associated with cardiopulmonary bypass are exacerbated in ECMO due to the longer blood exposure to the extracorporeal circuit. As for CPB circuits, ECMO circuits and oxygenators are heparin-coated to help minimize systemic heparinization, decrease inflammatory responses, and prevent thrombosis. One complication of ECMO not seen in CPB is plasma wetting of hollow fiber membranes from the longer-term exposure of the ECMO oxygenator to blood. Plasma wetting decreases gas exchange, can occur quickly and unpredictably, and requires replacement of the oxygenator. Microporous hollow fiber membranes can be coated with thin siloxane layers to prevent plasma wetting and increase the biocompatibility.^[48–52] New polymer coatings are also being developed to resist

plasma leakage while attenuating the inflammatory response. Saito et al.^[52] coated CBP circuits with poly(2-methoxyethylacrylate) (PMEA) and compared the inflammatory response with that caused by uncoated circuits in swine. Protein adsorption was significantly less on the PMEA circuits compared with control ($0.3 \pm 0.03 \mu\text{g}/\text{cm}^2$ versus $3.42 \pm 0.04 \mu\text{g}/\text{cm}^2$). Peek et al.^[53] performed an initial clinical trial with the Medos Hilite 7000LT oxygenator, which uses a polymethyl pentene (PMP) asymmetric hollow fiber membrane, which was also coated with heparin. Additional studies are needed to fully evaluate the effectiveness of these new coated fiber oxygenators.

SUMMARY

Artificial lungs use bundles of microporous hollow fiber membranes made into modules designed to bring blood and gas phases in intimate contact separated by only the thin walls of the hollow fibers. This article reviewed the basic principles of gas exchange in hollow fiber-based artificial lungs. Artificial lungs used today are extracorporeal modules called blood oxygenators primarily employed for pulmonary support during open-heart surgical procedures involving cardiopulmonary bypass. To a much lesser degree, blood oxygenators are also used clinically to provide support to the failing lung in acute respiratory failure. Several research efforts are underway on the development of next-generation artificial lungs designed specifically for respiratory support of the failing lung either acutely or as a bridge to lung transplant in patients requiring chronic respiratory support. These efforts, reviewed in a companion article (see Lung, Artificial: Current Research and Future Directions), involve paracorporeal, intravascular, and intrathoracic devices. Approaches developed to specifically overcome limitations in gas exchange, biocompatibility, and other design factors of the present-day blood oxygenator are described in this article.

INTRODUCTION

Artificial lungs are medical devices designed to take over or supplement the respiratory function of the lung: oxygenating the blood and removing carbon dioxide. They are generally classified as extracorporeal, paracorporeal, intravascular, or intrathoracic devices (Fig. 1). The artificial lungs used clinically today are extracorporeal blood oxygenators, primarily used in operations requiring cardiopulmonary bypass, but also used less frequently for support of patients with respiratory failure. The growing incidence of lung disease associated with the aging population has spurred recent work toward next-generation artificial lungs that may be used to successfully treat patients with a variety of respiratory failures. Next-generation artificial lungs include 1) paracorporeal approaches (wearable devices that will be attached directly to patients); 2) intravascular approaches (respiratory catheters placed within the vena cava through a peripheral vein); and 3) intrathoracic approaches (devices that will be placed internally within the thoracic or abdominal cavities). Intravascular artificial lungs are aimed primarily at treatment of acute respiratory failures, whereas paracorporeal and intrathoracic artificial lungs are aimed primarily at bridge-to-transplant respiratory support because of the more invasive procedures required to implement them. This article reviews the current state of research on next-generation artificial lungs for support of patients with failing lungs. The basic operational principles of artificial lungs and the current clinical applications of standard blood oxygenators are reviewed in a companion article (*Lung, Artificial: Basic Principles and Current Applications*).

ARTERIOVENOUS CARBON DIOXIDE REMOVAL

Arteriovenous carbon dioxide removal (AVCO₂R) is more the development of a new respiratory support technique than a next-generation artificial lung device. AVCO₂R represents a simpler means of extracorporeal

respiratory support and involves a blood oxygenator (either a standard blood oxygenator or one developed specifically for the application) connected directly from the arterial to venous circulations in a paracorporeal approach, thus obviating the need for a blood pump and associated tubing in the extracorporeal circuit. The goal of AVCO₂R is to provide lung rest to patients suffering from acute respiratory distress syndrome (ARDS) or other acute lung failures^[1] by reducing the tidal volume, minute ventilation, and pressures associated with mechanical ventilation.^[2,3] The specific technique used in AVCO₂R consists of diverting blood flow through a femoral arterial cannula to a commercial blood oxygenator (as the artificial lung) and back to the patient through a femoral venous cannula (Fig. 2). The AVCO₂R circuit principally removes CO₂ before returning the blood back to the patient, but some oxygenation of the blood occurs as well. The flowrate is much lower than in typical extracorporeal membrane oxygenation (ECMO) circuits and is dictated by the arterial-to-venous pressure difference of the patient and the hydraulic resistance of the artificial lung. Although AVCO₂R eliminates the need for a mechanical blood pump, it ideally requires an oxygenator/artificial lung with a sufficiently low hydraulic resistance to ensure adequate blood flow from the arteriovenous pressure difference to remove a sufficient amount of CO₂.

Recent animal studies using healthy adult sheep have characterized the flowrate and gas exchange capabilities of an AVCO₂R system.^[4] The artificial lung used in the AVCO₂R application was a 2.5 m² Affinity™ blood oxygenator connected to the left carotid artery via an 18-Fr cannula and the left jugular vein via a 22-Fr cannula. Blood flowrates through the AVCO₂R circuit were 25–29% of cardiac output during the 6-hour study, with a pressure drop across the oxygenator of less than 10 mm Hg. Maximum CO₂ removal was approximately 100 ml/min, or 96% of total CO₂ production by the animal. Importantly, the study showed a decrease in minute

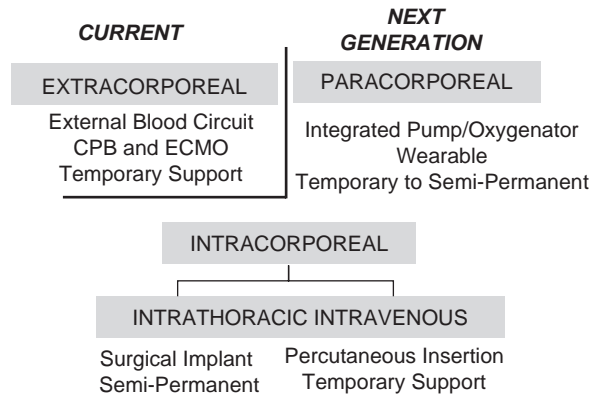

Fig. 1 Classification of artificial lung technology.

ventilation from approximately 10 l/min before AVCO₂R to 0.5 l/min, and peak inspiratory pressure also decreased from 41 cmH₂O to 20 cmH₂O in subsequent hours after initiation of the therapy. The effect of AVCO₂R blood flow on organ perfusion was investigated using colored microspheres in a conscious ovine model with the carotid-to-jugular arteriovenous circuit using the Affinity™ 2.5 m² oxygenator.^[5] AVCO₂R flow

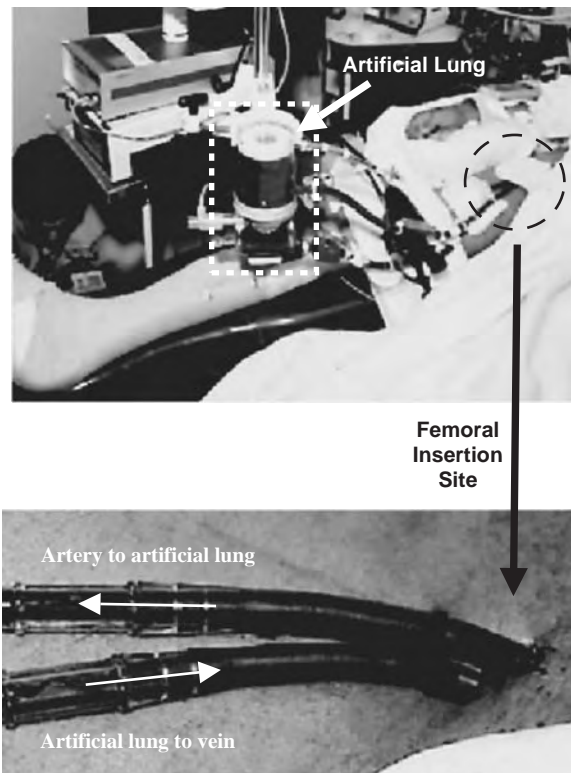

Fig. 2 This simple circuit consists of the inlet cannula, the artificial lung, and the return cannula to the patient. varied from 5–25% of baseline cardiac output and organ flow was measured using microsphere techniques. A 10–20% decrease in organ perfusion accompanied a 5% shunt, but organ perfusion did not decrease further with increased shunt flow through the AVCO₂R device. Hemodynamic parameters such as heart rate, mean arterial, and pulmonary arterial pressures remained unchanged throughout the study, indicating that blood shunting through the AVCO₂R system was well-tolerated by the animals.^[5]

A 7-day study of AVCO₂R in sheep using a smoke-inhalation injury model of severe respiratory failure showed gas exchange capabilities similar to those in previous AVCO₂R studies using the same Affinity™ blood oxygenator with no statistically significant changes in heart rate, cardiac output, mean arterial pressure, or pulmonary artery pressure.^[6] Increased survival among sheep managed with AVCO₂R versus ventilator-managed sheep has also been shown for this ARDS model.^[7] In the latter study, 18 sheep received an LD₅₀ severe smoke inhalation and a 40% third-degree burn on their external flanks. Animals were randomized to either a ventilator-managed sham group ($n=9$) or an AVCO₂R therapy group ($n=9$) and treated for 7 days. AVCO₂R allowed significant ventilator reductions in tidal volume, peak inspiratory pressure, minute ventilation, respiratory rate, and FIO₂ (Fig. 3). All AVCO₂R-managed animals survived the study, whereas only three of the ventilator-managed sheep survived the duration of the study.

Respiratory support with AVCO₂R has recently expanded into human clinical trials. In a pilot study of feasibility and safety, percutaneous AVCO₂R was

Fig. 3 Decreased ventilator parameters after instituting AVCO₂R in sheep with burn and smoke-inhalation-induced ARDS. This study lasted 7 days. TV: tidal volume; PIP: peak inspiratory pressure; MV: minute ventilation; RR: respiratory rate; FIO₂: fraction of inspired O₂.

studied in five patients suffering from severe ARDS and CO₂ retention who were unresponsive to standard mechanical ventilation protocols.^[8] AVCO₂R was initiated for 72 hours using the 2.5 m² Affinity™ blood oxygenator with 12- to 15-Fr venous and 10- to 12-Fr arterial cannulae inserted percutaneously into the femoral vein and artery, respectively. Average blood flowrates through the artificial lung ranged from approximately 600–1100 ml/min with maximum CO₂ removal rate of 208 ml/min. The minute ventilation was significantly decreased from 7.2 ± 2.3 l/min before initiation of AVCO₂R to 3.4 ± 0.8 l/min after 24 hours of AVCO₂R therapy. A follow-up phase I clinical study lasting 72 hours in eight patients with acute respiratory failure and hypercapnia was also conducted.^[9] Blood gas measurements, ventilator parameters, and hemodynamics were measured before and after initiation of AVCO₂R. The arterial CO₂ concentration decreased from 90.8 ± 7.5 mm Hg to 51.8 ± 3.1 mm Hg, and minute ventilation was reduced from 6.92 ± 1.65 l/min to 3.00 ± 0.53 l/min after 2 hours of AVCO₂R. Hemodynamic changes were not significant, nor were any major complications associated with AVCO₂R reported during the study. Zwischenberger and colleagues from the University of Texas Medical Branch continue work in this area, focused on developing AVCO₂R into a standard therapy for respiratory support during severe respiratory failure.

INTRAVASCULAR RESPIRATORY CATHETERS

Intravascular artificial lungs have been studied and are being developed as a less expensive, less personnel-intensive alternative to respiratory support with extracorporeal artificial lungs. Anatomical and physiological constraints of device placement in major blood vessels of the human body impose significant challenges in developing intravascular artificial lungs. Most of the intravascular devices that have been developed are intended for insertion through a peripheral vein (femoral or jugular) and placement in the vena cava, the largest blood vessel in the body through which blood returns to the heart (Fig. 4). The adult human inferior vena cava ranges on average from 2.2 cm to 3.3 cm in diameter and the superior vena cava ranges from 1.5 cm to 2.2 cm.^[10] Intravascular artificial lungs must be compact for insertion, yet possess sufficient membrane area to achieve adequate respiratory support. The primary objective of intravascular artificial lungs is to supplement the gas exchange of a failing lung, but not completely replace it. Respiratory support at 40–60% of the body's resting metabolic needs has generally been considered an appropriate target for intravascular artificial lungs.^[11]

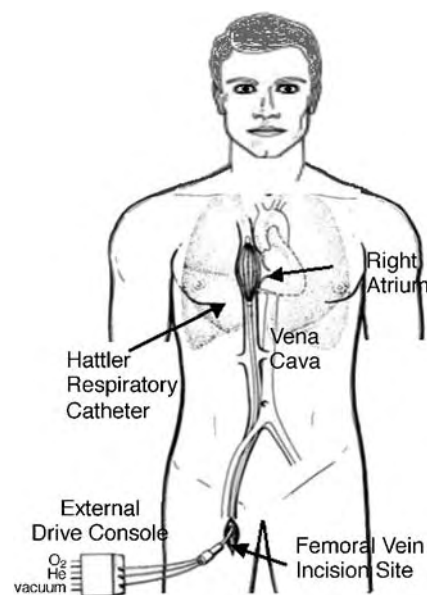

Fig. 4 Schematic of intravascular artificial lung or respiratory support catheter placed within the human vena cava.

Four principal development efforts have tackled the challenge of intravascular artificial lungs since the 1980s. Mortensen and colleagues at CardioPulmonics, Inc. (Salt Lake City, UT) developed the IVOX, the only intravascular artificial lung that has undergone human clinical trials.^[12–14] The IVOX consisted of a bundle of crimped hollow fiber membranes joined at the distal end to the inner lumen of a dual-lumen gas conduit, and at the proximal end to the outer lumen of the gas conduit, which led outside the body to a console for providing sweep gas flow through the fibers. The crimped fibers (Fig. 5) of the IVOX helped minimize fiber clumping in the vena cava and also helped disturb blood flow and diffusional boundary layers on fiber surfaces to improve overall gas exchange permeance.^[15,16] A total of 160 patients with severe acute respiratory distress were studied in applications that

Fig. 5 Crimped fibers were used in the IVOX device to minimize fiber clumping and disrupt blood flow.

lasted up to 28 days of support.^[12] The clinically tested IVOX ranged from 0.21 m² to 0.51 m² in membrane area, and the average rates of O₂ and CO₂ transfer accomplished in the trials ranged from 40 to 70 ml/min, or about 20–30% of baseline metabolic needs. The IVOX demonstrated that intravascular artificial lungs can be implanted within the vena cava and perform for extended periods without significant complications *in situ* (for example, from blood thrombosis). About 30% of the patients showed improvement in blood gases that allowed reduction in mechanical ventilation, but overall the level of respiratory support provided was considered marginal.^[12] The choice of a clinical trial without a random prospective control arm hampered efforts at gaining Food and Drug Administration (FDA) approval, and CardioPulmonics eventually discontinued its attempt at FDA approval and halted further device development.

Several innovative intravascular artificial lung prototypes were developed at Northwestern University as the ILAD, for intravascular lung assist device.^[17–19] To enhance gas exchange, an active or dynamic D-ILAD device was developed, consisting of sheets of short microporous fibers stacked, folded, and twisted around a central shaft to create a helical or screw-like arrangement of fiber surfaces.^[20] Rotation of the entire D-ILAD device increased blood convection across the fiber surfaces, thus improving gas transfer performance while also providing some pumping motion to blood flow. In pilot experiments, oscillatory motion of the D-ILAD bundle showed increased gas exchange compared to steady rotational motion. Prototype D-ILAD devices with membrane areas from 0.1 to 0.5 m² accomplished O₂ and CO₂ transfer rates of 208 ml/min/m² and 310 ml/min/m², respectively, in bench tests involving bovine blood flow through a mock vena cava at 2 l/min.^[21] The D-ILAD only achieved adequate gas exchange with significant fiber rotation, which may be difficult to implement in the vena cava; the efforts of the Northwestern group have shifted to developing a total artificial lung device.^[22,23]

An intravascular artificial lung designed to be placed through the right ventricle into the pulmonary artery (PA) was developed at Penn State University as the PENSIL, for Penn State Intravascular Lung.^[24,25] Placement within the PA allows the entire cardiac output to flow past the fiber surfaces to help maximize gas exchange. The PENSIL consisted of a central catheter with spaced manifold sleeves around it from which blind-ended hollow fibers emanated. The central catheter served as the spine of the PENSIL, and the fibers emanating from the manifold resembled long bristles of a bottle brush. The use of blind-ended fibers meant that sweep gas must diffuse into fibers rather than being convected through them, as in most

artificial lungs. Oscillation of the pressure in the central catheter was studied as a method to provide some oscillatory convection of sweep gas in and out of the blind-ended fibers.^[26] PENSIL devices were fabricated with membrane areas ranging from 0.04 to 0.38 m² and, compared to the IVOX, achieved reasonable O₂ exchange efficiencies at 140 ml/min/m². CO₂ exchange (corrected to a blood PCO₂ driving force of 50 mm Hg) was low, however, at only 25 ml/min/m². Catheter vibration was recently considered as a means of improving gas exchange in the PENSIL,^[14] but other than this effort, the development of the PENSIL appears dormant.

The only currently active development program on intravascular artificial lungs is the effort at the McGowan Institute for Regenerative Medicine at the University of Pittsburgh. This intravascular artificial lung or respiratory support catheter (also known as the Hattler Catheter, and formally referred to as the intravenous membrane oxygenator (IMO)) uses a centrally positioned pulsating balloon within a fiber bundle made from fiber fabric wrapped around the central balloon (Fig. 6). Balloon pulsation pumps blood around the hollow fiber surfaces at greater blood flow velocities than would otherwise flow in the vena cava, and as a result enhances gas exchange by decreasing diffusional boundary layers. Development efforts over the past seven years have led to improvements in balloon pulsation (faster possible pulsation rates) and balloon-bundle design to further increase the gas exchange of the respiratory catheter. The design of the respiratory catheter has evolved substantially from earlier prototypes^[27–31] and has been tested extensively in animals, including *ex-vivo* tests^[29] used to make comparisons with the IVOX, acute animal implants,^[32] and some limited chronic implant tests.^[33] Initially intended for surgical insertion in the femoral vein through a cut-down procedure, the respiratory catheter is now undergoing further

Fig. 6 Respiratory support catheter.

Fig. 7 Ex-vivo results for pulsating respiratory catheter (at 0 and 180 beats per minute) versus IVOX as function of blood flowrate.

development to reduce catheter insertion size and allow for percutaneous insertion.

The pulsating balloon has been a key component of our respiratory support catheter that allows for greater gas exchange than a passive device like the IVOX. Recent ex-vivo tests^[29] were conducted by placing the catheter in a mock vena cava vessel (1-inch tube) connected in an extracorporeal circuit to a calf, a test and setup analogous to those used to study the clinically tested IVOX.^[11] Figure 7 shows the CO₂ removal rate achieved with the respiratory (Hattler) catheter (HC) tested ex vivo in comparison to the IVOX over a range of relevant blood flowrates through the mock vena cava. Balloon pulsation increased gas exchange 200–300% at the lowest blood flowrate, compared to 50–100% enhancement at the highest blood flowrate. In this manner balloon pulsation eliminated much of the dependence of the gas exchange rate on blood flowrate as seen in passive oxygenators, suggesting that the respiratory catheter may exhibit less gas exchange variability related to cardiac output variability in patients. In the ex-vivo studies, the CO₂ and O₂ gas exchange rates of the catheter at maximal balloon pulsation varied from approximately 250 to 300 ml/min/m² and, depending on the blood flowrate, were from 50–500% greater than IVOX gas exchange in these tests.^[34] In a series of acute implants of the respiratory catheter in calves,^[7] the CO₂ transfer rate was 320 ml/min/m², comparable to that achieved in the ex-vivo tests.

TOTAL ARTIFICIAL LUNGS

Several research groups are developing total artificial lung (TAL) devices for treating chronic respiratory failure, primarily as bridge-to-lung transplant devices. Whereas implantable total artificial lungs that can be

placed in the thoracic or abdominal cavities may be an ultimate goal, the initial implementation and testing of total artificial lungs appears to favor paracorporeal applications, with the TAL external to but immediately attached to the patient. The attachment mode of the TAL is an important design consideration, and in-series, in-parallel, and hybrid configurations have been studied.^[35] The in-series configuration connects the artificial lung to the proximal pulmonary artery, diverting all the cardiac output through the device and returning it to the distal pulmonary artery immediately upstream of the natural lungs. Although this mode enables the natural lung to be an effective embolic filter, the mechanical load on the right heart increases because it must provide the pumping energy for blood flow through both the natural and the artificial lung. An estimated 0.11 W/(l/min) is required by the right ventricle with the TAL in-series configuration.^[36] The in-parallel configuration attaches the artificial lung between the pulmonary artery and the left atrium so that only a fraction of the blood flow diverts through the artificial lung. The fraction of blood flow through the artificial lung depends on its impedance relative to that of the natural lung. The in-parallel configuration has the clear advantage that the right heart workload is reduced, but only a fraction of total cardiac output receives respiratory support from the artificial lung and that fraction is not exposed to the metabolic and filtering functions of the natural lung. The power requirement of the in-parallel configuration (assuming 2/3 of total flow through the TAL and 1/3 through the natural lung) is roughly half that for the in-series configuration.^[36] The hybrid configuration attaches the inlet of the artificial lung to the proximal pulmonary artery, and uses a split return to the distal pulmonary artery (and natural lung) and to the left atrium. The hybrid configuration allows all the cardiac output to flow through the artificial lung with less resistance than the in-series configuration, and also allows greater flow through the natural lung than the in-parallel configuration. The power requirement of the right heart for this configuration depends on the amount of blood flow through the artificial lung relative to the natural lung, and has been estimated at between approximately 0.08 W/(l/min) and 0.10 W/(l/min).^[36] Patients with a weak or failing right ventricle would require either the in-parallel or hybrid configurations because of the reduced power required for adequate perfusion of the artificial lung and natural lung.

The implantable Intrathoracic Artificial Lung (ITAL) under development at Northwestern University focuses on resting the lung in acute respiratory failure and as a bridge-to-lung transplantation in chronic lung failure.^[37] Mathematical models were developed to estimate the required surface area for 200 ml/min of oxygen transfer at a blood flowrate of

Table 1 Specifications of a first ITAL prototype

Specification	Design target
O ₂ transfer rate	> 200 ml/min
Blood-side pressure drop	< 15 mm Hg
Blood flowrate	3–5 l/min
Fiber outer diameter	0.038 cm
Surface area	2.2 m ²
Priming volume	240 ml

5 l/min with a pressure drop of less than 15 mm Hg.^[38] Based on these analyses a prototype implantable artificial lung with the design specifications shown in Table 1 was fabricated and tested.^[39] In-vitro gas exchange rates in bovine blood were 150–200 ml/min of O₂ and over 200 ml/min of CO₂ at 4 l/min blood flow. The device was implanted in two Yorkshire pigs for less than 6 hours, and gas exchange rates were approximately 99 ml/min of O₂ and 86–144 ml/min of CO₂. The pressure drop across the device was approximately 10 mm Hg. The ITAL was later modified to reduce the resistance to flow of the device. These changes included increasing the device porosity—or void fraction—from 0.53 to 0.74, reducing the surface area from 2.2 m² to 1.83 m², increasing the inlet and outlet grafts to the device from $\frac{1}{4}$ " to nearly $\frac{3}{4}$ ", and adding an inlet compliance chamber made of thin-walled latex tubing 1 inch in inner diameter.^[37] The device, tested on three Yorkshire pigs, had average gas exchange ranging from 156–204 ml/min of O₂ and 187–242 ml/min of CO₂. The power requirements of the right ventricle were determined to be approximately 0.06 W/(l/min) for full blood flow through the ITAL. The effects of the device housing and inlet graft compliance on the right heart power requirements have also been studied using a computational model.^[36]

The BioLung™ total artificial lung under development at MC3, Inc. (Ann Arbor, MI) and the University of Michigan is intended for complete respiratory support as a bridge to transplant for 1–6 months (Fig. 8). Initial BioLung prototypes were evaluated paracorporeally and connected in series with the natural lung.^[22] Five of 7 sheep survived with 75–100% of cardiac output diverted through the device during a 24-hour study with oxygen transfer rates of approximately 150–240 ml/min. Two of the animals did not tolerate complete occlusion of the pulmonary artery; therefore total cardiac output was not diverted through the artificial lung in these animals. A 168-hour study found 50% of the sheep died of right heart failure when the device was placed in series with the natural lung due to increased flow impedance caused by the device.^[23] Several changes to the TAL were made to reduce its flow resistance (or impedance),

Fig. 8 BioLung™ artificial lung prototype from MC3, Inc. The center port is the blood inlet, and the two side ports are blood exit ports. (Courtesy of MC3, Ann Arbor, MI.)

including addition of an inflow cannula compliance chamber, and inlet blood flow separator and modification of the outlet geometry. A 72-hour healthy sheep survival model using the modified device showed 6 of the 7 sheep exhibited good cardiac function with gas exchange averages of 220 ml/min of O₂ and 166 ml/min of CO₂.^[40] The most recent study has compared volume-controlled mechanical ventilation to the modified BioLung TAL in a 5-day smoke inhalation/burn ARDS sheep study. Six of 8 animals survived when treated with the artificial lung, and only 1 of 6 animals survived when treated with mechanical ventilation.^[41] Average gas transfer rates for the artificial lung were 218.6 ± 17.7 ml/min O₂ and 183.0 ± 27.8 ml/min CO₂. Latest developments on the BioLung device have focused on using computational fluid dynamics (CFD) to optimize the device.^[42] A flow separator has been placed in the inner core of the fiber bundle and the axial length of the fiber bundle has been shortened, reducing the surface area from 2.1 m² to 1.6 m². A second outlet has also been added, which decreased the pressure drop across the device 10–40%. The newer design exhibited higher O₂ transfer efficiency (almost 300 ml/min/m² versus less than 250 ml/min/m² in the old design) in a 6-hour study of 6 adult male sheep at a flowrate of 6 l/min.^[42]

A paracorporeal total artificial lung for chronic respiratory support (Chronic Artificial Lung, or CAL) is under development at the University of Maryland as a continuation of earlier work at the University of Pittsburgh. The CAL is intended as a bridge-to-transplant device with the goal of 21-day support of basal metabolic needs using a device less than 0.5 m² in fiber membrane area.^[43] The CAL uses active mixing from a rapidly rotating disc made of microporous hollow fiber membranes that enhance gas exchange by increasing blood flow velocity past fiber surfaces

and reducing diffusional boundary layers. The disc rotates within a housing and the centrifugal motion imparted to blood enables the CAL to pump blood (which may reduce the impact of the CAL on the right heart in its intended in-series attachment mode). The motor controller directing disc rotation can generate pulsatile or nonpulsatile flow. The CAL generated 5 l/min flow against a 100 mm Hg pressure head at 1600 rpm during steady flow in bench tests using bovine blood, but adding pulsatility to the flow decreased pumping. Published data are lacking but the gas exchange efficiency of the CAL appears promising, with 550 ml/min/m² and 450 ml/min/m² reported for O₂ and CO₂ exchange efficiencies, respectively, in scaled-down prototypes.^[43]

OTHER EFFORTS IN ARTIFICIAL LUNGS

Several other artificial lung technologies are in various stages of development. The Integrated Heart–Lung Assist Device (IHLAD) combines the functions of a blood pump and artificial lung into one device with the goal of functioning as emergency percutaneous cardiopulmonary support.^[44] The IHLAD incorporates a central six-vane impeller driven by a magnetic coupling to an outer motor. The impeller is surrounded by gas-exchanging hollow fiber membranes. The blood-contacting surfaces are treated with covalently-bonded heparin to reduce thrombogenicity and allow pre-primed storage for emergency use. This IHLAD has a surface area of 0.85 m² and was evaluated in an in-vivo goat study with the device attached paracorporeally in a venoarterial bypass. Transfer rates of 180 ml/min O₂ and 110 ml/min CO₂ were achieved at 5 l/min of blood flow with sweep gas flows of three to five times the blood flowrate. The impeller enables pumping performance of 9 l/min output at 400 mm Hg pressure head at 3000 rpm. After 3 months of preprimed storage, the device was tested for gas exchange rates in an ex-vivo goat experiment. Whereas O₂ transfer rates were unaffected by storage, the CO₂ removal decreased approximately 30% after 3 months.

One artificial lung concept involves rotating an annular fiber bundle to promote active mixing and increased gas exchange, in addition to generating a pumping force.^[45] The annular fiber bundle is potted around a stationary central flow diffuser for distributing blood flow throughout the length of the rotating bundle. This is similar in concept to the CAL, in that the rotation of the fibers increases the relative velocity of blood flow past fiber surfaces to increase the efficiency of gas transfer, so less fiber membrane area is required for gas exchange, helping to reduce priming volume and adverse blood–material interactions. A prototype with a priming volume of 1250–2500 ml and

Fig. 9 The CORx™ integrated pump-oxygenator from cardiovention, Inc.

0.2 m² of membrane area exhibited a transfer rate of approximately 60 ml/min of O₂ at a rotational speed of 600 rpm.

The CORx™ System developed by Cardiovention in California consists of a hollow fiber membrane bundle similar to those used in typical commercial artificial lungs attached directly to an impeller pump (Fig. 9).^[46] The pump generates enough pressure to perfuse the artificial lung and return oxygenated and decarbonated blood back to the patient, thus achieving the primary gas exchange requirements and blood flowrates of standard cardiopulmonary bypass (CPB). The device also includes a special technology for removing air that inadvertently enters the circuit during the surgical procedure. This compact unit has a total blood-contacting surface area of less than 1.4 m², which reduces the blood surface contact area and minimizes hemodilution of the patient. The device has recently been approved by the FDA and is currently used for cardiac procedures at hospitals across the United States.^[46]

A novel photolytic artificial lung is under development that uses photosynthesis to convert CO₂ to O₂, obviating the need for O₂ to supply gas (as in membrane artificial lungs).^[47] The device consists of a blood pump, photolytic module of stacked cells, and a light source. The photolytic cells are created with vacuum-deposited titanium metal, a coating of photolytically sensitive TiO₂, and a layer of MnO₂ adhered to the surface of a glass substrate. In the photolytic modules, bicarbonate is protonated to form carbonic acid, which is converted to water and CO₂ in the presence of the carbonic anhydrase. The resultant water is converted to active oxygen at the TiO₂ catalyst when exposed to light, and the active oxygen is converted to dissolved oxygen at the MnO₂ catalyst.^[47] Many such photolytic

units will be integrated into a functional device to achieve relevant rates of O₂ production and CO₂ removal.

CONCLUSION

The next-generation artificial lungs described here derive directly in a conceptual sense from the hollow fiber membrane and membrane module technology used in standard clinical blood oxygenators. Many of these artificial lung devices will hopefully achieve some clinical success in the next five to ten years. On a more distant horizon, the future of artificial lungs may depart significantly from the use of purely synthetic devices based on existing hollow fiber membranes fabricated into modules resembling those used today. The natural lung is a remarkable gas exchange organ because of the microvascular scale of blood pathways combined with the intimate micron-scale juxtaposition of its blood and gas pathways (see the article titled “Lung, Artificial: Basic Principles and Current Applications” in this encyclopedia). Future artificial lung technologies are likely to be biohybrid artificial lungs, combining both synthetic and natural tissue components, into gas exchange units aimed at mimicking the scale and function of the alveolar-capillary units of the natural lung. Biohybrid artificial lungs of the future (Fig. 10) may involve micron-scale blood channels intimately contacting gas channels to provide not only for short diffusion paths and efficient gas exchange but to also create compact devices with surface area to blood volume ratios approaching those of the natural lung. The challenge of biocompatibility inherent in making these microvascular-scale blood channels, with an extensive blood contact area, non-thrombogenic and noninflammatory may require the

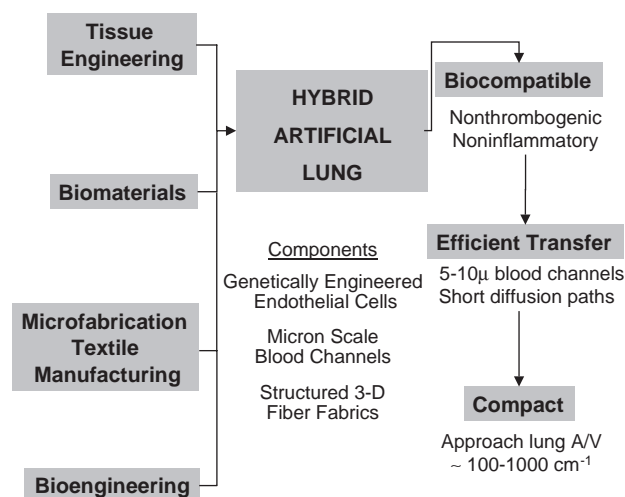

Fig. 10 The future of artificial lungs.

use of endothelial cells, perhaps genetically engineered for enhanced performance or for the robustness required in this application. Significant advances in tissue engineering, biomaterials, microfabrication, and bioengineering will all need to be harnessed for the technological development of these future artificial lungs. At the same time, the need for artificial lungs in the distant future may be eclipsed by significant advances in regenerative medicine that enable tissue repair and regeneration of the failing lung.

INTRODUCTION

This article reviews the composition, activity, dysfunction, and clinical significance of endogenous and exogenous lung surfactants. Pulmonary surfactant, a mixture of lipids and proteins produced in the alveolar epithelial lining, is required for normal respiration. Surfactant reduces the work of breathing, stabilizes alveolar inflation and deflation to optimize gas exchange, and reduces the driving force for pulmonary edema. Surfactant acts on pulmonary pressure-volume mechanics through specific surface properties generated by molecular interactions between its lipid and protein components. Biophysically important surfactant components include dipalmitoyl phosphatidylcholine (DPPC), a mix of other saturated and unsaturated phospholipids, and three surfactant proteins (SP)-A, -B, and -C. Severe disease results if lung surfactant is deficient or becomes dysfunctional. Surfactant deficiency is the cause of respiratory distress syndrome (RDS) in premature infants, and surfactant dysfunction is an important contributor to clinical acute lung injury (ALI) and the acute respiratory distress syndrome (ARDS), which can affect patients of all ages. One approach to treating diseases of surfactant deficiency and dysfunction is to administer exogenous surfactants by airway instillation or other methodology. Understanding the biochemistry, biophysics, and physiology of lung surfactant materials is crucial for optimizing surfactant-based therapies for RDS and ALI/ARDS.

ENDOGENOUS SURFACTANT AND ITS NORMAL ACTIVITY IN LUNGS

Although surface tension is a small force in many macroscopic systems, it is highly important in the lungs. The majority of the extensive alveolar surface in mammals ($\sim 1 \text{ m}^2/\text{kg}$ body weight) is covered by a thin aqueous layer or hypophase. This hypophase is

contacted by inspired air, resulting in a large liquid–air interface with associated surface tension forces. The significant contribution of surface tension to the mechanics of breathing was demonstrated by von Neergaard in 1929,^[1] who showed that higher pressures were needed to inflate lungs or maintain them at fixed volume with air than with liquid (normal saline). This difference is due to surface tension forces, which are present along with tissue forces in air-filled lungs but not in liquid-filled lungs. Although von Neergaard's work documented the importance of pulmonary surface tension forces, the understanding that normal respiration depends on surface active agents (surfactants) to moderate these forces came later. The existence of lung surfactant and the linkage between its deficiency and respiratory distress syndrome (RDS or hyaline membrane disease) in premature infants were demonstrated in the 1950s.^[2–5]

Lung surfactant is synthesized, packaged, stored, secreted, and recycled by type II cells in the alveolar epithelial lining.^{[6–8]a} Secreted surfactant in the alveolar hypophase exists as a heterogeneous population of phospholipid-rich aggregates with incorporated apoproteins. These aggregates vary from tens of nanometers to several microns in size, with larger aggregates typically having the greatest surface activity and highest apoprotein content. Surfactant adsorbs from the hypophase to form a highly active interfacial film that lowers and varies alveolar surface tension during breathing. By lowering surface tension, surfactant reduces the nonflow component of respiratory work (increases lung compliance, $\Delta V/\Delta P$). The extent of

^aType II pneumocytes not only produce and recycle pulmonary surfactant, but also are stem cells for the alveolar epithelium and participate extensively in intercellular signaling during lung development, growth, inflammatory injury, and repair. Some lung surfactant components, particularly apoproteins, are additionally found in airway cells such as nonciliated bronchiolar epithelial cells (Clara cells). The present article focuses on the composition and activity of whole surfactant synthesized by alveolar type II pneumocytes.

surface tension lowering in any given alveolus is proportional to the concentration of surfactant molecules in the film. Surface tension is lowered to the greatest extent when the film is compressed as alveolar radius decreases during expiration, and becomes higher when alveolar radius increases during inspiration. This moderates pressure differences within and between different-sized alveoli based on the Laplace equation,^b stabilizing small airsacs against collapse (reducing atelectasis) and promoting more uniform inflation. Alveolar stability in vivo is further increased by specialized connective-tissue support fibers and by an interconnected network structure that allows airsacs sharing common septa to help each other resist collapse. However, active alveolar surfactant is crucial for normal respiration, and the consequences of its deficiency are strikingly apparent in premature infants with RDS who exhibit alveolar collapse and overdistension, decreased lung volumes and compliance, intrapulmonary shunting with impaired arterial oxygenation, and diffuse pulmonary edema. The importance of active surfactant is also apparent in patients with surfactant dysfunction who develop acute respiratory failure in association with ALI/ARDS.

Alveolar surfactant is a complex mixture containing approximately 85–90% phospholipids, 7–10% protein, and 4–7% neutral lipid by weight^[6,9,10] (Table 1). Phosphatidylcholine (PC) is by far the most common phospholipid class, composing about 80% of total surfactant phospholipid. DPPC (C16:0, C16:0) is the most prevalent molecular species, accounting for 40–50% of the PC fraction. Other disaturated molecules make up about 10–15% of PC, including isomers of palmitoyl-myristoyl PC (C16:0, C14:0) and a small amount of palmitoyl-stearoyl PC (C16:0, C18:0). Fluid unsaturated compounds (one or more double bonds) account for about 35–45% of PC, with the most abundant being palmitoyl-palmitoleoyl PC (C16:0, C16:1) and palmitoyl-oleoyl PC (C16:0, C18:1). Anionic phospholipids (phosphatidylglycerol, phosphatidylinositol, and phosphatidylserine) together compose about 15% of total surfactant phospholipid, and sphingomyelin and phosphatidylethanolamine make up the remaining 5%. As with the PC fraction, each of these phospholipid classes contains a mix of disaturated and unsaturated compounds. The protein content of lung surfactant is much smaller than its phospholipid content, but is crucial to surface

^bThe Laplace equation is given by $\Delta P = 2\sigma/R$, where ΔP is the pressure drop across a spherical interface of radius R and surface tension σ . A similar stability argument can be made for nonspherical alveoli from the more general Law of Young and Laplace, which incorporates the two principal radii of curvature R_1 and R_2 defining an interface of arbitrary shape: $\Delta P = \sigma(1/R_1 + 1/R_2)$.

Table 1 Approximate composition of endogenous pulmonary surfactant

<u>85–90% Phospholipids</u>	
80%	Phosphatidylcholine (PC)
40–50%	DPPC
10–15%	Other disaturated PCs
35–45%	Unsaturated PCs
15%	Anionic phospholipids (PG, PI, PS)
5%	Other phospholipid classes (PE, Sph)
<u>7–10% Apoproteins</u>	
	SP-A
	SP-B
	SP-C
	SP-D (not involved in biophysical function)
<u>4–7% Neutral lipids</u>	
	Cholesterol
	Cholesterol esters, glycerides

Values are representative averages in weight percent for surfactant lavaged (washed) from the lungs of normal animals of different species and ages. *Abbreviations:* PC: phosphatidylcholine; PG: phosphatidylglycerol; PI: phosphatidylinositol; PS: phosphatidylserine; PE: phosphatidylethanolamine; Sph: sphingomyelin; SP: surfactant protein. Adapted from Ref. [6].

active function. Three biophysically active proteins, SP-A, SP-B, and SP-C, are found in lung surfactant (Table 2). SP-D, a fourth protein not involved in biophysical function but important in host defense, is also present. Lung surfactant also contains about 4–7% neutral lipids, primarily cholesterol plus small amounts of cholesterol esters, diglycerides and triglycerides.

The physiological actions of lung surfactant depend on its ability to generate specific surface properties (Table 3). Secreted surfactant in the alveolar hypophase must be able to adsorb readily into a film at the air–water interface. In order to reduce the work of breathing and stabilize alveoli, this film must reduce surface tension to low values during dynamic compression and it must vary surface tension with interfacial area during cycling. Theory does not predict a unique level of surface tension lowering required for active lung surfactant. However, multiple studies have shown that films and dispersions of lavaged lung surfactant and related organic solvent extracts can lower surface tension to extremely low values <1 mN/m under dynamic compression at physiological rates at 37°C.^{[6,9]c} Lung

^cMinimum surface tension values of “0 mN/m” are sometimes reported for lung surfactant in the literature. However, since surface tension is necessarily finite at a stable air–water interface, a lower-limit minimum value of <1 mN/m is utilized here.

Table 2 Molecular characteristics of lung surfactant proteins

Surfactant protein (SP)	Selected structural and functional characteristics
SP-A	<p>MW 26–38 kD (monomer), 228 AA in length in humans.</p> <p>Most abundant surfactant apoprotein, relatively hydrophilic.</p> <p>Acidic glycoprotein with multiple post-translational isoforms.</p> <p>C-type lectin and member of the collectin family of host-defense proteins.</p> <p>Oligomerizes to an active octadecamer (six trimer subunits).</p> <p>Aggregates and orders lipids.</p> <p>Necessary for tubular myelin formation (along with SP-B, Ca⁺⁺).</p> <p>Helps regulate surfactant reuptake/recycling in type II cells.</p>
SP-B	<p>MW 8.5–9 kD (monomer), 79 AA in length in humans (active peptide).</p> <p>Overall hydrophobic in nature, with 2–3 amphipathic helical regions.</p> <p>Sequence includes multiple charged AA (e.g., 10 positive Arg/Lys residues).</p> <p>Forms dimers of presumptive functional significance in humans.</p> <p>Interacts biophysically with both the headgroups and chains of phospholipids.</p> <p>Necessary for tubular myelin formation (along with SP-A, Ca⁺⁺).</p> <p>Disrupts and fuses lipid bilayers and promotes lipid insertion into surface films.</p> <p>Enhances adsorption, film spreading, and dynamic surface activity of lipids.</p> <p>Most active SP in increasing adsorption and overall dynamic surface activity.</p>
SP-C	<p>MW 4.2 kD (monomer), 35 AA in length in humans (active peptide).</p> <p>Most hydrophobic surfactant protein.</p> <p>Forms dimers and other oligomers of uncertain functional significance.</p> <p>Human form has two palmitoylated cysteine residues.</p> <p>Contains only two charged amino acids at neutral pH (2 Arg/Lys residues).</p> <p>Primarily α-helical in structure, with a length that spans a lipid bilayer.</p> <p>Interacts biophysically primarily with phospholipid fatty chains.</p> <p>Disrupts and fuses lipid bilayers.</p> <p>Enhances adsorption, film spreading, and surface activity of lipids.</p>
SP-D	<p>MW 39–46 kD (monomer), 355 AA in length in humans.</p> <p>Has significant structural similarity to SP-A.</p> <p>Oligomerizes to a dodecamer (four trimer subunits).</p> <p>C-type lectin and member of collectin family of host-defense proteins.</p> <p>Not implicated in lung surfactant biophysics.</p> <p>May participate in surfactant metabolism in addition to host-defense.</p>

surfactant films must also respread effectively at the air–water interface during repetitive cycling, i.e., molecules ejected from the surface film during compression must reintegrate with remaining interfacial components during expansion. Respreading from film-associated collapse phases or related structures in the interfacial region, along with adsorption from the subphase, ensure that sufficient surfactant remains present in the film to lower surface tension effectively during successive breathing cycles.

METHODS FOR MEASURING THE SURFACE ACTIVITY OF LUNG SURFACTANTS

Details about interfacial and molecular biophysical methods used in studying lung surfactant films and bilayers are given in the text by Notter.^[6] Two widely used instruments for measuring the overall surface activity of lung surfactants are the pulsating bubble surfactometer^[11] and the captive bubble surfactometer.^[12] Measurements of surface tension on the

Table 3 Physiological Actions and Surface Properties of Functional Lung SurfactantPhysiological actions of functional lung surfactant

- Reduces the work of breathing (increases lung compliance).
- Increases alveolar stability against collapse during expiration (reduces atelectasis).
- Improves the uniformity of alveolar inflation during inspiration.
- Reduces the hydrostatic driving force for pulmonary edema.

Biophysical properties of functional lung surfactant

- Adsorbs rapidly to the air–water interface.
- Reaches very low minimum surface tensions during dynamic film compression.
- Varies surface tension with surface area during dynamic cycling.
- Respreads effectively at the interface during successive cycles.

pulsating bubble surfactometer reflect a physiologically relevant combination of adsorption, dynamic film compression, and film resreading behavior at 37°C. A tiny air bubble in a surfactant dispersion is pulsated at 20 cycles/min between maximum and minimum radii of 0.55 and 0.40 mm (50% area compression for truncated spheres), and surface tension is calculated from the Laplace equation and the measured interfacial pressure drop.^[11] The sample chamber of the pulsating bubble apparatus has a volume of only 40 microliters so that very small amounts of surfactant can be studied. Pulsating bubble data are typically expressed as minimum surface tension (surface tension at minimum radius) as a function of time of pulsation. Maximum surface tension (surface tension at maximum radius) is also sometimes reported. Adsorption can also be defined with this instrument in the static mode, although a diffusion resistance is present. The captive bubble surfactometer determines surface tension from its theoretical relation to pressure, volume, and dimensional parameters in a bubble captured against an agar layer and compressed or expanded by an external piston.^[12] This design rules out film migration effects that can influence data during initial cycles in the pulsating bubble surfactometer. The captive bubble surfactometer provides data on surface tension as a function of surface area, and adsorption can also be measured with subphase stirring to minimize diffusion resistance. However, the apparatus requires more complex data analysis based on computer solutions to interfacial equations in conjunction with bubble shape measurements from recorded video images.

The Langmuir–Wilhelmy surface balance is another important experimental technique used to study molecular interactions and resreading in cycled films of lung surfactant and its components.^[6] Films are most commonly spread directly at the air–water interface in the balance trough, which is made of Teflon[®] or some other hydrophobic material. A transverse dam or continuous ribbon barrier allows the film to be compressed and expanded while surface tension is measured from the force on a finely roughened Wilhelmy slide (e.g., sandblasted platinum) dipped into the interface. Data are typically reported as surface pressure (the amount that surface tension is lowered below that of the pure subphase) as a function of surface area or film concentration in square Angstroms per surfactant molecule at fixed temperature, cycling rate, and compression ratio. Surface pressure–area isotherms from the Wilhelmy balance directly assess resreading and molecular interactions in compressed surfactant films, although cycling rates for this instrument are much smaller than in the lungs. Adsorption can also be assessed on the Wilhelmy balance, but is much more commonly studied in a small Teflon[®] dish containing a subphase stirred with a magnetic bar to minimize the effects of diffusion. Surfactant is injected into the stirred subphase at time zero, and adsorption surface tension (or surface pressure) is measured as a function of time from the force on a hanging Wilhelmy slide dipped in the surface.^[6]

ROLES OF SPECIFIC COMPONENTS IN LUNG SURFACTANT ACTIVITY

Lung surfactant is extraordinary in its ability to adsorb at the air–water interface and to lower surface tension in a dynamically compressed film (see Refs. [6,9] for detailed review and literature citations). Surfactant lavaged from normal animal lungs rapidly adsorbs to equilibrium surface tensions of 22–23 mN/m at 37°C (equilibrium surface pressures of 47–48 mN/m) at the air–water interface. Similar rapid adsorption into a surface film is also exhibited by chloroform:methanol extracts of lavaged surfactant dispersed in the aqueous phase. As noted earlier, when such films of whole or extracted lung surfactant are compressed at rapid physiological rates, extremely low minimum surface tensions <1 mN/m are generated. These surface active behaviors result from molecular interactions between the lipid and protein components of lung surfactant. As an overview, DPPC and other rigid long-chain disaturated phospholipids are major contributors to the low minimum surface tensions found in dynamically compressed lung surfactant films. DPPC and other disaturated phospholipids are also essential for varying surface tension with area during cycling.

Fluid lung surfactant phospholipids greatly enhance film respreading during cycling, and improve adsorption relative to DPPC. Neutral lipids such as cholesterol also help to improve film respreading and adsorption relative to DPPC, but are detrimental to dynamic surface tension lowering if present in excess amounts. The most crucial components for increasing lung surfactant adsorption are SP-A, SP-B, and SP-C. Surfactant proteins are also highly important in refining the composition of the surface film during cycling to maximize dynamic surface tension lowering and respreading.

The molecular biophysical behavior of lung surfactant phospholipids and proteins has received extensive research study.^[6,9,10] Due to their high gel to liquid crystal transition temperatures and tight chain-packing characteristics, disaturated phospholipids such as DPPC form rigid interfacial films that are highly effective in lowering and varying surface tension under rapid compression at 37°C. However, rigid long-chain disaturated phospholipids do not respread effectively in cycled films, nor do they adsorb readily at the air–water interface. Unsaturated phospholipids pack less tightly than their disaturated counterparts in films and bilayers, and are in the liquid-crystal phase at 37°C. They do not lower surface tension as well as DPPC in cycled films, but exhibit much better respreading. Unsaturated phospholipids also adsorb more rapidly than DPPC (although not nearly as well as whole or extracted lung surfactant that contains apoproteins). SP-A, SP-B, and SP-C all have extensive molecular biophysical interactions with phospholipids that contribute to surface activity (Table 2). SP-A functions biophysically as a large octadecamer containing six trimeric subunits. SP-A in the presence of calcium increases the molecular order and aggregation of phospholipids. It is cooperative with SP-B in forming tubular myelin, which along with other large aggregate forms has been associated with rapid lung surfactant adsorption. SP-B and SP-C can disrupt and fuse phospholipid bilayers, and SP-B also facilitates the insertion of phospholipids into surface films. Multiple studies have demonstrated that SP-B is the most active of all the surfactant proteins in increasing the adsorption and overall dynamic surface activity of phospholipids (e.g., Refs. [13–17]). Its amphipathic structure allows strong interactions with both the headgroups and chains of phospholipid molecules in films and bilayers, making it a particularly important functional component of endogenous and exogenous lung surfactants.

DEFICIENCY AND DYSFUNCTION OF ENDOGENOUS LUNG SURFACTANT

The term “lung surfactant deficiency” implies a decreased amount of surfactant in the alveoli, whereas

the term “surfactant dysfunction” (also called surfactant inhibition or inactivation) generally means a decrease in surface activity. Lung surfactant deficiency and dysfunction are not independent, because surface activity is decreased if surfactant concentration is decreased. However, surfactant deficiency is usually associated with abnormalities in type II cell function, either from incomplete development as in premature infants or from cellular injury or alteration. Surfactant dysfunction, on the other hand, can arise from any biochemical or biophysical process that compromises the surface activity of alveolar surfactant, and associated abnormalities in type II cells may or may not be present. Both endogenous and exogenous lung surfactants are potentially subject to surfactant dysfunction or inactivation.

INHIBITOR-INDUCED LUNG SURFACTANT DYSFUNCTION

Multiple compounds and processes can detrimentally affect the surface activity of lung surfactants (see Refs. [6,9,18,19] for detailed review and literature citations). Inhibitors that act biophysically to inhibit lung surfactant activity include plasma and blood proteins such as albumin, fibrinogen, fibrin monomer, or hemoglobin; cellular lipids and lysophospholipids; fluid free fatty acids; meconium; and antibodies to surfactant proteins. Plasma and blood proteins reduce surface activity primarily by competitive adsorption and interfacial shielding. These large molecules contain polar and nonpolar amino acids and have an intrinsic surface activity. When they adsorb, they form a relatively impenetrable film that occupies the interface and limits the entry of lung surfactant components. Smaller molecules such as fluid free fatty acids and unsaturated cell membrane lipids, on the other hand, act primarily by mixing with lung surfactant components within the interfacial film to compromise surface tension lowering during dynamic compression. In addition, free fatty acids and lysophospholipids can also damage the cellular integrity of the alveolocapillary membrane and generate pulmonary edema containing plasma proteins and other inhibitors.

The ability of albumin, hemoglobin, or red blood cell membrane lipids to reduce the dynamic surface tension lowering ability of lavaged lung surfactant is illustrated in Table 4.^[20,21] The degree of inhibition is strongly dependent on surfactant concentration. At a low surfactant phospholipid concentration of 0.5 mM, minimum surface tension values above 20 mN/m are reached in the presence of the inhibitors after 10 minutes of cycling on a pulsating bubble surfactometer. However, doubling surfactant concentration to 1 mM phospholipid results in minimum surface

Table 4 Inhibitory effects of plasma proteins and red blood cell membrane lipids on the dynamic surface activity of endogenous lung surfactant

Mixtures	Phospholipid concentration (mM)	Inhibitor concentration (mg/ml)	Minimum surface tension (mN/m) at time (min)		
			0	5	10
Albumin	–	2–200	45	45	45
Hemoglobin	–	2–200	36	35	35
Lung Surfactant (LS)	0.5	–	20	6	<1
LS + albumin	0.5	10	45	44	29
LS + hemoglobin	0.5	25	34	29	26
LS + membrane lipids	0.5	0.4	24	22	21
LS	1	–	19	<1	<1
LS + albumin	1	100	44	3	<1
LS + hemoglobin	1	100	36	25	<1
LS + membrane lipids	1	0.4	22	20	19
LS + membrane lipids	2	0.4	20	–	<1

LS was obtained by bronchoalveolar lavage of intact calf lungs. Minimum surface tension values at 0, 5, and 10 min are on a pulsating bubble surfactometer (20 cycles/min, 50% area compression, 37°C) with a subphase of 0.15 M NaCl + 1.4 mM CaCl₂. Time 0 is < 15 sec from the start of bubble pulsation. Data from Refs. [20,21].

tensions of <1 mN/m even if blood protein concentrations are increased. When surfactant concentration is raised to 2 m M phospholipid, the inhibitory effects of red blood cell membrane lipids on dynamic surface activity are also abolished. Concentration-dependent inhibition patterns conceptually similar to those in Table 4 for dynamic surface activity are also found for lung surfactant adsorption in the presence of blood proteins.^[20,22,23] In addition to their effects as individuals, some inhibitory substances exhibit additivity in reducing surface activity. For example, mixtures of albumin or hemoglobin with lyso-PC or red blood cell membrane lipids can impair the surface tension lowering of lung surfactant more severely than the individual inhibitors alone.^[24] Additive inhibition, if present, is again most apparent at low surfactant concentrations and is mitigated as surfactant concentration is raised.^[24] The magnitude of additivity also depends on the mechanisms of inhibitor action involved. The effects of some inhibitors can actually be lessened in mixtures, as occurs when free fatty acids are bound by albumin when the two substances are present together.^[24]

Lung surfactant activity can also be impaired by additional pathways during pulmonary injury and inflammation. This includes exposure to chemically acting inhibitors such as phospholipases, proteases, and reactive oxygen/nitrogen species that are present in the alveoli and interstitium during inflammatory injury. Enzymes such as phospholipases and proteases

not only reduce the concentration of functional surfactant components by chemical degradation, but also produce reaction products that can cause further inhibition (e.g., phospholipases A₁ and A₂ generate inhibitory free fatty acids and lysophospholipids when they chemically degrade phospholipids). Reactive oxygen and nitrogen species that can chemically alter lung surfactant lipids and proteins during inflammatory injury include nitric oxide (\bullet NO), superoxide anion (O₂ \bullet^-), hydrogen peroxide (H₂O₂), hydroxyl radical (\bullet OH), peroxynitrite (ONOO⁻), nitrogen dioxide (NO₂), dinitrogen trioxide (N₂O₃), and S-nitrosothiols. In addition, another important mechanism by which surfactant activity can be impaired during lung injury involves the selective depletion or alteration of large surfactant aggregates or subtypes, which as noted earlier normally have better surface activity and higher apoprotein contents than small aggregates. Aggregate-related changes in surfactant activity can result from direct interactions with inhibitory substances, impaired intraalveolar aggregate processing, injury to type II cells, or a combination of these factors.

PHYSIOLOGICAL CORRELATES OF LUNG SURFACTANT ACTIVITY AND DYSFUNCTION

Decades of research have shown the importance of correlating data on lung surfactant composition and

Table 5 Animal models of lung surfactant deficiency or dysfunction**I. ANIMAL MODELS OF SURFACTANT DEFICIENCY****A. Models emphasizing pressure–volume (P–V) mechanics**

- Excised adult rat lungs depleted in surfactant by multiple lavage.
- Small premature fetal animals (e.g., 27-day gestation rabbits).

B. Models emphasizing pulmonary function as well as mechanics in vivo

- Premature large animals (e.g., lambs, baboons, monkeys).
- Adult animals such as rats or rabbits depleted in surfactant by in-vivo lung lavage (also used as a model of acute lung injury).

II. ANIMAL MODELS OF SURFACTANT DYSFUNCTION

Multiple models of acute lung injury in adult or newborn animals. Initiators of lung injury include: hyperoxia, instillation or injection of bacteria or bacterial endotoxin, aspiration of acid or meconium, bilateral vagotomy, oleic acid infusion, viral infection, infusion of antibodies to lung surfactant or lung tissue, administration of toxic chemicals such as N-Nitroso-N-methylurethane (NNNMU), pulmonary radiation, inhalation of toxic dusts or particles, and in-vivo lung lavage.

For reviews of the tabulated animal models, and their use in surfactant replacement applications, see Refs. [6,9,19].

surface activity with physiological effects in intact lungs. Animal models of surfactant deficiency and dysfunction are reviewed in detail elsewhere.^[6,9,19] As an overview, the most meaningful assessments of any lung surfactant material include studies in animal models and correlation of physiological findings with data on composition, surface activity, and inhibition resistance. Animal models can be categorized as primarily involving surfactant deficiency or surfactant dysfunction (Table 5). Although there is overlap, models of surfactant deficiency generally relate most directly to RDS, whereas models of surfactant dysfunction and lung injury are applicable for ARDS. Within each category, animal models can be subdivided based on their detailed characteristics. For example, some models of surfactant deficiency emphasize measurements of pressure–volume (P–V) mechanics in small premature animals, whereas others emphasize functional assessments of respiratory physiology (Table 5). These latter models generally require animals of sufficient age and/or size to allow detailed lung functional measurements during mechanical ventilation over a timescale of hours. Models of acute lung injury and surfactant dysfunction

are generally categorized by the mechanism of injury-induction (Table 5). Adult animals are most commonly used in lung injury models, although newborn animals can also be studied. Research in animal models of lung surfactant deficiency, along with interfacial biophysical studies, were essential in laying the basis for successful clinical exogenous surfactant therapy in premature infants with RDS. Research in animal models of acute lung injury with surfactant dysfunction is similarly important to extend surfactant therapy to ARDS-related lung injury. The consensus of current animal research indicates that lung surfactant materials with the greatest overall surface tension lowering ability and resistance to inhibitor-induced dysfunction have the highest physiological activity in reversing surfactant deficiency and dysfunction in intact lungs.

DISEASES OF LUNG SURFACTANT DEFICIENCY AND DYSFUNCTION

The major disease of lung surfactant deficiency is RDS or hyaline membrane disease in premature infants (for clinical details see standard texts of pathology and pediatric medicine). The rate of occurrence of RDS is very low in infants ≥ 35 weeks gestation (term = 40 weeks; prematurity = < 37 weeks), and increases as gestational age and birth weight decrease. The incidence of RDS is most significant in infants < 32 weeks gestation. Approximately 77,500 infants < 32 weeks, and 219,000 infants 32–35 weeks gestation, were born in the United States in the year 2000.^[25] There were over 24,000 reported cases of RDS, with an overall incidence of 6 per 1000 live births.^[25] Aside from the degree of prematurity, the risk of RDS is increased by maternal diabetes, male sex, caucasian race, and perinatal factors such as caesarian section. RDS is caused by surfactant deficiency due to type II cell immaturity, but superimposed lung injury and surfactant dysfunction can also enter its clinical course as the result of mechanical ventilation, hyperoxia, and diverse complications of prematurity. However, surfactant dysfunction is more prominent in the acute respiratory failure associated with clinical ALI/ARDS.

ARDS was originally described primarily in adults,^[26,27] and was commonly referred to as the “adult” respiratory distress syndrome. The now standard nomenclature of the “acute” respiratory distress syndrome reflects the pathophysiological origins of this syndrome as a severe acute pulmonary injury that can manifest in patients of any age. The American–European Consensus Committee in 1994 defined clinical ARDS based on acute onset, bilateral infiltrates demonstrated on frontal chest radiograph, a

ratio of arterial oxygen partial pressure to inspired fraction of oxygen ($\text{PaO}_2/\text{FiO}_2$ ratio) of ≤ 200 mmHg, and a pulmonary capillary wedge pressure of ≤ 18 mmHg (if measured) or no evidence of left atrial hypertension.^[28] The Consensus Committee defined clinical ALI identically, except for a less severe $\text{PaO}_2/\text{FiO}_2$ ratio of ≤ 300 mmHg.^[28] Thus, by definition, all patients with ARDS have ALI. Clinical ARDS affects 50,000 to 150,000 patients in the United States each year, and has a substantial mortality of 30–50% despite sophisticated mechanical ventilatory support and intensive medical care. Surfactant abnormalities have been well-documented in bronchoalveolar lavage from patients with ALI/ARDS in multiple studies.^[18,29]

An additional group of surfactant-related diseases involves a genetic deficiency in a functional surfactant component (particularly an apoprotein). Such conditions are much more rare than RDS or ARDS, affecting only one in hundreds of thousands of infants. The best known is hereditary SP-B deficiency, the major form of which is a homozygous mutation in exon 4 of the SP-B gene at codon 121, referred to as 121ins2.^[30,31] Heterozygous infants do not have overt respiratory pathology. Because of the crucial functionality of SP-B, the homozygous 121ins2 mutation is associated with decreased surfactant activity and lethal perinatal respiratory failure (an early alveolar proteinosis is also common).^[30,31] Reduced levels of surfactant phosphatidylglycerol and abnormalities in SP-C processing with accumulation of abnormal proSP-C are also present in homozygous infants.^[31–33] SP-B knockout mice similarly have lethal acute respiratory failure and compromised surfactant activity.^[34] There is genetic heterogeneity in human SP-B deficiency, and some variants allow survival into childhood.^[35] Congenital SP-B deficiency is not effectively treated with exogenous surfactant^[32] or extracorporeal membrane oxygenation.^[36] Lung transplantation is the only current option for infants with severe forms of this condition,^[37] and gene therapy is under investigation. In contrast to SP-B deficiency, a congenital deficiency of SP-C is not associated with severe acute respiratory disease in humans^[38] or transgenic mice.^[39]

CLINICAL EXOGENOUS SURFACTANT THERAPY

Clinical surfactant therapy is straightforward in concept: if endogenous surfactant is deficient or dysfunctional, then it can be supplemented by delivering an active exogenous surfactant to the alveoli. This therapy is by necessity acute and requires that the lungs ultimately develop or recover the ability to

produce active endogenous surfactant. Although simple in concept, developing effective exogenous surfactant therapy for premature infants with RDS required a substantial time. Initial treatment of premature infants with aerosolized DPPC in the 1960s was ineffective, both because DPPC alone is not an adequate lung surfactant substitute and because pulmonary delivery by aerosolization was inefficient. Decades of subsequent biophysical and animal research were required to clarify the molecular basis of lung surfactant function and define clinically effective exogenous surfactants. The utility of surfactant therapy to prevent or treat RDS in premature infants is now well-documented.^[6,18,40] Exogenous surfactants are dispersed in saline and delivered by intratracheal instillation through an endotracheal tube at doses of ~ 100 mg/kg body weight (divided dosing by tracheal or bronchoscopic instillation is typically used in older patients). Despite having theoretical advantages, aerosol methods for delivering exogenous surfactants are still not perfected.

Surfactant therapy for clinical ALI/ARDS is currently not as developed as is the case for RDS in premature infants. As described earlier, basic research has shown that many forms of surfactant dysfunction can be reversed or mitigated by raising surfactant concentration even in the continued presence of inhibitor substances (e.g., Table 4). Multiple ARDS-related animal models have also been shown to respond favorably to exogenous surfactants, including acute lung injury from hyperoxia, meconium aspiration, anti-lung serum administration, bacterial or endotoxin administration, vagotomy, in-vivo lavage, N-nitroso-N-methylurethane administration, and viral pneumonia.^[6,9,19] In addition, clinical studies have shown that exogenous surfactant therapy is efficacious in term infants with meconium aspiration or pneumonia, and improves lung function in children with ARDS-related acute respiratory failure (for citations see Refs. [6,18]). Surfactant therapy in adults with ARDS has had less success. By far the largest published trial of surfactant therapy in adults with ARDS reported no clinical benefits following treatment with aerosolized Exosurf.^[41] However, Exosurf is known to have low activity compared to animal-derived exogenous surfactants (see below), and aerosol delivery methods are not as effective as instillation. Many of the most active exogenous surfactant drugs have not been studied in detail in adults with ARDS. Moreover, the complex lung injury pathophysiology of ALI/ARDS includes inflammation, vascular dysfunction, and multiorgan disease in addition to surfactant dysfunction. Exogenous surfactant may thus need to be used in a combined-modality approach with other therapies that target multiple aspects of pathology in ARDS.^[6,18]

CLINICAL EXOGENOUS SURFACTANTS

Clinical exogenous surfactants currently used to treat surfactant-related lung disease are listed in Table 6. These preparations are divided into three functionally relevant groups: 1) organic solvent extracts of lavaged endogenous lung surfactant from animals; 2) organic solvent extracts of processed animal lung tissue with or without additional synthetic additives; and 3) synthetic preparations not containing surfactant material from animal lungs. Organic solvent extracts of lavaged alveolar surfactant in Category I in principle contain all of the hydrophobic lipid and protein components of endogenous surfactant, although compositional details vary somewhat depending on solvents and processing. Extracts of minced or homogenized lung tissue in Category II are noted separately because they contain a higher content of tissue-derived material and require more extensive processing that can alter the content of surfactant components. The synthetic clinical surfactants in Category III that have been most widely studied to date are Exosurf and ALEC (artificial lung expanding compound). Exosurf is a mixture of DPPC:hexadecanol:tyloxapol (1:0.11:0.075 by weight) and ALEC is a mixture of 7:3 DPPC:egg PG. Synthetic KL4 and recombinant SP-C surfactant are currently under clinical evaluation.

Recombinant SP-C surfactant

Infasurf (ONY, Inc. and Forest Laboratories), Survanta (Abbott/Ross Laboratories), and Curosurf (Chesi Farmaceutici and Dey Laboratories) are currently FDA-approved in the United States, and KL4 is under clinical evaluation. Exosurf (Glaxo-Wellcome) is also FDA-approved, but is no longer used. Additional synthetic surfactants are under development as described in the text. Table adapted from Ref. [6].

RELATIVE ACTIVITY AND INHIBITION RESISTANCE OF EXOGENOUS SURFACTANT DRUGS

The relative activity and efficacy of exogenous surfactant drugs are crucial for evaluating and optimizing therapy. Differences in efficacy between clinical surfactants have been demonstrated in comparison trials in premature infants and in retrospective meta analyses.^[6] Such studies indicate that natural surfactants from animal lungs (Categories I and II, Table 6) have significantly greater efficacy than the protein-free synthetic surfactants Exosurf and ALEC. The hydrophobic surfactant proteins are highly active, and substituting for them in synthetic surfactants is a challenging task. The surface and physiological activities of Exosurf, for example, are significantly increased by the addition of purified bovine SP-B/SP-C, demonstrating that its synthetic components do not adequately replace these active endogenous apoproteins.^[42] Animal-derived clinical surfactants also differ markedly in their surface activity and ability to resist inhibitor-induced dysfunction. Biophysical and animal research indicates that the surface activity, inhibition resistance, and physiological effects of extracts of lavaged animal surfactant (Category I, Table 6) are greater than those of other available clinical surfactants. For example, the surface and physiological activities of Infasurf are substantially greater than Survanta in basic research.^[17,42-44] These activity differences correlate directly with the content of SP-B in the two preparations.^[17,32,43] Survanta has a very low SP-B content by ELISA of only 0.044% by weight relative to phospholipid, while Infasurf has an SP-B content of 0.9% by weight that approaches that of lavaged whole surfactant.^[17] As described earlier, SP-B is the most active of the hydrophobic surfactant proteins in enhancing the adsorption and overall dynamic surface activity of phospholipids.^[13-17] The addition of SP-B or synthetic SP-B peptides to Survanta significantly improves its activity towards that of Infasurf and whole surfactant.^[17,43,45]

FUTURE EXOGENOUS SURFACTANT DEVELOPMENT

The high activity, low toxicity, and close analogy to alveolar surfactant of surfactants from animal lung lavage in Category I of Table 6 provide significant challenges for new drug development. However, synthetic surfactants manufactured under laboratory conditions in vitro have significant potential advantages in manufacturing, formulation, quality control, and availability over animal-derived preparations. In addition, the risk of transmitting infectious agents

such as prions is negligible for synthetic surfactants. Examples of conceptual approaches being followed for new exogenous surfactants include: 1) Combining human sequence recombinant apoproteins or related synthetic peptides with synthetic glycerophospholipids or other components; 2) modifying current clinical exogenous surfactants with added recombinant apoproteins or synthetic peptides to increase activity; and 3) developing new exogenous surfactants for use in inflammatory lung injury that have added beneficial properties based on novel synthetic components. KL4 and recombinant SP-C surfactant in Table 6 are examples of the first of these approaches. Examples of the second approach include adding human sequence SP-A or SP-A peptides to enhance inhibition resistance in exogenous surfactants, or adding hydrophobic surfactant apoproteins or peptides to Exosurf or Survanta as described above.^[17,42,43,45] An example of the third approach is the use of synthetic phospholipase-resistant diether phospholipids that have dynamic surface-tension lowering ability comparable to DPPC, but greatly improved adsorption and respreading properties (e.g., Ref. [46]). Surfactant preparations containing such phospholipids combined with purified surfactant proteins or synthetic peptides have a potential for very high overall surface activity plus the ability to resist degradation by phospholipases in ARDS-related lung injury. For more detailed review and discussion of on-going basic research on exogenous surfactants see Refs. [6,9].

SUMMARY AND CONCLUSIONS

This article has detailed the composition, activity, dysfunction, and replacement of pulmonary surfactant. Lung surfactant is a physiologically essential mixture of lipids and proteins required for normal respiration. Its actions include reducing the work of breathing (increasing lung compliance), stabilizing alveoli against collapse and overdistension, and decreasing the hydrostatic driving force for pulmonary edema. Lung surfactant achieves its physiological effects through specific surface active properties that result from the molecular biophysical interactions of its components. Biophysically important components of endogenous surfactant include DPPC and related long-chain disaturated phospholipids, a mix of fluid unsaturated phospholipids, and three specific surfactant proteins SP-A, SP-B, and SP-C. SP-D, a fourth surfactant protein, does not participate in surfactant biophysics but is active in host defense along with SP-A and potentially other surfactant components.

Potentially lethal respiratory disease occurs when lung surfactant is deficient or dysfunctional. Surfactant

deficiency is the cause of RDS in premature infants, and surfactant dysfunction is an important contributor to the pathophysiology of clinical lung injury (ALI and ARDS). Clinical surfactant therapy involves the delivery of exogenous surface active material to the alveoli to supplement deficient or dysfunctional endogenous surfactant. Life-saving exogenous surfactant therapy is now available to prevent and treat RDS in premature infants. Surfactant therapy is currently being optimized in premature infants and is being extended to patients of all ages with ALI and ARDS. Biophysical and animal research indicates that detriments to surface activity in lung-injured patients can be reversed or mitigated if active exogenous surfactants able to resist inhibition are delivered effectively to the alveoli. Exogenous surfactant therapy has been shown to have significant benefits in term infants with lung injury from meconium aspiration and infection, and also to improve respiration in children with ARDS. Current experience with surfactant therapy in adults with ARDS is mixed, but many of the most active clinical exogenous surfactants have not been extensively evaluated in these patients. Combination therapies using exogenous surfactant in conjunction with other interventions against inflammatory lung injury have also not received detailed study. Optimizing surfactant therapy depends on a rational integration of mechanism-based basic biophysical and animal research with focused, prospective, controlled clinical investigations.

Department of Food Engineering, Central Food Technological Research Institute, Mysore, Karnataka, India

INTRODUCTION

Improved techniques for separating cells are increasingly important to biomedical science and biotechnology because separation is frequently a limiting factor in downstream processing. Other downstream processing contributes a large portion of the product cost.^[1] Magnetic and electrophoretic cell sorting is finding wide application due to multidisciplinary interactive research in areas such as physics, material science, physical and polymer chemistry, biology, medicine and engineering (electrical, electronics, and biomedical).

Many cell separation/sorting methods have been reviewed in the literature.^[2] Magnetic and electrophoretic techniques have the potential to be alternative or often complimentary to other methods currently used in biotechnology. In this article, new and improved separation methods are discussed with brief mention of existing methods.

Multistage methods, namely ADSEP (ADvanced SEPARATOR), MAGSEP (MAGnetic SEPARATOR) and ELECSEP (ELECTrophoretic SEPARATOR), for quantitatively separating cells are given a special emphasis. These methods are expected to cost much less in comparison with the competing technologies at similar scale and precision and are built on the counter-current distribution technology of classical chemical engineering separations. The theory behind field-assisted separations provide the opportunity to predict the performance of these extractors and also to improve their design. Hence, mathematical models are stressed in this chapter. We also present a few suggestions for future work while analyzing the scale-up and economic aspects of these separation methods.

MAGNETIC CELL SEPARATION

Magnetic separation methods are used in a variety of scientific applications, such as endocrinology, growth regulation, virology, carcinogenesis, infectious diseases, neurology, and nutrition. Magnetic separation

based on magnetic sorbents, carriers, and modifiers has been employed for isolation, modification, detection, immobilization, and removal of a variety of cells. The developments that aroused fresh technical interest in magnetic separation of cells are high magnetic field gradients, superconducting magnets, and newer magnetic labeling techniques.

Existing Methods

Magnetic separation methods are mainly classified into two types: 1) magnetic separation of separands that are intrinsically magnetic and 2) rendering one or more nonmagnetic components of a mixture magnetic by the attachment of a magnetically responsive entity, which can be manipulated using an external magnetic field. The cells exhibit magnetic properties, namely paramagnetism, ferromagnetism, and diamagnetism. The magnetoactive aquatic bacteria that are separated by high gradient magnetic separations (HGMSs) contain small single-domain crystals of magnetite, and the ability to be oriented in a magnetic field remains even when the organism dies. Most of the applications of HGMS of paramagnetic material is pertains to red blood cells. There are other ways to induce paramagnetism. For instance, large positive susceptibilities can be introduced into biological particles by their adsorption of magnetic cations. Ferromagnetic properties can be imparted to biological matter supplementing the solution with small magnetite particles. An improvement of this technique by employing ferrofluids is reviewed by Rosensweig.^[3] Diamagnetic materials can be separated by using a strongly paramagnetic background fluid, which increases the contrast. White blood cells and platelets have been extracted by this method although in general the range of concentration of the carrier medium is limited by the osmotic pressure effects on the cell membrane.

Two possible modes, direct and indirect, are available for the isolation of target cells. In the direct mode, the magnetic particles with immobilized affinity ligands are directly suspended in the solution or suspension. The target cells bind with the immobilized ligand

Fig. 1 Magnetic bead attached to cell receptor.

during the course of incubation. The whole complex can then be separated using a magnet. In the indirect mode, the target cells interact with the affinity ligand, usually a primary antibody that has first been added to the solution or suspension in the free form, which forms a complex during incubation. Magnetic particles with immobilized secondary antibodies are then added. Finally the magnetic complex formed is separated in a magnetic separator. This technique has been used for the isolation of various microbial cells from culture media^[4] and also used for the isolation of prokaryotic and eukaryotic cells.^[5-7]

The method of cell separation using a magnetic field has been implemented as a binary separation between cells that have and have not bound magnetic microspheres on the basis of a cell receptor (a specific type of surface ligand), as shown in Fig. 1. Many other applications in different biorelated areas are discussed by Safarik and Safarikova.^[8]

Different methods available for separating cells other than magnetic separation are sedimentation, flow cytometry, electrophoresis, and differential adsorption.^[9] From close observation of all the cell separation methods, magnetic separation is easy to implement and can be made quantitative based on the amount of the microspheres bound.

Multistage Magnetic Method

The development of user-friendly devices that are capable of separating particles according to quantity of ligand seems to be the area of greatest need in improving magnetically assisted separation devices. The

Fig. 2 One transfer in the multistage electromagnetic separator process.

magnetic separation industry has made considerable progress in this regard but the commercial technology to date has been limited to binary separation methods. Combination of magnetic extraction with counter-current extraction has made the magnetic separation of cells possible, as both quantitative and qualitative technique. It is quantitative with respect to the amount of ligand bound to cells of the same type and qualitative with respect to the amount of ligand bound to each kind of cell. The innovation presented here is magnetic separation (MAGSEP), a reliable method for differential magnetic separation of cells on the basis of small differences in surface composition.

In MAGSEP, capture could be isocratic or gradient mode. In the gradient mode (as shown in Fig. 2), the first stage has no magnet and no upper cavity and serves the purpose of homogenizing the cell mixture by stirring just before the beginning of transfers. The second stage also has no magnet and serves the purpose of adding magnetic particles to the cell suspension, mixing them together and allowing them to react. The third stage has a very weak magnet in the upper cavity and attracts only the highly magnetized cells, namely those with the most receptors for bonding with the magnetic microspheres. The fourth stage has a stronger magnet than the third stage in its upper compartment and attracts more weakly magnetized cells, and so on until, at the last-but-one stage, the strongest magnet of all captures the cells with the fewest receptors. The final stage has no magnet and will contain remaining unmagnetized cells after the final transfer. In the presence of gravity, uncaptured cells settle into the lower cavities by gravitational sedimentation if the transfer times are made sufficiently long. In the absence of gravity, uncaptured cells would remain in both the upper and lower cavities at each transfer. However, continued mixing with each transfer would have the effect of removing the uncaptured cells in each cavity. This method can separate both particulate (cells) and soluble (proteins) separands.

A comprehensive mass-balance model of multistage separation has been developed. Figure 3 is a schematic representation of a multistage electromagnetic separator showing comparison with a hypothetical magnetic chromatography column. The MAGSEP device

Fig. 3 Multistage electromagnetic separator compared with a magnetic chromatography column.

utilizes a step-wise rotary distribution and containment system, which selects, isolates, and stores particles of different magnetophoretic mobilities. Thus, cells are separated according to the quantity of ligand on their surface.^[10]

Mathematical Models

The range of magnetic field required for cell separation is obviously decided by the magnetic and mechanical properties of the cells. A review of the mathematical formulae that are relevant to cell extraction and their illustration by selected examples is presented well by Zboroswki.^[11]

The magnetic field is a space domain where an electrical charge, e , moving with velocity v_e experiences a magnetic force, F_m , given by

$$F_m = IlB \quad (1)$$

where I is the current intensity (A), l is length of element (m), B is the magnetic field intensity (kg A⁻¹s⁻² or Tesla, T). The presence of matter in the magnetic field modifies the field fluxes at given constant field strengths. The magnetic properties of matter are defined by induced polarization M to account for the variation in magnetic flux. For isotropic media

$$M = \chi_m H \quad (2)$$

where χ_m is magnetic susceptibility and H is the magnetic field strength (Am⁻¹). In the uniform magnetic field the magnetic particle undergoes rotation until Maxwell stress tensor becomes zero and then remains stationary with respect to the medium. In the nonuniform field, differences in the Maxwell stresses result in a net force, F_m , acting on the magnetic particle given as

$$F_m = V_p(M \cdot \Delta)B \quad \text{or} \quad F_m = V_p \chi_m H \frac{dB}{dz} \quad (3)$$

where V_p is the volume of the particle. In homogenous media, magnetic field B is parallel and proportional to

the magnetic field strength H . Magnetic force lines are defined as curves that are tangent to the direction of vector F_m . In general, due to nonlinear relationship between the magnetic force F_m and the magnetic field H , the lines of magnetic force do not follow the lines of magnetic field B . This is drastically different from the static electric field, in which electric force lines are synonymous with electric field lines.

Now the work required to bring all the components of the magnetic system from infinity to their given spatial position is defined as magnetostatic potential energy, U_m , which can be given as

$$U_m = V_p \chi_m u_m = -\frac{V_p \chi_m B^2}{2\mu_0} \quad (4)$$

where ' u_m ' is magnetic energy density, given by $-B^2/2\mu_0$ and μ_0 is the magnetic permeability of free space. The relationship between the force and the potential energy leads to the following expression of the magnetic force:

$$F_m = -\nabla U_m = -V_p \chi_m \nabla \mu_m = \frac{V_p \chi_m \nabla B^2}{2\mu_0} \quad (5)$$

The direction of the magnetic force F_m relative to the energy density gradient ∇B^2 depends on the sign of χ_m . For paramagnetic substances, $\chi_m > 0$ and the force vector points toward the direction of the maximum increase in magnetic field energy density, termed magnetic attraction. For diamagnetic substances, $\chi_m < 0$ and the force vector points in the opposite direction to the maximum increase in the field energy density, termed as magnetic repulsion. When the particles are suspended in a medium of magnetic susceptibility χ_m , then in the above expression χ_m is to be replaced by $\Delta\chi_m$ (magnetic susceptibility difference). Consequently the above discussion applies to $\Delta\chi_m$ rather than χ_m . Thus the very basis for all magnetic cell extractors is the observation that forces acting on small magnetic particles follow the lines of gradient of the magnetic field energy density.

Model for Viscous Medium

A simple mathematical model is developed based on the theory discussed so far in this article, for the motion of magnetically labeled cells in a viscous medium in the presence of magnetic field.^[11] The following assumptions are involved: 1) cells are small compared to the characteristic magnetic field and fluid flow dimension; 2) cells are treated as magnetized rigid spheres while calculating magnetic and fluid drag forces; 3) specific density of the cell is similar to that of the medium; and 4) inertial forces are too small to be considered when compared with the viscous ones. With these assumptions the equation of motion [involving the forces magnetic (F_m), drag (F_d), and buoyancy (F_b)] is written as

$$F_m + F_d + F_b = 0 \quad (6)$$

where

$$F_m = \frac{(\Delta\chi_m)V_{\text{cell}}\nabla B^2}{2\mu_0} \quad (7)$$

$$F_d = 6\pi\eta a_{\text{cell}}(v_{\text{cell}}) \quad (8)$$

$$F_b = V_{\text{cell}}(\Delta\rho)g \quad (9)$$

when the circulation in the medium is neglected (v_{medium}) due to high viscosity. It may be noted that $V_{\text{cell}} = 4\pi a_{\text{cell}}^3/3$ (volume of cell, m^3) where a_{cell} is cell radius (m) and η is viscosity (kg ms^{-1}), $\Delta\chi_m = (\chi_{\text{cell}} - \chi_{\text{medium}})$ with magnetic susceptibility is replaced by volume average cell susceptibility, and $\Delta\rho = (\rho_{\text{cell}} - \rho_{\text{medium}})$ where χ_{cell} is magnetic susceptibility of cell, χ_{medium} is magnetic susceptibility of medium, ρ_{cell} is density of the cell (kg m^{-3}), and ρ_{medium} is density of the medium (kg m^{-3}). On solving for v_{cell} (velocity of the cell, m/s)

$$v_{\text{cell}} = -\frac{(\Delta\chi_m)a_{\text{cell}}^2\nabla B^2}{9\mu_0\eta} - \frac{2(\Delta\rho)a_{\text{cell}}^2g}{9\eta} \quad (10)$$

In order to obtain the flux J , both sides are multiplied by concentration of cells C :

$$J = -\frac{C(\Delta\chi_m)a_{\text{cell}}^2\nabla B^2}{9\mu_0\eta} = C v_{\text{cell}} + \frac{2(\Delta\rho)a_{\text{cell}}^2g}{9\eta} C \quad (11)$$

This equation states that the flux of magnetically labeled cells relative to the medium follows the lines of magnetic energy density gradient. Here the mass flux of small magnetic cells/particles is coupled to the driving force of the magnetic energy density gradient. As the

magnetic particles are assumed to be rigid bodies of finite volume such that convective, gravity, and buoyancy forces can be neglected, the magnetic particles are expected to accumulate, forming layers around the magnetic surfaces. Further, the surfaces of the magnetic layers follow the surfaces of constant magnetic energy density or B^2 is constant.

This model of Zborowski^[11] could be easily adapted for MAGSEP. Additional assumptions made at this point include: 1) All particle motion is vertical; 2) the drag force is negligible except for in the vertical direction; 3) the axial magnetic field is constant over the radius of the cylindrical cavity of the MAGSEP; 4) creeping flow conditions (low Reynolds number); and 5) particle velocity is constant and is equal to the mean velocity of migration ($d^2z/dt^2 = 0$).

Magnets with large cross-sections (relative to the cavity cross-section) are assumed and, as a result, the magnetic field was considered to be constant over the radial cross-section ($\partial B_z/\partial r = 0$). By taking the dot product of the magnetic field and the gradient of the magnetic field, the following differential relationship is determined:

$$B \cdot \nabla B = B_z \cdot \frac{\partial B_z}{\partial r} + B_r \cdot \frac{\partial B_r}{\partial z} \quad (12)$$

where B_r is magnetic field component in r direction ($\text{kg A}^{-1}\text{s}^{-2}$ or Tesla, T), B_z is magnetic field component in z direction ($\text{kg A}^{-1}\text{s}^{-2}$ or Tesla, T), $\partial B_z/\partial r$ is rate of change of the magnetic field along the vertical axis r and $\partial B_r/\partial z$ is rate of change of the magnetic field along the vertical axis z .

This relationship, combined with the above assumptions to simplify the magnetic force equation, yields the scalar magnetic force relationship similar to that given in Eq. 7. If all variable parameters for the MAGSEP experiment in this equation (B and particle size radius, a_p) are set, then the susceptibility difference, $\Delta\chi_m$, is the controlling variable governing the magnetic force. Based on this calculation, the separation of the cells as it relates to the susceptibility difference can be governed by controlling the magnetic field, B , the vertical height of separation, Δz , and the time interval required for separation, Δt .

The volumetric susceptibility difference $\Delta\chi_m$ can be measured by sampling a distribution of particle positions. If the particles are placed in a thin flat layer across the bottom of a cavity and covered with a solution to a depth Δz , the particles can then be aligned below a shallow upper cavity with an activated magnet. The magnetic field of the upper magnet can then attract particles for a time Δt , and when a sufficient amount of particles have migrated into the shallow upper cavity, the cavities can be half-stepped to separate the particles as shown in Fig. 2. The volumetric

susceptibility can then be calculated by the following relationship:

$$\Delta\chi_m = \frac{9v_p\eta/a_p^2 + 2g(\Delta\rho)}{B \cdot \frac{\partial B}{\partial z}} \quad (13)$$

where v_p is the velocity (m/s) and can be assumed to be equal to $\Delta z/\Delta t$. The number of particles transferred represents a distribution of the total particles and is also a representation of the number of particles within a volumetric susceptibility range. If enough separation in these stages takes place, then this volumetric susceptibility range can be assumed to be an absolute volumetric susceptibility. Continuous flow magnetic cell sorting using soluble immunomagnetic label and the corresponding theory was presented by Zborowski et al.^[12]

ELECTROPHORETIC SEPARATION

Electrophoresis is a leading method for resolving mixtures of charged cells/macromolecules. Electrophoretic separations are influenced by many factors including the size (or molecular weight), shape, secondary structure, and charge. These features can influence electrophoretic properties either separately or jointly. In order to achieve the required scale-up, scientists and engineers resort to flowing methods.^[13] Scale-up of electrophoresis is hindered by Ohmic heating, which causes free convection/mixing within the system. Excess heat can also denature the labile cells.

Existing Methods

Free electrophoresis could enjoy more widespread use, because it is a high-resolution separation method that does not require adsorption to solid media and the subsequent solids handling. Furthermore, it can handle the cells/particles as well as solutes/macromolecules alike. Some of the applications of free electrophoresis include the separation of different cells of peripheral blood and bone marrow in hematological and immunological research with therapeutic applications. In spite of its positive applications, free electrophoresis has never gained popularity as a preparative or as an industrial separation method owing to gravity-dependent characteristics such as thermal convection, electroosmosis, particle sedimentation, particle aggregation, and electrohydrodynamic zone distortion. None of these principal gravity-dependent and gravity-independent processes have been investigated in multistage electrophoresis, which is designed to minimize the impact of these processes on separation quality.

Another type of mixing problem encountered in free electrophoresis, although less critical compared to Ohmic heating, is the mixing caused by gas release at the electrodes. This problem is addressed by employing nongassing electrodes or membrane-separated electrodes.^[14]

A score of methods have been developed to effect free electrophoresis.^[9] These methods can be broadly divided into static and flowing methods, neither of which has satisfactory capacity for application as a manufacturing tool. Batch and continuous methods have also been developed. In almost all cases, maximum sample input rates have been of the order of a few millilitre per hour. In one important case, Tulp et al.^[15] designed a reorienting free electrophoresis device consisting of a flat disk-shaped container with thin sample bands and a short migration distance. The top and bottom electrode fluids served as coolant and the total height of the separation column was 1–2 cm, and its diameter was greater than 15 cm. The distance between unrelated separands was about 1–2 mm, and this distance was increased during fractionation after electrophoresis by reorienting the disk.

Based on research experience an attempt has been made by using a multistage electrophoretic method to overcome the major bottlenecks of free electrophoresis in various fields of bioprocessing and analysis such as virology, endocrinology, enzymology, hematology, and mammalian cell culture.

Multistage Electrophoretic Method

The multistage electrophoretic method has been developed by combining free electrophoresis and multistage extraction and is explored as an improved alternate method for the purification and concentration of cells or macromolecules. The present discussion is restricted to cells. The design is based on a derivative of the thin-layer multistage extractor design of Albertsson^[16] and Treffrey et al.^[17] and called ADSEP, designed by SHOT, Inc.,^[18] which is shown in Fig. 4. The extractor consists of a 22-cavity, multistage, thin-layer extraction system.^[17] Half-cavities oppose each other in disks that are sealed together and rotate with respect to each other. The half cavities are disk shaped, and top cavities have flat tops while bottom cavities have flat bottoms. Both contain palladium (Pd) metal electrodes that produce an electric field when the two cavities are in phase with each other. This extractor, like the Tulp device,^[15] takes advantage of short column height to maintain isothermal conditions. Each cavity is only a few mm in height so that the fluid within it remains isothermal during the application of an electric field that transfers the separand particles or cells from the bottom to the

Fig. 4 ADvanced SEPARation (ADSEP) apparatus.

top cavity. As each separand is transferred to a new cavity, it is either drawn into the upper cavity by the electric field or left in the lower cavity, depending on its electrophoretic mobility. ADSEP is driven by an independent power supply (Lamda, Model # LP-532-FM) for rotating the plates to bring the chambers into interfacial contact with each other. This ADSEP is modified to use as ELECSEP by replacing the chamber bottoms with metal cover plates. Electrodes are kept over these cover plates with gaskets in between them.

A combination of free electrophoresis and multistage extraction is explored as an improved and alternative method for the extraction of cells. A simple mathematical model is presented to describe the mass and heat transfer during the electrophoretic separation process in an electrophoretic countercurrent extractor (ECCE). In order to validate the model and also to test the extractor, the extraction of fixed human red blood cells and latex particles of different sizes suspended in phosphate buffer is performed at different electric field

strengths. The experimental results are found to agree reasonably well with those predicted by the model.^[19]

It is observed that the cell transport velocity increases proportionally to the applied electric field strength under otherwise similar conditions (Eq. 14), and is also noted that when the field strength is doubled the cell extraction is completed in much fewer transfers.^[19]

Mathematical Models

In an ECCE apparatus, the separation of bioparticles having different electrophoretic mobilities is achieved by contacting the buffer solutions of top chambers with bottom chambers containing the bioparticles in buffer or fermentation broth, and then applying an electric field (E) at regular, predetermined intervals.

Mass transfer

Electrophoretic extraction of cells is a rate process (not an equilibrium process) and the particles having higher electrophoretic mobility are separated ahead of those having relatively lower mobility. The physical description of the multistage extraction is shown in Fig. 5. An ECCE apparatus has n extraction stages. Let us consider a situation in which all particles of electrophoretic mobility, μ_E , are initially in one (first) bottom chamber. In the first extraction step, the top and bottom chambers of stage 1 are brought into interfacial contact with each other. Then the field of preselected intensity (E) is switched on. Cells having negative mobility move to the top chambers (having an anode). After applying the field for a predetermined time period (τ), the field is switched off. The bottom cavity is moved to a position to be in contact with a

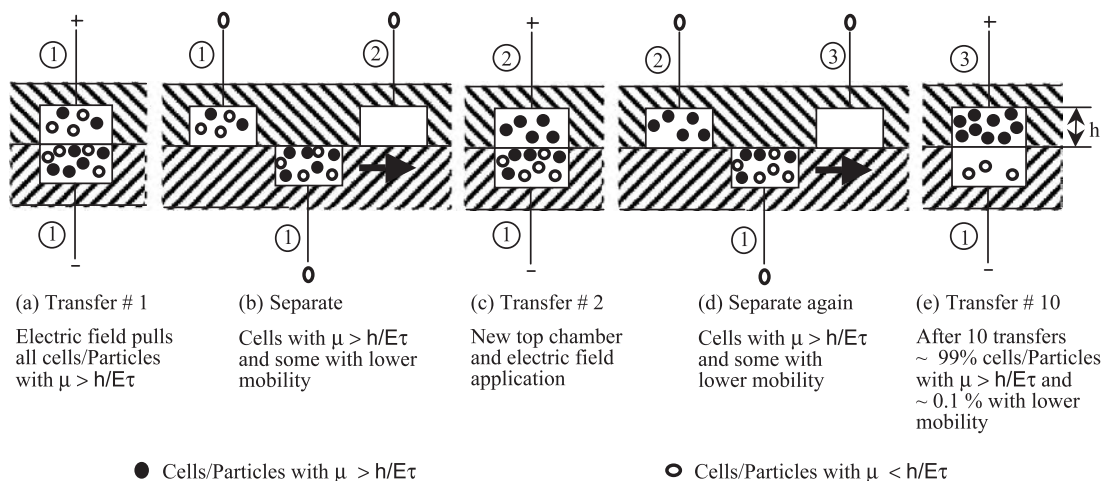

Fig. 5 Physical description of multistage extraction of cells/particles.

new top cavity having buffer. This process is repeated as many times as necessary to achieve the desired separation. Even when one type of particle is used, the particles usually have an approximately normal electrophoretic mobility distribution and not a single value. However, the average mobility can be estimated under actual conditions without the drawbacks of the conventional methods.

The quantity of bioparticles initially ($t=0$) present in the first bottom chamber is denoted by N . Now let us consider one chamber, whose total depth is H_t and radius is R with the bioparticles suspended in buffer solution filling the chamber. When a vertical electric field is applied, the bioparticles move upward as a slug due to their electrophoretic mobility. Their velocity will be proportional to the applied field. In other words

$$dy/dt \propto E \quad \text{or} \quad dy/dt = \mu_E E \quad (14)$$

where the proportionality constant, μ_E , is electrophoretic mobility and the characteristic of the bioparticle and its magnitude is decided by the surface charge of the bioparticles.

Integrating the above equation between the limits $y=0$ to h and $t=0$ to τ where τ is the time of application of the electric field results in

$$h = \mu_E E \tau \quad (15)$$

so that a bioparticle of mobility μ_E moves a distance h in an electric field of intensity E applied for a time of τ . It is obvious that if E is increased, τ can be decreased to achieve the same distance of migration and vice-versa, under otherwise similar conditions.

The bioparticles are randomly distributed in space over the volume of the bottom chamber. However, the time required for an individual particle to move into the top chamber increases as its distance from the top surface of the bottom chamber increases, under a given set of experimental conditions of E and τ ; that is, the ratio of these heights (h/H_t) gives the relative number of bioparticles that migrate to the top chamber at any given set of E and τ . To calculate the absolute number of particles transferred to the top chamber, the ratio of the distance to the top of the chamber to the total height H_t has to be multiplied by the concentration of the particles (i.e., number of particles per unit volume), since the ratio of the heights is nothing but the ratio of the volumes of the chamber corresponding to the location considered.

Therefore, if it were desired to capture the particles with mobility μ_E located at distance h from the top surface of bottom chamber, the number of bioparticles that would migrate during a single step is

$$m = (h/H_t)(N) = (\mu_E E \tau / H_t)(N) \quad (16)$$

where $N = (c)(\pi R^2 H_t)$, c is the cell concentration (cells/ml), $\pi R^2 H_t$ is the volume of the chamber, and $h = \mu_E E \tau$ (from Eq. 15). The particles move as a slug and in each transfer step a slice of slug of height h (containing m number of cells/particles) is extracted into the top chamber. In each transfer the slug of cells/particles move by the same distance and hence the same number of cells/particles is extracted in each transfer, until cells are exhausted.

The change in the number of particles in a stage n during step r will be equal to the number of bioparticles that migrated to the top chamber during step r . Thus the general equation can be written for this situation, by material balance, for number of particles extracted in each transfer step.

$$-(N)_{n,r} + (N)_{n,r-1} = (m)_{n,r} \quad (17)$$

where $(m)_{n,r}$ is the number of particles with mobility μ_E that migrated from stage n during step r to the top chamber N is the total number of bioparticles present in any of the n bottom chambers at $t=0$.

Now using Eq. 16, the above Eq. 17 can be written as

$$(N)_{n,r} = -(\mu_E E \tau / H_t)(N)_{n,r-1} + (N)_{n,r-1} \quad (18)$$

This is a general equation that enables us to estimate the number of bioparticles having mobility μ_E in any stage n , provided their concentration is known in the previous stage. Assuming that the bioparticles are uniformly distributed in the chamber and they move in a plug flow under the influence of an applied electric field and hence the same number of particles migrate to the top chamber in each transfer step (which are contained by the slug of height h of Eq. 16), the following material balance equation can be written as

$$(N)_{n,r} = -(r)(\mu_E E \tau / H_t)(N) + (N) \quad (19)$$

where r is the step number and N is the initial concentration of the bioparticles of mobility μ_E . From this generalized equation, the number of bioparticles in a given stage can be calculated directly from the number of transfers, r , instead of step-by-step sequence, especially at low field strengths.

Heat transfer

A major problem in scale-up of electrokinetic processes is known to be heating, which in turn causes mixing. However, the major advantage of the multistage process is the speed at which it performs separations. Hence the design is modified (such as provision for proper heat transfer/removal) in order to reduce the

adverse effects of heating, while scaling up the process based on the basic laws of heat generation and transmission. Electrical energy is dissipated as heat according to the following equation, which obeys Ohm's law

$$W = I^2/A^2K_E \quad (20)$$

where W is the power density (watts/cm³), I is the current (amperes), A is the area (cm²) over which the field is applied, and K_E is the electrical conductivity of the medium (mho/cm or Siemen/cm). It may be noted that the heat generation increases as the square of the current passed. For this reason, nearly all electrokinetic applications are in the most resistant media compatible with the unit operation, meaning that low-conductance solutions must be used to have low current in order to operate for longer periods of time.

In an adiabatic stagnant system, the temperature gradually increases uniformly with time as

$$\Delta T = \frac{IE_\tau}{C_p\rho} = \frac{I^2\tau}{K_E A^2 C_p \rho} \quad (21)$$

where τ is the time of application of electric field, C_p is the specific heat of the media carrying the current, and ρ is the density of the system (gm/cm³). The above equation represents the maximum (adiabatic) temperature increase in the electrophoretic system.

SCALE-UP AND ECONOMIC ASPECTS

Recent developments such as new methods of generating high magnetic field gradients and availability of reasonably priced efficient and superconducting magnets enable the use of magnetic extraction technology even on a large scale.^[1] Batch HGMS machines are in commercial use and continuous separators are also developed.^[1] Some of the following are already commercialized or have a very high possibility of being commercialized in the near future. Commercially introduced by Dynal A/S (Oslo, Norway) and Miltenyi Biotech (Bergish Gladbach, Germany), immunomagnetic cell separation has become an established method for cell analysis in clinical diagnostics. Its low price makes it an alternative to flow cytometry and very handy for rare cellular events.

The main advantage of magnetic separation here is to eliminate the need for centrifugation with its many associated disadvantages.^[19] Further magnetic separations are cheaper, faster, allow many samples to be handled simultaneously, and help to lend the process towards automation. Ease of conjugation of magnetic immunomicrospheres having the required size with

antibodies paved the way for large-scale immunological cell sorting.^[1] Performance data in simple and complex matrices for the process-scale cell separation with the help of bioreceptor ferrofluids and HGMS were reported.^[20]

On analyzing the available information, it appears that electroextraction may pose more scale-up problems when compared to magnetic extraction for cells. However, the actual situation varies depending on the application and each method has its own advantages and disadvantages. For instance, the advantages of using the magnetic rather than electric field are no need for medium modifications, no biological effects in the range of practical static magnetic field intensities, and no joule heating and therefore no flow distortion or need for a complex cooling system.^[21] On the other hand, the disadvantages are its complex interaction with paramagnetic and ferromagnetic labels, the additional cost of research and development, and its dependency on chemical reagents, antibodies, and magnetic colloids, while all other methods are based on cellular immunoreactivity.^[12]

Practically no reports are available in the literature to date regarding economic aspects of magnetic and electroextractions. However, we are optimistic about the prospects for the electrophoretic methods in processing of cells and macromolecules due to two main factors. As a source of energy due to low currents involved (only mA), electric fields are not expensive. As a force, electric fields are tunable to a very fine degree and involve no moving parts. Small-scale applications are already making a major impact on analytical and preparative separations.

OTHER APPLICATIONS

Magnetic extraction must be thoroughly explored for its application in other areas since it exhibits high specificity and easy scale-up. Therefore, it finds applications in various fields such as food processing, wastewater treatment, medicine parasitology, and clinical and environmental microbiology. Some possible applications are cited here, which will prompt researchers to look for similar applications.

Casein hydrolysis was carried out using chymotrypsin immobilized on magnetic supports.^[22] Magnetic separation is used for the detection of pathogenic microorganisms such as *Staphylococcus aureus*, *Salmonella enteritidis*, *Listeria monocytogenes*, and *Escherichia coli*.^[23]

Separation, immunoassy, magnetic resonance imaging (MRI), drug delivery, and hyperthermia are enhanced by the use of magnetic particles in medical applications and could be used as carriers to introduce DNA into cells. They can also be used as heat

mediators for cancer therapy. Hence, the use of magnetic particles with their unique feature will further improve medical techniques.^[24] Another potential application of magnetic particle separation technology is the use of magnetically delivered therapeutics. Carrier holding the drug can be concentrated at the desired site *in vivo* by a magnetic field.

Electrophoretic extraction can be explored in aqueous two-phase systems, because unlike the magnetic extraction method, it has influence on the partition behavior of cells, as well as on phase demixing rates.^[21] Similarly, electrophoretic methods are finding increasing applications in other areas. For instance, electrophoretic processes are established techniques for the dewatering of fine clays and latexes and also for enhancing liquid–liquid extraction. Adaptation of this method for the extraction of biochemicals was reported.^[25] Greater clarification and faster floc formation were claimed using electrocoagulation in comparison with conventional chemical methods.

SUGGESTIONS FOR FUTURE WORK

Only a few attempts at proportional magnetic particle separation have been made. The technical shortfall is related to the distance over which field gradients must be maintained. Using the preexisting ADSEP technology, these distances can be kept short, the apparatus is manageable, and the separation can be of adequate resolution. Although the technical feasibility of MAGSEP has been established, more research must be carried out to deliver the economically feasible design of multistage magnetic extractor.

There is a need for magnetic extraction of cells on the basis of receptor density. The relatively small sample of recent findings clearly indicates that tools for studying cells with modified receptor densities would be welcome. Identification of applications is one of the major aspects that need attention in the immediate future. A need for proportional (vs. binary) magnetic separation has to be identified in the areas of 1) immunological research, 2) pharmaceutical delivery, and 3) biomedical applications.

Our research work in electrophoretic extraction has confirmed the technical feasibility of multistage extraction of cells using electric fields.^[19] However, a good amount of research needs to be done before bringing ADSEP to the market as ELECSEP. For example, immediate study is required to examine the efficacy of the unit for the fractionation of a mixture of cells. Preliminary experiments have indicated that the resolution is hampered by the depth of the chamber. Thus in future designs, the depth of the chamber should be reduced while the diameter/cross-sectional area of the chambers should be increased.

CONCLUSIONS

Some of the new separation technologies that have considerable promise in the near future for the effective extraction of cells/particles are presented in this article. It is not difficult to appreciate the fact that separation technology is one of the most complex and important areas of biotechnology. Some successful applications of magnetic and electrophoretic extractions are commercialized.^[5] Magnetic and electrophoretic separation methods are undoubtedly complementary to other methods that are in use at present in the area of biotechnology and have the potential even to be alternatives in specific situations where other conventional methods normally tend to fail. Further, these advanced separation methods often result in relatively faster and more selective separation of the target cells. It may be noted that the scope of possible applications of magnetic and electrophoretic separation methods is very wide and obviously not limited to only those discussed here in this article. More and more new applications will be identified and studied in the near future.

An interdisciplinary effort involving a combination of physical, chemical, biomedical, and engineering aspects is essential for developing effective field-assisted separation methods. Some of these have received enough attention, but, the engineering aspects have been largely neglected. Mathematical modeling, which is highlighted in this article, will be of immense use in predicting the amount of cells extracted without the measurement of an inordinately large number of parameters and, hence, due importance should be given to this aspect. Some of the important aspects on which future research efforts need to be focused are suggested in this article. Even if some of these aspects are addressed in greater depth by future researchers, the objective of this article can be considered fulfilled in view of the recognized scientific and industrial potential of magnetic and electrophoretic separation methods.

INTRODUCTION

Nanometer-sized particles of nearly all materials exhibit novel properties because their state is intermediate between that of atoms or molecules and that of bulk, solid materials.^[1,2] Particles in the size range of 1–100 nm can exhibit quantum size effects, depending on their bulk Bohr radius. They may show size-dependent optical absorption and emission, coulomb staircase behavior in electrical transport, quantum tunneling of magnetic moment in magnetism, and other properties unique to materials in this size range. Nanoparticles of magnetic substances—metals, alloys, and oxides—acquire noteworthy new qualities and their magnetic characteristics are significantly altered relative to those of the corresponding bulk materials. Magnetic nanoparticles are active components of ferrofluids, recording tape, and flexible disk recording media. There are exciting future applications of magnetic nanoparticles in spintronics—a new paradigm of electronics that utilizes both the intrinsic charge and intrinsic spin of electrons for ultra-high-density data storage and quantum computing. Magnetic nanoparticles are also used in important biomedical applications. These include magnetic bioseparation of labeled cells and biological entities, therapeutic drugs, gene and radionuclide delivery, radiofrequency-induced destruction of cells and tumors via hyperthermia, and contrast-enhancement agents for magnetic resonance imaging (MRI). Magnetic nanoparticles are well suited for these applications for several reasons. First, they can be selectively fabricated in sizes that range from several to hundreds of nanometers making them smaller than or comparable to important biological entities such as cells (10–100 μm), viruses (20–250 nm), proteins (3–50 nm), and genes (10 nm wide and 10–100 nm long). Second, they can be surface functionalized with biological molecules that enable selective interaction with various target bioentities. Third, their motion can be manipulated and controlled by an external magnetic field.^[3,4] Fourth, they can absorb energy from a time-varying magnetic field and dissipate it at the cellular level in the form of heat.^[5]

Studies of magnetic nanostructures encompass a broad range of synthetic and investigative techniques involving tools from and knowledge of chemistry, physics, and engineering. There are two basic approaches to nanoparticle preparation and assembly: “bottom up and top down.” The bottom-up approach takes molecules or a cluster of molecules (nanoparticles) and assembles them up into a pretailored architecture. This approach relies on the energetics of the assembly process to guide it. Typical examples are templated film growth, self- and directed-assembly of colloidal particles, and spinodal wetting/dewetting. The top-down approach, on the other hand, relies on micromachining materials to the desired sizes and patterns, and is generally subtractive in nature. Typical examples of the top-down approach include photolithography, mechanical machining/polishing, laser beam and electron beam processing, and electrochemical removal. In this entry, we are particularly focused on the preparation by the bottom up approach and bioapplications of magnetic nanoparticles. The particle of particular interest is Fe_3O_4 and/or Fe_2O_3 in 10–100 nm size ranges that are built as an aqueous ferrofluid.

SUPERPARAMAGNETISM

Magnetic characteristics of ultra-small particles are very different from that of their bulk counterparts. Magnetic particles in the size range of less than ~ 20 nm consist of single magnetic domains unlike in a bulk ferromagnet where there are several domains. In a single-domain ferromagnetic particle, below the characteristic Curie temperature of the material, the individual spins are ferromagnetically coupled giving rise to a large magnetic moment, typically 10^3 to 10^5 μB , and thus the particle is spontaneously magnetized. Even as the ferromagnetic order within the particle remains intact, the magnetization vector of the particle as a whole points in random directions and thus, the particle as a whole acts as a giant paramagnet, hence the term superparamagnet. Thus, in the presence of an external

Fig. 1 Superparamagnetic nature of magnetic particles. There is no hysteresis at room temperature. Hysteresis develops owing to blocked states at low temperatures.

magnetic field, a collection of superparamagnetic particles will all point their magnetization vectors along the field direction. But as the field is withdrawn, they relax back to their paramagnetic state and the spins orient randomly. Therefore, the superparamagnetic particles do not show any magnetic hysteresis, except below their blocking temperature (Fig. 1). The super-spins are frozen in definite directions. This property is amply useful in bioapplications.

Another issue to have a magnetic ferrofluid ready for any bioapplication is to have the magnetic particles be colloiddally stable when dispersed in water. It is a technological challenge to control the dispersibility of nanoparticles in desired solvents. The nanoparticles have large surface to volume ratio and therefore high surface energies. Consequently, they tend to aggregate so as to minimize the surface energy. In addition to a high surface energy, magnetic nanoparticles experience interparticle dipolar attractions that tend to further destabilize a colloidal dispersion of them. A suitable surface functionalization and choice of solvent are crucial to achieving sufficient repulsive interactions to prevent aggregation so as to obtain a stable colloidal solution of magnetic nanoparticles—a ferrofluid.

NANOMAGNETIC PARTICLE SYNTHESIS TECHNIQUES

Homogeneous Precipitation

This is a method of precipitation where a short single burst of nuclei are formed when the concentration of the reagents crosses a critical limit.^[6] These nuclei so

formed are then allowed to grow by diffusion of solute within the solution that goes and adds to the surface of the nuclei. The nucleation and growth steps are temporally separated. At the end of the reaction, depending on the system, nearly uniform crop of particles are formed. Often in this process, there is a sharpening of the particle sizes by a process called Ostwald ripening where owing to energy consideration, smaller particles dissolve into the solution and the resulting solute gets added to the large particles surface to make them even bigger. The process continues to make the entire crop of particles nearly monosized.

Introduction of a suitable surfactant during or after the synthesis prevents aggregation of the nanoparticles, and makes a stable colloidal dispersion possible. Most surfactants adhere to surfaces in a substrate-specific manner. For example, thiols bind to gold and silver surfaces, carboxylic acids bind to oxide surfaces, and nitriles and amines bind to platinum. However, the mere presence of a functional group does not guarantee that a ligand will bind to the surface of a nanoparticle, or that a stable dispersion will form. Often, the chain length and solvent system have significant influence on the formation of a truly stable dispersion. In the case of magnetic ferrite particles, the carboxylate ends of long-chain carboxylic acids such as oleic acid and stearic acid bind well to the particles so that the aliphatic chains extending out from the surface of the particle make them effectively hydrophobic and dispersible in nonpolar solvents. Alkyl phosphonates and phosphates also bind to magnetite particles well, and render their surfaces hydrophobic.^[7] Intermediate length carboxylic acids from C₉–C₁₂ can form a bilayered structure and make the surface hydrophilic, enabling formation of a stable aqueous dispersion.^[8] Further if a different carboxylic acid ligand such as citric acid or dimercaptosuccinic acid is introduced onto the particle surface, adsorption takes place, but also the surface of the particle is terminated with a polar group.^[9,10] This results in particles that are soluble in polar groups such as water. In fact, aqueous solutions of magnetite particles with such ligands have been found to be stable for several months without any sedimentation. Fe₃O₄ particles that are surface terminated with carboxylic groups (citric acid) can further bind to a dye molecule and be fluorescently labeled, and cellular uptake can be imaged using fluorescent microscopy (Fig. 2).

Coprecipitation

Coprecipitation is an example of homogeneous precipitation to prepare a magnetite system. Magnetite (Fe₃O₄) particles are prepared by the Massart's coprecipitation of water-soluble iron salts in a basic

Fig. 2 Imaging of fluorescent magnetic nanoparticle uptake in cultured cells (KB—an oral adenocarcinoma cell line).

medium.^[11] A mixture of FeCl_2 and FeCl_3 (1:2 molar ratio) is taken as a concentrated solution ($\sim 10\text{ M}$) and heated to $70\text{--}80^\circ\text{C}$ in inert environment, and concentrated NH_4OH in excess of three molar equivalents is injected into the reaction vessel. This yields a black precipitate consisting of Fe_3O_4 nanoparticles that remain partially suspended in the reaction mixture at a high pH. At this time, a long-chain carboxylic acid such as oleic acid or stearic acid may be adsorbed on the surface of the particles by the carboxylate end, rendering the particle surfaces alkyl terminated and hence hydrophobic. These particle surfaces can also strongly adsorb phosphonic acids through the phosphonate end. The particles thus surface-modified are soluble in organic nonpolar solvents such as hexane, toluene, etc. Size-selective precipitation may be employed to narrow the size distribution. This method relies on the fact that surface-passivated particles of different sizes, while remaining in a dispersed state, selectively precipitate according to their sizes by differential centrifugation. Thus, a series of different fractions of particles of a different average size can be produced.

Nonaqueous Colloidal Precipitation

This is an example of homogeneous precipitation carried out in an organic medium. Metal complexes such as carbonyls can be decomposed at moderately high temperatures to form metal clusters. The growth of the

metal clusters can be arrested by concomitant surface passivation. Long-chain carboxylic acids, amines, and thiols are known to bind to the surfaces of metals and oxides. For instance, cobalt nanoparticles have been produced by the use of oleic acid as the surfactant and octyl ether as the solvent. The particles were synthesized by reduction of cobalt salt with superhydride at a high temperature. High temperature allows the formation of multiple nuclei, and a long heating time often allows crystallization, so that each nanoparticle is a single crystal. Ferrite particles such as Fe_3O_4 have been prepared by a high-temperature reduction called polyol process where usually a long-chain diol is employed to obtain these particles from the organic precursors.^[12] Organically soluble iron acetylacetonate decomposes at a high temperature ($\sim 240^\circ\text{C}$) in the presence of hexadecanediol to give Fe_3O_4 nanoparticles of uniform sizes (Fig. 3). In this process, the nucleation and growth takes place in the presence of the surface-binding ligand such as oleic acid or oleyl amine, or their mixture. Appropriate mixture of Co and Mn precursors gives rise to CoFe_2O_4 and MnFe_2O_4 nanoparticles, respectively. Because of the uniform sizes of particles already obtained by this method, there is no necessity of size-selective precipitation.

Fig. 3 Transmission electron micrograph of monodispersed Fe_3O_4 particles prepared by organic route.

Microemulsion Formation

Microemulsion is a homogeneous phase obtained from a mixture of water, oil, and surfactant. The surfactant is responsible to form a micelle or a reverse micelle depending on the ratio of water to oil. In oil-in-water microemulsions, small oil globules are formed called micelles, and in reverse stoichiometry, i.e., water-in-oil microemulsions, small droplets of water are formed in the oil phase, called reverse micelles. The micellar and reverse micellar droplets, can both be used as micro/nano reactors to cause a precipitation reaction, and often the product formed is regulated by the sizes of the reactor. Magnetic particles can be formed by appropriate reaction within these reactors. Magnetite particles of ~ 4 nm average diameters have been reported by controlled hydrolysis of ammonium hydroxide of a mixture of FeCl_2 and FeCl_3 in a reverse micelle reactor. Further, Fe_2O_3 nanoparticles of 4–6 nm diameters have been prepared by reaction of $\text{Fe}(\text{AOT})_2$ (AOT: Aerosol OT) with methyl amine in a micellar system.^[13]

Pyrolysis

There are important magnetic materials, such as metallic nickel, for which colloidal synthesis of nanoparticles is difficult or impractical. However, these particles can be readily prepared in the vapor phase by decomposition of suitable precursors. This is accomplished using a laser-driven aerosol synthesis reactor in which an infrared laser rapidly (in less than 1 msec) heats a dilute mixture of precursor vapors to decompose the precursor and initiate particle nucleation.^[14] The laser heating is followed by rapid cooling of the freshly nucleated particles by mixing with unheated gas. This quenches their growth at controllable sizes, typically from 5 to 50 nm diameter. Online aerosol instrumentations allows for direct measurement of the size distribution of particles larger than 10 nm in diameter. The particles can be collected directly into appropriate combinations of solvents and surfactants without exposure to the atmosphere, which may result in unwanted oxidation of the particles. If necessary, an additional size-selection procedure is adopted to narrow the size distribution of the particles produced. This is accomplished by adding a suitable nonsolvent (e.g., ethanol into a hexane dispersion) and centrifuging the mixture at various speeds and collecting fractions with different median sizes of the particles. With addition of small amounts of oxygen to the reactant stream, the same method can be used to prepare metal oxide nanoparticles.

For some materials, volatile precursors are readily available, such as iron carbonyl for preparation of iron

or iron oxide particles. For nickel, the corresponding precursor (nickel carbonyl) is highly toxic. However, for vapor-phase synthesis, nickel carbonyl can be generated in situ from activated nickel and carbon monoxide, and then immediately react it to form nanoparticles and decompose any residual precursor. Appropriate precursors for many materials can be readily identified from the vast literature on chemical vapor deposition of thin films on solid surfaces from vapor phase precursors.

BIOMEDICAL APPLICATIONS

Disease Therapy

Since 1950, magnetic probes or particles have been investigated as a potential alternative treatment for cancer. Studies have demonstrated that the hyperthermia generated by magnetic particles coupled to a high-frequency AC magnetic field could be used as an alternate or an adjuvant to therapy for cancer treatment.^[15] The hyperthermic activity (heat produced by the relaxation of magnetic energy of the magnetic material) was shown to effectively destroy tumor tissue surrounding the probes or particles. The development of ultra-small magnetic particles (ferrofluids) with high crystallinity provided the next step in magnetically induced hyperthermic therapy. This treatment resulted in reduction of tumor size when the particles were directly injected into the tissue, demonstrating the ability of magnetic nanoparticles to damage the protein synthesizing system in mouse liver, *in vivo*. The problem with this approach, like any thermal treatment, is that the heating cannot remain localized, and therefore there is collateral damage of neighboring healthy tissue.

Another mechanism for targeted disease therapy and imaging has been reported. The “nanoclinic” is a multifunctional magnetic nanoparticle having a magnetic core surrounded by a functionalized silica shell to which biotargeting agents can be attached (Fig. 4).^[16,17] These particles are fabricated by first making a nanometers sized magnetic core have a two photon fluorophore attached. This is followed by the encapsulation the surface with a layer of silica. The silica layer is surface terminated with carboxylate group to which a biological agent can be attached to provide targeting ability for specific cell types. This is prototypic magnetic nanoclinic that can selectively destroy specific cancer cells using a DC magnetic field. The significance of this work is that magnetocytolysis (cell lysis) with these magnetic-nanoclinics was achieved using a DC magnetic field. This type of field forms the foundation for MRI, which is commonly used in medical diagnostics. Previous hyperthermic

Fig. 4 Transmission electron micrograph of a nanoclinic showing the core/shell structure (with corresponding structured and unstructured pattern).

applications require special instrumentation for generation of AC field, which are not available in clinical settings. Our research has demonstrated that nanoclinics can be synthesized to selectively effect specific cell types with a controllable efficiency. We have fabricated nanoclinics coated with leuteinizing hormone-releasing hormone (LH-RH). The surface coupling of the peptide hormone analogy enables the selective targeting of cancer cells having LH-RH receptors on their surface. Magnetocytolytic activity (effected using a DC magnetic field) was effective only in those cells capable of interacting with these nanoparticles. This effect requires direct contact with and/or internalization into the target cell. These nanoclinics may provide a new noninvasive therapeutic approach to the treatment of selected cancers and could be functionalized to selectively target other cancer cell types.

MRI

In addition to the therapeutic properties that may be associated with magnetic ferrofluids, there has been a significant interest in the use of these nanoparticles as contrast agents in MRI. The MRI measures the changes in the magnetization of hydrogen protons in water molecules resident in the tissues when a pulse of radiofrequency (RF) hits them. Protons of different tissues have different rates of relaxation and mapping their relaxation times essentially maps the tissue system. Magnetic nanoparticles themselves generate a magnetic field and influence the local area around them. The MRI offers the advantage of high spatial resolution of contrast differences between tissues. Because of the relatively long T_1 and T_2 relaxation

times inherent for most tissues, advances in contrast agent-enhanced MRI have strongly favored the development of T_1 -weighted agents. T_1 -weighted agents allow protons to “relax” back to their equilibrium values in a shorter time, resulting in reduced RF saturation effects and an increased number of averages per unit time, yielding increased S/N per unit time or increased resolution per unit time. A desirable T_1 -weighted agent, however, should not significantly affect the bulk magnetic susceptibility of the tissue compartment in which it is localized to minimize any magnetic field inhomogeneities that could result in image artifacts and/or decreased signal intensity. This feature can be exploited in the MRI to enhance the contrast within the tissues of the body. Superparamagnetic iron oxide nanoparticles have been used for image enhancement in the brain of rats to study the morphological and physiological changes in neurological diseases.

Bioseparation

In molecular biology, the ability to separate biomaterials such as cells, enzymes, antigens, or DNA from their native environment is fundamental to the detection and analysis of such entities.^[18–20] Broadly speaking, the primary goal in bioseparation is to separate a low concentration of target biomaterial from a solution, and then release it in sufficiently high concentration to enable a desired analysis. Magnetic bioseparation is a versatile and well-established method to achieve this. It entails the use of magnetic microparticles/nanoparticles with surface treatments (immobilized affinity ligand) that are designed to bind with a target biomaterial. Magnetic particles are commercially available with a wide range of surface functionalizations, custom-tailored for various bioapplications.

Magnetic separation is typically implemented using either a direct or an indirect approach. In the more common direct approach, the surface-treated particles are first mixed with a solution containing the target biomaterial. The mixture is allowed to incubate so that a sufficient amount of biomaterial binds to the particles (bound biomaterial is said to be magnetically tagged or labeled). The labeled biomaterial is magnetically separated from the solution and then released in a higher concentration for further processing. In the indirect approach, the target biomaterial is first incubated in a solution with an affinity ligand (primary antibody), which is added in free form. After a sufficient amount of biomaterial binds to the primary antibody, magnetic particles with surface-bound secondary antibodies (antibodies against the primary antibodies) are introduced into the solution. The mixture is allowed to incubate until a sufficient amount of

the target biomaterial becomes magnetically tagged. This material is then separated from the solution and released in higher concentration for further analysis.

The use of magnetic separation in molecular biology has enjoyed a resurgence of interest over the last decade, and has several advantages over other techniques.^[21] Specifically, it is significantly faster than other methods, and enables the target biomaterial to be isolated directly from crude samples such as blood, bone marrow, tissue homogenates, cultivation media, food, water, etc. Furthermore, the relatively low permeability of the aqueous medium enables efficient coupling between the applied field and the magnetically labeled material. In addition, because biomaterials have a relatively low intrinsic magnetic susceptibility, there is substantial contrast between tagged and untagged material, which enables a high degree of selectivity.

In conventional magnetic separation systems, rare-earth magnets or electromagnets are used to produce a nonuniform field distribution throughout the separation region. When magnetic particles enter this region, they experience a force that moves them toward areas of high field gradient where they are ultimately captured. The particles have a high susceptibility and acquire a dipole moment in an external field, but quickly relax back to an unmagnetized state once the field is removed. Thus, when the field is removed, the separated particles redisperse, thereby enabling the primary function of the separator—isolation of a biomaterial and enhancement of its concentration.

A variety of conventional magnetic separation systems are commercially available and effective, but are less than ideal in that they tend to be relatively large, and they can also be costly and complex requiring significant energy to operate. Accurate manipulation of small particles in small sample volumes is awkward and time consuming in such systems, and the ability to precisely monitor the separation process is limited. However, recent advances in microsystem technology have led to the development of novel magnetic bio separation microdevices that overcome these limitations. Specifically, microbioseparators are energy efficient, and well suited for the analysis and monitoring of small samples (potentially picoliters). Moreover, such devices can be integrated into comprehensive “lab-on-a-chip” systems that comprise several independent stations, each with a different functionality (e.g., biomaterial is isolated in the bioseparation station, and then passed to other biochemical characterization stations).

Several bioseparation microdevices have recently been fabricated and characterized.^[22–24] The performance of such devices can be predicted and optimized from first principles.^[25] Fundamental to such analysis is the ability to predict the behavior of a magnetic

colloid in the presence of an applied magnetic field. The motion of a suspended magnetic particle is governed by several factors including 1) the magnetic force owing to all field sources; 2) viscous drag; 3) inertia; 4) gravity; 5) buoyancy; 6) thermal diffusion; and 7) interparticle effects including: i) magnetic dipole interactions; ii) electric double-layer interactions; and iii) van der Waals force. The relative importance of these factors depends primarily on particle size, and therefore the approach to analyzing particle capture can be broadly divided on this basis. Specifically, for applications involving micron-sized particles, classical Newtonian dynamics suffices. However, for nanoparticles particles, Brownian motion is important and one solves an advection-diffusion equation for the particle concentration, rather than a Newtonian equation for the trajectory of an individual particle. It is difficult to specify the particle radius at which the thermal kinetics become significant, because this depends on the magnetic properties of the particle and the magnitude of the local magnetic field gradient. However, it is generally accepted that when the particle radius is above 50 nm, the classical Newtonian approach is predictive.^[25]

For applications involving micron-sized magnetic particles in low flow regimes (low Reynolds number), the magnetic and viscous drag forces dominate, and the motion of the particle can be predicted using Newton’s second law

$$m_p \frac{dv_p}{dt} = F_m + F_f \quad (1)$$

where m_p and v_p are the mass and velocity of the particle, and F_m and F_f are the magnetic and fluidic forces, respectively. The magnetic force is given by

$$F_m = \mu_0 V_p (M_p \cdot \nabla) H_a \quad (2)$$

where V_p and M_p are the volume and magnetization of the particle, and H_a is the applied magnetic field intensity at the center of the particle. The fluidic force is obtained using Stokes’ law for the drag on a sphere

$$F_f = -6\pi\eta R_p (v_p - v_f) \quad (3)$$

where η and v_f are the viscosity and the velocity of the fluid, respectively. In Eq. (2), it can be assumed that M_p is a linear function of the field intensity up to saturation, at which point it remains constant at a value M_s . Thus, below saturation

$$M_p = \chi_p H_{in} \quad (4)$$

where $\chi_p = \mu_p/\mu_0 - 1$ is the susceptibility of the particle, μ_p is its permeability, and $H_{in} = H_a - H_{demag}$. $H_{demag} = M/3$

is the self-demagnetization field that accounts for the magnetization of the particle.^[26] If the particle is suspended in a magnetically linear fluid of permeability μ_f , the force on it is

$$F_m = \mu_f V_p \frac{3(\chi_p - \chi_f)}{[(\chi_p - \chi_f) + 3(\chi_f + 1)]} H_a \cdot \nabla H_a \quad (5)$$

The Newtonian equation [Eq. (1)] does not account for Brownian motion, which can substantially influence particle capture when the particle radius is much smaller than 25 nm. For particle motion at the nanoscale, one solves the following advection-diffusion equation for the particle concentration $c(r,t)$

$$\frac{\partial c(r,t)}{\partial t} + \nabla \cdot J = 0 \quad (6)$$

where $J = J_D + J_F$ is the total flux of particles, which includes a contribution $J_D = -D\nabla n(r, t)$ owing to diffusion, and a contribution $J_F = v c(r, t)$ owing to the action of all external forces. The diffusion coefficient D is given by the Nernst–Einstein relation $D = \mu kT$ where $\mu = 1/(6\pi\eta R_p)$ (R_p replaces R_F) is the mobility of a particle of radius R_p in a fluid with viscosity η (Stokes' approximation). The drift velocity also depends of the mobility $v(r) = \mu F(r)$, where $F(r) = F_m(r) + F_f(r) + \dots$, is the total force on the particle.

In summary, advances in both microsystem technology and the synthesis of multifunctional magnetic microparticles/nanoparticles for bioapplications have spawned a renewed interest in magnetic bioseparation. Various microbioseparators have been fabricated, and have proven to have significant advantages over conventional devices. Perhaps most importantly, these novel devices will enable a high degree of integration in which the isolation and multiphase analysis of a biomaterial can be performed rapidly and efficiently in a “lab-on-a-chip” environment.

Magnetic Resonance Imaging (MRI)

Simon J. Doran

Department of Physics, University of Surrey, Guildford, Surrey, and CRUK clinical Magnetic Resonance Research Group, Institute of Cancer Research, Sutton, Surrey, U.K.

INTRODUCTION

Since its introduction in 1973, magnetic resonance imaging (MRI) has become arguably the preeminent modality of medical imaging and an indispensable tool in hospitals. Should any confirmation of its status be needed, it comes emphatically from the award, in 2003, of the Nobel Prize for Physiology and Medicine to Paul Lauterbur and Sir Peter Mansfield for their seminal contributions to the development of MRI. They joined a growing number of other nuclear magnetic resonance (NMR) laureates: Stern (1943), Rabi (1944), Bloch and Purcell (1952), Ernst (1991), and Wüthrich (2002). It is safe to assume that none of these scientists could, at the time of their initial discoveries, have imagined the enormous scope for applications of NMR and MRI by the early years of the 21st century.

This article will outline: 1) the early history of the subject; 2) the key physical principles; 3) MRI equipment and technology; 4) the sources of contrast in MR images; and 5) the applications of MRI. Whilst the majority of these occur in clinical practice and biomedical research, a significant number of problems in the nonbiological arena may be addressed using MRI, and some of these have great industrial relevance. Given the breadth of the subject, this article does not claim to list exhaustively even all the generic areas of study, let alone the many hundreds of interesting subtopics that have evolved over the last 30 years.

HISTORY

Although the history of MRI is generally traced to the discovery in 1945 of the NMR phenomenon independently by Bloch^[1] and Purcell, Torrey, and Pound,^[2] the foundations of the subject go back at least as far as the discovery of spin in the 1920s. Important experimental work during the 1930s by Stern and Gerlach, Gorter, and then Rabi showed how spin orientation could be measured via an inhomogeneous magnetic field and manipulated using a radiofrequency (RF) field.

During the decades after the second World War, huge strides were made in the understanding of NMR as a *spectroscopic* (i.e., not spatially resolved)

technique. Relaxation was described theoretically by Bloembergen, Purcell, and Pound in 1948. Chemical shift was discovered by Proctor and Yu and by Dickinson, and the spin echo by Hahn, in 1950. The effect of diffusion was analyzed by Carr and Purcell in 1954 and pulsed NMR was first introduced by Ernst and Anderson in 1966. Although all these would later prove invaluable in clinical applications, the focus during this period was primarily on the capability of NMR as a tool for chemical analysis.

Although there had been a number of studies on animal and human tissues throughout the 1950s and 1960s, the undoubted impetus for the use of NMR in medicine came from the 1971 work of Damadian, which showed a systematic difference in the T_1 relaxation properties of cancerous and normal tissues. Damadian filed a patent in 1972 for an “Apparatus and Method for Detecting Cancer in Tissue” and he became a significant player in the subsequent development of MRI. Whilst the originality of the idea proposed in his patent (granted in 1974) was evident, his method for spatial localization of the NMR signal is disputed. No mention is made of magnetic field gradients, now accepted to be key for the formation of an MR image. To this day, he remains a controversial figure. It is generally accepted that the first demonstration of MRI occurred in a Nature paper of March 1973 by Lauterbur,^[3] which showed an image of two tubes of water. Lauterbur’s “projection reconstruction” technique had strong parallels with the x-ray computed tomography (CT) scanning method demonstrated by Hounsfield in the previous year. In September 1973, Mansfield and Grannell,^[4] with a different starting point—their background was in solid state NMR—described theoretically what they called “NMR diffraction.” The graphs that they produced might now be termed one-dimensional (1-D) images, whilst one of the formulae in the paper is instantly recognizable with hindsight as the basis for what is now known as Fourier imaging, a method introduced formally in 1975 by Ernst’s team in Zurich.

The remainder of the 1970s saw a succession of achievements: the first image of a laboratory animal by Hutchison et al. in 1974; the first image of human anatomy in vivo—a finger—and the first MR abdominal images showing the body’s internal organs by

Mansfield and Maudsley in 1976–1977; a cross-sectional image of the chest obtained by Damadian et al. in 1977; and the first brain images from Clow and Young in 1978.

By the early 1980s, clinical applications of MRI were being pioneered in a handful of institutions, notably at the Hammersmith Hospital in London by Young and Bydder. However, at this stage, examinations were slow and the results often of limited clinical utility, hampered by the available technology and a lack of knowledge of some of the fundamental NMR properties of human tissue. Pioneering work by Haase and colleagues in Göttingen, Hennig in Freiburg, and Mansfield's group in Nottingham led to the development of much faster imaging sequences.

With rapid commercialization of MRI in the 1990s, scanners moved from being expensive and speculative research tools to items of routine hospital equipment. Initially, expertise in the field had lain with the manufacturers of spectrometers for chemical research, such as Bruker (Europe), Varian (U.S.A.), and JEOL (Japan). These were joined by a raft of other companies, both big and small. However, by the turn of the century, mergers, acquisitions, regulatory demands,

and other commercial forces had left the majority of production of MR scanners in the hands of three multinationals: General Electric, Philips, and Siemens. Enormous investment continues to be made in technological development by these companies and, with the increased availability of hardware, the number of MRI researchers, both in hospitals and universities, has mushroomed.

PHYSICAL PRINCIPLES^[5]

Signals and Magnetization

Many subatomic particles possess a property called spin (represented by the vector \mathbf{I} in Fig. 1A). Whilst a number of the characteristics of spin may be understood by analogy with the classical angular momentum of a rotating macroscopic body such as a top, spin along a given direction is quantized in half-integer multiples of the basic unit \hbar (Planck's constant/ 2π). Quantum mechanics tells us that it is impossible to measure simultaneously the x -, y -, and z -components

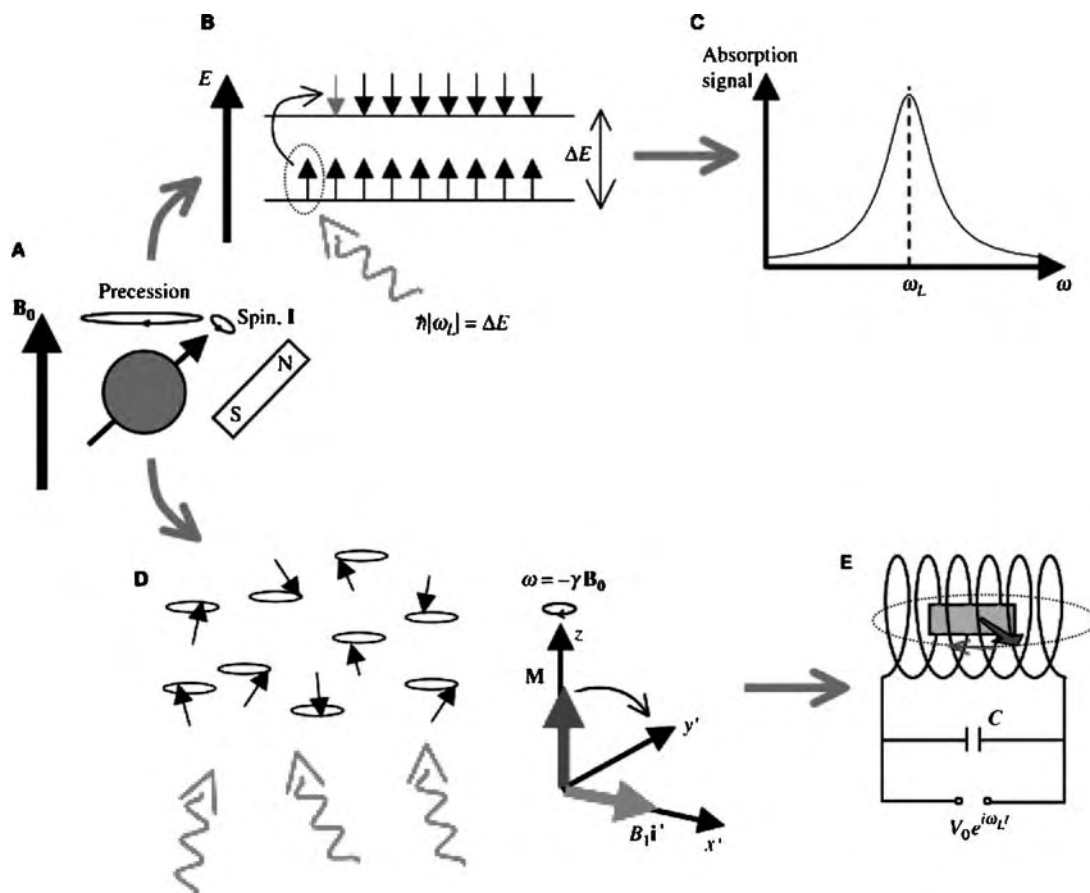

Fig. 1 Physical principles of MRI.

of the spin vector, i.e., to ascertain “the direction” in which a single nuclear spin is pointing. The equations that follow imply that such a definite direction does exist, specifying as they do \mathbf{I} and the associated magnetic moment $\boldsymbol{\mu}$ for an individual nucleus, but the semiclassical approach in this article is justified by a more rigorous quantum statistical mechanical argument.

The nuclei most commonly imaged in medical MRI are those of the hydrogen that is present in the body’s water and fat. For these, quantum mechanics imposes the further restriction that $|\mathbf{I}| = \sqrt{3}\hbar/2$. Suppose one applies a large and constant magnetic field B_0 in the z -direction. Each spin makes an angle $\theta = \cos^{-1}(I_z/|\mathbf{I}|) = \cos^{-1}([\pm\hbar/2]/[\sqrt{3}\hbar/2]) \approx 55^\circ$ or 125° with the z -axis. As $\boldsymbol{\mu} = \gamma\mathbf{I}$, where γ is a constant known as the *gyromagnetic ratio*, the potential energy in the magnetic field is different for spins whose z -components point with and against the field (Zeeman Effect).

$$\mu_z = \gamma I_z = \pm\gamma\hbar/2 \Rightarrow E = -\mu_z B_0 = \mp\gamma\hbar B_0/2 \quad (1)$$

The magnetic field exerts a torque $\mathbf{T} = \boldsymbol{\mu} \times \mathbf{B}_0$, which causes the direction of the spin vector \mathbf{I} to change. The extension of Newton’s Second Law of Motion to this rotating system yields,

$$\mathbf{T} = \frac{d\mathbf{I}}{dt} \Leftrightarrow \boldsymbol{\mu} \times \mathbf{B}_0 = \frac{d(\boldsymbol{\mu}/\gamma)}{dt} \Leftrightarrow \frac{d\boldsymbol{\mu}}{dt} = \gamma\boldsymbol{\mu} \times \mathbf{B}_0 \quad (2)$$

which represents a *precession*, at the so-called Larmor angular frequency $\omega_L = -\gamma B_0$. The spin vector traces out a cone (Figs. 1A and D).

Even the smallest sample interrogated by MRI contains a large enough number of spins for the distribution between the two energy levels (Fig. 1B) to follow accurately Boltzmann’s Law, $n_\downarrow/n_\uparrow = \exp(-\Delta E/kT)$, where n_\uparrow is the number of spins per unit volume in the energetically favorable “up” state ($I_z = +\hbar/2$), n_\downarrow is the number with $I_z = -\hbar/2$ and the energy gap between the levels is $\Delta E = \gamma\hbar B_0 = \hbar|\omega_L|$, k is the Boltzmann constant, and T the absolute temperature. For a sample consisting of an ensemble of many spins, we define the *magnetization* (Fig. 1D) as the magnetic moment per unit volume.

$$\mathbf{M} = \sum_i \boldsymbol{\mu}_i / V \quad (3)$$

It follows that, when the sample is in thermal equilibrium at any finite temperature, there is a population excess in the lower level, leading to a net positive z -magnetization. Because there is no preferred azimuthal angle for the spin vectors, the random x - and y -components of the individual nuclear magnetic moments cancel and $\mathbf{M} = M_0\mathbf{k}$ (Fig. 1D).

RF Excitation and Signal Detection

Two complementary pictures have historically been used to understand the origin of signals in NMR. In Fig. 1B, a quantum of RF energy is absorbed by a nucleus, promoting it from the low to the high energy level. This interpretation, attributable to Purcell, is useful in explaining how resonant absorption (Fig. 1C) of energy occurs in a continuous wave NMR spectrometer. In terms of classical fields, this RF energy is input to the sample in the form of a magnetic field \mathbf{B}_1 , rotating in the transverse (xy -) plane at the Larmor frequency. The equation of *forced precession* is

$$\frac{d\mathbf{M}}{dt} = \gamma\mathbf{M} \times (\mathbf{B}_0 + \mathbf{B}_1) \quad (4)$$

It is very common in the theoretical treatment of MRI to consider a frame of reference rotating about the z -axis at the Larmor frequency (Fig. 1D). In this rotating frame, the spiral motion of \mathbf{M} described by Eq. (4) is replaced by a simple precession about the (now static) vector $\mathbf{B}_1 = B_1\mathbf{i}'$, where \mathbf{i}' is the unit vector in the x' -direction of the rotating frame. In the absence of relaxation (see section “Relaxation”), application of the \mathbf{B}_1 field for a length of time t leads to a rotation of the magnetization through angle $\alpha = -\gamma B_1 t$ about the x' -axis. α is known as the RF pulse (flip) angle and plays an important role in MRI.

Once the RF excitation has been turned off, Eq. (4) applies in the laboratory frame with $\mathbf{B}_1 = \mathbf{0}$. The component of magnetization excited by the pulse into the transverse plane undergoes *free precession* about the longitudinal (z -) axis. The rotating magnetic field thus created can induce an electromotive force (EMF) in a receiver coil that is part of a tuned circuit and this is the way that the NMR signal is detected in most modern spectrometers (Fig. 1E). This interpretation, due to Bloch, turns out to be surprisingly difficult to reconcile with the quantum picture painted by Purcell. A common misconception is that, by analogy with optical spectroscopy, the origin of the signal is the downward transitions in Fig. 1B, whose RF photons are then intercepted by the probe. This is not true:^[6] in fact, there are two terms in the classical expression for the magnetic field of the rotating magnetization, the near- and far-fields. The EMF induced in the probe corresponds primarily to the former (which, in a quantum picture, is mediated by *virtual* photons), whilst the RF photons described above are associated with the (radiative) far-field.

Relaxation

The spins’ environment is a complex of rapidly fluctuating fields created by the precession of neighboring

nuclei, all of which are also in random translational and tumbling motion. Analysis of the effect of these fields is not easy but, happily, the results are entirely consistent with the phenomenological Bloch equations, which are experimentally derived

$$\frac{dM_z}{dt} = \frac{M_0 - M_z}{T_1}, \quad \frac{dM_{xy}}{dt} = -\frac{M_{xy}}{T_2} \quad (5)$$

Upon excitation, the longitudinal component of magnetization M_z returns toward its thermal equilibrium value M_0 in an exponential fashion, with time constant T_1 , whilst the transverse component M_{xy} created by the RF pulse decays exponentially to zero with time constant T_2 . The detail of the quantum mechanics is hidden in the two constants T_1 and T_2 and, for the majority of applications, these relaxation times may be treated as experimentally measured properties of the system. T_1 and T_2 are often referred to by the alternative names *spin-lattice relaxation* and *spin-spin relaxation* time.

Gradients and Imaging

Nuclear magnetic resonance spectra have long been used to obtain *chemical* information about samples: The precession frequency of a nucleus is modified by its electronic environment (chemical shift) as $B_{\text{nucleus}} = (1-\sigma)B_0$, where σ is known as the shielding parameter. Lauterbur and Mansfield's key insight was that one could create a corresponding spectrum in which Larmor frequency was related to *spatial position* by applying a magnetic field gradient. This process is known as *frequency encoding* and the Fourier transform of the signal thus obtained yields a 1-D projection of the sample.

To obtain the full 3-D distribution of spins, one needs to employ additional techniques. *Slice selection* uses a time-varying \mathbf{B}_1 field, in the presence of a gradient, to excite selectively only a thin slice of the sample. To obtain spatial resolution for the second "in-plane" dimension, Lauterbur rotated the direction of the frequency-encoding or "read" gradient, such that he obtained projections over a range of angles. These were reconstructed using the filtered back-projection algorithm. However, the majority of applications today use *phase encoding*, in which a third gradient, orthogonal to both read and slice, is applied during a preparation period before the frequency encoding. By acquiring the 1-D projections with a range of values of this gradient (phase-encoding steps), one obtains a dataset, which is the 2-D Fourier transform of the desired image.

Rapid Imaging

There exist many ways—referred to by an array of acronyms, often vendor specific and baffling to the neophyte—of acquiring an MR image. These are distinguished by the order and duration of the various gradient and RF pulses. The description of a particular MRI experiment is generally called a *pulse sequence* and often presented in diagrammatic form. In the gradient-echo pulse sequence of Fig. 2, the image intensity is given by

$$I(x, y) \propto \rho(x, y) \frac{1 - e^{-T_R/T_1(x, y)}}{1 - \cos \alpha e^{-T_R/T_1(x, y)}} \sin \alpha e^{-T_E/T_2^*(x, y)} \quad (6)$$

Here ρ is the proton density and T_2^* is a modification of the T_2 relaxation time, which takes account of the local magnetic field inhomogeneity, something that may result from the design of the magnet itself, or, more commonly, from spatial variations in the sample's magnetic properties. By an appropriate choice of T_R and T_E (the sequence repetition time and the echo time) and the RF flip angle α , which are all controlled by the user, we may obtain images whose contrast reveals differences in the relaxation times T_1 and T_2^* . By using a so-called "spin-echo," rather than a gradient-echo sequence, T_2 weighting is available.

Whereas a traditional gradient-echo MR image might take a few minutes to acquire, a key goal of medical MRI development is the design of methods to

Fig. 2 Pulse sequence for a simple gradient-echo experiment. The various elements of the diagram describe the operation of the RF and gradient systems of the MR scanner.

obtain the necessary information as fast as possible. This is generally achieved either by using short T_R values together with a low flip angle, or by a single excitation followed by a “train” of refocused echoes. If gradient echoes are acquired, then the technique is generally a variant of echo-planar imaging (EPI), whilst, in the technique originally known as rapid acquisition with relaxation enhancement (RARE) and now often referred to as fast spin-echo, spin echoes are refocused by additional RF pulses. The choice between the techniques will be dependent, among other factors, on the T_2^* of the sample. Single-slice imaging is possible within tens of milliseconds and it is now routine for entire 3-D volumes to be acquired within a single breath-hold—this avoids image degradation by respiratory motion.

Ultimately, imaging speed is limited by the image signal-to-noise ratio (SNR). The noise power P_N entering into the NMR measurement is given by the Nyquist/Johnson equation $P_N = 4kT\Delta f$, where the signal bandwidth Δf is inversely related to the gap between data sampling points. Until recently, engineering issues such as the switching speed of the gradients provided other acquisition bottlenecks. However, we now operate close to the *physiological limit* where faster gradient pulses would cause nerve stimulation or even pain, by the induction of EMFs in the body, and thermal deposition of power in the patient from more rapidly repeated RF pulses would exceed regulatory limits.

MRI TECHNOLOGY

Fig. 3 illustrates schematically the apparatus required for a clinical MRI scanner. The main magnet, which produces the B_0 field, represents the largest capital cost. Huge improvements in both the available field strength (currently up to 8 T for human and over 20 T for microscopy systems) and its homogeneity (which is related to T_2^*) have been made over recent years.

The gradient set, together with its associated controllers and current amplifiers, produces the controlled variation in magnetic field required for spatial localization. Here, the key performance parameters are ramp time (i.e., the speed at which the gradient may be changed from one value to another), maximum gradient (currently around 40 mT/m for a typical clinical system), and uniformity of the gradient throughout the imaging region. It was the introduction in the 1980s of *active gradient screening* that revolutionized the performance of gradient systems and made possible all of the rapid imaging we take for granted today.

The part of the clinical scanner that has seen the largest change in recent years has been the RF system. Until the 1990s, this consisted of a single “RF probe”

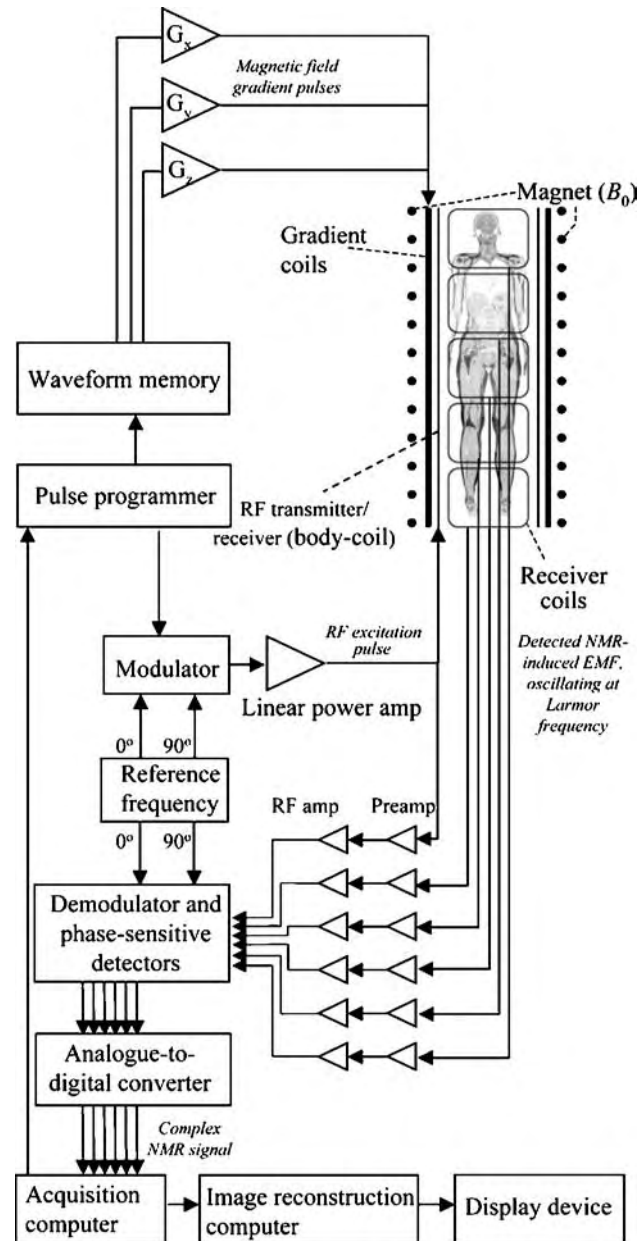

Fig. 3 Schematic diagram of a clinical whole-body MRI scanner.

or antenna, which performed the dual task of transmitting the excitation pulse and receiving the NMR signal. The introduction of *phased array* coils allowed higher SNR with greater coverage and paved the way for the introduction of *partially parallel imaging*. This technique, whose principal methods are known as SMASH and SENSE, uses multiple receiver coils to dispense with the need for a large fraction of the phase-encoding steps. Speedup factors of, typically, 2-6 are obtained without needing to change the RF pulse or gradient pattern, although at the cost of some degradation in SNR. Partially parallel imaging may use

over 30 simultaneously acquired receiver channels, each attached to its own independent RF probe (now restyled “coil element”). Further developments in RF technology allow the patient to be covered in receiver coils, allowing whole-body 3-D coverage via a moving-table technique.

SOURCES OF IMAGE CONTRAST IN MRI^[5]

Image Weighting

Magnetic resonance imaging is possibly the most flexible of all medical imaging modalities, because the image acquisition may be *tailored* to highlight a particular sample property. This is sometimes known as “weighting” the image and leads to the terms “proton-density-weighted,” “ T_1 -weighted,” “ T_2 -weighted,” etc. Compared with the alternative imaging modalities of x-ray CT and positron emission tomography, MRI is sensitive to many more aspects of the sample, as detailed below.

Proton Density

Image intensity is always proportional to M_0 and hence the proton density ρ , but we say that an image is “proton density weighted” when the sequence is specifically desensitized to all the other factors that might affect image intensity. ρ is similar for many types of biological tissue and so this mode of contrast is relatively rare clinically. However, there are numerous industrial applications where quantitative determination of ρ can be very important, for example in the imaging of oil-bearing rock cores. Calibrating such experiments is difficult, but recent developments in multiple-quantum imaging have allowed M_0 to be measured directly in A/m.

Relaxation Times (T_1 , T_2 , T_2^* and $T_{1\rho}$)

Relaxation times are very sensitive probes of structure and environment. Nonspatially resolved NMR uses relaxation times to determine molecular distances and investigate protein–protein interactions, polymer dynamics, and chemical exchange, to name but a few applications. Relaxation times provide the dominant contrast mechanism in clinical imaging, particularly in conjunction with the injection of contrast agents that lower relaxation times as a (reciprocal) function of their concentration. Uptake and dispersion profiles in so-called dynamic contrast studies yield parameters that can be correlated with the blood supply to tumors. Agents with tailored pharmacokinetic properties and the ability to bind to different targets allow image

contrast to be increased for selected organs or pathologies. Analysis of multiple relaxation time components allows one to identify more than one tissue type within a single voxel and thus infer information at a higher spatial resolution than can be imaged directly. T_1 is also temperature sensitive, although latterly measurements based on changes in chemical shift have been used for temperature mapping. In cancer applications, gel dosimetry uses a radiation-induced variation in T_2 to map the distribution of absorbed dose. The dynamic variation of T_2^* around blood vessels is the basis of the blood oxygenation level dependent (BOLD) effect [see section Functional MRI (fMRI)] and the relationship between T_2 and T_2^* may be used to infer the size distribution of blood vessels in some tissues.

Magnetic resonance imaging forms images using signals obtained primarily from hydrogen nuclei that are “mobile” or “weakly bound,” such as those in tissue water. This is because the T_2 values for strongly bound protons are very short (microseconds, rather than the milliseconds) and there is not enough time for imaging pulse sequences to run before the signal decays. Recent hardware developments have dramatically pushed back the frontiers, with the advent of so-called ultrashort T_E sequences, which provide previously unseen contrast in cortical bone, cartilage, tendons, and ligaments. Contrast may also be generated by the mechanism of *magnetization transfer* from bound to mobile protons in close proximity. This occurs though a combination of direct chemical exchange and transfer of the spin state via magnetic interactions, leading to images of mobile protons that are influenced by the “unseen” bound component.

A further relaxation time $T_{1\rho}$ describes the process of relaxation in the rotating frame of off-resonance irradiation. $T_{1\rho}$ is rarely encountered in biomedical imaging, but has an important role in materials MRI.

Motion-Induced Contrast

Macroscopic motion may usefully be divided into two classes: *coherent* within a voxel (e.g., spins in blood flowing along large vessels) and *diffusive*. Perfusion may be considered as a hybrid of these two cases: molecules flow coherently, but along a myriad of randomly oriented capillaries within a single imaging voxel, mimicking diffusive motion, but on a different length scale.

Consider the effect on the NMR signal of spin motion through a gradient applied along x . The Larmor frequency is $\omega_L = -\gamma(B_0 + G_x x)$ and, in the rotating frame of reference, the phase evolution during

the interval $[t_1, t_2]$ is

$$\begin{aligned}\Delta\phi &= -\gamma \int_{t_1}^{t_2} G_x x(t) dt \\ &= -\gamma \int_{t_1}^{t_2} G_x [x_0 + vt + \frac{1}{2}at^2 + \dots] dt\end{aligned}$$

where v and a are the x -components of velocity and acceleration of the spins initially at x_0 .

Random diffusive motion leads to a distribution of phases $\Delta\phi_i$. Summing over all spins, the net magnetization decays exponentially. It is common to write the image intensity as $I(x, y) = I_0(x, y)\exp[-bD(x, y)]$, where the so-called b -value incorporates the influence of the pulse sequence parameters. The gradient G_x initially arose from the imperfect B_0 field of early magnets. However, it soon became convenient to generate controlled field variations, and hence different b -values, via pulses of the imaging gradients of specified amplitude and duration. If two or more such images are available, a quantitative calculation of $D(x, y)$ in m^2/s is possible. Given the need to detect such small displacements, the influence of gross sample motion (both involuntary patient movement and physiological motion associated with respiration and the cardiac cycle) is very destructive in an imaging context, where the measurement takes place over an extended period. The introduction of so-called *navigator echo* techniques was a major advance in this area.

Tissue perfusion may be measured either in terms of a “pseudo-diffusion” coefficient or in terms of a blood flow in ml/min per 100 g of tissue via the relaxation-based techniques of arterial spin labelling or dynamic contrast enhancement.

Where the motion is coherent, all the spins in a given voxel have a similar value of $\Delta\phi$ and the value of v may be extracted from Eq. (7) on the assumption that a and higher order derivatives are zero. By applying gradients along different axes, we are able to map the 3-D velocity field with high spatial resolution. Important clinical applications of this mode of contrast are flow mapping in the heart and angiography (discussed in section “MRI Methodology and Applications in the Clinic”).

Two other types of MRI experiment that exploit motion are worthy of note. In *spin-tagging* experiments, a specialized RF pulse scheme is used to excite tissue whilst leaving thin and regularly repeating “stripes” of unexcited material. As the stripes are associated with the tissue rather than the corresponding image location, they will move if this part of the tissue moves. Such a technique is often used to measure strain in images of the heart. *Magnetic Resonance Elastography* is used to create images whose contrast depends on the local amplitude of an elastic wave

passing through the sample. By synchronizing the timing of a motion-sensitive MRI sequence with the forced mechanical vibration of the object being examined, displacement amplitudes as small as $1\ \mu\text{m}$ may be measured. With various assumptions, the elastic properties of tissue may be mapped. This provides a quantitative assessment of many breast, thyroid, prostate, and abdominal pathologies, which have historically been identified by palpation.

Current Density Imaging

The imaging modality magnetoencephalography uses detectors positioned outside the head to measure electric currents deep inside the brain by making exquisitely sensitive measurements of the tiny ($\sim 10^{-14}$ T) magnetic fields they generate. It has been suggested that direct 3-D imaging of these currents, of major importance in the location of epileptic seizures, might be possible using MRI because of the local changes in Larmor frequency they create. A number of artificial studies have been successful but detection of the effect in vivo remains elusive and it may remain forever below the sensitivity limits of the MRI experiment.

Spectral Information

A modern imaging scanner offers several means to access information on the chemical environment of hydrogen in the body. (Other nuclei of medical interest do give an NMR signal, for example ^{31}P , ^{13}C , and ^{23}Na , but the signal available at physiological concentrations and “natural abundance,” i.e., without isotopic enhancement, is generally insufficient for imaging.) Single voxel spectroscopy allows one to excite a small 3-D region of the sample and apply sophisticated chemical analysis techniques. However, it does not produce an image and if information is required from more than one part of the sample, the procedure must be repeated, which is time intensive. An alternative is to acquire a spectroscopic image, which is a dataset containing an extra dimension, such that each voxel has an entire NMR spectrum associated with it. If information is required about only a single metabolite, then a *spectrally selective* RF pulse may be used, creating a single image whose contrast depends on the concentration of spins within the selected chemical shift range.

The compounds one wishes to detect are generally present in much lower concentrations than water and fat. Hence, an efficient *suppression scheme* is required to avoid swamping the detector with unwanted signals. The weak metabolite signal means spectroscopic images have low SNR and poor resolution. To improve SNR, one may average the signal from multiple

acquisitions, thus increasing the imaging time, or move to higher B_0 fields.

Polarization Transfer^[7]

The cause of the low SNR in MRI is the very small difference between n_{\uparrow} and n_{\downarrow} . The *nuclear polarization* $P = (n_{\uparrow} - n_{\downarrow}) / (n_{\uparrow} + n_{\downarrow})$ for hydrogen at room temperature and 1 T is $\sim 3 \times 10^{-6}$. For certain applications, one may image species whose polarization can be artificially enhanced to a nonthermal state. The most common examples in biomedical MRI are the noble gases, ^3He and ^{129}Xe , which are *hyperpolarized* to $P > 0.1$ by spin-exchange or other techniques with an optically pumped alkali metal vapor. Helium is widely used for imaging the air spaces in the lungs, whilst the enormous chemical shift range of xenon in different environments and its solubility make it an extremely sensitive probe.

Electron spin resonance (ESR) is a well-established method of detecting free radicals, but one not well adapted for high resolution imaging. The proton-electron double-resonance imaging (PEDRI) technique combines ESR with an MRI readout. Electron spins in the free-radical target are irradiated in a low magnetic field, which is then rapidly increased to one suitable for MRI. Spin angular momentum is transferred from the electron to the nuclear spins, thus leading to contrast in the NMR image that reflects the density of the free radicals. Electron spin resonance may also be used for measuring the oxygenation of tissue.

MRI METHODOLOGY AND APPLICATIONS IN THE CLINIC

Cancer^[8,9]

Magnetic resonance imaging plays a major role in all stages of our treatment of cancer, from research on the fundamental biochemistry, through diagnosis (which involves the identification of a lesion, characterization of tumors as benign or malignant, and determination of their extent), to treatment planning, image guidance during surgery and monitoring of the outcome of therapy, assessment of residual disease, and finally detecting relapse in treated or distant tissues.

Key imaging targets are the pelvic organs, breast, and liver (Fig. 4D) and brain, reflecting the prevalence of cancers of these organs. However, MRI is used routinely to diagnose cancers in all parts of the body and also in experimental animal models of disease.

Early imaging studies were based on intrinsic differences in relaxation times between tumors and healthy tissue. However, over the last decade, better

understanding of the tumor microenvironment and improved hardware have dramatically increased the range of techniques available. Dynamic contrast-enhanced (DCE)-MRI measures the leakage of exogenous contrast agent from the capillary vasculature into the extravascular extracellular space, via a rapid succession of T_1 - and T_2^* -weighted images. It gives quantitative values of vessel permeability (elevated in the “new” blood vessels created by tumors) and tissue perfusion. This makes the method ideal for monitoring the treatment efficacy of *antiangiogenic* drugs, which have recently been developed specifically to target the tumor microvasculature. Other techniques used in cancer are the following: targeted contrast agents (see sections “Molecular Imaging” and “Cellular Imaging”); spectroscopy (^1H , ^{19}F , ^{23}Na , ^{31}P) for monitoring tumor and drug metabolism; diffusion-weighted imaging to probe the response to treatment; diffusion tensor imaging to determine tumor infiltration into white matter tracts; BOLD imaging (section “functional MRI”) for both tumor oxygen utilization and functional MRI (fMRI) in surgical planning; correlation of histopathology with micro-MRI of biopsy samples; elastography; monitoring of thermotherapy treatments; and surgical guidance in biopsy.

In many cases, cancer diagnosis requires the development of *biomarkers*, i.e., properties measurable via MRI, which can be correlated with changes taking place at a microscopic level. It is believed that properties such as diffusion or the identification of drug metabolites may be earlier indicators of the success or failure of treatment than gross morphological changes in the tumor.

Neurology

White matter diseases^[11]

One of the diseases most readily detected via MRI, but possibly least understood is multiple sclerosis (MS). Lesions are conspicuous on standard T_2 -weighted scans and change over time, but their presence correlates very poorly with clinical symptoms of the disease. The three major characteristics of MS—*inflammation*, *destruction of the myelin sheaths surrounding axons*, and *axonal injury*—may all be detected via MRI, using a combination of DCE-MRI, cellular imaging of macrophages (see section “Cellular Imaging”), whole brain volumetry, magnetization transfer, diffusion imaging, and spectroscopic imaging.

Some half a dozen or so categories of other white matter disease exist. Standard MRI techniques are not able to distinguish between all of them and research work is therefore ongoing to develop more specific tests.

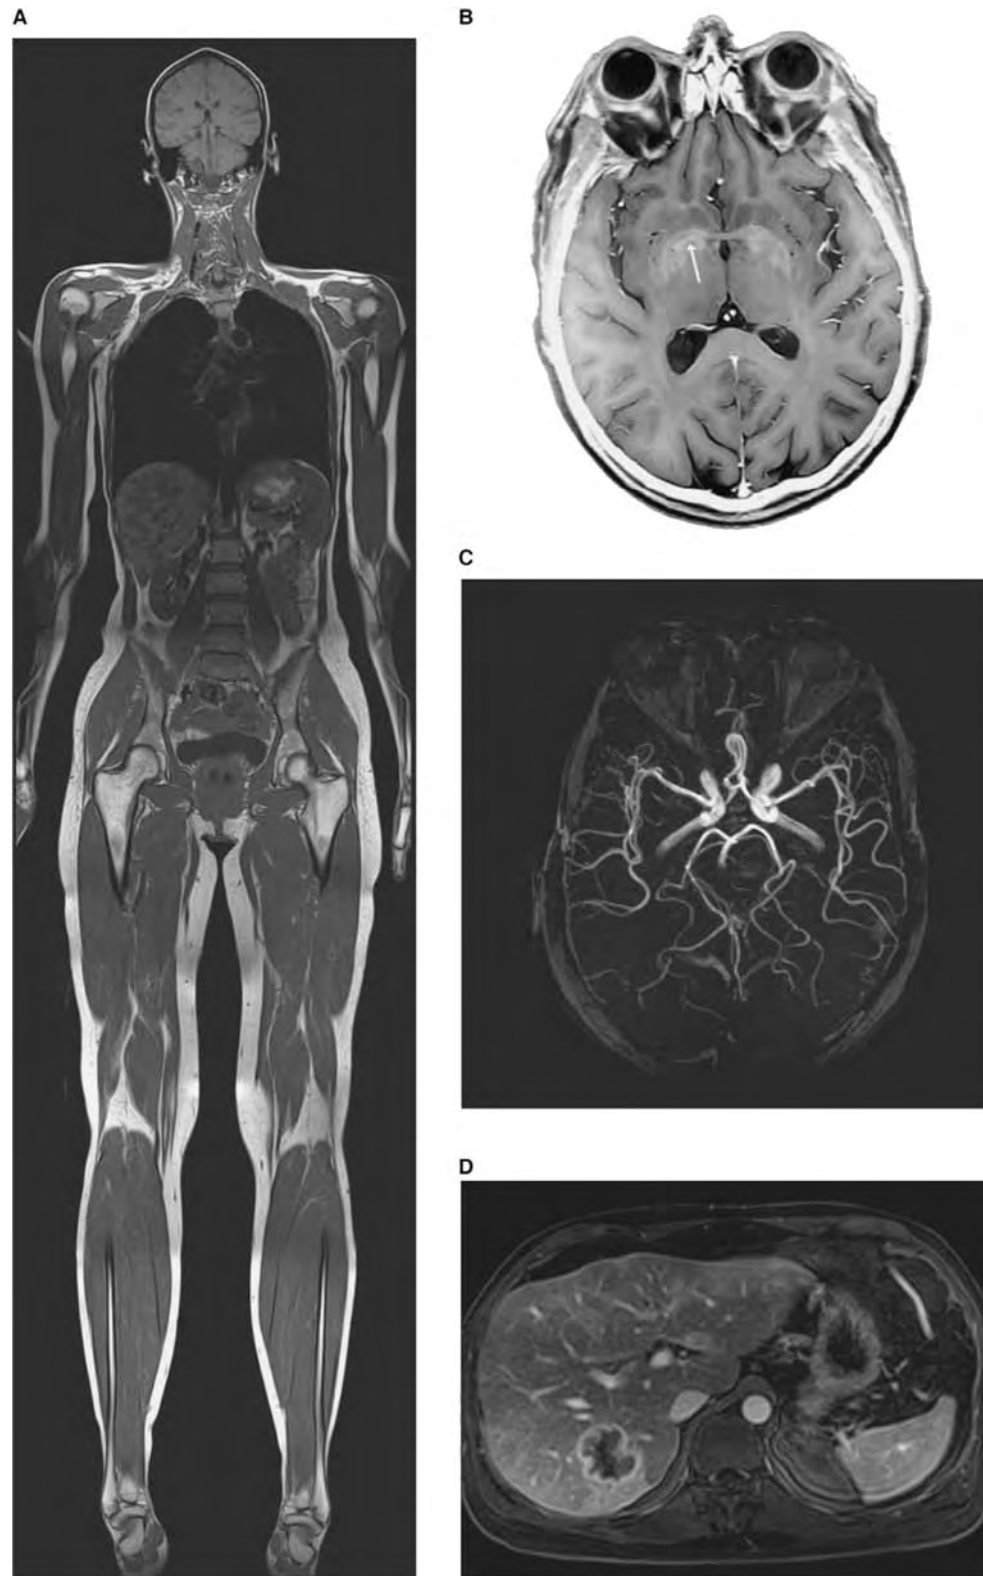

Fig. 4 (A) Whole-body coronal MR image; (B) high-resolution anatomical image of a transverse slice of the brain; (C) MR angiography image of cranial blood vessels; and (D) clinical image showing metastases of a pancreatic carcinoma. (A, C, D: Data courtesy of Siemens Medical Systems; B: from Ref. [10].)

Degenerative diseases^[12]

Although Alzheimer's disease is the most widely known neurodegenerative disease, a number of others are similarly characterized by the loss of nerve cells in the brain. It is often difficult to diagnose these diseases radiologically, because of the lack of distinctive lesions or obvious changes in brain morphology and also because of the significant overlap with the symptoms of normal aging. Magnetic Resonance Imaging in these conditions is important primarily to exclude other conditions such as tumor or stroke. Nevertheless, at a research level some progress is being made in using imaging (e.g., whole-brain volumetry) and spectroscopy (in particular, levels of the compound *N*-acetylaspartate) to investigate the mechanisms of brain damage in these diseases and develop biomarkers markers to assess treatment outcomes.

Diffusion tensor imaging and tractography^[13]

In biological tissues, MRI diffusion imaging (section "Motion Induced Contrast") measures not D , the free diffusion coefficient of water given by the Stokes–Einstein equation $D = kT/6\pi\eta r$, but a quantity known in the literature as the *apparent* diffusion coefficient (ADC). This is usually a factor of 2–5 smaller than D and reflects *restriction* of the diffusive motion of water molecules by the cellular microstructure. It is well known that many tissues (e.g., cardiac muscle tissue and white matter tracts) consist of arrangements of elongated cells with a preferred alignment. Because water diffuses more readily along the cells than across the membranes, the quantitative values of ADC measured in diffusion-weighted imaging (DWI) are strongly dependent on the orientation of the diffusion-encoding gradient. This is known as *anisotropic diffusion* and is studied systematically by repeating the DWI experiment with a number of different diffusion

gradient directions. The output of such measurements is a spatial mapping of the so-called *diffusion tensor*.

Clinical applications of diffusion tensor imaging (DTI) in the heart and brain have developed very rapidly over recent years, supported by technical improvements in rapid imaging capabilities. A typical acquisition with 30 gradient orientations can now be achieved in as little as six minutes. By considering the principal eigenvector of the tensor to be representative of the local fiber orientation and following it from one pixel to another, fiber tracking is now capable of producing extremely high quality atlases (Fig. 5). These classify different regions of white matter in the brain, allow the visualization of the relation of the different tracts with each other and with the gray matter that they connect, and monitor their disruption by pathological processes.

Functional MRI^[14]

The magnetic properties of blood vary depending on its oxygen content. Oxygenated hemoglobin is diamagnetic, while deoxygenated hemoglobin is paramagnetic and has a shorter T_2^* . A sequence such as EPI that gives T_2^* weighting will thus produce images with BOLD contrast. The difference in image intensity between the two states is in the region of 3–5% and depends on B_0 , being larger at higher field strengths. It was found in the early 1990s that brain images obtained in the presence of a stimulus (e.g., a flashing light) differed from those obtained under control conditions (darkness in this case). Furthermore, by appropriate processing of the two datasets—most simply, by subtracting one from the other, although other more sophisticated methods are now used—the regions of the brain *activated* by the stimulus can be determined.

What is observed in fMRI is not the direct activation of neurons, but rather the increased blood flow that accompanies it. Nerve impulses travel from

Fig. 5 (A) Transverse DTI color map. Red, green, and blue components of each color represent fibers running along right–left, anterior–posterior, and superior–inferior axes, respectively. Various anatomic landmarks visible are annotated on the basis of existing anatomic knowledge and (B) white matter “parcellation” map with locations of white matter tracts assigned. (From Ref. [13].)

neuron to neuron via the release of neurotransmitters at synapses and the process of recycling these neurotransmitters back into the cell requires energy. This is provided, with a latency of some 4–6 s after the onset of the task, by the hemodynamic response and it is this that the BOLD effect detects.

This discovery has revolutionized the way in which the brain is studied. Because MRI involves no ionizing radiation, studies may be performed repeatedly on healthy volunteers as well as patients. By designing appropriate stimuli, neurophysiologists have been able to elucidate the regions of the brain associated with perception, recognition, interpretation, movement, memory, learning, pain, and a whole host of other functions in normal subjects. Diseases of many types have been studied, including psychiatric conditions such as schizophrenia and compulsive disorders for which objective measurement was hitherto unimaginable. Functional magnetic resonance imaging is now used routinely prior to surgery to map out the position of eloquent structures. Monitoring the rehabilitation after acute stroke has demonstrated the plasticity of the brain, with new areas being recruited to take over functions from damaged regions. It has even been shown that parts of the brain may change in size in response to high usage in the same way that muscles enlarge in response to exercise.

Although fMRI is primarily associated with the brain, the BOLD effect also has applications in other types of tissue (e.g., for cancer studies).

Stroke^[15]

Strokes can be divided into two categories: *ischemic*, caused by a blockage in one of the arteries supplying blood to the brain, and *hemorrhagic*, in which a blood vessel has ruptured. Although the latter can be imaged using susceptibility-weighted MRI, x-ray CT is more commonly used, and it is for the detection of ischemic stroke that MRI finds its greatest application.

When blood flow is interrupted, a cascade of events is set in train, involving altered metabolism and changes in the distribution of neurotransmitters and electrolytes. Cells start to swell as the “pump” maintaining homeostasis fails and there is an influx of water (cytotoxic edema). An accompanying decrease occurs in the water ADC and, within minutes of arterial occlusion, changes in signal intensity can be obvious on diffusion-weighted images.

The extent of neurological deficit can be minimized if a thrombolytic agent is administered while the tissue is still viable (within approximately three hours of the onset of symptoms). However, this treatment is not without risk itself—there is a 10–15% chance of hemorrhage—and so early assessment via MRI is vital.

Lesion size, as measured using DWI in the acute phase, has been shown to correlate well with standard neurological scores and represents *infarcted* tissue. The DWI data may be compared with a map of the corresponding cerebral blood flow (CBF), as measured using perfusion-weighted MR imaging (PWI). This usually indicates a larger abnormal region and so the PWI–DWI mismatch is assumed to represent tissue whose blood supply is compromised but that is still potentially salvageable. The competing modality for the measurement of CBF is currently $H_2^{15}O$ positron emission tomography.

Changes in the MR appearance of stroke continue over about 10 days and the final state is well visualized using T_2 -weighted imaging. Fluid-attenuated inversion-recovery sequences are particularly beneficial in this respect as the strong confounding signal from cerebrospinal fluid is removed.

Angiography^[16]

Angiography is the imaging of the body’s blood vessels (Fig. 5C). This is done for a number of reasons, but primarily because vessels become blocked as a result of atherosclerosis, the deposition of fat in the vessel walls. This leads to ischemic symptoms such as pain, loss of function, severe disability, or even death. Early detection of the plaques that form is routinely obtained with high specificity and sensitivity (>90%) via MR angiography (MRA). Typical targets are the intracranial, carotid, renal, abdominal, pelvic, and peripheral arteries. Further reasons for performing MRA are the visualization of aneurysms and arteriovenous malformations, preoperative planning, the tracking of intravascular catheters as they are moved through the body during surgical procedures, and the positioning of intravascular devices such as stents and filters.

For many years, the “gold standard” for angiographic imaging has been x-ray digital subtraction angiography. However, in more recent times, this method has been superseded by rotational x-ray angiography (RA), which can give true 3-D information. However, in both cases, patients are exposed to ionizing radiation, particularly during the monitoring of interventional procedures, when many such images are acquired. Magnetic resonance angiography provides a radiation-free alternative, with the potential to acquire images of comparable quality. Recent research indicates very high correlations in anatomical depiction between RA and MRA.

Three different classes of MRA technique exist, using different physical properties of the blood to distinguish it from background tissue. *Time-of-flight* measurements exploit the relaxation and flow properties of blood to enhance its signal relative to the

background tissue, whilst *phase contrast* angiography measures quantitative values of flow velocity using the effects described in Section “Motion-Induced Contrast.” In recent times, both methods have been largely superseded by studies in which a large dose (bolus) of contrast agent (CA) is injected and ultrarapid 3-D images are acquired during the first passage of the agent through the vasculature. The CA lowers dramatically the T_1 of blood such that, even at short T_R values for which background tissue is completely saturated, a strong blood signal is still obtained. It is likely that even this technique will be superseded by angiography performed after the administration of macromolecular contrast media that are retained within the vasculature. Other, more experimental, methods for labelling the blood vessels involve the injection of hyperpolarized contrast agents.

Cardiology^[17]

Capturing sharp 3-D images of a moving target with the time-resolution necessary to see individual phases of the heart cycle is a daunting task. Cardiac MRI is, arguably, the field of diagnosis that has seen the greatest impact over recent years of the phenomenal increase in acquisition speed of MR scanners. This has been brought about via the introduction of fast, high-contrast sequences such as fast imaging with steady-state free precession (FISP), gradient modulation strategies (e.g., spiral imaging), and parallel imaging techniques and improvements in gradient performance.

Respiratory motion creates significant difficulties and when cardiac imaging was first introduced, it was necessary to *gate* (i.e., synchronize) the acquisition with both the cardiac and respiratory cycles. This led to extremely long acquisition times. 3-D images may now be acquired within a single breath-hold and so the motion artifacts introduced by respiration are removed. Nevertheless cardiac patients are precisely the group that find holding their breath difficult and so free-breathing strategies are sometimes used (usually in conjunction with navigator techniques) despite the difficulties this may lead to in coregistering slices acquired at different times.

The applications of MRI in cardiology make use of many of the principles described in section “Sources of Image Contrast in MRI.” Standard morphological imaging and cine imaging, employing various mechanisms of contrast to distinguish between different tissues, enable measurement of ventricular volumes and visualization of valve operation, wall thickening, congenital abnormalities, and aortic or pulmonary anomalies. Flow imaging may be used to quantify blood velocities in the chambers of the heart, allowing the ejection fraction (a key diagnostic variable) to be

calculated by integrating over the whole cycle. Velocity-sensitive MRI has the potential to replace color Doppler ultrasound in diagnosing problems such as mitral valve regurgitation. In conjunction with computational fluid dynamics simulations, it may predict pressure gradients across stenoses and regions of turbulence. Angiography techniques are employed for 3-D visualization of the coronary arteries and the evaluation of bypass grafts. Cardiac tagging studies allow one to quantify wall motion, strain, and twisting in the heart muscle. The orientation of the muscle fibers themselves, despite their subvoxel size, can be measured via diffusion tensor mapping. Perfusion imaging via dynamic susceptibility contrast is used to measure regional variations in blood supply to the myocardium and thus to assess the areas of tissue compromised by ischemic heart disease, with a vastly better spatial resolution than the previous technique of ^{99m}Tc single-photon emission computed tomography (SPECT). ^{23}Na MRI can be used to gain an insight into sodium homeostasis in myocytes and thus may allow discrimination between viable and nonviable tissue after a heart attack, whilst specially developed Gd contrast agents may be used to similar effect with ^1H imaging.

In short, MRI is now routinely described as a “one-stop shop” for cardiac diagnosis, allowing visualization of both acute and chronic cardiac problems, including hypertensive and ischemic disease, cardiomyopathies, valve problems, and congenital disorders.

Therapeutic Monitoring^[18]

The use of MRI for monitoring surgical procedures is highly attractive but the challenges to be solved for this to become reality have been considerable. The most fundamental of these is the geometry of the main magnet. For imaging *during* surgery, two designs of “open-access” magnets are currently available. The 0.5 T “double doughnut” consists of two coils, separated by about 50 cm. It gives the surgeon vertical access to the homogeneous region of magnetic field where imaging occurs, allowing operations to be carried out with real-time feedback and with the patient in a seated position. Neurosurgery, in particular, benefits from this arrangement. By contrast, the C-arm approach involves the use of permanent magnet pole pieces above and below the patient. It allows a much wider access from the side of the patient but until recently has only been available as a low-field option (around 0.25 T). A major disadvantage of using many open-access magnets is poor image quality, resulting from the low B_0 field and poor field homogeneity. It is thus often desirable to superimpose the perioperative data onto previously acquired images from a high-field

scanner; this raises important questions of image registration and accuracy. However, newly developed techniques of frameless stereotaxy, involving stereo views from multiple cameras, may improve this situation, as will the recent introduction of higher field systems. An alternative is to use an “in-out” protocol: The patient is slid repeatedly into a standard scanner at one end of the operating theatre, while the interventional procedure itself is performed outside the magnet.

The manufacture of MR-compatible surgical tools represents a second technological challenge. Although nonmagnetic stainless steel is “safe” and not attracted into the magnet bore, it still perturbs the local homogeneity of the magnetic field, causing massive disruption to the resulting images. Titanium and some plastics are better in this regard, but cannot be made as sharp or stiff and may not be so easy to sterilize.

Applications of interventional MRI include *biopsy*, where one wishes both to localize accurately the tissue to be sampled and to visualize structures to be avoided en route to the target; *surgery of brain and skull base tumors*, where access is limited and where there are many critical areas that must not be damaged; and *endovascular treatments*, in which the progress of a catheter or device must be monitored as it passes from the point of insertion to the site of action or placement. Here, MRI has the potential to replace x-ray fluoroscopy, which provides a dynamically updated view of the surgery, but at the expense of a large patient dose of ionizing radiation.

Unique to MRI is the ability to make images of *temperature distribution* within a sample. This allows us to monitor the delivery of clinical hyperthermia treatments, for example, the ablation of liver tumors by laser or thermal catheters or a high-intensity focused ultrasound beam. By a feedback-controlled coupling of the scanner to the delivery system, very precise manipulation of the tissue temperature may be achieved.

Other Medical Applications

Numerous other specialist application areas of MRI exist, the description of which lies beyond the scope of this article. These include: MRI of the musculoskeletal system (with important applications in surgical planning for the lumbar spine, for trauma patients, and for the knee and other joints; the study of the ligaments, tendons, and cartilage and of arthritis); imaging of the gastrointestinal tract; MRI of the kidneys and urinary system; and imaging of the fetus and placenta in utero. Magnetic resonance imaging is also becoming increasingly important for drug development. Whilst this

report has focussed on the significant role of quantitative imaging, the importance of exquisitely detailed morphological information, such as that shown in Fig. 4, must never be underestimated.

BIOMEDICAL APPLICATIONS

Molecular Imaging^[9]

In an era when the human genome has been sequenced and in which we are rapidly learning the biological function of the individual genes that make it up, it is predicted that medical therapy will move rapidly toward a model where drugs are purpose-designed to act on specific genetic/molecular targets. One might imagine that it would be impossible to image such phenomena, as they occur at concentrations and at length scales far below the resolution limits of MRI. However, localization of the point of action of a drug to a value better than the 0.1 mm available on today's MRI scanners is clinically unnecessary. To visualize the effects of a molecularly directed therapy, we simply (!) need a probe with: 1) a high affinity and specificity for the target molecule, enzyme, or receptor; 2) a delivery route to the tissue of interest; and, crucially, 3) the ability to *amplify* nanomolar changes in concentration to signals detectable at the level of an imaging voxel. The most commonly used amplification mechanism in MRI is relaxation: Small quantities of ferromagnetic or paramagnetic materials have an effect on the NMR signal over a large region. Thus, the signal we detect comes not from the relatively few target molecules, but from the much larger pool of surrounding water molecules.

Probes may be divided into two classes: agents that influence water relaxation merely by an increase in concentration, and “smart” agents that change their conformation on interaction with the target. An example of the former is a so-called “polymerized vesicle” containing the relaxation agent Gd^{3+} , which is conjugated to an antibody targeting the compound $\alpha_v\beta_3$ integrin found in many tumors. By contrast, the “Egad” complex contains a β -galactose subunit that prevents access of water molecules to the paramagnetic Gd^{3+} ion trapped inside it. When the enzyme β -galactosidase is present, the ring is cleaved and the relaxation efficiency of the Gd^{3+} is vastly increased. This mechanism has a potentially wide application, because expression of β -galactosidase is widely used as a marker to report successful gene transfection. A ballpark figure of the number of Gd complex units required per cell to obtain successful visualization on an image is $\sim 4-5 \times 10^7$ and initial studies appear to show that this will be achievable in vivo.

Cellular Imaging^[19]

The distinction between molecular and cellular imaging is somewhat muddy. The terms are used loosely and would perhaps be better replaced by “molecular *detection*” and “cellular *detection*,” because (in the common usage) neither is forming images of individual molecules or cells. Broadly speaking, cellular imaging aims to pinpoint the location of specific cells, rather than macromolecules, although it may achieve this via the types of molecular imaging technique described above.

The relaxivity of paramagnetic Gd decreases on internalization (uptake into the cell). This and its poor biocompatibility—the metal is toxic if it becomes dechelated—have led to a preference for iron, in the form of ultrasmall superparamagnetic iron oxide particles as a cellular labelling agent.

Early clinical applications have imaged the distribution of *macrophages* (e.g., visualizing lesions in the liver caused by a deficiency of Kupffer cells, or microscopic metastases in normally sized lymph nodes), but the majority of other studies have been proofs of principle, often in animal models. Nevertheless, the potential applications in humans are already becoming clear. One of the most exciting is the ability to follow labelled *stem cells* as they migrate from the site of injection to their target. The detectable limit for a $100\ \mu\text{m} \times 100\ \mu\text{m} \times 200\ \mu\text{m}$ voxel—the distinction between MRI and MR microscopy is not well defined—at 1.5T has been estimated at $1.4\text{--}3.0 \times 10^{-12}$ g of iron per cell and, given that it appears possible to internalize up to 25×10^{-12} g per stem cell, this opens the possibility of finding the destinations of the first four generations of daughter cells.

True microscopy studies at ultrahigh B_0 fields have demonstrated the feasibility of acquiring images of individual large cells in vitro.

Genetic Phenotyping^[9]

It is known that humans share a very large fraction of the genome with other mammals and, thus, there is a strong likelihood that human gene function may be inferred from studies on transgenic mice. To this end, a systematic program is underway to produce heritable mutations in every gene and study the phenotype of each resulting mouse.

High-resolution ($\sim 100\ \mu\text{m}^3$) 3-D MRI is a valuable screening approach. It has a number of advantages compared with traditional histological methods: 1) it is nondestructive, allowing serial studies; 2) the data do not exhibit the geometric distortion that can be caused by stresses or dehydration during histological sectioning; 3) small organs can be isolated and imaged at

higher resolution, then coregistered with the main dataset; 4) the data acquisition procedure is easier to automate than physical sectioning of the animal—important, as it has been estimated that some 20,000 mouse strains will need to be examined just to characterize the effects of modifying dominant genes; and 5) MRI is inherently 3-D and digital. Not only does this allow the researcher to slice the dataset in any arbitrary orientation to view features of interest, but also via image registration and pattern-matching software, the data for a transgenic phenotype might be compared automatically with a control.

Over recent years, this type of research has led to a growing database of phenotype images with rapid dissemination of data via web-based archives.

INDUSTRIAL AND NONBIOMEDICAL APPLICATIONS^[20]

The role of MRI outside medicine is already huge. However, the high capital cost of equipment and the need, in an industrial setting, to demonstrate profitability have tended to limit the user base to small but active communities in each area. The potential for further growth is considerable as more disciplines discover the capabilities of MRI. All of the techniques hitherto described may be brought to bear on non-medical samples, along with others (for example, stray field imaging, or high-speed magic angle spinning) that cannot be used in vivo.

Materials imaging is a major industrial application, with the compounds investigated including emulsions, paints and coatings, washing powders and other domestic products, plastics, rubbers, composites, dental resins, concretes and cements, textiles, and explosives. Ingress of solvents into polymers and the dissolution of solids (e.g., drug capsules) can be studied, as can be the penetration and efficacy of skin care products. Magnetic resonance imaging has demonstrated its potential in the food industry, for example tracking the migration of fat and water as products are cooked, or measuring the water content of breakfast cereals (and hence determining their crunchiness!). There are applications of imaging in the timber industry (from the mechanism of fungal infection in growing trees to the drying of wood and the manufacture of paper); in the oil industry for studying rock cores and other porous media; and in chemical engineering, where flow through reactors can be monitored and the rheology of complex fluids studied.

Magnetic resonance imaging has many applications in basic science, for example, in following the progress of chemical reactions (particularly those in reaction-diffusion systems, which exhibit spatial heterogeneity), in elucidating mechanisms of water transport in plants,

and in the development of biomaterials, such as artificial tissues.

CONCLUSIONS

This article has provided an introduction to the physics, technology, and applications of MRI. It is clear that the scope of MRI is enormous and spans the physical and medical sciences. Here, we have merely scratched the surface of the subject, providing a starting point for further study.

Magnetic Resonance Imaging in Temperature Measurement

Nadine Barrie Smith

Department of Bioengineering, Pennsylvania State University, University Park, Pennsylvania, U.S.A.

INTRODUCTION

Magnetic resonance imaging (MRI) techniques offer attractive methods for determining noninvasive temperature changes during thermal therapies for treatment of diseased tissue. For pathological tissues such as tumors, noninvasive or minimally invasive procedures that use heating or cooling are increasingly being employed in clinical applications. Heat is either applied in the form of irreversible tissue ablation, where the temperature of the tissue is increased above 50–60°C for time periods of a few seconds, or hyperthermia in which the tissue temperature is increased to 42–45°C for 30–60 minutes. Cryotherapy/cryosurgery destroys tissue by freezing a local region of tissue over a period of a few minutes. In each case, the treatment protocol aims to attain the required temperature distribution as quickly as possible and to affect only the diseased tissue without damaging surrounding healthy tissue. Noninvasive MRI can be used to locate the position, with respect to the therapy device, of the desired anatomical area for thermal treatment, determine noninvasively the temperature distribution within the target, and also monitor the effects of the treatment after the treatment protocol has finished.^[1–5]

OVERVIEW

Much of the research in clinical MR thermometry has resulted from the desire to monitor temperature changes from new interventional therapeutic treatments using, for example, lasers, radiofrequency (RF) and microwave antennas, cryotherapy probes, or ultrasound transducers.^[3] As a minimally invasive device, laser energy (known as laser interstitial thermotherapy, or LITT) is delivered via a thin, flexible optical fiber to deep-lying lesions or tissues that are usually surgically inaccessible.^[6] In RF ablation, high frequency alternating current is used to thermocoagulate the target tissue through a 1 mm diameter active electrode. Typical RF lesions form an ellipsoidal pattern and are created in 30–60 seconds with temperatures up to 80°C.^[7] For minimally invasive or noninvasive delivery, microwave energy can be delivered to the target through individual antennas or arrays of antennas for either hyperthermia or ablation.^[8] Ultrasound, commonly

used for both hyperthermia and ablation, has been used either as a minimally invasive or noninvasive thermal treatment. One advantage of ultrasound is the ability to treat noninvasively deep tissues and the ability to shape the energy deposition patterns using various transducer designs.^[9] As an alternative to heating tissue, cryosurgery involves the in situ ablation of a target tissue by application of extremely cold temperatures, down to –60°C, using liquid nitrogen.^[10,11]

Determination of the exact location of energy deposition, and associated tissue temperature, in three-dimensional space has been a recurring problem with thermal treatment protocols. Traditionally, invasive thermometric techniques have been used to measure temperatures in the target region. However, these techniques provide only temperature measurements at certain specific points in the target volume. Additionally, devices such as thermocouples can potentially bypass the regions of greatest temperature elevation. MRI methods provide good tissue contrast for detection of pathologies, and excellent visualization of coagulated tissue posttreatment, while MR thermometry provides good spatial and temporal localization of the temperature changes during therapy.

A large number of parameters can be used to measure temperature via magnetic resonance techniques.^[5] For imaging applications, the majority of studies have used temperature-dependent changes in the molecular diffusion coefficient (D) of water, the proton spin-lattice relaxation time (T_1), or the proton resonance frequency (PRF) as a noninvasive thermometer. This article presents the physical basis for the temperature dependence of each of these parameters as well as interventional MRI examples used in conjunction with the clinical thermal therapy techniques described earlier. The reader is also directed to several recent articles and books for further reading on this topic.^[1–5]

TEMPERATURE DEPENDENCE OF MR PARAMETERS

Molecular Diffusion Coefficient

The temperature dependence of the molecular diffusion coefficient of water is described by the Stokes–Einstein

equation:

$$D = D_{\text{inf}} \exp\left(-\frac{E_a}{kT}\right) \quad (1)$$

where D_{inf} is the diffusion coefficient at infinite temperature, k is the Boltzmann constant, T is the temperature measured in degrees Kelvin, and E_a is the activation energy associated with the breaking of hydrogen bonds between water molecules, and is assumed to vary little between different tissue types in medical applications.^[12,13] For temperature imaging, a series of diffusion-weighted images are acquired using a spin-echo sequence, or a fast-imaging sequence preceded by a spin-echo based preparation module. In a particular image, the signal intensity, S , in a voxel is given by:

$$S \propto \exp\left[-\gamma^2 G^2 \delta^2 D \left(\Delta - \frac{\delta}{3}\right)\right] \quad (2)$$

where γ is the gyromagnetic ratio, G is the diffusion encoding gradient strength, δ is the gradient duration, and Δ is the time between the two diffusion-encoding gradient pulses. The pixel-by-pixel value of D is calculated from a series of images, each acquired with a different value of G . Temperature changes from either heating or cooling protocols can be determined based on the acquisition of images at an initial known baseline temperature (T_i) and corresponding diffusion coefficient D_i . The temperature, T_f , at any time during the protocol is given by:

$$T_f = \left(\frac{1}{T_i} - \frac{k}{E_a} \ln \frac{D_f}{D_i}\right)^{-1} \quad (3)$$

where D_f is the corresponding measured diffusion coefficient.

The first imaging study using the temperature dependence of D measured thermal changes in a polyacrylamide gel phantom at 0.5 Tesla using a simple spin-echo sequence.^[13] Using a whole body MR system, temperature images were obtained within the gel, which was heated by an MR-compatible phased array RF applicator. To verify the accuracy of the diffusion technique, a thermocouple was placed adjacent to the heated region. The results indicated that the MR-derived temperature inside a 0.8 cm^2 image region agreed within 0.5°C to that measured by the thermocouple.

One of the drawbacks with conventional diffusion-weighted spin-echo MRI is that the measurement is very sensitive to patient motion. This motion sensitivity can be reduced by using rapid diffusion-weighted echo-planar imaging (EPI), a technique which has been tested on acrylamide gel phantoms and canine brain

in vivo.^[14] Heating of the gel was performed using a surface microwave applicator at 433 MHz and resulted in a temperature sensitivity of the value of D of $3.04 \pm 0.03\%/^\circ\text{C}$ with a temperature resolution of 0.55°C in a 1.8 cm^3 volume. For in-vivo experiments, canine brain was heated with a whole body RF hyperthermia using an annular phased array (130 MHz) and was found to have a temperature sensitivity of $1.9 \pm 0.1\%/^\circ\text{C}$ with a temperature resolution of 0.55°C in a 0.9 cm^3 volume. Although EPI minimizes the effects of patient motion since the data can be collected extremely rapidly, the imaging technique does suffer from a number of disadvantages, including an intrinsically broad point spread function and sensitivity to image artifacts and distortion from both chemical shift and magnetic susceptibility.

Another approach to reducing motion artifacts and data acquisition times, while avoiding the image artifacts associated with EPI, is to use a diffusion-sensitive single-shot rapid acquisition with relaxation enhancement sequence. Using this technique, temperature mapping has been employed for observing temperature changes with in-vivo human calf muscle.^[15] The muscle was cooled using ice, and temperature drops of 18 and 4°C were recorded using a temperature dependence of the diffusion coefficient of $2.4\%/^\circ\text{C}$ in a 2 Tesla clinical magnet. Using both gels and in-vitro muscle samples, temperature changes of $\pm 0.5^\circ\text{C}$ and $\pm 2^\circ\text{C}$, respectively, were detected with a $2 \times 2 \times 8 \text{ mm}$ spatial resolution.

With respect to clinical studies, diffusion-weighted imaging is rarely used in interventional thermal therapies.^[3] In addition to the problems of motion sensitivity and long acquisition times, the temperature dependence of the diffusion coefficient can, in fact, vary with tissue type. Changes in D can also arise from other sources, such as the water content of the tissue, which changes during a heating protocol. Even though there are continuing attempts to improve temperature mapping with diffusion-weighted imaging, T_1 and PRF based techniques are generally the preferred clinical temperature monitoring methods.

Spin-Lattice Relaxation Time

The temperature dependence of the proton T_1 in water (tissue) can be approximated by:

$$T_1 \propto \exp\left(-\frac{E_a}{kT}\right) \quad (4)$$

where E_a is the activation energy for the T_1 process. Although this equation shows an exponential temperature dependence, T_1 is generally linear with T^{-1} over the temperature ranges used for clinical heating

therapies. However, the temperature sensitivity of T_1 varies between tissue types and thus, for each tissue, the T_1 dependence must be known or measured in order to determine accurately the in-vivo tissue temperature. If the tissue is sufficiently heterogeneous, the temperature dependence will be multiexponential, with no corresponding simple linear approximation.

For clinical applications, a pixel-by-pixel estimation of the change in the T_1 value is determined. This can be achieved using a number of different sequences, the most simple being a spoiled gradient-echo sequence in which the image signal intensity (S) is given by:

$$S \propto M_o \frac{\sin \alpha (1 - E_1)}{1 - \cos \alpha E_1} E_2^* \quad (5)$$

where M_o is the net equilibrium magnetization, α is the tip angle, TR is the repetition time between each phase-encoded step, $E_1 = \exp(-TR/T_1)$, T_2^* is the inhomogeneous spin-spin relaxation time, TE is the echo time, and $E_2^* = \exp(-TE/T_2^*)$. Since the temperature dependence of T_2^* is considered negligible, only the temperature dependence of M_o and T_1 contributes to the change in the signal intensity. Although the change in signal intensity is dominated by the temperature dependence of T_1 , the variation in M_o must also be taken into account. Temperature changes are determined by initially acquiring a pretreatment baseline image and then acquiring subsequent images during thermal treatment.

Use of T_1 for temperature imaging was first demonstrated for monitoring local temperature variations in blood samples.^[16] Over a range of 0–40°C, the T_1 was found to vary linearly with T^{-1} with a temperature sensitivity of roughly 1.4%/°C. At higher temperatures, a hysteresis effect was found between the MR signal intensity and temperature. In another study using a neodymium:yttrium–aluminium–garnet (Nd:YAG) laser to heat minced rabbit brain, reversible decreases in M_o and reversible increases in T_1 were found for temperatures up to 45°C.^[17] Above this temperature, up to 60°C, both reversible and irreversible increases in T_1 were found, which were attributed to transformations in cellular metabolism and water distribution within the cell. Above 60°C, only irreversible changes in T_1 were found, corresponding to tissue coagulation and protein denaturation. More recently, a study has been performed to understand the changes in T_1 and other MR parameters (T_2 , diffusion, and magnetization transfer) of tissues due to thermal coagulation using temperatures from 37–90°C.^[18] Using animal and human ex-vivo tissue such as skeletal muscle, cardiac muscle, cerebral hemisphere, white matter, liver, adipose tissue, prostate, and blood, the T_1 value decreased for increasing temperatures except for fat and prostate.

Clinical Applications of T_1 Measurements

While many of the clinical applications of T_1 -based thermometry methods have qualitatively evaluated temperature changes, the application of quantitative temperature imaging using T_1 is increasing. For example, quantitative T_1 thermometry has been used clinically for MR guidance of LITT for inoperable renal tumors.^[19] Delivering the laser therapy via a Nd:YAG source, thermal lesions within kidney were monitored in real time. As the tissue temperature rose, the reduction in signal intensity due to increases in tissue T_1 was determined using continuous-subtraction colorization software, which monitored the development of necrosed tissue. Clinical results for patients with renal carcinoma indicate the feasibility of MR guided laser ablation for inoperable renal tumors.

One important application of quantitative T_1 -based thermometry is for monitoring temperature in breast tissue. As it will be shown in the next section, the PRF technique is limited in its application to adipose tissue since the proton chemical shift in fatty tissue is essentially temperature independent. A recent clinical study investigated the use of focused ultrasound to non-invasively ablate deep malignant breast tumors combined with MR image guidance and on-line MR temperature control.^[20] For treatment of human breast tumors, a focused ultrasound surgery (FUS) therapy unit was designed to operate in a clinical 1.5 Tesla MR scanner. Prior to FUS treatment, T_1 -weighted mammography was performed on the biopsy-confirmed breast cancer. One image is shown in Fig. 1A after injection of a gadolinium-based paramagnetic contrast agent. Strong signal enhancement can be seen in the tumor, revealing a well-circumscribed mass that was located in the central part of the right breast (Fig. 1A). For the FUS treatment, the patient was positioned in the MR scanner and T_1 -weighted images of the breast were acquired perpendicular to the plane of ultrasound propagation. In treatment planning, the target volume was outlined as the MRI visible tumor boundaries to facilitate the pathological analysis of the effects of therapeutic ultrasound on cellular proliferation. Temperature monitoring during the ultrasound sonications used a T_1 -weighted saturation–recovery–turboFLASH sequence. MRI thermometry during FUS with color-coded temperature display for a typical sonication is shown in Fig. 1B. The maximum temperature detected in the breast was approximately $70 \pm 5^\circ\text{C}$; thermometry images were reported to have a temperature resolution of $\pm 2^\circ\text{C}$ and spatial accuracy better than 2 mm. At the end of the sonications, the effect of the ultrasound on the tumor vasculature was evaluated with injected gadolinium contrast agent. Fig. 2B shows a sharply demarcated area with an absence of contrast agent in the treated area, which suggests a complete

Fig. 1 (A) Before ultrasound treatment, T_1 -weighted images were obtained of the tumor located in the central part of the breast. (B) A temperature map of the spatial heating in the tumor from the focused ultrasound based on the change in the T_1 signal. (C) After FUS treatment and with contrast, a T_2 -weighted image of the breast was acquired exhibiting a complete lack of contrast enhancement after ultrasound therapy. interruption of blood perfusion, and the area correlates well with the region outlined on the pretherapy MR images. Overall, the results show that clinical non-invasive MRI-guided therapy of breast cancer is both feasible and effective.

One of the drawbacks of using T_1 -based thermometry is the tissue-specific nature of the thermal sensitivity and the complex nature of relaxation in tissue. Above ablation temperatures of 65°C , at which point protein denaturation occurs, changes in T_1 are probably related more to structural changes in the tissue than to the actual temperature.

Proton Resonance Frequency Shift

Temperature information from MR images using the PRF shift method exploits the temperature dependence of the Larmor frequency of protons in water.^[21] The resonant frequency (ω) is given by:

$$\omega(T) = \gamma B_{\text{muc}}(T) = \gamma B_0 \left(1 - \sigma(T) - \frac{2}{3} \chi_v(T) \right) \quad (6)$$

where γ is the proton gyromagnetic ratio, B_{muc} is the local magnetic field experienced by the protons, B_0 is the strength of the external magnetic field, $\sigma(T)$ is the temperature-dependent shielding constant, and χ_v is the temperature-dependent magnetic susceptibility of water. In terms of temperature dependence, the dominant term is the shielding constant, which has a sensitivity of -0.01 parts per million (ppm)/ $^\circ\text{C}$.^[22] The physical mechanism involves the increase in the hydrogen bond length with temperature, which leads to a reduction in the deshielding effect of the oxygen atom.

Use of the PRF for MRI temperature mapping was first introduced by Ishihara et al. in 1992.^[23] Gradient-echo images are used to determine temperature changes, from an initial baseline level, during thermal treatment. To determine the temperature change, phase-sensitive images are processed to estimate the PRF shift. The spatially-dependent temperature change, $\Delta T(x, y, z)$, in a gradient-echo MR image with an echo time, TE , is given by:

$$\Delta T(x, y, z) = \frac{\Delta\phi(x, y, z)}{\gamma \cdot B_0 \cdot \alpha \cdot TE} \quad (7)$$

where $\Delta\phi(x, y, z)$ is the pixel-by-pixel phase change between the baseline image and an image acquired during thermal therapy, and α is a constant (≈ -0.01 ppm/ $^\circ\text{C}$). In practice, the PRF shift is best determined by a complex-subtraction method, instead of a direct phase subtraction, since this process avoids problems of phase wrapping.^[24] Long scan times also require correction of system instabilities such as drift in the

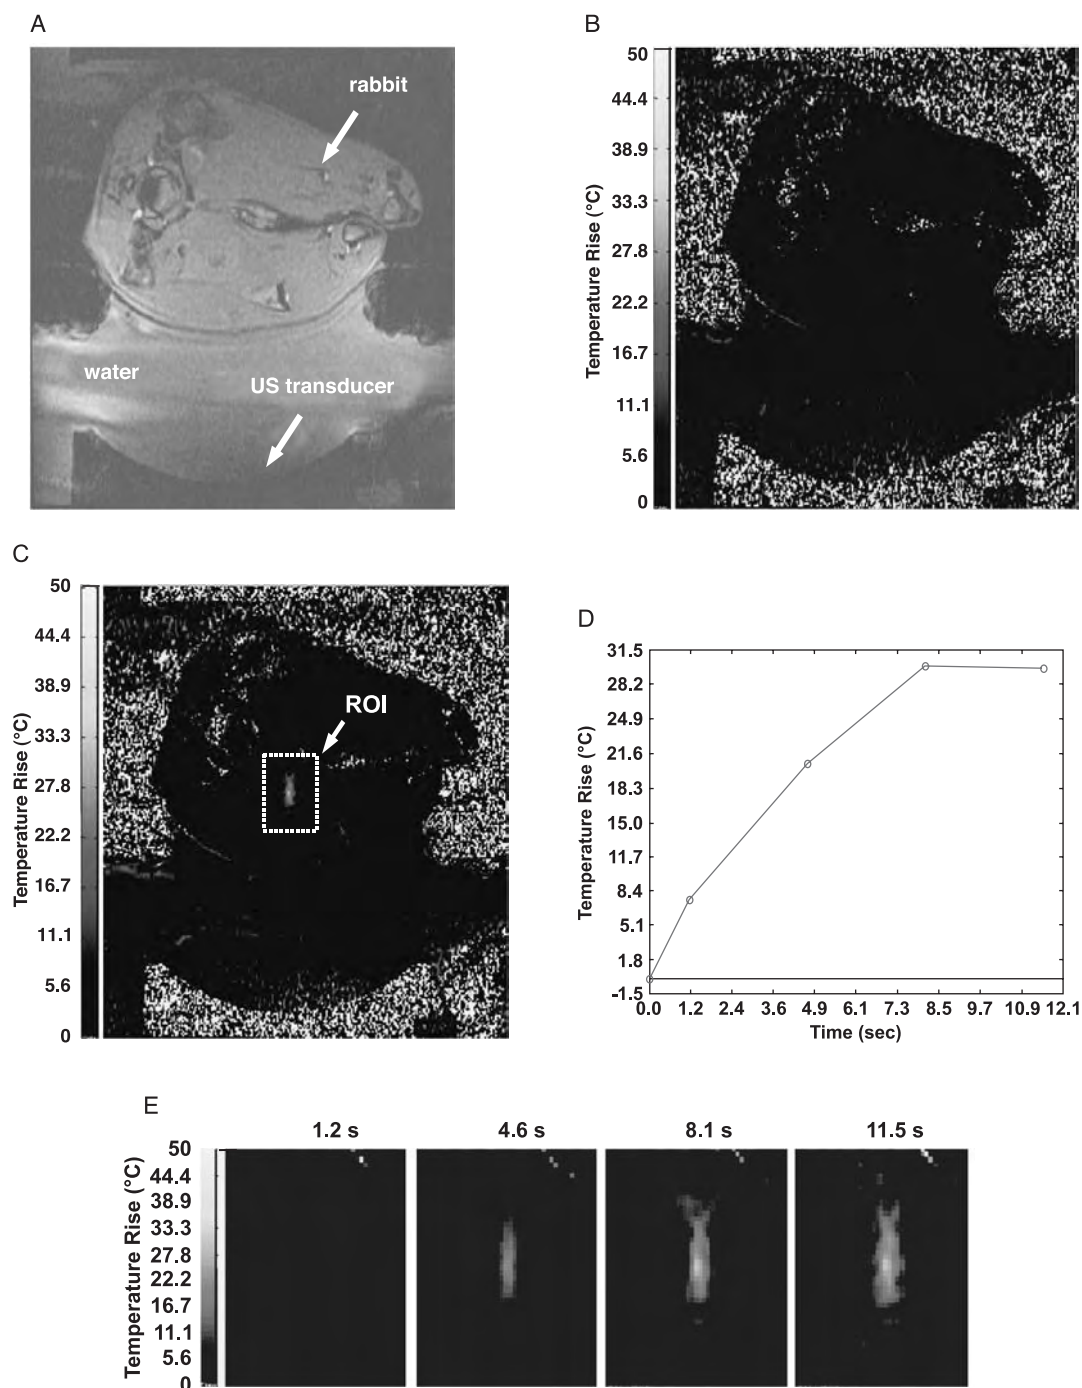

Fig. 2 Magnitude image (A) showing the experimental setup for the delivery of focused ultrasound in rabbit thigh muscle in vivo. Initially, a phase-difference image is obtained before the thermal therapy (B) as a baseline or reference. During the ultrasound sonication deep in the rabbit thigh, the change in phase (C) within the image is used to quantify the temperature change within the ROI. Phase images across the focal point illustrate the temperature elevation during a sonication. The four images (D, left to right) were made at approximately 1.2, 4.6, 8.1, and 11.5 seconds from the beginning of the sonication. As a function of time (E), the temperature rise determined within the ROI is also graphed. (Figures courtesy of Drs. Hynynen and McDannold, Brigham and Women's Hospital, Boston, MA.)

main magnetic field.^[25] First-order-phase-drift correction algorithms use reference phantoms made of oil, which have a very low temperature dependence, $\alpha(T) = -4.59 \times 10^{-5}$ ppm/°C.^[26] Since the drift typically

varies linearly over the imaging plane, spatial interpolation using several phantoms placed around the target can be used to correct for the phase drift in the heated region.

Fig. 3 Spatial and temporal change in the MR temperature mapping during continuous irradiation from a bare end fiber laser interstitial thermotherapy (LITT) for intracranial tumors tested in rabbit brain. (Reprinted with permission, Copyright 2001, John Wiley & Sons, Inc.)

As an example of an in-vivo ultrasound heating procedure monitored using PRF thermometry, Fig. 2A shows a magnitude image of an axial view of a rabbit above a focused ultrasound transducer. The transducer, which was designed to ablate tissue deep within the rabbit's thigh muscle, consisting of a single focused crystal, which had a diameter, radius of curvature, and resonant frequency of 100 mm, 80 mm, and 1.5 MHz, respectively. For this application, the phase shifts were measured using a fast spoiled gradient-echo (FSPGR) sequence. Spherical transducers are known to produce ellipsoidal-shaped heating patterns or lesions,^[27] and the temperature maps shown in Fig. 2 show this type of behavior. The maximum temperature rise within the region of interest (ROI) in Fig. 2C is plotted as function of time in Fig. 2D. Spatial changes in the temperature are plotted as a function of time in Fig. 2E, with both the size of the heated region and the maximum measured temperature increasing with time.

The PRF method has also been used for in-vivo laser heating studies. Lasers have been used to perform thermal ablation in areas such as the brain, head, neck, tongue, liver, kidney, and prostate. Laser designs include variations that can focus energy directly out of the tip (bare end), though a lens, out from a beveled side, or in a diffuse projection pattern. PRF methods have been used to quantify the different temperature profiles produced by each design in rabbit brain.^[28] The results indicated that all of the designs mentioned produced a spherical distribution of elevated temperatures, except the diffuse projection laser, which produced a cylindrical temperature distribution. An example of the spatial heating over time from a bare end fiber design in rabbit brain is shown in Fig. 3. Compared to a fiber optic thermometer also located in the brain, the accuracy of the MR temperature data was reported to be 0.88°C.

With the robustness and rapid data acquisition associated with the PRF technique, evaluation of therapy procedures can be performed close to real time.^[29] One particular application is the use of the MR temperature measurements to control the heating procedure via closed-loop feedback.^[30–32] An example of an in-vivo ultrasound hyperthermia procedure using MR temperature data to control the temperature rise within

tissue is shown in Fig. 4A.^[31] The experiment used a 16-channel ultrasound intracavitary array for localized hyperthermia treatment of prostate tumors. Oil phantoms were placed around the rabbit to correct for drift in the main magnetic field while the ultrasound array was used to heat the thigh muscle of the rabbit. A fiber optic temperature probe was also placed near the ROI to monitor the precision and accuracy of the measurements. MRI-derived temperature measurements within the ROI were used to adjust the power to the transducer through a proportional-plus-integral controller. With the controller programmed to aim for a target temperature of 44°C, the measured steady-state temperatures were within $\pm 1^\circ\text{C}$ of their targets (Fig. 4B). These results demonstrate the feasibility of MR feedback control of hyperthermia treatments.

The advantage of using the PRF method over using the spin-lattice relaxation time is that the temperature coefficient is independent of the type of tissue, unlike the tissue-specific T_1 value. Also, the spatial and temporal resolution of the PRF is superior to that of T_1 thermometry.^[2] A drawback similar to T_1 -based methods is that the PRF technique is susceptible to motion. If the therapy procedure is short, then usually the patient can remain motionless during the treatment and images can be acquired to determine the in-vivo temperatures. However, if the procedure is long, like a hyperthermia treatment, then motion artifacts often arise. One method proposed to reduce the detrimental effects of motion is to acquire multiple echoes rather than a single echo to determine the frequency shift.^[33] The trade-off is that although the sequence improved the temperature measurements in the presence of motion, the temperature sensitivity was reduced. Another problem is that the temperature-dependent magnetic susceptibility is not negligible. Physiologically induced volume magnetic susceptibility changes can arise from blood flow or an altered oxyhemoglobin to deoxyhemoglobin ratio during a hyperthermia treatment. Finally, the mechanism that makes the PRF method attractive for temperature monitoring in muscle, brain, and kidney, for example, cannot be applied to tissue with a high component of fat. One approach to address this problem is to use the PRF technique with a binomial lipid-suppression sequence to remove the

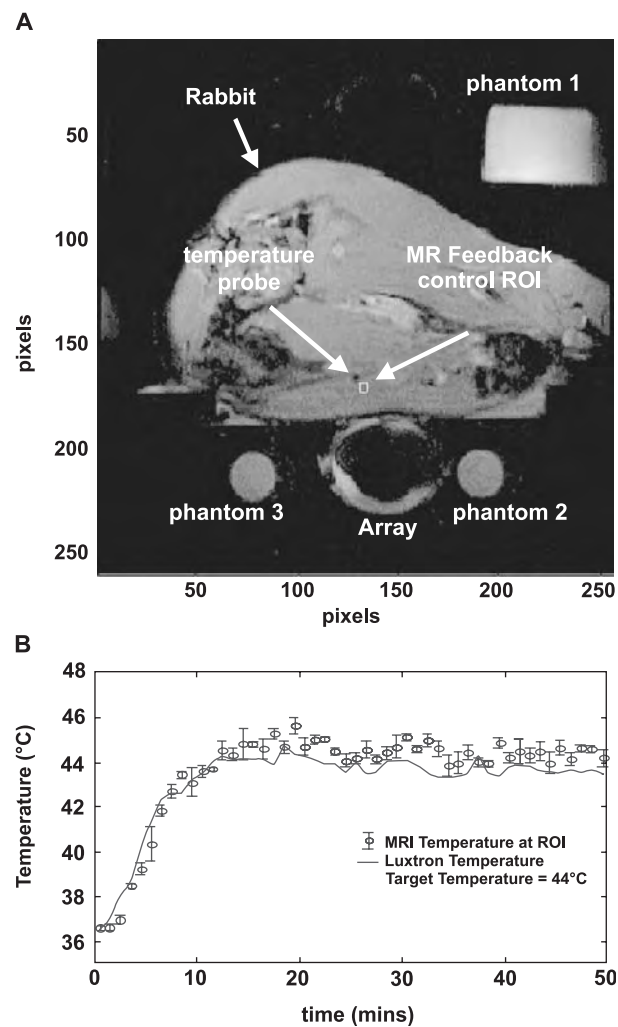

Fig. 4 (A) For in-vivo test of the controller, axial view for a rabbit, and the array along with the three reference oil phantoms used for correcting for the magnetic field drift. (B) The feedback system was set to control the temperatures within the ROI. Temperatures measured by the fiber optic were compared against the MR temperatures determined using the PRF method (mean \pm S.D.) in the ROI. effects of adipose tissue from the temperature map,^[34] but considerable care is still needed in interpreting the results.

Clinical Applications of the PRF Method

PRF shift methods have found applications in both animals' experiments and human clinical interventional MR. With MR guidance and temperature control, percutaneous interstitial microwave thermoablation of locally recurrent prostate carcinomas have been performed.^[35] Microwave heating with an

interstitial therapeutic system (Urowave, Dornier MedTech), which consisted of a 915 MHz microwave generator, has been used to increase temperature in the prostate. Each applicator consisted of a 1.2-mm-diameter element housed in a sterile water cooling jacket to prevent carbonization of tissue immediately adjacent to the applicator. The goal of the procedure was to ablate as much as possible of the prostate tissue in the patient by reaching a temperature of at least 50°C, but not exceeding 80°C, for 20 minutes and to preserve the urethra and rectum by not exceeding 45°C in these locations. On-line control monitoring of thermal therapy was performed with a standard fast spoiled gradient-echo sequence modified to support real-time imaging. MR temperature results correlated well with fiber optic temperature probes located on the applicators.

MRI temperature imaging has also been used in conjunction with RF hyperthermia treatments of human high-grade sarcoma of the lower leg.^[36] For the hyperthermia treatment, an RF phased array (130 MHz, 28 cm diameter), which was magnet compatible was designed to fit inside the head coil of a 1.5T whole body scanner. As with much electrical therapy equipment used in conjunction with an MRI scanner, the RF equipment was isolated from the scanner by means of high-order RF filters. Standard gradient echo sequences were used to acquire phase-difference images during the 65-minute-long treatment. Drift in the main magnetic field, B_0 , was corrected using regions of interest within the bone marrow.

One advantage of the PRF shift method over the other thermometry techniques is that the temperature dependence had been shown to be linear above the coagulation or ablation threshold. Thus, this method was used for the first clinical trial of noninvasive MR imaging-guided focused ultrasound surgery of benign fibroadenomas in the breast.^[37] Initially, the tumor was outlined on T_2 -weighted images for multiple sonication treatment planning. Phase-difference imaging was performed during each ultrasound exposure to monitor the change in tissue temperature and focus localization. Results from the temperature mapping indicated that fibroadenoma temperature elevation ranged from 12.8°–49.9°C for the separate sonications. Moreover, the feasibility of this treatment method was demonstrated by the complete or partial lack of contrast material uptake on posttherapy T_1 -weighted images in eight of the 11 lesions treated. Unfortunately, many of the temperature measurements were reported to be unreliable due to patient motion during the sonications. Future treatments may employ such techniques as multiple gradient-echo imaging sequences, mentioned earlier, to overcome motion artifacts.^[33]

Other Clinical Applications and MR Thermometry Methods

One area in which the thermometry methods mentioned previously become problematic is the application to cryotherapy. As the tissue water transitions from the liquid- to solid-state, the signal intensity becomes extremely small in the MR images. This is because the T_2 relaxation of solid ice crystals is so short that, under normal imaging conditions, the ablated area appears as a signal void. In fact, this signal disappearance can be useful since the sharp contrast between the frozen and unfrozen tissue enables a clear estimation of the cryolesion volume.^[10,38] Post cryosurgical treatments have shown good correlation between the MR image lesion volume and the excised necrosed tissue volume. However, temperature measurements within the iceball formed during cryosurgery are not possible unless imaging sequences with very short echo times can be used. Recent successful efforts have quantified the relationship between temperature with ice formation by mapping the R_2^* ($R_2^* = 1/T_2^*$) of bovine liver in vitro.^[11] As the tissue freezes, some extracellular fluid remains in a dehydrated yet unfrozen state from which signal can be measured. With a cryosurgical probe, the temperature was reduced from 37°C to -100°C. Using sequences incorporating a Gaussian half-pulse excitation and a short spiral readout for a very short echo time (0.2 msec) for the first image, while the second image was obtained with a TE of 1.2 msec, allowed determination of the R_2^* . The relationship was found to be linear with temperature down to -25°C.

Besides proton, other heteronuclei such as ^{13}C , ^{15}N , ^{19}F , ^{23}Na , ^{59}Co have been proposed as internal MRI spectroscopic thermometers by measuring temperature-dependent chemical shifts. For example, although not used clinically, tris(ethylenediamine) cobalt(III) trichloride has been used as a temperature sensor due to the large temperature dependence of its ^{59}Co nuclear magnetic resonance chemical shift. Encapsulation of this complex within liposomes was used to target the agent to the reticuloendothelial system, and temperature changes of the order of 0.1°C have been measured in vivo on rats from ultrasound hyperthermia.^[39] An agent that contains two resonances with temperature-dependent chemical shifts, such that the differences in the chemical shifts is also temperature-dependent, can potentially be used to address issues of motion and magnetic susceptibility changes. One example used two fluorine peaks of perfluorooctylbromide to measure the absolute temperature and temperature changes in the liver induced by ultrasound exposure. The chemical was encapsulated in protein microspheres, injected into rats, and subsequently taken up by the macrophages of the liver and spleen.^[40] Though these methods have

been for thermometry with in-vitro and in-vivo animals' experiments, they have yet to be applied for clinical interventional thermal therapies.

CONCLUSIONS

The use of MRI techniques to map temperature during thermal therapies has increased significantly over the past decade. The PRF method provides a robust and easily implemented tool for both measuring and controlling temperature in specific areas for predetermined treatment times. The use of noninvasive or minimally invasive thermal therapies used in combination with MR planning, thermal monitoring, and follow-up has already been shown to be effective in a number of applications.^[3] Interventional MR techniques translate clinically into reduced infections, scar formation, reduced recovery time, and, ultimately, reduced health care costs.

Magnetic Resonance Microscopy

Egidijus Uzgiris

Rensselaer Polytechnic Institute, Troy, New York, U.S.A.

INTRODUCTION

What do we mean by the term magnetic resonance (MR) microscopy? MR imaging is typically done with an in-plane resolution of about 1 mm^2 and slice thickness of 1–3 mm (this resolution can be routinely increased to $300 \times 300\ \mu\text{m}^2$ in-plane resolution with 1-mm slice thickness) at magnetic field strengths of 1.5 T (or, more frequently now, at 3 T) in imaging times of the order of 1 to 10 min or so, depending on the precise nature of the imaging sequence. The field of view in MR images is typically $20 \times 20\ \text{cm}^2$, or larger in the case of whole body imaging with parallel coil signal receive arrangements. The magnetic field gradients used to generate the spatial resolution are on the order of 10–20 mT/m. At this clinical scale of resolution, the soft tissue contrast is superb and superior to all other imaging modalities. Higher resolution is desirable, however, in some clinical applications—in evaluating the microvasculature of tumors, in detecting amyloid plaque in Alzheimer’s patients, in detecting atherosclerotic plaque in arteries, and in detecting small tumorous lesions. These structures and lesions range from 10 to 100 μm in the first case, from 40 to 200 μm for amyloid plaques, and up to 500 μm for small tumor lesions. Typically, the highest resolution in a clinical scanner may be on the order of $300 \times 300 \times 1000\ \mu\text{m}^3$, which fails to meet the above clinical needs (except for tumor detection at the half-millimeter size range). Thus, MR microscopy may be defined as MR imaging at yet a higher resolution than the best clinical case or, specifically, a resolution of at least 100 μm or better. This partitioning into two classes of imaging occurs in practice because of the need for specialized gear to generate the necessary high magnetic field gradients and specialized receive coils for capturing the weak signals from each imaging voxel, as well as the use of very high magnetic fields, 9–14 T.

As we shall see in this review, it is a daunting task to generate MR images with such high resolution and the commensurate small imaging voxels. In fact, we shall demonstrate that *in vivo* MR microscopy will be practical only in rodent studies or in embryology studies for which high-field, small-bore magnets and high-field gradient coils exist. *Ex vivo* imaging may push the resolution limits of MR microscopy to the cellular level, but only with rather difficult

implementations of the limiting geometries of the necessary coil hardware and still very long imaging times: not minutes, but many hours. The fundamental limits of detecting weak radiofrequency signals generated by an ever smaller number of precessing nuclear spins per imaging voxel are not, in the end, to be circumvented.

Can we expect any movement toward meaningful clinical applications such as those listed above? Perhaps only in one or two of the applications will progress with adapted clinical MR systems yield possible resolution (application of gradient coils and specialized receive coils in clinical MR systems magnets) high enough to meet a clinical need. Certainly in preclinical studies of rodents we may expect MR microscopy to develop much valuable information (such as the phenotyping of mice or mouse embryos). There may be a role in developmental studies as well. In *ex vivo* studies, MR microscopy may provide useful delineations of tissue lesions and abnormalities that could complement histology (in terms of organization of cells or cellular structures). Finally, techniques such as labeling with suitable contrast agents may allow detection of a few cells at time and their migration and localization in organs of interest using standard or adapted clinical MR imaging (MRI) systems.

How then can we judge progress in this field? Are efforts that push the resolution limits by the use of ultrasmall receive coils and very strong gradient coil assemblies relevant to important biological or clinical applications? Such efforts are technically admirable but are very distant from the main applications listed above. High-resolution mouse phenotyping by MR microscopy was one important achievement. We must determine whether atherosclerotic plaque can be adequately visualized—with or without contrast agent. Can tumor microvasculature be visualized directly by MR microscopy? Will contrast agent approaches allow the visualization of cell trafficking? Will *in vivo* amyloid plaque imaging be at all possible and clinically relevant? I examine these questions below.

SIGNAL TO NOISE IN MR IMAGING

The physics of MR imaging is discussed in any number of monographs^[1,2] in great detail. Briefly, the MR signal is derived from precessing nuclear spins (spins of

protons of water) that are prepared by a suitable radiofrequency pulse excitation in a magnetic field. The time-varying magnetic fields produced by this precession are sensed by a suitable receive coil (placed around or near the sample) as an induced voltage at the precession frequency. Because the precession rate depends on the field strength, the spatial position of a particular precession frequency is encoded by applying a magnetic field gradient in a suitable fashion in all three spatial directions. Thus, for high spatial delineation, it is necessary to apply high magnetic field gradients. This becomes a hardware problem that was solved for small-bore systems. But the spin signals are weak and noise from the receiver coil (the Johnson noise) and equivalent resistive losses in the sample under study are limiting factors in generating adequate image quality.

What are the barriers to high resolution with MR? Fundamentally, the principal barrier is the loss of signal in direct proportion to the voxel volume—the loss of the number of participating proton nuclear spins that generate the MR signal in that voxel, in direct proportion to the voxel volume. To illustrate this barrier, consider a voxel of $400\ \mu\text{m}^3$ (the limiting resolution for typical clinical imaging) shrinking to $100\ \mu\text{m}^3$ for the case of MR microscopy (in our classification criteria). The signal loss for the latter case is by a factor of $4^3 = 64$. To alleviate this loss with increased averaging time (signal increases linearly with averaging time, whereas the noise increases as the square root of averaging time) requires $64^2 = 4096$ longer imaging times to obtain the same signal-to-noise ratio (SNR). Thus, an imaging time of some 10 min in the clinical case becomes 68 hr in the microscopy case. Clearly, without some other helping factors, that would be the end of it. Imaging at such a high resolution would not be at all practical. But one such factor is the magnetic field, and in MR microscopy the fields used are typically 7 to 14 T, increasing detected signal up to 50 over equivalent voxel size at 1.5 T. Another helping factor is the receive coil configuration for the smaller volume microscopy samples. Together these conspire to give measurement times of about 14 hr for 110- μm voxel resolution at 2 T for whole-mouse imaging (ex vivo and fixed in formalin).^[3] Increasing the magnetic field increases the resolution further for the same measurement time: at 7.1 T a resolution of 50 μm was achieved. Thus, it is clear that MR microscopy is technically hard and even with high fields the necessary measurement times for acceptable SNR quickly explode to impracticality as resolution approaches the biological cell size. Let us keep in mind that the example above is for a formalin-fixed animal. Imaging in vivo has further issues of the effects of breathing motion on the signals and the challenge of keeping animals under anesthesia for

prolonged periods of time. Progress on both of these fronts has been made by gating strategies and animal monitoring in real time. However, for these and other reasons, resolution much below 100 μm in living animals is unlikely.

Another approach may allow visualization of groups of cells even with voxel sizes that are large compared to individual cells: the use of contrast agents to label the cells. A signal amplification results, which allows detection of the cells in those voxels containing the cells. Without resolving the cells individually, one can still detect them and follow their migration in situ in tissues and organs of interest. This is likely to be an important application of MR imaging, but, strictly speaking, it is not MR microscopy by the criteria of resolution limits used in such studies (clinical resolution may be adequate).

The reader may refer to any number of monographs and research articles for a detailed consideration of MR signal to noise.^[2,4,5] As always in MRI, the detected signals are weak and the most challenging barrier for faster imaging or for higher resolution is that of signal to noise. An image must have some minimum value of SNR in order to detect interesting features. For example, an SNR of less than 20 is inadequate for detecting amyloid plaques in brain sections.^[6] The scaling of SNR with the principal experimental variables can be expressed straightforwardly. To this end, and including explicitly only those variables of significance for scaling, the signal to noise of an MRI experiment may be expressed as

$$\text{SNR} \propto A(\text{seq}) \times f(B_0) \times \frac{V}{s} \sqrt{T_{\text{img}}}, \quad (1)$$

where $A(\text{seq})$ is a factor involving pulse sequence details (which may be optimized experimentally), V is the voxel volume, s is the imaging scale size, i.e., the diameter of the receive solenoid or receive coil, T_{img} is the imaging time, and $f(B_0)$ is the magnetic field dependence, which we take to be

$$f(B_0) = B_0^{\frac{7}{4}}. \quad (2)$$

This field dependence assumes that the dominant noise source is the Johnson noise of the receive coil and not the resistive losses of the sample. This assumption seems to hold in many high resolution cases compared below. The important factor of receiver coil scale size, s , can be understood in that the induced current in a coil for a given rate of magnetic field change within the coil is inversely proportional to coil diameter: the smaller the coil diameter, the larger the induced voltage in the coil for a given rate of magnetic field change (see Ref. [4] for detailed discussion of size scaling).

Given fixed values for the first three terms, the coil size, the field, and the pulse sequence, the resolution size and imaging time are the only remaining variables. For some necessary SNR level to adequately distinguish image features, the necessary imaging time rapidly blows up to

$$T_{\text{img}} \propto \frac{1}{A^2 f^2 d^6}, \quad (3)$$

where d is the voxel size. Even with improvements in coil sensitivity and the use of high fields, it is apparent that the last term causes T_{img} to blow up quickly as d becomes less than $100 \mu\text{m}$. As a result, in vivo MR microscopy remains extremely challenging, even for the case of rodent brain studies. Not only must the imaging time utilized in ex vivo studies of 10–30 hr be reduced to something like 1–2 hr, compatible with animal anesthesia exposure, but also the effects of breathing and cardiac motion present yet another set of severe technical impediments.

For clarity, consider a further example. In the imaging of mouse brains,^[6] the voxel sizes used were $50 \times 50 \times 500 \mu\text{m}$ in 2–3 hr for an SNR of about 20, the lower limit for acceptable SNR. To go to the next step, the imaging of a majority of amyloid plaques in rodent brains, for example, one would require voxels sizes not larger than $50 \times 50 \times 50 \mu\text{m}^3$. The imaging time would increase to 200 to 300 hr, which is clearly not practical in live animals. Where can the necessary factor of 100–300 come from? The field is already high in this example and no large improvement can be gained at any further practical field level. The coil sensitivity is as high as the geometry of mouse brain allows. Are we at an impasse for in vivo studies? Not entirely. There are several gambits to pursue in the near term and perhaps more exotic detection schemes in the future.

What can, perhaps, be done is to use high-temperature superconducting (HTS) coils to help reduce

the noise further.^[7,8] It was estimated previously that SNR is improved by a factor of 5–6 over copper receive coils in some experimental situations. These situations seem to require limiting the electromagnetic loading of the sample on the HTS coil. This is hard to do when attempting to image a mouse brain, but perhaps achievable when imaging smaller structures such as embryos. HTS coils are implemented in nuclear MR spectroscopy to good effect, but implementation of such coils for MR imaging has not been widely implemented, as discussed below.

The remaining gambit, after all other optimization knobs have been turned, is to apply contrast agents to ex vivo samples or to live animals. The contrast agents have the effect of reducing tissue longitudinal relaxation times, T_1 , and lead directly to larger signals with certain common pulse sequences for imaging (although such gains are only of the order of factors of 2 or so). This approach has been applied ex vivo to visualize amyloid plaques in 1–2 hr^[9] and it may be that such contrast agents can lead to adequate signal amplification in vivo as well. More exotic approaches have been suggested for MR signal detection and we shall consider these below.

What are the experimental realities? We have considered signal scaling relationships and determined they have some serious limitations for MR microscopy. Have experimenters been able to circumvent these limitations by clever approaches to SNR enhancement? We consider several applications below and see that, indeed, progress is being made and clever solutions exist to the problem of obtaining adequate signal to noise in imaging at high resolution.

For projecting practical resolution limits in MR imaging, it is instructive to compare key experimental data points of SNR thus far achieved with MR microscopy in Table 1.

This comparison of achieved SNR spans many orders of magnitude in voxel size, and the predicted

Table 1 SNR for various experimental conditions in microscopy and the clinic case

Reference	Field (T)	Volume, voxel (mm ³)	Scale size (mm)	Time (hr)	SNR	SNR ^a scaled	Pulse sequence	Sample

scaling behavior of the SNR by Eq. 1 is within a factor of ~ 2 of the observed value in the worst case and better than that in the remaining comparisons. Eq. 1 works quite well in predicting SNR behavior, especially if the extrapolations are for optimum pulse sequence conditions. In Table 1, the different pulse sequences were not factored in the comparisons. The best SNR conditions in detail were achieved by Wecker et al.^[11] in their study of insects. In Table 1, Eq. 1 was used to extrapolate the necessary FOV/receive coil size for achieving a given SNR and the resulting resolution limit using a field of 14 T and an imaging time of 1 hr.

For biological systems, cellular resolution (i.e., voxel size less than $10 \mu\text{m}$ on one side) is achieved with acceptable SNR and reasonable imaging time, as illustrated by the work of Lee et al.^[10] at 14 T and a “microscopic” receive coil of 0.5-mm diameter. This rather specialized hardware, as well as the high-resolution image of a leaf stem, is illustrated in Fig. 1. At a more general size scale we are constrained above the cellular resolution limit, even for a low SNR of 10. Nevertheless, MR imaging at a resolution somewhat larger than the biological cell scale size would be valuable in the study of insect morphology and embryology development. Furthermore, future staining techniques may bring out more contrast in the images and increase the available SNR.

HTS RECEIVE COILS

In cases where the sample resistive losses are small, HTS coils in place of copper coils provide a way of increasing the SNR by a factor of ~ 6 .^[7,8] For a voxel size of $3.8 \times 10^{-5} \text{ mm}$, or $17 \times 17 \times 134 \mu\text{m}^3$, Hurlston et al.^[8] achieved an SNR of 29 at 9.4 T for a kidney

sample in 1 hr and a rectangular coil size of $10 \times 15 \text{ mm}$. When this result is scaled in accordance with Eq. 1, the expected SNR for the condition of Wecker et al.^[11] is 61, not very different from the SNR of 70 reported by Wecker et al. for a copper coil of $\sim 20\text{-mm}$ diameter. The samples are not the same and the sequences are similar, but not the same. Nevertheless, this rough comparison suggests that the HTS coil geometries are not as ideal as the configurations that can be fabricated from copper. The evident advantage of HTS in exact comparisons with copper is perhaps reduced in comparison with more optimum copper coil configurations of the same size. There is also the question of signal homogeneity in the HTS coil configuration (see, for example, Fig. 2 in Ref. [8]). This approach is promising in principle, but in practice there are challenges and further work to be done to understand the limitations of the HTS coil systems.

PHENOTYPING OF THE MOUSE

Perhaps the first useful application of MR microscopy was demonstrated in the high-resolution imaging of intact fixed mice for the purpose of phenotyping.^[3] The relationship of genome and structure and function is of vital importance for biological understanding of the many mouse phenotypes generated by genetic alterations, such as in discerning the function of knockout genes. The whole mouse was imaged *ex vivo* at 2 T at a resolution of $110 \mu\text{m}$ isotropically in 14.5 hr. The issue of signal sensitivity was addressed with efficient signal encoding and efficient array of receive coils, but these in themselves were insufficient to yield adequate SNR. The key step in this study was the use of “active” staining with a T_1 contrast agent, together with

Fig. 2 MR image of whole fixed mouse at 2 T. Voxel size is 110 μm isotropically; imaging time is 14.5 hr. Cross-sections of 110- μm thickness are indicated by arrows. Reproduced by permission from Johnson et al.,^[3] Fig. 3.

formalin fixation by perfusion of the mouse through the jugular vein. The reduction in T_1 by almost a factor of 6 in most tissues gave a useful high-resolution image of the mouse and a data set that could be manipulated in many ways to give desired views of the mouse anatomy, as illustrated in Fig. 2. This study required more than turning “resolution knobs,” as the authors state. The large data sets required separated reconstruction methods and further visualization methods to render rather low SNR images of thin slices into more useful thick-slice rendered images, as illustrated in Fig. 3. Thus, the effective resolution of anatomical structures even with staining is much larger than the voxel size used in data acquisition.

Interpretation of structures at a level of 100 μm from such images is challenging. The effects of staining on the tissues are not known in detail and the visualized anatomical structures may require further studies for correct interpretation. The simplest effect of such staining is the delineation of blood vessels. The question remains, At what level of microvasculature structure can MR microscopy be applied reliably? The

images in Fig. 3 indicate that microvasculature below some 100- μm size is not yet effectively visualized and, thus, application to tumor biology and angiogenesis imaging may require different staining procedures (such as the use of intravasculature staining only) and significant amplification of SNR—which is already pushed to the limit, even in fixed and stained tissue samples.

At high fields, one is generally limited to small bore sizes and studies at fields beyond about 7 T will be used for tissue imaging and perhaps for ex vivo organ imaging, as done here. The severity of the SNR problem in MR microscopy is quite evident in these ex vivo images and the extension of this microscopy to in vivo studies is daunting.

MR MICROSCOPIC HISTOLOGY AND AMYLOID PLAQUES

A less formidable application for MR microscopy is that of histology. The samples are small, suitable for

Fig. 3 MR images of Gd-perfused mouse kidney at 9 T with an array size of $256 \times 512 \times 512$, yielding a slice thickness of 25 μm (A). A rendering technique was used to produce (B) a 250- μm -thick section and (C) a 2500- μm -thick section. Imaging time, 14.5 hr. Reproduced by permission from Johnson et al.,^[3] Fig. 5.

very high field systems and for efficient receive coils of small diameter. We shall now examine an important area of research, determining plaque burden in transgenic mice models of Alzheimer's disease. Can amyloid plaques be visualized reliably and give a useful measure of disease progressions in these animal models? If yes, then this would indeed be a significant contribution to the study of this disease. Alternative histological methods exist, and it is still important to demonstrate that the MR technique brings new information or information in a new form (digital encoding, for example, and non-destructive imaging) over the standard optical methods.

It has now been confirmed that an earlier study of human amyloid plaques in the brain^[6] did indeed detect at least a fraction of the amyloid plaques in the *ex vivo* brain sections on T_2 imaging at high spatial resolution. The source of the contrast is thought to be iron deposition in plaques (through an unspecified mechanism). This deposition is age dependent, present in older mice and not in younger mice, and may occur only for a subset of larger plaques.

Benveniste et al.^[6] in a careful study of postmortem Alzheimer's brain sections, delineated the resolution and SNR limits for detection of plaques by MR microscopy. They used T_2^* weighting to visualize hypointense spots in Alzheimer's brain sections but not in control, disease-free samples. The identification was through coregistration of MRI sections with histology sections that were stained for amyloid. The coregistration of histology sections with MR image sections is technically challenging, as demonstrated in this and all subsequent studies of plaque visualization. Errors in registration present real issues of image interpretation in detail. However, no hypointense spots were observed in disease-free sections, giving credence to the interpretation that the spots are associated with amyloid plaques and the hypointensity is most likely caused by associated iron deposits in the plaques leading to susceptibility effects that manifest themselves as loss of signal in T_2^* -weighted imaging. The images were taken at a field of 7.1 T and required 14 hr of acquisition time to achieve an SNR ≈ 30 , a necessary limit for plaque visualization. Importantly, the resolution also had to be of the order of $40 \times 40 \times 40 \mu\text{m}^3$ for the hypointense spots to be reliably discerned. At coarser resolution, the spots became indistinct owing to the partial volume effect associated with voxels larger than the objects of interest.

This early result was encouraging and an impetus for numerous groups to join in this effort. However, this is still a long way from *in vivo* imaging. For example, in 1–2 hr acceptable SNR can be achieved for $50 \times 50 \times 500 \mu\text{m}^3$ at 7.1 T for live mouse brain imaging. To achieve the extra factor of 10 in voxel size reduction and maintain an acceptable SNR, one would

need 200-hr imaging times, clearly untenable for live animals. Because this comparison is already for a high field, the remaining “knobs” are in part more efficient receive coils, more efficient pulse sequences, and the use of contrast agents. We shall examine all of these approaches below. Furthermore, the effects of motion as a result of breathing and cardiac output must also be addressed in order to obtain the necessary high resolution without loss of SNR caused by blurring and other motion artifacts.

Wadghiri et al.^[9] used specific contrast agents to bring out plaque conspicuity at a relatively coarse resolution of $78 \times 78 \times 500 \mu\text{m}^3$ in a ~ 1 -hr scan time at 7 T for transgenic mice. In their study either a Gd or Mion agent was linked to A β 1–40 peptides, which bind strongly to amyloid plaques. These constructs were injected intraarterially, together with mannitol, and the brain scans commenced 6 hr later. In the absence of agents, no spots were observed in the brains of the transgenic mice *in vivo* and *ex vivo*, and no spots were observed in wild-type mice *in vivo* and *ex vivo*. *Ex vivo* MR images were registered with histologic slices and amyloid staining to isolate a few coregistered spots as an indication of specificity for amyloid plaques.

This work was followed by that of Jack et al.^[13] Remarkably, they extended *in vivo* imaging of mouse brains for amyloid plaques without the use of contrast agents using a field of 9.4 T with a pair of small surface coils and a reduced FOV. An optimized spin-echo sequence was used with very careful procedures for mitigating breathing and cardiac motion effects. In transgenic mice, APP/PS1, they were able to visualize numerous hypointense spots at a resolution of $60 \times 60 \times 120 \mu\text{m}^3$ that they could coregister with *ex vivo* images and *ex vivo* histologic slides stained specifically for amyloid with thioflavin S, as illustrated in Fig. 4. Importantly, no spots were observed for control animals *in vivo*, *ex vivo*, or in histologic stains.

How is it that these workers were able to surmount the SNR barriers first indicated by Benveniste et al.^[6] With careful gating and attention to movement artifacts they may have been able to accept lower SNR and still visualize plaques. More efficient pulse sequences also contribute to reduced imaging time. The use of small surface coils and a limited FOV are other significant differences from the earlier work. All in all, a factor of about 10 or so in reduced imaging time was obtained with somewhat coarser resolution.

In all of these studies of amyloid plaques, there is a characteristic that remains troubling. Some spots coregister with stains for amyloid, but most do not. Thus, the specificity for amyloid appears low. Second, many more spots exist in histology stains than appear in the *ex vivo* MR images (see Fig. 4), so the sensitivity is also limited. This would suggest that the MR microscopy images may have limited use in longitudinal studies of

Fig. 4 Three-way correlation of AD mouse brain. (a, c, and e) Full FOV images; (b, d, and f) magnified subregions. (a and b) In vivo images; (c and d) ex vivo images; and (e and f) histological section. Voxel size, $60 \times 60 \times 120 \mu\text{m}^3$, imaging time, ~ 1 hr. Hypointense spots are correlated with histological stain spots (arrows). Reproduced by permission from Jack et al.,^[13] Fig. 5.

pathology or in following therapy response. However, such spots are not observed in control animals. The link to the amyloid gene function in the transgenic animals seems to exist. Perhaps some associated structures in the brains of these animals cause the hypointense spots to appear—these could be microhemorrhages, microvessels, or some sort of filamentary structures associated with this phenotype.

In one study at 11.7T using T_2 imaging and very high resolution of $\sim 23 \mu\text{m}$ isotropically, hypointense spots could not be associated with iron staining (not all that surprising because not all plaques are associated with iron uptake) in ex vivo samples of Alzheimer patients' brains.^[12] They associated hypointensity in all but one case, a rather large 100- μm plaque, with blood vessels and associated blood cell aggregates. This kind of phenomenon may explain the somewhat poor sensitivity and specificity in MR microscopy studies of Alzheimer's brains.

A more convincing demonstration of plaque imaging was obtained by staining in a passive protocol, i.e., soaking ex vivo samples in a Gd-based contrast agent.^[14] The idea in this study was to increase signal to noise by lowering the T_1 of tissue. Because plaques would not take up the agent, a susceptibility difference would develop between the plaques and the surrounding tissue that could be detected more readily and even for plaques smaller than the imaging voxel size (by virtue of the fact that the susceptibility effect has a considerable extension in space). Hypointense spots were delineated only in APP/PS1 mouse strains, with spot density increasing with age and in expected brain areas. The hypointense spots could be coregistered with Congo Red staining (a specific marker of amyloid plaques). The imaging parameters were $\sim 60 \times 60 \times 60 \mu\text{m}^3$ voxel sizes, with 3-D gradient echo

sequence and imaging time of 7–9 hr. Without the passive staining the SNR and plaque contrast was insufficient to reveal specific hypointense spots, as might be expected from the earlier work of Benveniste et al.^[6] and the considerations of SNR and resolution.

CELLS AND GENE EXPRESSION

Visualization of biological cells directly has not been performed, except in the case of the large cylindrical cells found in the leaf stem.^[10] The majority of biological cells of interest are of the order of $10 \mu\text{m}$ in size and there is, as yet, no practical way to get sufficient SNR to visualize such structures. There is also the issue of contrast. What distinguishes a cell from its surrounding medium are differences in terms of MR contrast parameters: T_1 , T_2 , diffusion, proton density. These parameters may not differ much from the interior to the exterior of cells and thus may not offer much contrast, especially at high resolution and low SNR. One way to ameliorate these difficulties is by the use of contrast agents. It was suggested that T_2 agents, superparamagnetic iron oxide particles (SPIO), if internalized by the cell, would, by the previously mentioned susceptibility effect, spread out their magnetic field influence many times the diameter of a single cell. A single cell may thus be visualized at a coarser resolution than the cell dimension. The cell would be detected but not resolved, an acceptable objective for many applications, in particular in studies of cell trafficking and cell lineage development in embryology. Ex vivo imaging of single cells labeled in this manner was successful at visualizing increasingly more dilute solutions of labeled cells. As demonstrated above, in the absence of motion and with small

imaging volumes, adequate SNR can be achieved in reasonable imaging times. However, *in vivo* detection of single cells remains problematic. Nevertheless, groups of cells can be followed in studies of cell migration in living animals. For example, the fate of injected stem cells is of great importance in current clinical investigations. In a recent study, stem cell migration was followed *in vivo* over a 3-week period in a mouse model of stroke using iron oxide particles.^[15] Visualization of the migrating cells was performed at 7 T with a $78 \times 78 \times 78 \mu\text{m}^3$ voxel volume in 1 hr with a SNR of 8–10, sufficient to pick up hypointense voxels in the migrating path. With an efficient cell incorporation technique, these investigators were able to saturate the MRI susceptibility effect so that they could follow cells with no loss of apparent contrast over 10 cell divisions after the initial incorporation. They estimate that for *in vivo* imaging they were able to detect clusters of cells as small as 100 cells, with the rather short imaging time given above. They were able to do so in part by using a specialized small receive coil and in part by the large contrast of the cell clusters relative to background enabled by the high uptake of the dextran-coated iron oxide particles.

An extension of the above approach is to use very large, micrometer-size iron oxide polymer particles to get larger susceptibility effects, which could, in principle, darken a large voxel with just a single cell within.^[16] This contrast agent was able to efficiently label hematopoietic cells without apparent alteration of cell function. An important extension of this approach is to visualize stem cells and their fate after injection in blood or tissue and possibly to do so in a practical manner, with clinical scanners and readily adapted hardware. This would be an important clinical application advance derived from microscopic imaging studies of this kind. The sensitivity of SPIO labeling, in principle, can be quite high, approaching a detectability in the femtomolar range, that of positron emission tomography or single photon emission computed tomography sensitivities, but with submillimeter resolution.^[17]

Louie et al. conducted an elegant study of gene expression by MR microscopy.^[18] They constructed a novel contrast agent responsive to β -galactoside (β -gal) and injected the contrast agent at the two-cell development stage in *Xenopus laevis* and mRNA for β -gal in just one of the two cells. Subsequently, the descendants of the cells with β -gal became bright in T_1 -weighted images (11.7 T, $27 \times 16 \times 16 \mu\text{m}^3$, 3–4 hr image time) in the developed embryo.

TUMOR MICROVESSELS

Visualization of tumor angiogenesis, the development of new neovasculature, is an important clinical need

for prognosis and therapy monitoring. The microvasculature is composed of vessels as small as $10 \mu\text{m}$ in diameter and therefore these structures, most numerous in a developing tumor, are to date not directly visualized by clinical MR or MR microscopy. Their delineation in tumor biology is important in understanding how antiangiogenesis therapy proceeds. This need is an important challenge for MR microscopy that could be addressed in preclinical animal tumor models. In a recent study by Kiessling et al.,^[19] a correlation was demonstrated between the very fine detailed rendition of tumor vascular density by 3-D histological reconstruction and MR angiography data with an intravascular agent ($160 \times 200 \times 320 \mu\text{m}^3$ at 1.5 T) and MR vascular volume parameter data at a much coarser resolution, as illustrated in Fig. 5. Understanding the very fine structure and how it might respond to therapy is of principle importance. Can it be achieved with MR microscopy for a rodent tumor model?

As illustrated in Fig. 5, the resolution required to visualize individual vessels must be much higher than that of the angiography data set indicated. Again, we may apply high-field, small FOV and small surface coils and contrast agents to this problem and see how far the visualization can be pushed. From the work of Wecker et al.,^[11] we may extrapolate to a 7-T system, suitable for animal imaging, and a 1.5-mm size scale, again suitable for tumor imaging in rodents and contrast agent signal amplification. With 1-hr imaging, the delineation of tumor microvessels in great detail should be possible: With an acceptable SNR of 10 achieved through the use of a long circulating contrast agent with high signal amplification of the vessels, it should be possible to achieve $\sim 25\text{-}\mu\text{m}$ isotropic resolution in an imaging time of ~ 1 hr. Thus, with further rendering techniques for 3-D representation of thick sections, the microvessel structures of rodent tumors could be substantially visualized with available hardware and imaging techniques.

VISUALIZING BIOLOGICAL CELLS

Assuming some contrast is available for distinguishing a cell from its surroundings, such as the extracellular matrix, the resolution requirement of $10 \times 10 \times 10 \mu\text{m}^3$ for the delineation of single cells possesses severe limits on required imaging time and available FOV. Table 2 illustrates that for some reasonable imaging time of the order of 1 hr, only a very high field with a microscopic coil arrangement such as that used by Lee et al.^[10] can approach this resolution. The use of contrast agent to help the SNR may alleviate the size constraints, perhaps by factors of 2 or so. Here, the attempt is to resolve the cells and not merely detect them in a tissue

Fig. 5 Images of mouse tumor, HaCaT-ras-A5RT3. (A) Immunofluorescence images of vasculature at 5- μ m thickness. (B) Reconstructed, color-coded vessel volume density (VVD) for a 2-mm-thick section. (C) MR angiography image at 2 mm thickness and (D) an MR parameter map of vascularization. Large vessel bundles in the VVD map are picked up in the angiography image. Arrowhead in D corresponds to the vessel bundle in B (arrowhead). The fine vascular structure in the VVD map is not resolved in the angiography image or the MR parameter map. Reproduced by permission from Kiessling et al.,^[19] Fig. 4.

Table 2 Isotropic resolution in micrometers for a magnetic field of 14 T and 1-hr imaging as a function of imaging scale size and SNR

Scale size (mm)	SNR = 10	SNR = 35
0.5	5.8	9.7
5	10	21
10	12	26
15	13.7	30

milieu, for which the use of susceptibility agents can render cells visible in a coarse voxel resolution, as demonstrated previously.

MOLECULAR IMAGING

Molecular imaging is a term, much in vogue currently,^[20] used to describe *in vivo* imaging of molecular targets in tissues or of molecular processes, such as gene expression in specific tissues. In these efforts, high resolution is not strictly necessary because in many cases the targets are distributed over a reasonably large volume, such as for a tumor of >1 mm in diameter. However, in other cases, such as for the molecular imaging of atherosclerotic plaque, visualization requires if not microscopic resolution, at least sub-millimeter resolution. This is a challenge for *in vivo*

imaging with clinical scanners with limited imaging times in the face of motion artifacts.

The principle challenge for MR in molecular imaging is one of sensitivity. MR contrast agents, small T_1 or T_2 agents, must be in the 10s of micromolar to even the millimolar range (per active ion, Gd for a T_1 agent, or per Fe in an iron oxide Mion T_2 agent) to give detectable MR signal changes, whereas many *in vivo* targets are in the nanomolar to femtomolar range. This mismatch is not addressed by higher resolution, but rather with amplification schemes (many agent molecules per ligand binder or by increase of agent relaxivity, although there are physiochemical limits to such improvements). We described one scheme of large iron oxide particles to give sufficient amplification to detect single cells in *ex vivo* imaging. In some cases the detectability may approach the femtomolar range in Fe.^[17] However, the particles in this case are large, ~ 100 nm or so, and do not readily distribute in the extravascular space to reach targets beyond those of the blood circulation.

ATHEROSCLEROTIC PLAQUES

The imaging of atherosclerotic plaques is a big and challenging enterprise that is beyond the scope of this review. I mention this topic only to emphasize a very great clinical need that conventional MR imaging meets only partially. Atherosclerotic plaques may be of the order of approximately millimeters in size and are,

therefore, not essentially microscopic. But their classification into vulnerable and non-vulnerable classes may push the limits of available SNR and available contrast in clinical protocols. Thus, the techniques of MR microscopy and molecular imaging may contribute to this clinical problem. In small animal models of atherosclerosis, MR microscopy techniques will be essential.

CONCLUSIONS

MR microscopy has demonstrated much potential for clinical and fundamental biological studies. The truly high magnification range in optical microscopy is exceedingly difficult to achieve with MR because of the inherent low signals associated with proton nuclear spins. At present, only one study resolved cells in a biological sample^[10] and it required extremely high fields and very specialized, miniaturized gradient and signal receive coils, not to mention the choice of large cell structures in leaf stems for visualization. Can the SNR barrier be somehow surmounted to yield more practical visualization of biological cells? This problem requires a solution for MR microscopy to be truly microscopic in a more general way. Perhaps it is insurmountable as viewed by current proton staining techniques and a truly clever advance is required. For example, imaging schemes involving hyperpolarized xenon are being investigated for the promise of large sensitivity gains.^[21] Nevertheless, even at a lower resolution than that of the cell, MR microscopy has been demonstrated to be valuable in the visualization of Alzheimer's amyloid plaques in brain, in rodent brain studies, in following cell migration in vivo, and in rodent and embryo phenotyping, to name just the most prominent studies.

Mass Transfer in Tissue Function: Roles

E. N. Lightfoot

Karen A. Duca

Virginia Bioinformatics Institute, Virginia State University, Blacksburg, Virginia, U.S.A.

INTRODUCTION

From a philosophical standpoint living organisms can be considered transport–reaction systems that have as one of their primary aims the preservation and reproduction of particular genomes. However, all true organisms exhibit a markedly hierarchical structure, and each level in this structure has its own transport–reaction characteristics. Genome-based reactions appear only in the last stages of this hierarchy. Biochemical reactions, almost always mediated by enzymes, can be surprisingly fast and normally do not limit metabolic rates. Mass transport mechanisms are, however, few, and two are dominant in all but the smallest systems: convection, or flow induced transport, and various forms of concentration diffusion. These are very difficult to augment—or to slow down. As a result the structure and function of living organisms is determined to a very large degree by mass transfer considerations.

However, almost all physiological processes are “designed” by evolutionary processes with a safety factor on the order of 10, and as a result mass transfer limitations only manifest themselves under conditions of extreme stress in the healthy organism. The result is a structural hierarchy paralleled by a time constant hierarchy notable for marked time constant separation. This latter characteristic greatly simplifies physiological analysis. The situation is far different under pathological conditions, and this lack of orderly behavior can complicate the treatment of disease. Moreover, the slow progression of many chronic diseases is hidden by the safety factor of physiological design until functional capacities are much reduced.

While the study of physiological mass transfer began centuries ago, major new insights are still emerging. Early macroscopic descriptions are still useful and will be included here. However, based on technological advances, interest has progressed toward even smaller length scales, and our discussion will follow this same path. Because of space limitations we must satisfy ourselves with short overviews of the topics covered and with references limited largely to major reviews and monographs. A particularly useful summary that covers many unique biological processes, e.g., facilitated or hindered diffusion, excitatory phenomena, and inter-cellular communication, is provided by Keener and

Sneyd.^[1] A more detailed introduction to mass transfer is available in Bird, Stewart, Lightfoot.^[2]

SPATIAL AND TEMPORAL HIERARCHIES

Finding one’s way requires a hierarchical organization and here we use the pronounced spatial hierarchy of living systems. There are six well-defined levels, representing different length scales, which we will explore: whole organisms (m), organ systems (dm), functional units (10–100 μm), cells (1–10 μm), formed elements (0.1–1 μm), and molecular clusters (nm).

Major Organ Systems

Near the top of the hierarchy are the major organs interacting directly with the external environment via a wide variety of mass transport processes: the gut, kidneys, lungs, and skin. The gut absorbs nutrients through the small intestine and discharges solid wastes through the large intestine or colon. The kidneys discharge liquid wastes while the lungs perform a dual role. They provide for oxygen input from the air and discharge of a number of gases, primarily carbon dioxide and water vapor. The skin plays a relatively minor role in mass transfer, but sweating is an important means for release of metabolic heat. The descriptions of organ architecture at the macroscopic level are the province of anatomy, a subject that goes back to Leonardo da Vinci.^[3]

These and other major organs are connected by the blood circulation in an organ network suggested in the pharmacokinetic diagram given in Fig. 1. In addition to the above external organs we will be particularly interested in the brain and the liver that along with the kidneys are the most active metabolically. Examples of metabolic activity are shown in Fig. 2, and more fully described in Schmidt-Nielsen (Ref. [4], p. 94) and Krebs^[5] with units extracted from examination of the original source: ml O₂ (sTP)/100 g dry mass (min). These are tissue slice data that tend to be smaller than in vivo data, but they are sufficient for our present purposes. In particular, they show that metabolic rates

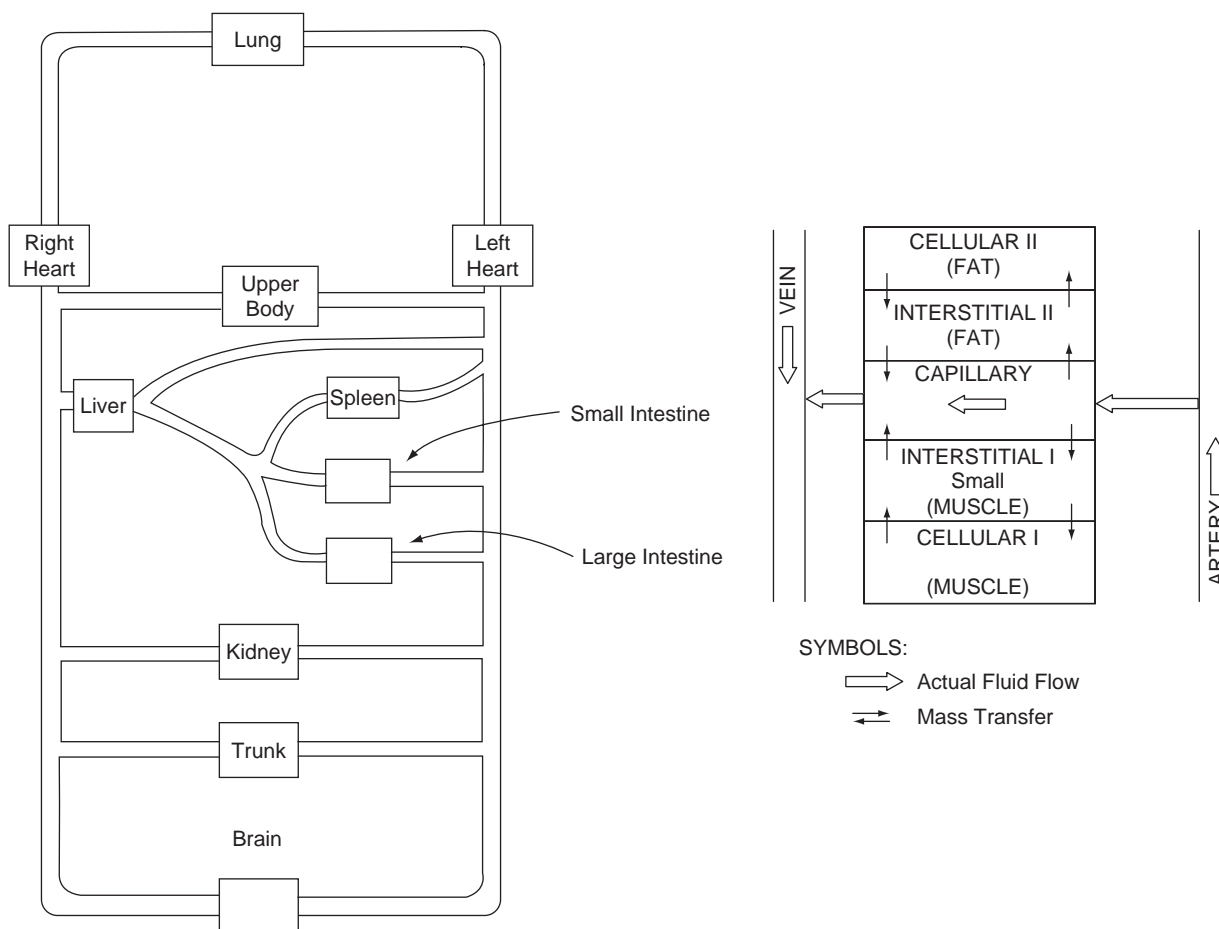

Fig. 1 Pharmacokinetic approximations.

per unit mass tend to decrease with increase in animal size.

The sizes of these organs vary, surprisingly systematically, with body size, but they are always large enough to see with the unaided eye, and the distances between them are large.^[6] It is common practice

Fig. 2 Specific oxygen consumption and capillary spacing: (1) brain, (2) kidney, (3) liver, (4) spleen, (5) lung [ml O₂ (sTP)/100 g dry mass (min)], and (6) intercapillary spacing for cerebral gray matter (μm). (From Refs. [4,18].)

to express macroscopic body properties, P_i , relative to body mass, M , by an allometric equation of the form:

$$P_i = a_i M^{b_i} \quad (1)$$

and some widely used examples of interest are shown in Table 1. Mass is expressed in kilograms. A wide variety of similar information is available in specialized references and in physiology texts.^[4,6,7,10,11] There have been many attempts to explain the mechanistic basis of the allometric equations in terms of underlying physiology, some quite recent, but none has been completely convincing. They should be considered as useful empiricisms, and it should be recognized that some are based on inadequate sampling.

An instructive example is provided by the first entry of Table 1, fasting whole-body metabolic activity. The first form of this correlation, for a fasting basal state, and prominently reported in a number of sources, is almost certainly badly skewed by misuse of large-animal data (Ref. [10], p. 195). A more thorough study by White and Seymour strongly suggests the second form, adjusted to a temperature of 36.2°C.^[7] The latter

Table 1 Commonly accepted mammalian allometric relations

Item	Allometry
Oxygen consumption [L(STP)/hr]	$0.676M^{0.75}$ (commonly accepted) $0.444M^{0.67}$ (Ref. [7]) ^a
Cardiac output (L/min)	$0.187M^{0.81}$
Blood volume (L)	$0.055M^{0.99}$
Kidney mass (kg)	$0.021M^{0.85}$
Liver mass (kg)	$0.082M^{0.87}$
Lung volume (L)	$0.063M^{1.02}$

^aSee Refs. [8,9] for details of the conditions used.

investigators also discuss the problems of comparing animals of different normal body temperatures and the ambiguities of determining a common reference state. Both correlations are an attempt to reduce a large mass of data taken under a variety of conditions to a single allometric equation, and one is well advised to read the White and Seymour paper, and the literature they cite, carefully before using either. Similar remarks are appropriate for the other table entries.

Functional Units of Organs

We shall find in the next section that diffusion is far too slow to supply nutrients or to eliminate wastes at the size scales of whole organs. As a result, organs are subdivided into large numbers of parallel structures or functional units where the metabolic reactions of the organism actually take place. These form the parenchymal tissues, and they are supported by structural elements, branching blood vessel structures acting as manifolds and the like. The functional units take a wide variety of forms, and describing them is the province of histology.^[12] A classic case, of parallel capillaries, is shown in Fig. 3: grey matter in the brain.^[13] The circular cylinders are approximations to the actual hexagonal prisms and are widely used in transport modeling. For a more detailed cross section see Kessel (Ref. [12], fig. 12.18, p. 269). The spacing between capillaries, which defines the sizes of the corresponding functional units, is quite regular. Moreover, as suggested in line 6 of Fig. 2, it varies little with body size. This spacing results from a compromise between diffusional access and structural constraints.

Thus, we shall find shortly that in typical functional units rates of blood perfusion, lateral diffusion to the parenchymal tissue and chemical reaction in this tissue are in balance with each other. Moreover, capillary density tends to be limited by as yet unidentified material constraints. They represent an intermediate

situation between the organ networks, where diffusion is too slow to be significant, and cell interiors where it typically needs to be suppressed.

Whole Cells

Cells are one of the defining features of true living organisms, and cellular transport and reaction processes are among the most active of research areas today.^[14,15] They come in almost infinite variety: Alberts et al. estimate that there are more than 10 million living species on the earth, and most of them are unicellular. However, the cells share a number of common features, and most are of about the same size: 10 μm to perhaps 50 μm in diameter for animal cells and a few micrometers for bacteria. All are surrounded by a cell membrane with highly selective permeability, and their interiors, or cytoplasm are the sites of most metabolic reactions. As a result the cytoplasm is not only crowded, but it must provide for segregation of this myriad of reactions. Diffusion can now often be considered inconveniently fast, and cells have developed a wide variety of interior structures, surrounded by additional selective membranes, and other means to channel individual reaction sequences spatially. Even the simple prokaryotic cell interiors of bacteria are very crowded.^[16] In bacteria there is, however, minimal organized structure above the level of protein or DNA molecules.

We shall shortly find this crowding to lower diffusion rates substantially, especially for larger entities such as protein molecules. Cell membranes also have elaborate structures based on bilayer lipid membranes to limit transport between the cell interior or cytoplasm and the exterior. Penetrating these bilayers are a wide variety of protein complexes to permit, or actively transport, specific entities into or out of the cell.

Intracellular Organelles

Eukaryotic cells, characteristic of all higher organisms, from yeasts and amebae to fungi, plants, and animals, contain large numbers of substructures, e.g., peroxisomes, endoplasmic reticulum, Golgi apparatus, endosomes, and lysosomes, as suggested in Fig. 4. The mitochondria are particularly important in producing the high-energy phosphate bonds that power most metabolic reactions (Ref. [14], chap. 14). Microtubules permit transport of large entities over distances comparable to cell dimensions. New transport mechanisms come into our story at this point, and we shall lay the groundwork for describing them shortly.

Fig. 3 Cerebral functional unit. (From Ref. [13].)

Molecular Complexes

There are also a very large number of molecular complexes, individual enzymes, enzyme complexes, ion pumps, and other entities of mass transport interest. Among the simpler are the enzyme complexes of Fig. 5 and ion channels (see http://anusf.anu.edu.au/Vizlab/viz_showcase/shinho_chung/) (Ref. [14], p. 99). Much more complex is the electron transport chain of Fig. 6 (Ref. [14], p. 787). This structure, imbedded in the inner mitochondrial membranes, includes simpler enzyme complexes as elements. It would appear from recent research that even this picture can prove to be oversimplified.^[17-19]

Microtubules, as shown in Fig. 4, and more schematically in Fig. 7, in addition to providing structural support, are of particular transport interest as they serve to transport vesicles and small organelles around

the cell. The roles of these various complexes in mass transfer will be discussed below.

FLOW DOMINATED SYSTEMS

Owing to both the above-mentioned safety factor and timescale separation many important biological processes can be described successfully without any significant consideration of diffusion. We shall consider two approaches that are particularly in wide use: application of the method of temporal moments for analysis of transient tracer pulses (Stewart and Spalding in Ref. [2], section 23.6-3, p. 756) and the use of compartment models (Ref. [20], especially Bischoff and Dedrick referenced on p. 3). Both were pioneered by biologists and chemical engineers long

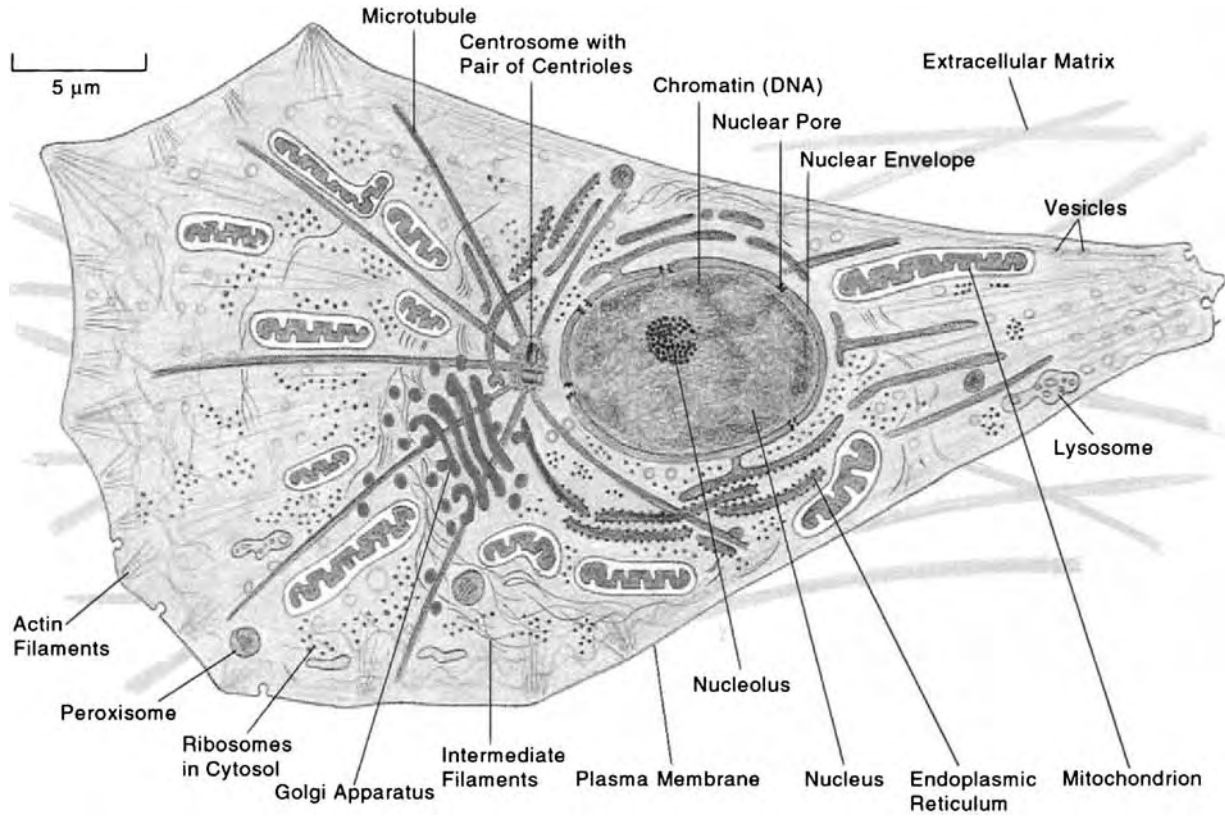

Fig. 4 The internal structures of eukaryotic cells. (From Ref. [14].)

ago and have since been used extensively in both conventional process engineering and environmental studies.

Temporal Moments

Temporal moments, defined immediately below, are restricted in principle to investigation of a simple closed flow system as illustrated in Fig. 8. A system of constant volume V with impermeable walls except for one inlet and one outlet is shown in the figure. Fluid, for example, blood, flows through this system at a

constant volumetric flow rate Q , and a tracer solute “ i ” is transported by the fluid under such circumstances that solute diffusion across the inlet and outlet by diffusion relative to the flow is negligible. The most important temporal moments of the tracer are defined by:

$$M_0 = \int_{-\infty}^{\infty} c_{i0} dt \tag{2}$$

$$M_1 = \int_{-\infty}^{\infty} t c_{i0} dt \tag{3}$$

$$m_2 = \int_{-\infty}^{\infty} (t - \bar{t})^2 c_{i0} dt \tag{4}$$

$$m_3 = \int_{-\infty}^{\infty} (t - \bar{t})^3 dt \tag{5}$$

Fig. 5 The pyruvate hydrogenase complex. (From Ref. [14].)

These are known as the zeroth and first absolute moments, and the second and third moments relative to the mean residence time, respectively. Here, c_{i0} is the instant outlet tracer concentration, and t is time. For closed systems in series the values of M_1 , m_2 , and m_3

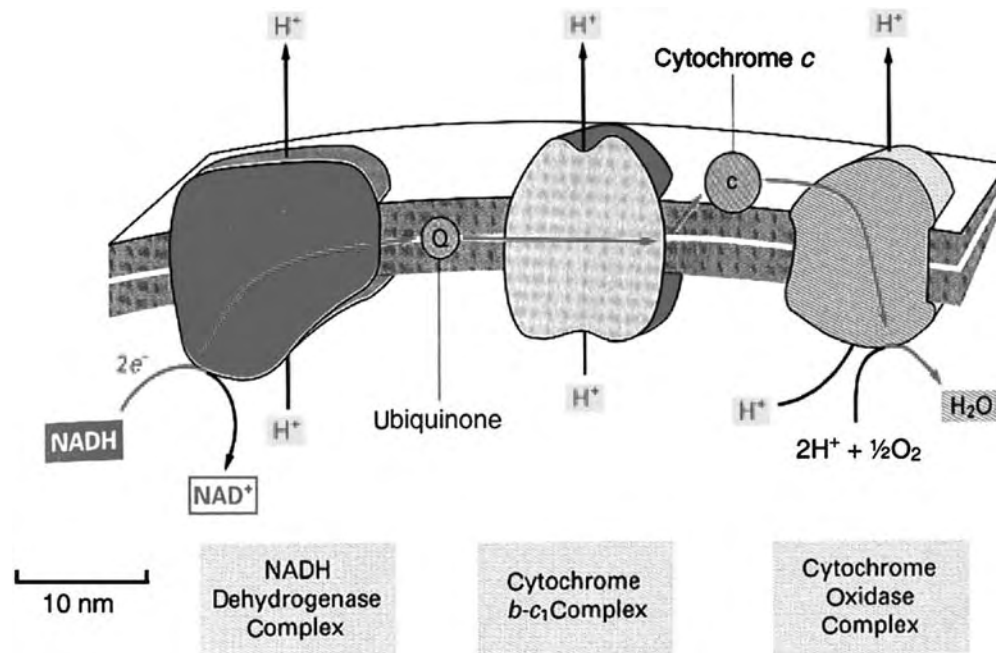

Fig. 6 The mitochondrial electron transport chain. (From Ref. [14].)

are additive, a property that permits subtracting out the effects of tubing and sensors. However, one must be careful to eliminate convective dispersion [Ref. [2], p. 643].

In practice, all of these requirements can often be relaxed, for example, by using time average flows. Moreover, in most cases it is possible to start the

integrals at time zero. However, the validity of these approximations must be determined in each new application. For medical applications recirculation of tracer is a serious problem (see Ref. [21]). Tracer responses for two simple flow situations are shown in Fig. 8.

Fig. 7 Microtubules, mitochondria, and ribosomes.

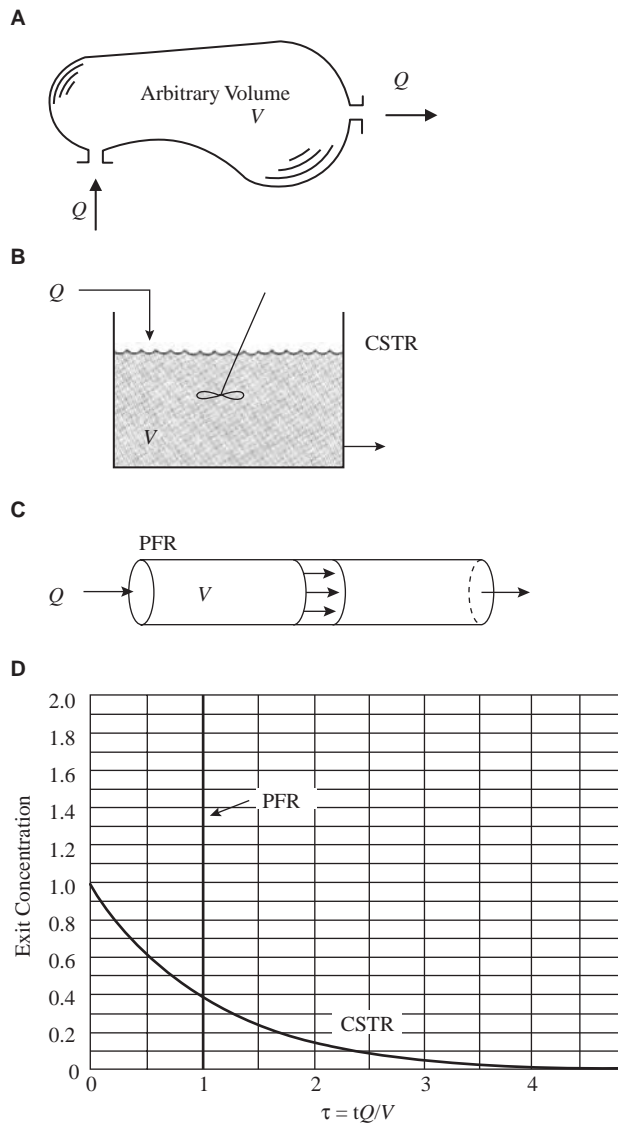

Fig. 8 Closed flow systems.

Eqs. (2) and (3) are particularly useful in providing the flow rate Q and effective volume V without any detailed knowledge of the system. Thus, from a simple mass balance:

$$Q = \frac{M}{\int_{-\infty}^{\infty} c_{i0} dt} = M/M_0 \quad (6)$$

Here, M is the mass of tracer fed. The mean solute residence time \bar{t} is defined as

$$\bar{t} = M_1/M_0 = V/Q \quad (7)$$

If the system is heterogenous with regions of varying solubility for the tracer, V must be replaced by effective volume:

$$V_{\text{eff}} = \sum_{j=1}^n V_j r_j \quad (8)$$

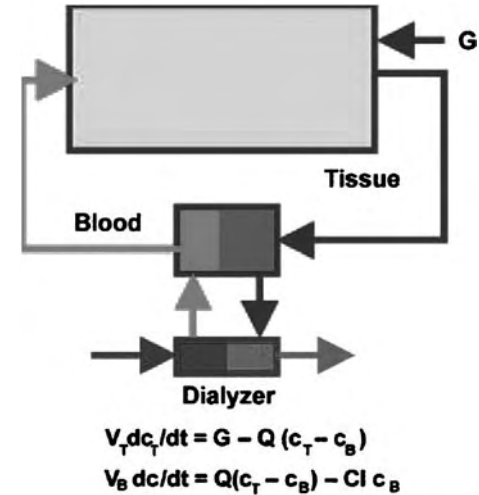

Fig. 9 Hemodialysis dynamics. (From Ref. [14].)

where r_j is the ratio of solubility in region j relative to that of the permeating fluid.

The second and third central moments m_2 and m_3 describe the dispersion and skew of tracer relative to \bar{t} , respectively. These two higher moments are particularly useful for evaluating parameters in structural models of the system. It is normally impossible to obtain accurate values of moments higher than 3, but one can use more than one tracer, a process often referred to as multiple indicator dilution. The use of tracers has become very sophisticated, and there is now a large literature available.^[22,23]

Pharmacokinetic Approximations

One can also construct many physiological models independent of diffusional considerations, and these are perhaps best known as the basis for calculating transient drug concentrations, hence the name of pharmacokinetics. They are often obtained by simplification of Fig. 1, but many are empirical.^[20,24,25] They depend on lumping substantial portions of the body into homogenous compartments and are also known as compartmental models.

The hemodialysis model is a classic example that has been thoroughly tested (Fig. 9) (Ref. [2], p. 733). Here, all body fluids except blood are lumped into a single mixing tank (denoted as tissue), and the blood is represented by another. Toxin buildup is modeled as a constant, continuous input, the dialyzer is described by a single parameter known as clearance. Predictions from this model are typically indistinguishable from actual data (see Fig. 10). Neither the body fluids nor blood act like mixers, and the success of this simple model results from the excellent

Fig. 10 Test of hemodialysis model. (From Ref. [2].)

separations of timescales for the different processes taking place. Under such circumstances, system transient responses are quite insensitive to the actual dynamics of individual components, and it is possible to use very simple approximations (Ref. [2], fig. 23.1–8, p. 737).

The corresponding model of an alveolus of the lung, the small air sacs at the ends of airway branching, is rather different (Fig. 11). The air sacs are surrounded by a net of capillaries where entering venous blood is aerated. We examine the situation of a small amount of a volatile tracer at concentration c_V entering with the venous blood. Part of it evaporates and enters a previously tracer-free alveolar air, which then leaves with a tracer partial pressure p_{Alv} (see Fig. 12). The arterial blood then has a reduced tracer concentration c_A . This resulting arterial blood is very nearly in equilibrium with the alveolar gas, so that we may assume:

$$p_A = Hc_A = p_{Alv} \quad (9)$$

where H is Henry's law constant. By a simple mass balance we may write:

$$Q(c_A - c_V) = \dot{V}p_{Alv}/RT \quad (10)$$

We may then write:

$$p_V - p_A = p_{Alv}(\dot{V}/Q\lambda) \quad (11)$$

where R is the international gas constant, T is absolute temperature, and λ is just H/RT . The volumetric flow rates of blood and air are Q and \dot{V} , respectively, following the usual convention.^[26]

We may now define fractional retention R , and an extraction E by

$$R = p_A/p_V = \frac{\lambda}{\lambda + \dot{V}/Q} \quad (12)$$

$$E = p_{Alv}/p_V = \frac{\lambda}{\lambda + \dot{V}/Q} \quad (13)$$

For any one alveolus, these quantities are the same, and they are functions only of λ and \dot{V}/Q . However, if these local partial pressures, p_{Alv} and p_A , are replaced by average values for the lung as a whole, the global retention and extraction differ. These differences can be used to estimate the heterogeneity of the lung as shown in Fig. 13. A dead space is defined as one with no gas flow at all, and such a region can provide no extraction. A shunt is a region where the blood sees no gas, and it must have a retention of unity. Thus, in a real lung the global E is always less than unity, and the global R is always greater than zero. Such heterogeneities reduce the oxygen content of arterial blood, and they tend to become more severe with age and lung damage. Similar heterogeneities occur throughout the circulatory system.^[21]

CONCENTRATION DIFFUSION

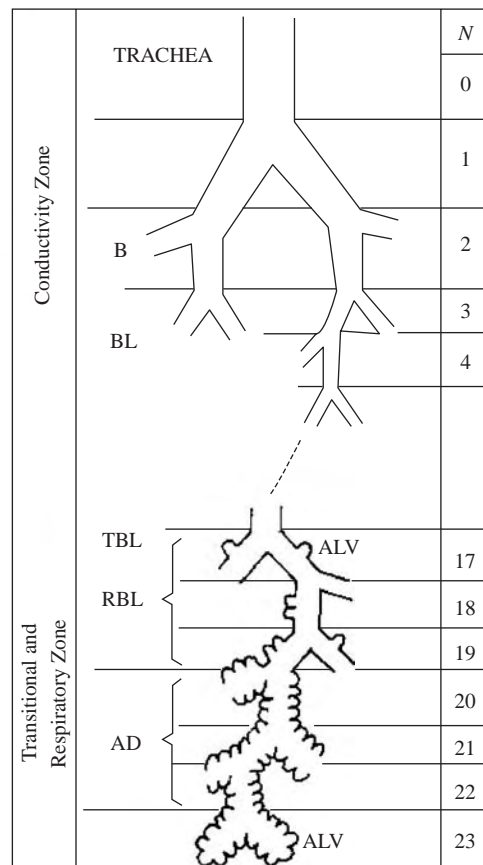

There are many situations where diffusion must be taken into account explicitly, and we will consider a few of them here. Perhaps, the most familiar is the oxygenation of tissue via the lungs and circulating blood. However, there are a large number of less familiar

Cat Pulmonary Tree

Alveoli

Pulmonary Organization

Fig. 11 Pulmonary branching. (From Ref. [9].)

situations requiring detailed analysis of concentration diffusion, and we shall touch on a few of these as well.

The lungs exhibit a branching structure with pronounced fractal characteristics as suggested in Fig. 11.^[9,26] The upper airways in the schematic diagram act as manifolds to distribute air to the alveolar sacs, which in turn are surrounded by a capillary net. It is primarily at this last region that transport of oxygen to the blood occurs. However, particulates of many kinds can enter the lungs and be deposited in the upper airways, and it is important to understand these deposition processes also (Ref. [26], p. 78, 28).

The circulation also forms two branching networks, pulmonary and systemic, and again transport, whether from air or to tissue, takes place via the smallest vessels.^[28] One example, brain capillaries, is shown in Fig. 3. Understanding these transport processes requires an introduction to the laws of diffusion, and we begin with a short overview of those.

Time Constants and Fick's Laws of Diffusion (Ref. [2], chap. 17)

Essentially, all physiological processes depend on individual metabolites moving relative to their surroundings, and the most common mechanism is random, or Brownian, motion. This undirected process, which is primarily responsible for concentration diffusion, tends to move individual molecules of species "i" away from their initial position, and the mean square distance traveled in a quiescent medium "m" over a time interval "t" is:

$$r^2 = x^2 + y^2 + z^2 = 6D_{im}t \tag{14}$$

$$x^2 = 2D_{im}t \tag{15}$$

Here r is distance from the origin, and its components in the direction of the three rectangular coordinates are

Fig. 12 Alveolar transport.

$x, y,$ and z . The quantity D_{im} is the Brownian diffusivity of species “i” through medium “m.” Eqs. (14) and (15) can be used to define diffusional time constants of the form:

$$T_{dif,R} = R^2/6D_{im} \tag{16}$$

$$T_{dif,L} = L^2/2D_{im} \tag{17}$$

That is, transient diffusion in spheres of radius R or slabs of half-width L will be “essentially” complete in times $T_{dif,R}$ or $T_{dif,L}$, respectively. They are particularly

useful for order-of-magnitude analysis, and we shall illustrate this shortly.

For our present purposes D_{im} may be considered equal to the diffusivity appearing in Fick’s law, which we will approximate here as (Ref. [2], section 17.1, p. 514):

$$N_{ix} = c_i v_{ix} = -D_{im} \partial c_i / \partial x + c_i v_x \tag{18}$$

Here, c_i is the molar concentration of species “i”, v_{ix} is the observable velocity of species “i” in the x direction, and v_x is the corresponding velocity of the surrounding medium.

Eq. (16) can be put into a mass balance to obtain:

$$\frac{\partial c_i}{\partial t} = D_{im} \left(\frac{\partial^2 c_i}{\partial x^2} + \frac{\partial^2 c_i}{\partial y^2} + \frac{\partial^2 c_i}{\partial z^2} \right) + \frac{\partial(c_i v_x)}{\partial x} + \frac{\partial(c_i v_y)}{\partial y} + \frac{\partial(c_i v_z)}{\partial z} + R_i \tag{19}$$

For the common case of quiescent media Eq. (17) takes the form

$$\frac{\partial c_i}{\partial t} = D_{im} \left(\frac{\partial^2 c_i}{\partial x^2} + \frac{\partial^2 c_i}{\partial y^2} + \frac{\partial^2 c_i}{\partial z^2} \right) + R_i \tag{20}$$

Here, R_i is the rate of formation of species “i” per unit volume. Eqs. (14), (17), and (18) suffice for this stage of our discussion.

Thus, Eqs. (16) and (17) are used to define diffusional response times in three-dimensional and one-dimensional systems, respectively. Eq. (19) serves to describe the combined effects of diffusion, reaction, and flow, and Eq. (17) can be used to describe transient

Fig. 13 Global pulmonary retention and extraction. (From Ref. [26].)

processes in quiescent media. We are now ready to look at some characteristic examples.

Orders of Magnitude

We begin by asking ourselves if there is any significant diffusional resistance in the alveolar sacs shown in Fig. 11 under physiological conditions. To do this we need to know that the diffusivity of oxygen in air at 37°C is about 0.21 cm²/sec, and that the normal respiration rate is about 12 breaths/min, or a cycle time of 5 sec (Ref. [2], table 17.1, p. 517; eq. 17.3–12, p. 526). For this system then, the diffusional time constant is about:

$$T_{\text{dif},R} = \frac{(5 \times 10^{-3} \text{ cm})^2}{6 \times 0.21 \text{ cm}^2/\text{sec}} = 1.98 \times 10^{-5} \text{ sec} \quad (21)$$

This is extremely small relative to 5 sec so we may assume that the gas phase concentration is always quite uniform: the general experience is that the transient process can be considered complete in about three time constants.

We next try to identify those blood vessels able to supply oxygen to tissue, and all we have available is the summary of data in Fig. 14. The key to success is to recognize that the last column heading can be rewritten as (Ref. [2], table 22.2–1, p. 676):

$$L/DReSc = (L/\langle v \rangle)/(D^2/D_{O_2B}) \quad (22)$$

where $\langle v \rangle$ is flow average velocity and D_{O_2B} is the effective diffusivity of oxygen through blood. Now in two-dimensional (radial) diffusion the diffusional time constant:

$$T_{\text{dif}} = R^2/4D_{O_2B} \quad (23)$$

while the blood holdup or residence time:

$$\bar{t} = L/\langle v \rangle \quad (24)$$

These two characteristic times are equal when

$$L/DReSc = 1/16 = 0.0625 \quad (25)$$

This is intermediate between the entries for terminal arteries and arterioles in the figure.

Thus, none of the arteries provides enough time for dissolved oxygen to reach the arterial wall, let alone into the surrounding tissue. These are convective transport vessels. The arterioles and venules can provide some oxygen, but it is clearly the capillaries that are the major suppliers. Note also how quickly the characteristics change from “convector” to “diffuser”! Body “design” is truly impressive. Note also how much information we have obtained without any real effort. The very large values of $L/DReSc$ reflect the need to have sufficient transport capacity to permit tissue oxygenation. We return to this point below.

Next, we show how one can often estimate the time course of rather complex diffusional processes, and for this we use bacterial gene expression. The critical process here is reaction of a promoter molecule with the gene to be activated, and this can be envisioned as taking place in three steps.^[29]

First, the promoter diffuses at random in the cell until the probability of its being in all positions is the same. This occurs over the diffusional time scale:

$$T_{\text{dif}} = R_{\text{cell}}^2/6D_{\text{pc}} \quad (26)$$

where R_{cell} is the effective cell radius, and D_{pc} is the effective protein diffusivity in the cytoplasm. It is reasonable to assume the cell radius to be about 1 μm.

Mass Transfer Effectiveness of Blood Vessels 13-kg Dog				
Vessel	Radius (cm)	Length (cm)	$\langle v \rangle$ (cm/s)	L/DReSc
Aorta	0.5	40	50	0.000032
Large Arteries	0.15	20	13.4	0.000033
Main Art. Branches	0.05	10	8	0.005
Terminal Arteries	0.03	1.0	6.0	0.00185
Arterioles	0.001	0.2	0.32	6.25
Capillaries	0.0004	0.1	0.07	89.4
Venules	0.0015	0.2	0.07	12.7
Terminal Veins	0.075	1.0	1.3	0.0014
Main Venous Branches	0.12	10	1.48	0.0047
Large Veins	0.3	20	3.6	0.00064
Venae Cavae	0.625	40	33.4	0.000031

Fig. 14 Classification of blood vessels. (From Ref. [28].)

However, protein diffusion, much slowed down by the crowded nature of the cytoplasm, is about 71 times slower than in water or about 10^{-8} cm²/sec (Ref. [29], Table 115.5, p. 115.7). This randomization process then takes place in about:

$$\begin{aligned} T_{\text{ran}} = T_{\text{dif}} &= (10^{-8} \text{ cm}^2)/(6 \times 10^{-8} \text{ cm}^2/\text{sec}) \\ &= (1/6) \text{ sec} \end{aligned} \quad (27)$$

We shall shortly see that this is very fast, and we are left with the classic problem of diffusion to a spheroid from large surroundings (e.g., ex. 2.2.2, p. 205) with fast irreversible reaction at the surface. It can therefore be shown that the probability of the promoter finding the gene is:

$$P = 1 - \exp[-t/T_{\text{rxn}}] \quad (28)$$

with

$$T_{\text{rxn}} = 3D_{\text{PC}}[(R_P + R_{\text{eff}})/R_{\text{cell}}^3] \quad (29)$$

where R_P is the effective radius of the protein and R_{eff} that of the gene. If one uses just the actual size of a typical protein, 5 nm, and neglects the size of the gene proper:

$$T_{\text{rxn}} = \left[\frac{3 \times 5 \times 10^{-7}}{(10^{-4})^3} \times 10^{-8} \right]^{-1} = 67 \text{ sec} \quad (30)$$

This is in good agreement with extensive numerical calculations (see Berg).^[29] However, actual kinetics are substantially faster because the promoter molecule can sample substantial lengths of DNA on each encounter.

Diffusion and Reaction

The primary purpose of diffusion is to provide feeds for chemical reaction, i.e., organ metabolism. This always requires a concentration gradient as described by Fick's law, Eq. (18), and here we consider diffusion in the absence of flow. We take as a specific example a slab of tissue as described in Fig. 15, but the behavior of cylinders or spheres is almost identical using the reaction modulus:

$$\Phi = \frac{\langle R_i \rangle (V/S)^2}{c_{i0} D_{iT}} \quad (31)$$

shown as an abscissa in the figure (Ref. [2], p. 566). Here, $\langle R_i \rangle$ is the average rate of consumption of species "i," in moles per unit volume and time over the whole tissue volume, V . The surface area exposed to reactant "i" is S , the molar concentration of "i" at the

Fig. 15 Effectiveness factors.

surface is c_{i0} , and its diffusivity through the tissue is D_{iT} . The figure is drawn for "power-law" kinetics where local values of consumption rate are given by:

$$R_i = k_n c_i^n \quad (32)$$

with values of reaction order n equal to 0, 1, and 2 as shown. The effectiveness taken as origin is the ratio of observed consumption rates to those at the exposed surface. First, it should be noted that effectiveness is not greatly dependent on n .

More important for our discussion, the results for all biological kinetics, for example, the familiar Michaelis–Menten model, lie between the zero- and first-order lines (Ref. [14], p. 164). It follows that we can obtain a fairly good estimate of diffusional effects just from examination of the tissue involved. We begin by showing the demand for circulating blood in a normal adult human of 70 kg. We need only orders of magnitude here so we can make the following approximations:

$$V = 70 \text{ L} = 70,000 \text{ cm}^3$$

$$S = 10 V^{2/3} = 17,000 \text{ cm}^2; (V/S) = 4 \text{ cm}$$

$$\langle R_i \rangle [0.25 \text{ L(sTP)/min}]/70,000 \text{ cm}^3$$

$$= [0.25/(22.4 \text{ L/gmol} \times 60 \text{ sec/min})]/70,000 \text{ cm}^3$$

$$= 2.66 \times 10^{-9} \text{ gmol/sec/cm}^3$$

$$c_{i0} = 0.21 \times 1.0 \times 10^{-6} \text{ gmol/cm}^3$$

$$= 2.1 \times 10^{-7} \text{ gmol/cm}^3$$

$$D_{O_2T} = 10^{-5} \text{ cm}^2/\text{sec}$$

It follows that the value of the modulus is on the order of 10^4 and the effectiveness factor is on the order

of 0.0001. The bottom line then is that all vertebrate animals need a blood circulation to supply oxygen.

It is perhaps more useful to note that almost all enzymes operate with a modulus between 1/3 and unity (see Ref. [15], section 12.3.2 and in particular the Ref. [31]). There are at least two reasons for the existence of enzyme clusters such as that shown in Fig. 5. First, if an intermediate is present at very low concentration one can still obtain a high effectiveness if the diffusion distance to the next is sufficiently small. Second, a cluster may act to keep an intermediate from diffusing away into the cytosol.

Diffusion, Reaction, and Convection

In most functional units diffusion, reaction, and convection are in balance, and we take as our example oxygenation of Krogh cylinders in the brain (Fig. 3). The brain must obtain all of its metabolic energy from aerobic oxidation of glucose, and the combination of low oxygen diffusivity and solubility is the primary constraint on design.^[21] There have been many descriptions of these processes over the years, but the results shown in Purves are still reasonable (Fig. 3). The diffusion–reaction modulus Φ at the distal (venous) end of cerebral capillaries is usually estimated to be about 1/4. This is a little lower than the range claimed by Weisz, but this is an extraordinary case (Ref. [15], ref. 375). It is critically important that cerebral metabolism be maintained very close to normal values even while the organism is heavily stressed.

MORE COMPLEX TRANSPORT MECHANISMS

Intracellular transport is far more complicated than the above-described situations, and so are the morphologies of the systems involved. One must now consider additional motive forces, for example, coupled processes such as passive and active carrier transport through membranes vesicular traffic along filamentous networks (microtubules), chemotaxis, or single-protein transport using dedicated motors (Ref. [14], chap. 11).^[1,30,32,33] These are too complex for extensive coverage here, but they are too important to ignore.

Many of the diffusing species are electrically charged, and their motion is therefore heavily influenced by electric fields (Ref. [2], eqs. 24.2–8, p. 769, ex. 24.4-3, p. 780). A more limited but simpler picture is provided by Alberts et al. (Ref. [14], p. 634). There are potential differences of some tens of millivolts across most biological membranes, and these are used to control concentrations of charged species c_i , notably

small ions. This action can be explained to a fair approximation by the Nernst equation (Ref. [14], p. 634):

$$V_2 - V_1 = \frac{RT}{z_i F} \ln \left(\frac{c_{i1}}{c_{i2}} \right) \quad (33)$$

Here, V is the electric potential in volts for sides 2 and 1 of the membrane, R is the international gas constant, 1.987 cal/mol $^\circ$ K, T is absolute temperature, and F is Faraday's constant, 2.308×10^4 cal/V(g/eqt.). The ionic charge z_i is, for example, +1 eqt./mol for sodium ion, and –2 eqt./mol for sulfate. Thus, cation concentrations will be higher on the low-voltage side. Membrane potentials are produced by ion pumps (Ref. [1], chap. 3, p. 74; Ref. [14], p. 635). One of the most complex biological mass transfer situations is the transmission of nerve impulses by transient disturbance of membrane potentials (Ref. [1], chap. 4, p. 116).

CONCLUSIONS

It is hoped that even this cursory discussion of biological mass transfer will prove useful and, more specifically, that it will make the large mass of information in the references accessible. The accumulated literature is enormous and the subject matter exceedingly complex. For this reason it is important that the goals of investigators be very carefully posed and that only needed information be sought. Fortunately, the hierarchical design of living systems frequently makes surprisingly simple models useful, and much of the above discussion has been based on such simplified descriptions. At the same time the difficulty of obtaining reliable data, and the tendency of living systems to oppose attempts to probe them, can severely limit the numbers of model parameters that can be determined. It is most important to read the literature critically, and in particular, to examine all basic data carefully, before accepting any generalizations drawn from them. That warning applies also to those provided here. A good point to make!

INTRODUCTION

The development of clinically relevant tissue-engineered products is highly dependent upon the identification of suitable scaffoldings that can be used to mimic the native extracellular matrix (ECM), a daunting barrier. In vivo, the native ECM defines the architectural organization and the passive mechanical properties of nearly every solid human tissue. This complex network of fibrous proteins also functions as a repository for soluble peptides that can regulate a variety of physiological processes in the surrounding cell population. Classically, this network is often viewed as a static structural scaffolding. However, the composition and tertiary structure of the ECM are subject to regulation throughout life. This natural scaffolding can undergo profound changes in composition in development, at the onset of disease, and during the progression of normal wound repair. Even during homeostasis, constituents of the extracellular matrix are routinely broken down by proteolytic events and replaced by nascent proteins.

In the bioengineering paradigm, scaffoldings play a central role in the fabrication and delivery of tissue-engineered organs to a host site. The mechanical and biochemical perturbations that inevitably occur to the local microenvironment when a tissue-engineered organ is implanted can markedly alter homeostasis and stimulate the remodeling of the surrounding ECM. Fundamental to these remodeling processes is the proteolytic breakdown of pre-existing proteins in the ECM of the host and, potentially, the scaffolding elements of the implanted tissue-engineered organ. As a class, enzymes of the matrix metalloproteinase (MMPs) family exhibit broad specificity against the principal structural proteins of native extracellular matrix (ECM). The implantation of nearly any tissue-engineered organ can be expected to induce the expression, synthesis, or activation of these proteases at the host-implant interface.

There is a dynamic interaction between the ECM and the cellular elements of an organ. Changes in the composition of the ECM can impact the physiological state of the surrounding cells. Conversely, changes in the physiological state of the cellular compartment can

impact the synthesis, deposition, and turnover of matrix constituents. Our laboratories believe that this dynamic interaction must be recognized and incorporated into the design of tissue-engineered organs. For example, when a tissue-engineered organ is implanted, a complex set of events must occur to promote the structural and functional integration of the construct into the host site. At implantation, interstitial fibroblasts from the surrounding tissue are stimulated to migrate into the tissue-engineered organ. If these cells cannot freely penetrate the borders of the implanted tissue, the construct may initiate fibrosis and inflammation, potentially leading to the delamination of the construct from the host site. Notably, as an integral part of the integration process, microvascular endothelial cells must rapidly penetrate and migrate throughout a tissue-engineered organ to establish capillary beds and cardiovascular support. Matrix degradation and remodeling are integral to the processes of cell migration and the formation of these nascent blood vessels.

BACKGROUND

The interrelationships between matrix proteolysis and cell migration place constraints on the design of tissue-engineering scaffoldings. A scaffold composed solely of synthetic materials is not typically subject to enzymatic attack. In this type of matrix, cell migration will be limited by physical constraints imposed by the porosity of the scaffolding and the rate at which the material dissolves. Strategies designed to facilitate scaffolding remodeling include the fabrication of synthetic scaffoldings with MMP-sensitive cleavage sites and biologically active peptides.^[1] The efficacy of this approach in a tissue-engineering application remains to be determined; the synthetic components of these structures still represent a potential nexus for inflammation. Scaffoldings composed of native materials that are subject to proteolysis can be expected to support more rapid and extensive cellular migration, facilitating the integration process. One caveat: if a natural tissue-engineering scaffolding lacks sufficient structural coherence, premature or

excessive rates of proteolysis can lead to the catastrophic failure of the implant before the construct can be fully integrated into the host site. Matrix proteolysis is mediated by a variety of different endopeptidases acting on compositionally distinct ECM proteins. Members of the matrixin subfamily of metalloproteinases, the MMPs, have been implicated in the proteolytic destruction of nearly all the protein constituents of the ECM.^[2,3]

Members of the MMP family are ubiquitously distributed throughout mammalian tissues. These enzymes are expressed, deposited into the extracellular environment, and activated in response to a host of environmental events. The differentiated resident cells and interstitial fibroblasts that populate the organ systems can synthesize and deposit both active and inactive MMPs into the surrounding ECM. Circulating cells of the cardiovascular system that mediate inflammatory processes also produce these proteases. As a result, MMP activity within an implant site can originate from nascent enzymes synthesized by the resident cells of the surrounding tissue, pre-existing enzymes present within the ECM that are activated in response to an environmental signal, or from inflammatory cells that respond to an implant construct.

Jerome Gross and Charles Lapiere (1962)^[4] published the first study describing an enzyme displaying proteolytic activity against ECM constituents in the vertebrate system during morphogenesis. Since that report, members of the MMP subfamily have been implicated in numerous physiological events including developmental processes,^[5,6] cell migration,^[7] normal homeostatic maintenance,^[8] reproduction, wound healing, and pathological processes such as metastatic cancer,^[7] fibrotic disease,^[9] arthritis,^[10,11] ulcerations,^[12,13] and other matrix-weakening diseases.^[3] It is clear from the wide distribution and diversity of functions ascribed to these enzymes that nearly any tissue-engineering application has the potential to invoke the expression and/or activation of these proteases. The MMP subfamily has been divided into five groups: the 1) collagenases, 2) gelatinases, 3) stromelysins, 4) membrane-type MMPs (MT-MMP), and 5) other MMPs^[2,3] (Table 1). These groups are distinguished from one another on structural considerations and substrate specificity.

STRUCTURE AND REGULATION: AN OVERVIEW OF MMPs

Members of the MMP family exhibit a broad range of enzymatic activity against matrix constituents. This robust proteolytic activity is subject to regulation from the transcriptional to the posttranslational levels of control. It is not at all surprising that the unregulated expression and activation of MMP proteolytic activity

can have profound effects on the local microenvironment and the overall structural integrity of a tissue. For example, the consequences of MMP dysregulation are evident in the chronic, nonhealing ulcer.^[20] The local microenvironment of the nonhealing ulcer exhibits elevated levels of MMPs derived from the neutrophils that infiltrate the interstitium surrounding these injuries.^[20,21] The protease activity associated with these enzymes exacerbates the inflammatory process and directly contributes to the pathogenesis of the lesion.^[21] In addition to the increased levels of MMPs found in nonhealing wounds, these sites also often exhibit decreased concentrations of the endogenous inhibitors of these proteases, the tissue inhibitors of matrix metalloproteinases (TIMPs).^[20] Therapeutic agents targeted at suppressing MMP activity represent a fundamental shift in the clinical treatment of chronic ulcers.

At the transcriptional level of control, growth factors and cytokines, including IL-1, PDGF, and TNF- α , hormones, and oncogenic factors have all been demonstrated to induce the expression of MMPs.^[22-24] In contrast, TGF- β , retinoic acid, IL-4, heparin, and corticosteroids suppress the expression of selected MMPs. The regulatory effects of these environmental factors are not uniform across the MMP family, suggesting that a degree of variation exists in the signal transduction pathways that control the expression and activation of these enzymes in different tissues. For example, TGF- β accelerates the synthesis of selected MMPs in the gelatinase subfamily in some tissues, yet the expression of the collagenases and the stromelysins can be inhibited by this growth factor in other tissues.^[25]

At the posttranscriptional level of control, the proteolytic activity of the MMPs is regulated by the tertiary structure of the molecule. The prototypic MMP is expressed and deposited into the extracellular environment as an inactive proenzyme. Activation of enzymatic activity subsequently occurs in the extracellular space in response to specific environmental signals. In the propeptide MMP isoform the catalytic site is sequestered and rendered inactive by a conformational feature in the molecule that is maintained by a cysteine switch. An unpaired cysteine sulfhydryl group located near the C-terminal end of the protein interacts with a regulatory zinc ion that is present within the catalytic domain.^[2,3] Disruption of this cysteine switch by enzymatic cleavage of the propeptide sequence leads to a conformational change and the activation of the enzyme.

In addition to the zinc-dependent cysteine switch, the majority of MMPs contain other common structural features (Fig. 1). Each MMP exhibits a signal sequence. This signal sequence, typically 17–20 amino acid residues in length, directs the nascent polypeptide chain to the endoplasmic reticulum where it is packaged and prepared for deposition into the extracellular compartment. The propeptide domain is approximately

Table 1 MMP subfamilies

Group	MMP-No.	Other names	ECM substrate/proteins digested
Collagenases	MMP-1	Collagenase 1/ fibroblast collagenase	Type I, II, III, VII, VIII, X, and XI collagens, Gelatin, Fibronectin, Vitronectin, Laminin, Tenascin, Entactin, Aggrecan, Link Protein, Myelin basic protein (MBP)
	MMP-8	Collagenase 2/ neutrophil collagenase	Types I, II and III collagens, Aggrecan
	MMP-13	Collagenase 3/ rat interstitial collagenase	Type I, II, III, VI, IX, X, and XIV collagens, Fibronectin, SPARC, and Aggrecan
	MMP-18	Collagenase 4	Unknown
Gelatinases	MMP-2	Gelatinase A	Type I, III, IV, V, VII, X, and XI collagens, Elastin, Fibronectin, Vitronectin, Laminin, Tenascin, Entactin, SPARC, Aggrecan, Decorin, Link Protein, and MBP
	MMP-9	Gelatinase B	Type IV, V, XI, and XIV collagens, Gelatin, Elastin, Vitronectin, Laminin, SPARC Aggrecan, Decorin, Link Protein and MBP
Stromelysins	MMP-3	Stromelysin 1	Type III, IV, V, VII, IX, X, and XI collagens, Gelatin, Elastin, Fibronectin, Vitronectin, Laminin, Tenascin, Entactin, SPARC, Aggrecan, Decorin, Link Protein, and MBP
	MMP-10	Stromelysin 2	Types III, IV, and V collagens, Gelatin, Elastin, Fibronectin, Aggrecan, and Link Protein
	MMP-11	Stromelysin 3	Does not degrade classic extracellular matrix components, ^[14,15]
Membrane-type MMPs	MMP-14	MT1-MMP	Type I, II, and III collagens, Gelatin, Fibronectin, Vitronectin, Laminin, Aggrecan, Nidogen, ^[16] and Perlecan, ^[16]
	MMP-15	MT2-MMP	Fibronectin, Laminin, Tenascin, Aggrecan, Nidogen, ^[16] and Perlecan, ^[16]
	MMP-16	MT3-MMP	Type I and III collagens, Gelatin Fibronectin, Vitronectin and Laminin ^[17]
	MMP-17	MT4-MMP	Unknown
Other MMPs	MMP-24 & 25	MT5-MMP & MT6-MMP	Unknown
	MMP-7	Matrilysin	Type I and IV collagens, Gelatin, Elastin, Fibronectin, Vitronectin, Laminin, Tenascin, Entactin, SPARC Aggrecan, Decorin, Link Protein, and MBP
	MMP-12	Metalloelastase/ macrophage elastase	Type I and IV collagens, Gelatin, Elastin, Fibronectin, Vitronectin, Laminin, Entactin, Aggrecan, and MBP
	MMP-19	No trivial name	Aggrecan and cartilage oligomeric matrix protein (COMP) ^[18]
	MMP-20	Enamelysin	Amelogenin, ^[19] Aggrecan, and COMP ^[18]

Substrate degradation as determined by in-vitro experimentation. Modified from Refs. [2] and [3].

80 amino acids in length and highly conserved with a PRCXXPD sequence containing the cysteine residue that forms the cysteine switch. The catalytic domain is 160–170 amino acid residues and includes calcium-binding sites, a second zinc atom that is integral to the structure of the peptide, and a binding site for the catalytic zinc atom.^[2]

Depending on the specific identity and subtype of MMP under consideration, other domains that may be present include a furin-cleavage site, hemopexinlike

domain, a hinge region, a variable number of fibronectinlike repeats, and/or a membrane insertion extension. Enzymatic cleavage at Furin-sensitive sites occurs within the trans-golgi network and, in some instances, appears to down regulate proteolytic activity of the mature enzyme.^[27] The hemopexinlike domain has a 200-amino-acid sequence that resembles the extracellular proteins hemopexin and vitronectin. This domain is believed to contribute to substrate specificity and represents a binding site for the natural inhibitors of the

Fig. 1 Domain structure of representative MMPs. Signal peptide; propeptide with the cysteine switch; catalytic domain containing the Zn^{2+} binding site; hemopexin domain that purportedly contributes to MMP substrate specificity; fibronectin type II domains for gelatin binding, collagen-like domain with an unknown function; furin susceptible site, transmembrane domain and the cytoplasmic tail. (Modified from Ref. [26].)

soluble MMPs, the TIMPs. The hinge region acts as a linker that connects the catalytic domain to the hemopexinlike domain. No specific functional characteristics have been ascribed to this structural feature. The fibronectinlike repeats consist of three fibronectin type II-like domains arrayed sequentially in the primary structure of the peptide. These repeats appear to mediate the adhesion of gelatinases to denatured collagen. The membrane insertion domain is a hallmark of the membrane-bound MMPs (MT-MMP); this domain traverses the cell membrane and anchors the MT-MMP protein to the plasma membrane.^[3] We will consider the specific characteristics of representative MMP enzymes from each of these subgroups in the following discussion.

COLLAGENASES

In humans, members of this MMP subfamily include MMP-1 (Collagenase 1), MMP-8 (Collagenase 2) and MMP-13 (Collagenase 3).^[2] These enzymes exhibit activity against fibrillar types I, II, and III collagen. These collagen isotypes represent the most abundant extracellular structural proteins in man and play a role in the development, maintenance, repair, and regeneration of almost every tissue type. Type I collagen is present in high concentrations in bone, skin, and the connective tissue of muscle. A blend of type I and type III collagen is observed in the myocardium and in blood

vessels. Type II collagen predominates in cartilage. Considerable effort has been directed at processing proteins of the collagen family into tissue-engineering scaffolds that mimic the structure of native tissue.^[28,29]

In clinical practice, we believe that MMP-1 and MMP-8 will have the most relevance to a bioengineering paradigm. Specific roles for the collagenases in developmental and pathological processes have been defined in transgenic mice models. For example, mutations at or around the collagenase cleavage site on the alpha 1 (I) chain of type I collagen render it resistant to collagenase digestion *in vitro*. Mice carrying a collagenase-resistant Colla-1 transgene die in late embryogenesis. When the same mutation is introduced into the endogenous Colla-1 sequence by gene targeting, the host undergoes normal development into early adulthood. However, with aging the animals develop marked fibrosis in the dermis in a pattern similar to that observed in human scleroderma.^[30]

MMP-1 (Interstitial Collagenase)

MMP-1 is expressed by interstitial fibroblasts in a variety of tissue types and macrophages.^[31] The nearly ubiquitous distribution of MMP-1 virtually ensures that this protease will be present and activated within any tissue-engineering site. The enzyme contains a minimal set of MMP-specific domains. There is a signal peptide, a propeptide, a hinge region, a catalytic domain, and a hemopexinlike domain. Molecular weight

Fig. 2 Representative gelatin zymography. Equal concentration concentrated media proteins were electrophoresed at a constant voltage of 120 V for 1½ hrs. Lane A, No evidence of gelatinolytic activity in serum-free media (DMEM/F-12 supplemented with 5 ml ITS liquid media supplement (100 ×), 1.2% bicarbonate, 1.2% antimycotic-antibiotic). Lane B, Clear bands at 92 kDa and 72 kDa present in 7.5% serum-supplemented media representing the inactive zymogens MMP-9 and MMP-2 respectively. Lane 3, neonatal cardiac fibroblast plated onto a bed of fibronectin [10 µg/ml] in serum-free media. Clear bands observed for both the inactive and active forms of the gelatinases.

of the proisoform is 52 kDa and 41 kDa for the active enzyme. MMP-1 is synthesized and deposited into the extracellular environment as an inactive zymogen (proMMP-1) in response to environmental signals.

The activation cascade of MMP-1 is a multistep process, a feature that represents a common regulatory pattern for the enzymes of this subclass. In the extracellular space the propeptide is partially cleaved from the enzyme to form an intermediate, inactive zymogen species^[2,3] (Fig. 2). This initial cleavage event can be mediated by several different extracellular proteases, including plasmin,^[2] mast cell factor,^[32] soluble proteases present in rheumatoid synovial fluid,^[33] and cartilage procollagenase-activating protein.^[2] The partial cleavage of the propeptide sequence results in a conformational change that initiates an autocatalytic event and the removal of the remaining amino acid residues of the propeptide sequence, forming an intermediate 42 kDa isoform.^[3] This partially activated isoform is relatively short-lived and is further processed to a mature 41-kDa protein that exhibits full collagenase activity. The final proteolytic events that lead to the maturation of the enzyme appear to be mediated predominately by MMP-2 and MMP-3.^[2] The mature isoform of MMP-1 exhibits a degree of substrate specificity and cleaves type III collagen 100 times more rapidly than type II collagen and 10 times more rapidly than type I collagen.^[3]

MMP-8 (Neutrophil Collagenase)

MMP-8 is similar in molecular size to MMP-1 and shares several subdomains with this peptide. Despite this structural homology, MMP-8 exhibits very different

patterns of regulation. MMP-8 was originally believed to be specific to neutrophils and polymorphonuclear leukocytes (PMNs). Further study has demonstrated that normal chondrocytes, synovial fibroblasts, and endothelial cells all express this protease. Notably, the expression of MMP-8 is accelerated in chondrocytes during the onset of osteoarthritis.^[34] This is a degenerative condition associated with the inflammation of the articular cartilage and the surrounding synovial lining. The elevated levels of MMP-8 observed in osteoarthritis originate from intrinsic sources (i.e., the chondrocytes)^[34] and from extrinsic sources (i.e., the PMNs that accumulate in response to the inflammatory process). It remains to be determined if the activation of MMP-8 represents a cause or a consequence of this disease process. However, collagen degradation is recognized as an irreversible step in the destruction of cartilage, ultimately leading to a failure in joint function.^[35]

The molecular weight of the proisoform of MMP-8 is 60 kDa and the mature active enzyme has a molecular weight of 40 kDa. Two different regulatory cascades have been described for this protease. In the PMN cell, MMP-8 is stored within specific intracellular granules.^[36] During the progression of an inflammatory response, macrophages release cytokines and promote the accumulation of PMNs. Once activated, the PMNs release MMP-8 as a bolus into the local microenvironment, accelerating matrix degradation.^[36,37] The release of MMP-8 in this fashion results in a highly localized and concentrated response.

In other cell types, for example, the chondrocyte, MMP-8 is expressed and deposited into the ECM as an inactive proenzyme. Within the extracellular space the enzyme can undergo activation by an autocatalytic cascade similar to that described for MMP-1. Activation can also occur through proteolytic events mediated by a variety of other soluble extracellular proteases.^[3] For enzymes stored in the extracellular matrix, the rate of activation can be modulated by the relative amount of oxygen present within the interstitium. This regulatory pathway can have direct implications in the tissue-engineering paradigm where implanted tissue may be subject to hypoxia. Under aerobic conditions during an inflammatory response, oxidizing substances formed by neutrophils can rapidly initiate the autocatalytic cascade.^[38] Subsequent to this initial processing event the enzyme appears to be cleaved by cathepsin G, leading to a fully activated isoenzyme.^[38] On the surface the activation of this protease through this pathway appears to be completely detrimental to the healing process. However, the matrix remodeling that transpires under these conditions appears to be associated with the re-expression of a more natively like ECM architecture. In contrast, under anaerobic conditions a slower, more progressive proteolytic activation that is mediated cathepsin G, chymases, and/or tryptases

predominates.^[31] Activation through this cascade, while slower, may lead to aberrant ECM remodeling and subsequent fibrosis. In the absence of circulatory support, the accumulation of cellular debris and remnants of provisional matrix constituents results in the build-up of protein within the interstitial fluid.

The complex interplay of regulatory events that control the deposition and activation of MMP-8 are clear demonstrations of how difficult it can be to manage protease activity associated with the MMP family. In osteoarthritis, MMP-8 originates from intrinsic and extrinsic sources and is deposited into the extracellular environment by two completely different processes. Once deposited into the extracellular environment the regulatory cascades can be further modulated by the local concentration of proteases, oxidizing agents, and oxygen tension.

GELATINASES

Members of the gelatinase family include Gelatinase A (MMP-2, 72 kDa) and Gelatinase B (MMP-9, 92 kDa). Collagen is not degraded solely by any one proteolytic enzyme and, in effect, the enzymes of the gelatinase subfamily mediate the relatively late stages of collagen degradation. The complete degradation of this natural polymer is mediated by a battery of proteases. During initial processing, a MMP collagenase or other protease may degrade fibrillar collagen into a smaller fragment. Subsequently, the fragments are further digested by enzymes of the gelatinase family into yet smaller entities. Gelatinases are expressed in nearly every tissue type^[39] and have been described in a variety of interstitial fibroblasts. Expression has also been detected in fully differentiated cell types including, skeletal, cardiac, and smooth muscle cells and endothelial cells. Proteolytic activity associated with these enzymes is critical during angiogenesis,^[40,41] a process essential to the bioengineering paradigm. MMP-2 is usually expressed constitutively at low levels; MMP-9 is expressed in response to environmental signals.

The gelatinases share extensive structural homology with the other members of the MMP family. However, the fibronectin type II repeats within these proteases represent a distinguishing, and diagnostic, feature. This motif contains a 58-amino-acid repeat that adds considerable mass to the gelatinase MMP, making these proteases among the largest of the MMP family. The fibronectin II repeats mediate the adhesion of the MMP gelatinase to elastin and denatured, or partially degraded, collagen (gelatins). This physical interaction appears necessary for the proteolytic activity of the enzyme against these structural proteins.^[42,43] Subtle differences in the sequence of the fibronectinlike repeats

appear to confer a degree of substrate specificity to the enzymes of this family.^[44,45]

Gelatinase activation is classically studied *in vitro* by zymography. Zymography involves electrophoretic separation of denatured but nonreduced proteins in a gelatin-infused poly-acrylamide gel. At the conclusion of the separation, proteins are renatured by exchanging the SDS with a nonionic detergent such as 2.5% (v/v) of Triton X-100 in ddH₂O or proprietary renaturation buffer (BioRad Laboratories, Hercules, CA). The renatured proteins in the gel are incubated in development buffer: 0.05 M Tris-HCl pH 8.8, 5 mM CaCl₂, 0.02% NaN₃. Development buffers are also available commercially. Gels are incubated for 12–24 hours at 37°C revealing clear bands, indicating proteolysis of the gelatin substrate. After the appropriate incubation period, developed gels are fixed in destaining solution (20% methanol, 5% acetic acid, and 75% distilled H₂O) and stained with 0.5% Coomassie brilliant blue R-250 prepared in 45% methanol, 10% acetic acid, and 45% dH₂O. Stained gels are destained in destaining solution until clear bands against a blue background can be visualized (Fig. 2). Clear bands can be analyzed by using densitometry software. For molecular weight comparison, gelatinase zymography standards are available commercially through Chemicon (Temecula, CA). For a complete and more detailed description of zymography refer to *Methods in Molecular Biology*, edited by Ian M. Clark.^[46]

The gelatinases are expressed at elevated levels during tissue remodeling and accelerated gelatinase activity is associated with trophoblast implantation,^[47] bone resorption,^[8] and the process of angiogenesis.^[40,41] In the cardiovascular system, increased gelatinase expression is correlated with morphogenic events during early cardiogenesis, including the remodeling of the pharyngeal arches, heart tube looping, cardiac cushion formation, and the migration of neural crest cells.^[6] In disease states, gelatinase activity is augmented during wound healing and in the progression of rheumatoid and osteogenic arthritis, arthrosclerosis,^[48] dilatory cardiovascular disease,^[49] and the abnormal resorption of periodontal ligaments.^[50] The metastatic potential of some cancers has been correlated with increased gelatinase expression; presumably, this proteolytic activity facilitates the migration of the cells through the basal lamina and into the interstitial compartments.^[51,52]

MMP-2 (Gelatinase A)

MMP-2, a prototypic enzyme of the gelatinase family, is constitutively expressed at low levels by many different cell types. It is secreted into the ECM as a 72-kDa latent proenzyme (zymogen). A series of parallel and overlapping activation cascades regulate the catalytic

activity of the enzyme. The activated isoform of the protein exhibits proteolytic activity against gelatin (denatured triple-helical type I and type III collagen), type IV, V, VII, and IX collagen, fibronectin, laminin, elastin, a variety of proteoglycans, and entactin.^[2] Over prolonged periods of time, MMP-2 also has been shown to bind and cleave soluble type I collagen.^[3]

In the extracellular space the cleavage of the propeptide from the parent proMMP-2 isoform can be achieved through several different pathways. In one well-characterized pathway, proMMP-2 is activated through the formation of a multimolecular complex. In the inactive state the proMMP-2 isoform binds to Tissue Inhibitor Metalloproteinase-2 (TIMP-2), a peptide inhibitor that suppresses the conversion of 72-kDa proMMP-2 to the active 68-kDa isoform.^[2,3] There are two separate binding sites on the proMMP-2 molecule for TIMP-2. One site is adjacent to the active site of the enzyme and the other appears to represent a novel stabilization site. At equimolar concentrations of TIMP-2 and proMMP-2, the conversion of proMMP-2 to the active isoform is inhibited. The binding of TIMP-2 to the stabilization site appears to maintain the tertiary structure of the enzyme and preserve the proisoform by preventing the progression of an autocatalytic activation cascade.^[3] As the concentration of TIMP-2 is increased, the inhibitor binds to a membrane-bound protease of the MMP family, MT1-MMP.^[53,54] The interaction of a TIMP-2 : proMMP-2 complex to MT1-MMP forms a ternary complex at the cell surface. This complex positions the bound proMMP-2 in proximity to an adjacent and free MT1-MMP, leading to the proteolytic processing and subsequent activation of the MMP-2 molecule. At very high concentrations TIMP-2 binds proMMP-2 and saturates the MT1-MMP compartment, neutralizing the activation cascade.^[55] MMP-2 may also be activated by an autoactivation pathway. At high local concentrations, proMMP-2 can be processed by a proteolytic event to an active enzyme, without the addition of exogenous activation factors. It is unclear if the autocatalysis represents a physiologically relevant event.

MMP-9 (Gelatinase B)

MMP-9 is the largest (92 kDa) of the known MMPs. This enzyme exhibits a unique collagen type V-like domain that is located between the catalytic and a hemopexinlike domain. *In vitro*, activated MMP-9 degrades type IV and type V collagen, aggrecan, link protein, myelin basic protein, and amyloid B peptide.^[3] The substrates degraded *in vivo* have not been fully characterized. However, MMP-9-deficient mice exhibit a specific defect in endochondral bone formation that is associated with the accumulation of hypertrophic

cartilage at the growth plates. These animals also exhibit diminished angiogenic activity.^[56]

Unlike MMP-2, MMP-9 is not expressed constitutively.^[57] This isotype is expressed in response to specific environmental signals including, growth factors, cytokines, cell-cell interactions, cell-matrix interactions, and external events that alter cell shape.^[3] The proteolytic activation cascade that regulates the processing of MMP-9 is subject to TIMP-dependent regulation in a pattern similar to MMP-2. TIMP-1 and TIMP-2 can both bind and suppress the conversion of proMMP-9 to the active state. TIMP-2 binds to MMP-9 with a higher affinity than TIMP-1 and is more effective at suppressing activation cascade; however, the TIMP-1-dependent regulation of MMP-9 appears to predominate *in vivo*.^[58]

Like other latent MMPs, the activation of proMMP-9 is mediated by the proteolytic disruption of the cysteine/ Zn^{2+} switch (coordination bond). During processing, the (92-kDa) proMMP-9 species is converted to an (82-kDa) active isoform. The specific pathway to full activation is dependent upon whether MMP-9 is bound in a complex with TIMP-1 or in a free state.^[3] In most cell types, proMMP-9 is deposited into the extracellular environment in complex with TIMP-1. Under these conditions the proMMP-9 : TIMP-1 complex is resistant to cleavage by MMP-3, a soluble protease of the stromelysin MMP subfamily.^[59] As the relative concentration of active MMP-3 increases with respect to the local TIMP concentration, MMP-3 is believed to cleave proMMP-9 to an 82-kDa isoform. This isoenzyme exhibits an intermediate degree of proteolytic activity against ECM substrates.^[59] In the absence of TIMP-1, the intermediate 82-kDa MMP-9 is processed further by MMP-3 to a fully active 67-kDa isoform^[3] (Fig. 3). A plasmin-dependent, TIMP-independent activation pathway for MMP-9^[57] also has been described. This pathway may provide a substantial contribution to the activation of MMP-9.^[60] Plasmin is derived from plasminogen, a peptide secreted by hepatocytes that is a nearly ubiquitous component of plasma.^[61]

STROMELYSINS

Members of the stromelysin subfamily include MMP-3 (Stromelysin-1) and MMP-10 (Stromelysin-2). MMP-3 and MMP-10 both contain typical MMP subdomains, including the signal peptide, the propeptide, and the catalytic domain. These enzymes have broad substrate specificity and can degrade basement membrane collagens, laminin, fibronectin, vitronectin, proteoglycans, and matrix glycoproteins. The stromelysins do not degrade fibrillar collagen;^[62] however, the enzymatic activity of this class of proteases plays a central role in the full activation of the collagenases and gelatinases

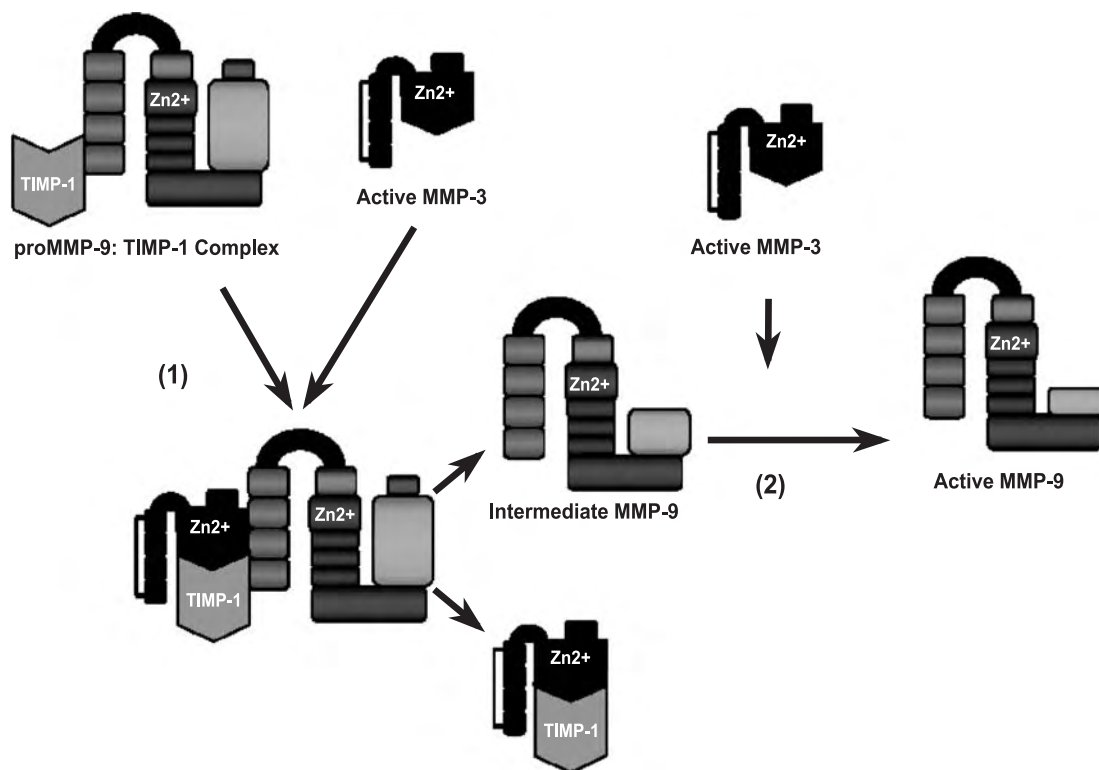

Fig. 3 Schematic representation for the activation of ProMMP-9. Step (1), the relative concentration of active MMP-3 increases with respect to the local TIMP concentration. This interaction is believed to cleave proMMP-9 to an 82-kDa isoform (intermediate level of activity). Step (2), now with the removal of TIMP-1, the intermediate 82-kDa MMP-9 is processed further by MMP-3 (stromelysin) to a fully active 67-kDa isoform. (Modified from Ref. [59].)

(refer to Fig. 3). Given this regulatory role and the broad substrate specificity of the stromelysins against matrix constituents, it is not surprising that these enzymes have been implicated in a wide variety of biological processes. During development there is coordinate expression of the stromelysins, the collagenases, and the gelatinases during blastocyst outgrowth and the early stages of implantation. Stromelysins are concentrated in the growth plates of developing and maturing bone. Tissue culture experiments suggest that osteoblasts express the stromelysins in response to bone resorptive agents and mediate the degradation of non-mineralized collagen.^[63]

Specific patterns of MMP-3 and MMP-10 expression have been observed in keratinocytes in the immediate vicinity of epithelial injuries.^[64] During the onset of proliferation, keratinocytes that are in contact with the basement membrane express MMP-3 but not MMP-10. The enzymatic activity associated with MMP-3 is correlated with the contraction of the wound bed. In MMP-3-null mice there is a delay in the onset of incisional wound closure,^[65] and dermal fibroblasts from these animals exhibit decreased capacity to contract collagen gels *in vitro*.^[66] MMP-10, but not MMP-3, is expressed in cells within the migrating front that forms the

epithelial tongue at the margin of a wound. The specific function of this enzyme in the migration of cells across the provisional matrix of a wound site remains to be fully defined.

MMP-3 (Stromelysin-1)

MMP-3 is expressed by many cell types; including interstitial fibroblasts, vascular smooth muscle cells, chondrocytes, keratinocytes, macrophages, and endothelial cells in response to extrinsic signals. RGD-dependent binding events, mechanical perturbations, cytokines, and growth factors can all invoke the expression and synthesis of this enzyme. The proMMP-3 molecule is a 52-kDa protein that has a signal sequence, a propeptide, a catalytic domain, and a hemopexinlike domain. The hemopexinlike domain, although not essential for catalytic activity, appears to define substrate specificity. This domain contains an amino acid repeat that represents a high-affinity binding site for the extracellular matrix proteins hemopexin and vitronectin.

The activation of proMMP-3 (52 kDa) to its 45-kDa active isoform follows a pattern similar to that of proMMP-1. The initial cleavage of proMMP-3 is

mediated by a large number of proteinases that attack the first α -helix of the peptide. This appears to destabilize the Cysteine/Zn⁺² switch, resulting in an activated intermediate isoform. The final activation steps of MMP-3 do not require other members of the MMP family and a diverse variety of proteases can mediate this event.^[3]

MEMBRANE-TYPE MATRIX METALLOPROTEINASES

The membrane-type matrix metalloproteinases (MT-MMP) are tethered to the cell membrane. The prototypic MT-MMP contains a C-terminal hydrophobic transmembrane domain that passes through the plasma membrane terminating in a short cytoplasmic tail. The characteristic location of these enzymes establishes focused sites of proteolytic activity. Common to all MT-MMPs is the insertion of a potential furin cleavage site adjacent to the propeptide domain.^[3] The function of this furin site remains controversial. In some cell types the cleavage of this site appears to down regulate the proteolytic capacity of the mature enzyme.^[27] In other cell types this site appears to mediate the association of the MT-MMPs with TIMPs during the initial stages of the activation cascades that regulate the maturation of the soluble MMPs.^[67]

MT1-MMP

Of the six known MT-MMPs, MT1-MMP is perhaps the most well characterized. The molecular weight of the pro-MT1-MMP is 64 kDa, whereas the fully active form has a molecular weight of 54 kDa. The pro-MT-MMP can be activated during intracellular transport to the cell surface by a furinlike proteinase and/or at the cell surface by furin or plasmin-mediated processing events. Activation can also be mediated at the cell surface by other proteases, but these events have not yet been fully characterized.^[3] As discussed, MT1-MMP is best recognized for its essential role in the activation of proMMP-2 (Gelatinase A), but this protease can directly degrade gelatin (denatured collagen), aggrecans, fibronectin, vitronectin, and laminin.

MMPs IN TISSUE ENGINEERING

Enzymes of the MMP family are widely distributed in the mammalian system and exhibit robust proteolytic activity against a wide variety of matrix constituents. A broad spectrum of regulatory factors controls the synthesis, expression, and activation of these proteases. Within in any given local domain protease activity

associated with the MMPs may arise from the resident cells of an organ system or from cells that originate from the circulatory system. As a consequence of the ubiquitous distribution of these enzymes nearly any surgical procedure designed to implant a bioengineered organ can be expected to initiate MMP protease activity.

In the design of tissue-engineering scaffolds a balance must be achieved between structural and functional considerations. Scaffolds that can withstand manual manipulation and simultaneously support cell infiltration and the integration of the implant into the host site must be developed. The support of cellular infiltration is critical to the formation of nascent blood vessels. Ideally, a tissue-engineering scaffold should define the initial structural properties of a bioengineered construct until the cells of that construct can elaborate a native extracellular matrix. To reduce the risks of inflammation and fibrosis, the ideal fabrication scaffolding also should be biodegradable and be replaced by matrix materials expressed by the implant.

Prospects for developing synthetic materials that meet the enumerated design considerations seem unlikely. Identifying synthetic materials that exhibit biological, regulatory, and commercial efficacy is not a trivial task. Synthetics that function well in the research setting may face intense scrutiny from regulatory agencies (e.g., The Food and Drug Administration). The tripartite hurdle of demonstrating biological efficacy, meeting regulatory approval, and exhibiting commercial viability is often overlooked and represents an unappreciated constraint that can limit the movement of materials from the laboratory setting to clinical practice.

Our laboratories believe that novel methods must be developed to process native or true analogs of native materials into surgical biomaterials suitable for use as tissue-engineering scaffolds.^[68,69] This approach, coupled with tissue fabrication and surgical strategies that limit the remodeling response, represent an avenue to manage the potentially destructive protease activity associated with the MMP family. We have approached this issue by developing scaffolds that more closely mimic the chemical composition and material properties of the host site of an implant.^[70] MMP-mediated protease activity is critical to a diverse variety of homeostatic processes and it seems unlikely that it will be feasible to suppress the activity of these enzymes completely, even within the local microenvironment of a tissue-engineered implant. Some degree of targeted disruption, perhaps directed at key regulatory steps in the MMP activation cascades, may be tolerated and have efficacy over short intervals of time.^[71] However, with nonspecific or prolonged suppression of MMP-mediated protease activity, cell infiltration and capillary formation will be primarily defined by the porosity of the scaffolding material and density of the implant. This

places additional design constraints on the scaffold and the bioengineered organ. Until a functional capillary network can develop, most bioengineered constructs must be supported by the passive diffusion of nutrients from the surrounding interstitium. Nonspecifically inhibiting MMP-mediated protease activity can be expected to slow healing^[49] and disrupt the formation of nascent capillary networks, placing additional limitations on the mass of tissue that can be successfully implanted.

INTRODUCTION

Cardiovascular disease remains the number one cause of death in the United States. Congestive heart failure (CHF) continues to increase in frequency and prevalence, even as the mortality from coronary artery disease and valvular disease decreases. In the United States alone, more than two million outpatient CHF clinic visits occur per year, at a cost of more than \$10 billion annually. Failure to optimize outpatient management leads to added inpatient care, burdening the healthcare system and the individual patient with additional demands. Total annual direct costs for managing and treating heart failure approach 60 billion dollars, a significant part of national healthcare expenditures. The median survival of patients with new-onset congestive heart failure (CHF) is five years. CHF affects some 4 to 5 million Americans, with approximately 500,000 new cases diagnosed each year. Coupled with the aging of the American population, CHF continues to present clinicians and policymakers with vexing clinical and financial complexities. Heart failure is a particularly important problem in the elderly population, where its prevalence is approaching 10%. In fact, more than 75% of patients with heart failure are more than 65 years old. With the continued aging of the population, both the incidence and the prevalence of heart failure are expected to increase. Heart failure is also the most frequent cause of hospitalization in those older than 65.

OVERVIEW

CHF is a complex clinical disorder. Both systolic and diastolic heart failure are associated with high rates of morbidity, mortality, and cost. New York Heart Association (NYHA) functional class assignment is widely recognized as a classification schema for severity of CHF. At any given time, 30% of patients are at

NYHA Class III or IV, indicating severe impairment in functional ability. Despite recent advances in medical therapy, the one- to two-year mortality rate is 40% to 50% for advanced heart failure, and the four- to five-year mortality rate ranges from 15% to 40% for those with asymptomatic left ventricular (LV) dysfunction or only mild to moderate symptoms. Pharmacologic therapy can ameliorate CHF symptoms and slow disease progression, but there are limitations. These include patient compliance with complex medical regimens and access issues relating to the cost of newer therapies (including natriuretic peptides). For severe end-stage disease, cardiac transplantation provides improvements in quality of life and intermediate long-term (10 year) survival approaching 50%. It is the therapy of choice for patients with refractory failure, for whom medical therapy has failed. The downstream effect of this is seen in the number of patients awaiting cardiac transplantation each year, a number limited by the critical shortage of donors. The lack of donor organs has provoked intense interest in mechanical devices to support the failing heart.

Research into cardiac assist devices gained momentum in the 1970s, when the National Heart, Lung, and Blood Institute (NHLBI) began funding research that resulted in the development of intra-abdominal left ventricular assist devices (LVADs). These devices evolved as a means to support the left ventricle (LV) in an era when the total artificial heart had not been fully developed. While clinical outcomes were initially discouraging, progress was made. The use of such devices as a temporizing measure for patients awaiting transplantation gained support and ultimately received FDA approval in 1997.

Several iterations of these assist devices have been developed. The Randomized Evaluation of Mechanical Assistance for the Treatment of Congestive Heart Failure (REMATCH) was conducted from 1998 through July 2001 in 20 cardiac transplant centers in the United States. The study enrolled 129 patients with

end-stage heart failure who had not responded to medical management and were ineligible for cardiac transplantation. This randomized trial showed significant extension of life and improvement in quality of life for a subset of heart failure patients.^[1] This has added evidence to support potential clinical destination applications where assist devices are utilized as permanent therapy, instead of the transplantation option. Also of interest is the finding by some clinicians that CHF patients supported by mechanical circulatory assist devices apparently recover and actually improve myocardial function (which allows removal of the assist device), achieving adequate cardiac function that sustains them for a period of time.

This article will focus on three FDA-approved ambulatory LVADs: the TCI HeartMate Vented Electric (VE), the TCI HeartMate Implantable Pneumatic (IP) (Thoratec Corporation, Pleasanton, CA), and the Novacor LVAS (WorldHeart Corporation, Ottawa, Canada). We will also provide some insights on the status of the total artificial heart, specifically highlighting the AbioCor Artificial Heart (Abiomed Corporation, Danvers, MA).

Each of these devices allows the patient to be ambulatory, and some patients can even be at home while waiting for transplant. But each device has its merits and potential problems, as will be seen when these

devices are described in detail. Complications including thromboembolism, bleeding, infection, and device failure will be reviewed, and future directions will be addressed.

PUMP PHYSIOLOGY

The left ventricular assist devices support the left side of the heart and hence require an adequately functioning right side and low pulmonary vascular resistance to allow blood flow through the lungs (Fig. 1). The inflow cannula drains the left ventricle passively, so the entire left ventricle becomes a passive conduit. The pump body then ejects the blood through the outflow graft, unidirectional bloodflow being maintained by the inflow and outflow valves. The blood is ejected into the ascending aorta, so the aortic valve remains closed. Also, due to the drainage of the LV the interventricular (IV) septum is moved toward the LV. This may in fact reduce the efficiency of the right ventricular function, but in most instances the reduction in left ventricular pressure leads to improved afterload reduction to the right ventricle. This is more than enough to improve the RV function to compensate for the IV septum shift.

Fig. 1. LVAD pump physiology.. (Reprinted with permission from Thoratec Corporation.)

AMBULATORY IMPLANTABLE LEFT VENTRICULAR ASSIST DEVICES

HeartMate Vented Electric (VE)

The HeartMate VE is an implantable pulsatile pump made of titanium (Fig. 2). It has a polyurethane diaphragm that is interposed between two pusher plates. The power source is an internal electric motor supplied by a battery pack that the patient can wear. The inflow cannula is attached to the left ventricular apex after removing a circular core of heart muscle. Blood is passively drained from the left ventricle and ejected into an outflow cannula that is attached to the ascending aorta.

Porcine valves, each 25 mm, are attached to both the inflow and the outflow cannula. This allows for unidirectional flow. Blood is pumped through the device into a 20 mm woven Dacron graft.

The blood-pumping surfaces, composed of titanium microspheres sintered onto a titanium surface, are textured. The polyurethane diaphragm is also textured. This environment provides a nidus for growth of a thin layer of intima comprising both acellular and cellular components that form a biocompatible layer. The

Fig. 2 The HeartMate vented electric pump. (Reprinted with permission from Thoratec Corporation.)

exact mechanism by which this layer forms is unknown but has been studied.^[2] Thrombus formation is unusual, so patients only need to be maintained on low-dose antiplatelet therapy (aspirin 81 mg).

The polyurethane diaphragm separates the titanium housing from the blood. Between this membrane and the housing lies the rotor that moves the diaphragm and propels the blood forward. A long driveline enters the skin above the umbilicus and is tunneled percutaneously to attach to the left side of the device. The driveline attaches to an external power pack for venting.

The HeartMate VE is 11 cm in diameter and 4 cm thick, and occupies a volume of 460 cc. Two batteries and an external controller supply the external power pack, and their sum weight is approximately 1.5 kg. The batteries supply 4 to 7 hours of function, with an emergency 24-hour battery and an external power source available if battery failure should occur.^[3]

The HeartMate VE can eject blood at a maximum stroke volume of 83 ml. Volumes should be adjusted by changing the heart rate or preload from the patient's intravascular volume status, so that stroke volumes stay between 70–80 ml. Anything less risks thromboembolism due to an overall decreased flow through the pump. Heart rates can be adjusted to between 50 and 120 beats per minute (bpm), which makes cardiac output 4 to 10 L/min. Decreased flows also reduce the patient's exercise tolerance. Hence, flows can be optimized via the patient's intravascular volume and the pump's stroke volume and rate. The HeartMate VE ejects independently of the patient's rhythm, but that has not been problematic clinically.

The HeartMate VE can be implanted within the rectus sheath, preperitoneally, or within the abdomen. Factors that contribute to the choice of site are potential length of LVAD implantation, previous abdominal surgery, abdominal location of cardiodefibrillators, and the surgeon's preference.

HeartMate Implantable Pneumatic (IP)

The HeartMate IP was the original version, followed by the HeartMate VE. The IP unit is very similar to the VE, containing a textured titanium housing with a polyurethane diaphragm. An air chamber lies between the rigid titanium housing and the flexible membrane. Air is pumped through the external driveline and displaces blood in the diaphragm, thereby ejecting blood into the outflow conduit.

The HeartMate IP is powered by one of three sources: an external power cart, a portable driver, or a small hand pump for emergencies. The cart weighs 73 pounds and the portable driver weighs 20 pounds, thereby making home use difficult.

Pumping and flow characteristics of the VE and IP are similar. Both devices have an 83-ml maximum stroke volume and pump rates between 50 and 120 bpm, and both function independently of intrinsic heart function and rate. Neither device can be placed into a patient with a body surface area less than 1.5 square meters, because the large size of the devices impedes the function of intra-abdominal organs.

Novacor LVAS

The development of the Novacor device (Fig. 3) was initiated in 1969, and in 1984 it was first successfully used as a bridge to transplant.^[4] This device is a fully implantable, electrically powered system attached to a percutaneous driveline that exits the anterior abdominal wall in the right lower quadrant.

The Novacor device consists of a seamless, smooth polyurethane sac that is compressed between two solenoid pusher plates. The housing is composed of fiberglass and epoxy. Inflow and outflow conduits are composed of a 25-mm gelatin-sealed polyester graft (Sulzer Vascutek Ltd., Renfrewshire, Scotland, UK) attached to porcine valves that ensure unidirectional flow.

The Novacor device is implanted in the left posterior rectus abdominus sheath. Inflow and outflow conduits are tunneled through the diaphragm on the left and right side, respectively. The inflow cannula is attached to the left ventricular apex, whereas the outflow cannula is attached to the right side of the

Fig. 3 The Novacor LVAS. (Reprinted with permission from WorldHeart Corporation.)

Fig. 4 Anatomical placement of Novacor LVAS. (Reprinted with permission from WorldHeart Corporation.)

ascending aorta. The external driveline is tunneled subcutaneously and exits through the abdominal wall to the right of the umbilicus.

The system controller is worn on the body and is connected to the external driveline that acts as an electrical lead and a vent (Fig. 4). The control system provides electrical energy to the solenoid pusher plates, which are coupled to a spring mechanism. Overall, the energy conversion process is approximately 65% efficient.^[5]

Unlike the HeartMate devices, the Novacor can function both asynchronously or synchronously with the patient's heart rate, but it is usually programmed in the latter mode. The pump fills passively during ventricular systole and ejects during diastole. The device has a stroke volume of 65 ml and can generate outputs of 7 liters per minute.^[6]

COMPLICATIONS

Thromboembolism

Clinically significant neurological events, defined as any change in neurological status detected by physical exam, can often be attributed to thromboembolism in

LVAD patients. LVADs activate the coagulation cascade, resulting in clot formation on the devices. Clot on the devices, in combination with turbulent blood flow across the surfaces, leads to thromboembolic events such as stroke, kidney failure, and distal extremity ischemia. Even with anticoagulation therapy, these events occur in up to 30% of LVAD patients.^[7] Thromboembolic events can occur with both HeartMate and Novacor devices, but they are much more prevalent with the latter device.

The HeartMate systems have a textured interior surface on which an adherent pseudointima may form.^[8] This may become a layer between the device surface and blood flow. The exact nature and cell types involved in this layer remain controversial. However, it is likely that soon after implantation, platelet deposition on the blood-contacting surfaces of the LVAD leads to rapid deposition of a fibrin matrix, which acts as the initial scaffolding for the attachment of a variety of hematopoietic cells, including monocytes and pluripotent cells. This process then leads to myofibroblast attachment and proliferation—possibly as a result of chemotactic factors released by monocytes—which leads to the formation of a pseudointima of collagenous matrix. This can later lead to the attachment of host endothelial cells.^[9] In one series of 223 patients, a clinically significant thromboembolic rate of 2.7% was observed.^[10] Other design characteristics that minimize clot formation are a short, rigid inflow cannula and a cornerless pumping chamber. The diameter of the inflow and outflow grafts is 20 mm in the HeartMate device, compared to 25 mm in the Novacor.

The incidence of neurologic complications is more frequent with the Novacor device. Thus, all patients with this device need systemic anticoagulation with warfarin. Studies report up to 47% incidence of neurologic complications.^[11] In most patients with the Novacor device, a poorly adherent pannus was seen in the inflow conduit. The Novacor inflow conduit is longer than the HeartMate's and also more flexible, which allows for separation and embolization of this pannus material. Portner et al. demonstrated, in a nonrandomized, retrospective review, that the incidence of embolic strokes was significantly reduced from 21% to 12% by changing conduit materials from a woven, crimped polyester graft to a gelatin-sealed, knitted graft with wall reinforcement. These authors also found a more stable neointima on the latter grafts, and computer modeling of both grafts showed lower mural shear rates, with less variation, in the gelatin noncrimped grafts.^[12] Further reduction in length of the inflow and change to polytetrafluoroethylene (PTFE) with more rigidity will likely reduce the evidence of embolic strokes.

Infection

Currently, the risk of infection from the LVADs remains the single most important factor precluding long-term support. The presence of an external power source requiring the percutaneous driveline, ill patients with multiple vascular access lines, and the poor nutritional status of patients may all contribute to infection. Infection, in turn, directly increases the risk of device failure, thromboembolic events, and bleeding. The Cleveland Clinic reviewed more than 200 patients receiving LVADs between 1992 and 2000, and 49% of them had a bloodstream infection. The most common pathogens were coagulase-negative *Staphylococcus* (23%), *Staphylococcus aureus* (13.5%), *Candida* (13.5%), and *Pseudomonas*. Bloodstream infection was associated with a higher mortality. Fungal infections had a hazard ratio of 10.9 for death.^[13]

In a nonrandomized prospective trial comparing the Novacor and HeartMate devices, there was a significantly higher incidence of infections in the HeartMate group (55% vs. 20%). Although the exact reason for this is unknown, it is suggested that the rotary movement of the HeartMate pump increases the reaction between the pump and surrounding tissues, thereby increasing infection.^[14] Studies have also shown a state of aberrant T cell activation, progressive defects in cell-mediated immunity, and increased risk of opportunistic infections in patients supported with LVADs.^[15]

Bleeding

Bleeding remains a significant problem after LVAD insertion. Most of these patients are quite ill before surgery, with significant hepatic dysfunction and low levels of clotting factors synthesized in the liver. The use of vitamin K parenterally prior to surgery and aprotinin—a serine protease inhibitor—during surgery is recommended to minimize bleeding and the need for blood products. Patients with HeartMate LVADs may have significant activation of coagulation with secondary fibrinolysis, despite both clinical stability and “normal” screening values of routine hemostatic parameters such as platelet count, prothrombin time, and activated partial thromboplastin time.^[16] Similar studies of the Novacor device are not available. Since most studies advocate aggressive early anticoagulation within a few hours of implanting the Novacor device, the amount of blood loss was higher when compared with the HeartMate. El-Banayosy demonstrated that although blood loss was greater in the Novacor group, there was no difference between groups in the frequency of reoperation to control bleeding.^[14]

Device Failure

Multiple device failures plagued the HeartMate devices prior to initial FDA approval as a bridge to transplantation. McCarthy noted that 12 patients out of 100 in the Cleveland Clinic series had device failure, which included driveline fractures, leaking from inflow conduits, and failure of the electrical system. Half of the patients died.^[17] Since then, mechanical failure of the device has been extremely uncommon in support durations of less than one year. Data from the manufacturer indicate an average exchange rate of 2.4% for device failure from 1993 to 1999.^[3] These numbers may not truly reflect deaths caused by device failures.

One of the modes of device dysfunction relates to failure of the HeartMate inflow valve. This is manifested as an increase in pump rates and calculated flows, with decreased exercise tolerance in the patient.^[18] In the recent REMATCH trial, the incidence of device failure was 17% during long-term support (more than one year).

Mechanical failure of the Novacor device has been uncommon. The main mode of late failure appears to be wear in the bearing of the actuator. This seems to occur after three to five years and can be detected by analysis of the pump's electrical signals. This information can then be used to electively exchange the pump.

THE ABIOCOR IMPLANTABLE ARTIFICIAL HEART

The modern left ventricular assist devices have been improved and developed in extraordinary ways over the past 20 years to provide excellent hemodynamic support for patients with left ventricular failure. Despite the many potential complications in the perioperative and postoperative periods, including bleeding, infection, and thromboembolic events, the major limitation of modern-day left ventricular assist devices is that these pumps need an external power source. Obviously, the ultimate goal of any investigative and research effort in the field of mechanical circulatory support is the development of a fully implantable replacement heart that allows the patient to be fully ambulatory without tethering to external power sources. The AbioCor™ implantable replacement heart is an advanced medical system that has been designed to fully sustain the body's circulation. These devices have been developed over the past 30 years in collaboration with and support from the NHLBI. Currently, the AbioCor is being tested in patients with irreversible, end-stage, biventricular heart failure with no other therapeutic options and with a life expectancy of less than 30 days.

The Federal Drug Administration is testing the AbioCor and has authorized up to fifteen implants in groups of five, with review after each group. The primary end point is mortality from any cause, evaluated 60 days following implantation. The secondary end points include quality-of-life measurements and adverse events determinations involving complications. The device requires the utilization of three decision support tools: 1) the Abio-score, a prognostic tool comprising laboratory and clinical data significant to 30-day mortality in advanced heart failure patients; 2) the AMI-shock index, a second prognostic tool for patients with acute myocardial infarction and cardiogenic shock; and 3) the Abio-fit screening tool, used prior to surgery to test the anatomical compatibility between potential subjects and the AbioCor thoracic unit. The Abio-fit accepts a range of digitalized thoracic imagery, including computed tomography, magnetic resonance imaging, or conventional X-rays. Prior to surgery, it creates a three-dimensional image of the AbioCor superimposed on the imagery of the patient's thoracic structures to help surgeons gauge the feasibility of implanting the replacement heart. This ensures that the AbioCor fits within the borders of the left chest cavity, with good alignment of the inflows to the two atria and of the outflow track to the great vessels, while not interfering with the pulmonary veins or the left bronchus.

The AbioCor consists of four implanted subsystem components. The implanted controller drives the thoracic unit and is powered by the implanted battery or the internal transcutaneous energy transmission secondary coil (TET), and it interfaces with the AbioCor console via radio frequency link (Fig. 5). The portable console provides primary power to the system transcutaneously, via the external TET primary coil that is placed on the skin area overlying the internal TET coil. It also provides two-way radio frequency communication with the implanted controller through an RF communication module, for monitoring alarm

Fig. 5 The AbioCor totally implantable artificial heart. (Reprinted with permission from Abiomed Corporation.)

and system control if needed. The implanted TET converts high-frequency power received from the external coil to a DC output suitable for powering the internal components.

The thoracic unit has three primary functional subunits: 1) a balance chamber that manages the right and left blood flow by maintaining physiologic left-atrial pressures; 2) the self-contained hydraulic unit, separated by pairs of flexing membranes situated between the two blood pumps, which serves as an undulating pseudo-septum actuating the left and right blood pump alternately; and 3) the blood-contacting components, including tri-leaflet valves and blood pumps, that are fabricated from a nontoxic, non-mutagenic, polyurethane called Angioflex^R. The thoracic unit, weighing approximately 1000 grams and the size of a grapefruit, includes two artificial ventricles with corresponding valves and a motor-driven hydraulic pumping system. This pump performs the back-and-forth movement of an internal ball within a sphere, supplying blood to all the vital organs. Between the two chambers, the small ball hits the soft walls with jets of fluid compressing the ventricles in a quick pulsation, forcing their contents into the arteries. The AbioCor operates on internal and external lithium batteries. The internal batteries are considered to be for emergency purposes lasting one-half hour only, but they allow the patient to move around without the external power source and the external battery pack. The external battery packs can be used for many hours, depending on the number of batteries that are carried.

To implant the device, the surgeon removes most of the patient's diseased heart, leaving only the left and right atrial cuffs. The device is then attached to the atria and to the aorta. The AbioCor can pump up to 8 liters per minute from physiologic left filling pressure into a mean arterial pressure range of from 60–160 mm of mercury, and from physiologic right filling pressure into a mean pulmonary pressure range of from 15–120 mm of mercury. This allows it to support patients with chronic obstructive pulmonary disease and pulmonary hypertension. The AbioCor has durability and reliability consistent with one year of trouble-free operation, with potential for longer operational life. Durability and reliability tests of valves and blood pumps have exceeded 20,200 and 100,000,000 cycles, respectively, under physiologic load conditions.

Since July of 2001, the AbioCor has been implanted in six patients. The first patient had a remarkable physiologic recovery and survived 151 days, but died of a stroke-related complication. Other patients have now survived with the device in place for longer than a year without significant complication. They are fully rehabilitated and functional, with an excellent quality of life. Significant obstacles to widespread utilization

of this technology continue to be biomechanical and materials problems; incompatibility with foreign blood elements; and the need for an external power source and the size of the pump, which prohibit its use in women and adolescents weighing less than 90 kg.

FUTURE DIRECTIONS IN THE USE OF IMPLANTABLE PULSATILE DEVICES

As the numbers of patients with advanced heart failure increase, the use of LVADs as long-term therapy will become more important. The landmark study—Randomized Evaluation of Mechanical Assistance for the Treatment of Congestive Heart Failure (REMATCH)—was conducted from 1998 to 2001 in 20 centers in the United States. Eligible patients were adults with chronic endstage heart failure and with contraindications to heart failure. One type of vented electric device—the HeartMate LVAD—was selected for the study. This device contains textured internal surfaces, and patients receiving it do not require anticoagulation. Study patients were randomized in a 1:1 ratio to the vented electric system or to optimal medical therapy. The primary endpoint was death from any cause. The trial was designed to enroll 140 patients and to continue until 92 deaths occurred. Secondary endpoints included the incidence of serious adverse events, the number of days of hospitalization, quality-of-life indices, symptoms of depression, and functional status. A total of 129 patients were enrolled, 68 receiving left ventricular assist devices and 61 assigned to undergo optimal medical management. There was a reduction of 48% in the risk of death from any cause in the group that received the left ventricular devices, compared to the medical therapy group ($P=0.001$). The Kaplan–Meier estimates of survival at one year were 52% in the device group and 25% in the medical therapy group ($P=0.002$). At two years, these estimates had dropped to 23% and 8%, respectively ($P=0.09$). Terminal heart failure was the cause of most of the deaths in the medical therapy group, whereas most deaths in the device group were caused by sepsis (41%) and failure of the device (17%). Clearly, in patients ineligible for transplantation, the left ventricular devices offer a superior survival outlook compared to optimal medical therapy.

Unfortunately, despite substantial survival benefit, there was considerable mortality and morbidity associated with the device. Infection was a major limiting factor. Predisposing factors for infection included the status of the percutaneous driveline, malnutrition, and severe preoperative debilitation due to heart failure. Mechanical failure of the device, inflow valve insufficiency, and neurological events were the other major limiting factors. It is apparent that these problems will

have to be addressed before further generalized use of these devices in patients with CHF.

With the AbioCor total artificial heart system, novel power sources, transcutaneous delivery of power with no percutaneous lines, acceptable improvements in device reliability, and a deeper understanding of patient–pump interactions have been advanced. The newer pumps also are expected to be smaller in order to accommodate a wider range of patients, including women and children.

Mechano-Regulation of Fibroblast Function

James H.-C. Wang
Bhavani P. Thampatty

MechanoBiology Laboratory, Departments of Orthopaedic Surgery, Bioengineering and Mechanical Engineering, University of Pittsburgh, Pittsburgh, Pennsylvania, U.S.A.

INTRODUCTION

The human body is subjected to various types of mechanical forces. For example, a state of tension exists naturally in the skin, and mechanical forces generated during motion exert on the tendons and ligaments of joints. The cardiovascular and respiratory systems are organ systems that are constantly subjected to mechanical forces; varying levels of tensile, compressive, and shearing stresses because of blood flow in the cardiovascular system and air flow in the respiratory system constantly act on blood vessels and the lining of the lungs. As a result of their dynamic environment, cells in the skin, tendons, ligaments, blood vessels, and lung respond to mechanical forces by altering gene expression and the levels of protein secreted, which lead to changes in the extracellular matrix (ECM) and eventually in the tissue structure and function. These cells are referred to as mechano-responsive cells.

A major type of mechano-responsive cells in the human body is the fibroblast, which is a mesenchymal cell that plays an essential role in maintaining, repairing, and remodeling cardiac and lung tissues, as well as other connective tissues including the skin, tendons, and ligaments. This entry will review the mechano-regulation of fibroblast function, with a focus on the effects of mechanical forces on ECM gene expression and protein synthesis. In addition, the interactions of mechanical loads with growth factors and cytokines in terms of their effects on the ECM and tissue engineering constructs will be presented. This will be followed by a discussion of cellular mechano-transduction mechanisms by which mechanical forces are transduced into a cascade of cellular and molecular events, and the discussion will conclude with the authors' views on future research directions in the area of fibroblast mechano-biology.

MECHANO-REGULATION OF GENE EXPRESSION IN FIBROBLASTS

Fibroblasts in cardiac, lung, and connective tissues are responsible for the production of ECM proteins, including different types of collagens, elastin, fibronectin,

and proteoglycans. All these matrix components provide for the structural and functional integrity of the tissue. In addition, fibroblasts secrete various soluble factors, including hormones [e.g., insulin-like growth factors I and II (IGF-I and IGF-II)], growth factors [e.g., transforming growth factor- β (TGF- β), platelet-derived growth factor (PDGF), fibroblast growth factor (FGF), endothelial growth factor (EGF), and connective tissue growth factor (CTGF)], and cytokines [e.g., interleukin-1 (IL-1) and tumor necrosis factor- α (TNF- α)].^[17,18] These factors modulate many cellular functions such as DNA synthesis, protein secretion, cell migration, and differentiation.^[19] They also play an essential role in tissue wound healing.^[20]

Fibroblasts are subjected to various forms of mechanical loading that regulate their functions. To study the mechano-regulation of fibroblast function in a controlled environment, several cell loading systems have been developed.^[21,22] These devices make use of flexible substrates with smooth culture surfaces, such as silicone elastomer coated with ECM proteins to which the cells are attached. Cyclic biaxial strains are applied by stretching the substrate in two orthogonal directions. When equibiaxial stretches are applied, the substrate strains transmitted to the cell are the same in all directions; however, when non-equibiaxial stretches are applied, the substrate strains change with the cell's orientation with respect to the stretching direction. As a result, the strains that cells experience depend on their orientations (Fig. 1A). On the other hand, cyclic uniaxial strains can also be applied by stretching the substrate in one direction, and as a result, the substrate is lengthened in the stretching direction whereas it is shortened in its perpendicular direction (Fig. 1B). Again, the strains that cells experience are cell orientation dependent. In both cases of stretching, the strain level ranges from 1% to 30%, and the strain rates commonly vary from 0.1 to 10 Hz.^[23]

Besides stretching fibroblasts on the substrates with smooth surfaces, a microgrooved silicone substrate coated with ProNectin-F, an engineered fibronectin-like protein, has also been used.^[24,25] When tendon fibroblasts in the microgrooved substrate are subjected to uniaxial stretching, they assume an elongated shape and are oriented in the direction of stretching,

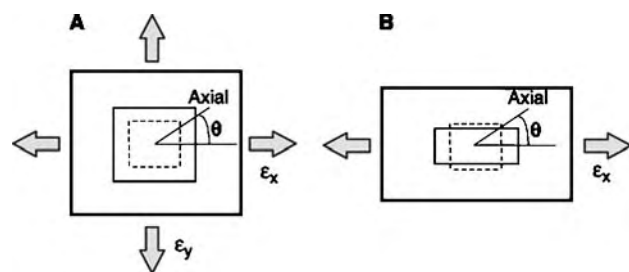

Fig. 1 The application of biaxial stretching and uniaxial stretching to fibroblasts. (A) Biaxial stretching. There are two cases of biaxial stretching: One is the equibiaxial stretching conditions, where $\epsilon_x = \epsilon_y$; the other is the non-equibiaxial stretching, where $\epsilon_x \neq \epsilon_y$. Under the equibiaxial stretching, the surface strains do not change with the orientation, θ . Therefore, the cells on the surface are subjected to the same strains, regardless of their orientation with respect to stretching direction. However, under non-equibiaxial stretching, surface strains change with the orientation, θ . In other words, the cells on the surface are subjected to different levels of surface strains, depending on their orientation. (B) Uniaxial stretching. Under uniaxial stretching, surface strains change with the orientation, θ . This means that cells with different orientation are subjected to different levels of surface strains.

mimicking the alignment and loading conditions of tendon fibroblasts in vivo (Fig. 2).

Fibroblast-populated collagen gels (FPCGs) are also suitable in vitro cell culture models to study the response of cells to mechanical forces.^[26,27] Three-dimensional collagen gels provide improved maintenance of cell morphology and phenotype, which create an environment for studying fibroblast response to mechanical loading that more closely mimics the in vivo environment. The FPCG is maintained in a culture dish with growth medium, and fibroblasts in it generate contraction (Fig.3). As a result, the FPCG is under tension if its bottom is attached to the dish, or if its two ends are held in place. However, when the

Fig. 2 The application of cyclic uniaxial stretching to tendon fibroblasts in a microgrooved substrate. It is seen that tendon fibroblasts in the microgrooves are elongated and aligned in the direction of the microgrooves, which is also the stretching direction. The advantage of this type of stretching is that one can control the alignment and mechanical stretching conditions of tendon fibroblasts to mimic their in vivo organization and loading conditions.

Fig. 3 The tension in the FPCG. Fibroblasts in the gel generate contraction, so that the gel changes from rectangular to a parabolic shape (arrow). Note that tension is maintained by holding two ends of the gel in place. Once the ends are released, the tension disappears, such as in the case of a floating gel in medium. When this occurs, the cells in the gel are in the stress-free state.

FPCG is detached, it floats in the medium, and all tension is released. Besides internal tension generated in FPCGs, external loading can also be applied to the FPCGs.^[28-30]

In response to mechanical loads, fibroblasts alter DNA synthesis, the expression of ECM genes and proteins, and activation of signaling molecules (Table 1). For example, cyclic and static uniaxial stretching of cardiac fibroblasts increased both collagen III mRNA expression and the ratio of collagen III to collagen I.^[31] Cyclic mechanical stretching also significantly elevated the procollagen I mRNA levels of these cells^[32] as well as collagen I mRNA expression and protein secretion.^[2] These results are consistent with the fact that cardiac hypertrophy through mechanical loading is accompanied by an increase in the deposition of ECM proteins.^[33]

Also, mechanical stretching in cardiac fibroblasts was found to regulate collagen type III and fibronectin mRNA levels and TGF- β 1 activity in a stretching magnitude-dependent manner.^[1] A 10% stretching magnitude significantly increased mRNA expression levels of collagen type III and fibronectin while collagen I mRNA only increased slightly. However, a 20% stretching magnitude decreased collagen type III and fibronectin mRNA levels while collagen I did not change significantly. Similarly, equibiaxial strain also caused up- or down-regulation of specific ECM genes, where the genes affected depended on the magnitude of stretching applied. For instance, 3% equibiaxial strain increased both collagen III and fibronectin mRNA levels, whereas a 6% strain decreased collagen III mRNA levels but did not create a significant change in fibronectin levels compared to the unstretched control. In addition, both low and high levels of compressive equibiaxial strains decreased fibronectin mRNA levels,^[1] suggesting that cardiac fibroblasts show a differential response to tensile and compressive strains in terms of their ECM gene expression and protein synthesis.

Table 1 Mechano-regulation of fibroblast function

Cells	Response	Type of load	Substrate	Significance	References
Cardiac fibroblasts	Increase in collagen type III and fibronectin mRNA levels and TGF- β 1 activity	Cyclic uniaxial and biaxial stretch, 10% and 3%, respectively	Collagen type I coated	Differential response to different stretching magnitudes and types of loading (stretching vs. compression)	[1]
	Decrease in collagen III and fibronectin mRNA	Cyclic uniaxial stretch, 20%			
	Decrease in collagen III mRNA, no change in fibronectin mRNA	Cyclic biaxial stretch, 6%			
	Decrease in fibronectin mRNA, no significant change in collagen III mRNA	Compressive equibiaxial strain, 3–6%			
Cardiac fibroblasts	Increase in collagen III mRNA	Cyclic uniaxial stretch, 5%	Laminin coated	Substrate specific response	[2]
	Mitogen-activated protein kinase (MAPK) activation, increase in collagen-I mRNA	Cyclic uniaxial stretch, 5%	Randomly organized collagen and uncharged silastic membrane		
Cardiac fibroblasts	Increase in procollagen mRNA	Cyclic equibiaxial stretch, 20%	Elastin coated	Synergistic stimulation by load and growth factors	[3]
Lung fibroblasts	Increase in procollagen mRNA and protein	Cyclic biaxial stretch, 20%	Elastin and laminin coated	Matrix protein specific response	[4]
	Decrease in procollagen mRNA	Cyclic biaxial stretch, 20%	Fibronectin coated		
Dermal fibroblasts	Increase in α (I) collagen mRNA and matrix metalloproteinase-1 (MMP-1) mRNA	Cyclic biaxial and static stretch, 20%	Collagen type I coated vs. plastic dish	Substrate and strain specific gene regulation	[5]
Dermal fibroblasts	Increase in tenascin-C mRNA and protein	Cyclic equibiaxial stretch, 10%	Fibronectin coated	Additive effect with growth factors; requirement of Rho-ROCK signaling for strain-induced effects	[6]
Dermal fibroblasts	Cell alignment, orientation toward stretching direction and increase in β 1-integrin and collagen I mRNA	Cyclic uniaxial stretch, 10%	Smooth surface vs. microgrooved surface	Surface topography based response	[7]
Tendon fibroblasts	DNA synthesis stimulation	Cyclic biaxial stretch, 5%	Collagen type I coated	Synergistic action of growth factors and mechanical load	[8,9]
Tendon fibroblasts	Stimulation of collagen type I and TGF- β 1 gene expression	Cyclic uniaxial stretch, 8%	ProNectin-F coated and microgrooved	TGF- β 1 mediated response to load	[10]

(Continued)

Table 1 Mechano-regulation of fibroblast function (*Continued*)

Cells	Response	Type of load	Substrate	Significance	References
Tendon fibroblasts	Increase in MMP-1 and MMP-3 mRNA	Cyclic biaxial stretch, 5%	Collagen type I coated	Matrix degradation initiation by synergistic effect of cytokine and mechanical load	[11]
Ligament [anterior cruciate ligament (ACL)] fibroblasts	Increase in collagen I and III mRNA, and TGF- β 1 protein	Cyclic uniaxial stretch, 10%	Collagen type I coated	TGF- β 1 mediated response	[12]
Ligament [ACL and medial collateral ligament (MCL)] fibroblasts	Increase in collagen I mRNA with no change in collagen I (ACL), increase in collagen III with no change in collagen I mRNA	Cyclic equibiaxial stretch, 5%	Collagen type I coated	Differential response to different cell source	[13]
Ligament (ACL) fibroblasts	Increase in collagen synthesis, cell alignment in the direction of stretch	Cyclic uniaxial stretch, 5%	Aligned nanofiber sheets	Surface material and topography specific response	[14]
Ligament (periodontal) fibroblasts	Increase in collagen I and fibronectin synthesis, decrease in tropoelastin synthesis	Cyclic equibiaxial stretch, 5%	Collagen type I coated	Differential ECM protein synthesis in response to specific magnitudes of stress	[15]
Ligament (periodontal) fibroblasts	No change in collagen I synthesis, increase in fibronectin synthesis, decrease in tropoelastin synthesis	Cyclic equibiaxial stretch, 10%			
Ligament (periodontal) fibroblasts	Decrease in collagen I and fibronectin protein, increase in MMP-2 and no change in tissue inhibitor of metalloproteinase-2 (TIMP-2) mRNA	Cyclic compressive force, 10%	Collagen type I coated	Differential ECM synthesis and degradation in response to different types of mechanical load	[16]
Ligament (periodontal) fibroblasts	Increase in collagen I protein, no significant increase in fibronectin synthesis, increase in MMP-2 and TIMP-2 mRNA	Cyclic equibiaxial stretch, 10%			

Furthermore, synergistic stimulation of procollagen gene expression by mechanical loading and growth factors was observed. Tensile mechanical loading of cardiac fibroblasts in combination with IGF-I was shown to stimulate procollagen mRNA levels three fold compared with that of IGF-I treatment alone. Also, a combination of tensile mechanical loading and TGF- β increased procollagen α_1 (I) (*COL1A1*) mRNA levels 4.3-fold compared with that of TGF- β treatment alone.^[3] The strain-induced *COL1A1* promoter activation in cardiac fibroblasts is TGF- β dependent, suggesting a novel TGF- β response element in the *COL1A1* gene.^[34]

The response to mechanical load also depends on the composition of the ECM in cardiac fibroblasts. In vitro studies have shown that different ECM components (underlying ECM substrates) modify cardiac fibroblast activity differently during mechanical stretch. For example, stretched cardiac fibroblasts cultured on silastic membrane coated with different ECM substrates (i.e., aligned collagen, randomly organized collagen, fibronectin, laminin, and charged membrane) responded differently in terms of cell morphology, proliferation, collagen production, and cell signaling.^[17] In cells stretched on randomly organized collagen and uncoated charged membrane, mitogen-activated protein (MAP) kinase was most rapidly activated, and collagen I mRNA expression was most abundant. Decrease in cell proliferation was observed in stretched cells regardless of the nature of the ECM substrate; however, the decrease was most marked in cells stretched on randomly organized collagen. Finally, cells stretched on all ECM substrates increased their surface area, but the most significant increase was noted in cells adherent to aligned collagen, randomly organized collagen, and uncoated charged membrane compared to the membrane coated with fibronectin or laminin.

Similar to cardiac fibroblasts, lung fibroblasts are also mechano-responsive cells that alter procollagen gene expression in response to changes in mechanical tension.^[4] The mechano-response of lung fibroblasts appears to depend on ECM proteins because cells cultured on elastin or laminin, but not on fibronectin, increased procollagen gene expression.^[4] Furthermore, mechanical stress in FPCGs regulates gene expression of collagen α_2 (I) and collagen α_1 (III).^[35] Also, mechanical stress in conjunction with TGF- β induces a high level of CTGF, which is known to influence the synthesis of ECM proteins.^[35] Hence, it is likely that this growth factor is responsible for the increased synthesis of collagen and other ECM proteins in stressed fibroblasts. Besides CTGF, PDGF released by mechanically loaded lung fibroblasts also stimulates procollagen production.^[36]

Mechanical forces as regulators of ECM synthesis have been the subject of various studies in dermal

fibroblast monolayer as well as in FPCGs. When subjected to biaxial stretching in the presence of serum or TGF- β 1, these cells increased procollagen α_1 (I) mRNA expression.^[37] Also, both static and cyclic stretching of dermal fibroblasts cultured on silicone substrate increased α_1 (I) collagen mRNA expression^[5] and tenascin-C mRNA and protein levels.^[6] In addition, cyclic stretching of cells on silicone membranes at low frequencies increased the MMP-1 mRNA level whereas expression remained low in cells cultured on plastic dishes or stressed collagen gels.^[5] The results suggest that the type of stress (cyclic vs. static) as well as the substrate properties can influence the gene expression of dermal fibroblasts.

Furthermore, mechano-responsive genes encoding ECM proteins [collagen α_1 (I) and tenascin-C], growth factors, protease inhibitors, components of focal adhesions, and the cytoskeleton in dermal fibroblasts in mechanically stressed collagen gels have been identified by microarray technology and confirmed by Northern blot hybridization.^[5] This study demonstrated that cells adapt to mechanical stress by modulating the transcription of various genes and reorganizing their intracellular structures. The application of tension leads to an increase in the transcription of genes that are involved in cell proliferation.

The combined effect of mechanical stretching and soluble factors on the ECM synthesis has also been studied. Cyclic tensile strain and growth factors, such as TGF- β 1 and PDGF, increased tenascin-C mRNA expression in an additive manner,^[6] and a mechano-responsive regulatory sequence in the promoter of tenascin-C gene has been identified.^[38] This mechano-responsive sequence enables a mode for tightly regulating the cell's response to mechanical forces.

Interestingly, neonatal and adult dermal fibroblasts displayed a differential response to varying strain patterns in terms of cell proliferation and collagen synthesis.^[29,30] Neonatal cells were significantly stimulated in response to uniaxial strain but were unaffected by non-uniform and biaxial strains. Similarly, uniaxial strain stimulated adult fibroblast proliferation, but the other two strain patterns inhibited cell proliferation. Collagen synthesis in neonatal cells also increased slightly by uniaxial strain while synthesis in adult cells was significantly inhibited.

Additionally, in dermal fibroblasts, the topography of a substrate surface has been shown to influence cell shape, spreading, and orientation under mechanical stretching.^[29] Cells stretched on microgrooved surfaces were better aligned along the groove direction while cells on smooth surfaces were oriented randomly.

Fibroblasts are the dominant cell type in connective tissues, where they respond to mechanical forces by changing their expression of several ECM proteins including collagen type I.^[39] Mechanical stretching also

modulated the secretion of growth factors such as TGF- β 1, PDGF, and bFGF in human tendon fibroblasts, which may stimulate cell proliferation, differentiation, and matrix formation.^[40] In the presence of PDGF and IGF-I, mechanical loading stimulated DNA synthesis in tendon fibroblasts.^[8,9] Moreover, cyclic mechanical stretching significantly stimulated collagen type I and TGF- β 1 gene expression and protein secretion in the absence of serum. In addition, anti-TGF- β antibody eliminated the elevated collagen type I production, which suggests that TGF- β 1 mediates stretch-induced collagen type I production in tendon fibroblasts.^[10] Furthermore, using micro-grooved deformable substrates, the fibroblast response to mechanical stretching was shown to depend on cell orientation with respect to stretching direction because they expressed higher levels of smooth muscle actin (α -SMA) when they were stretched parallel to their long axes compared to stretching perpendicular to the long-axis direction.^[41] In addition, mechanical stretching of tendon cells in the presence of IL-1 β induced the gene expression of matrix-degrading enzymes such as MMP-1 and MMP-3, suggesting that when an inflammatory mediator such as IL-1 β is present, mechanical loading has catabolic effects on cells, which may eventually lead to tendon matrix degeneration.^[11] A recent study further showed that 4% cyclic uniaxial stretching of human tendon fibroblasts decreased the cyclooxygenase-2 (COX-2) and MMP-1 gene expression and prostaglandin E₂ (PGE₂) production that were stimulated by IL-1 β (10 pM); however, a 8% stretching further increased these gene expression and PGE₂ production in addition to the effects of IL-1 β stimulation. Therefore, the study suggests that repetitive, small-magnitude stretching is anti-inflammatory, whereas large-magnitude stretching is proinflammatory.^[42]

Similar to tendon fibroblasts, ligament fibroblasts also respond to mechanical loading by altering ECM gene expression. Mechanical stretching increased collagen types I and III mRNA expression in human ACL fibroblasts^[12] and increased the secretion of TGF- β 1 protein. This increase was ablated by anti-TGF- β 1 antibody, which suggests that the stretch-induced collagen expression is mediated via an autocrine mechanism of TGF- β 1.^[12] In addition, the ACL and MCL fibroblasts exhibited a differential response in the collagen mRNA induction to equibiaxial strain.^[13] In response to cyclic strains, ACL fibroblasts increased the expression levels of collagen type I mRNA with no apparent changes in type III mRNA. MCL fibroblasts, however, exhibited a significant increase in collagen type III but not in collagen type I mRNA. The effect of mechanical loading on gene expression has also been studied in an organ culture system, where an increase in collagen I mRNA expression was found when the

ACL was subjected to mechanical loading.^[43] Similar to the differential responses in collagen gene expression, differential responses in terms of MMP-2 protein expression due to biaxial stretching were also observed in ACL and MCL fibroblasts.^[44] Although both ACL and MCL fibroblasts induced MMP-2 within 72 hr after stretching, ACL fibroblasts produced significantly more pro-MMP-2 protein than MCL fibroblasts. Thus, mechano-regulation of gene and protein expression appears to depend on the source of fibroblasts.

Furthermore, mechanical stretching of ACL fibroblasts aligned on nanofibers in the direction of mechanical strain affected the ECM production.^[14] More collagen was produced in cells on aligned nanofiber sheets than on randomly oriented sheets when subjected to mechanical stretching. Also, an *in vitro* bioreactor was used to test the effect of stretching and alignment of MCL fibroblasts on the intracellular calcium concentration response to mechanical stretching.^[45] The cells that were both aligned and subjected to mechanical stretching propagated a calcium wave better than cells that were aligned, but not subjected to stretching.

Besides ACL and MCL fibroblasts, the effect of mechanical loading on expression patterns of ECM proteins and matrix-degrading enzymes has also been noted in periodontal ligament (PDL) fibroblasts. These cells exhibited differential expression patterns of ECM proteins in response to varying mechanical loads. For instance, PDL fibroblasts subjected to 5% biaxial strain exhibited a significant increase in the synthesis of collagen type I and fibronectin and a decrease in tropoelastin.^[15] Similarly, a 10% strain also increased the fibronectin synthesis and decreased the tropoelastin synthesis. However, at this strain level, collagen type I protein levels did not differ from that secreted by control cells. The differential synthesis of collagen I observed at 5% and 10% strain may be because of the differential effect of mechanical loading on genes encoding collagens and collagenases. Furthermore, these cells exhibited differential synthesis of ECM proteins such as collagen I and fibronectin and MMP-2 and TIMP-2 mRNA when subjected to different loading conditions: tensile and compressive.^[16] In addition, mechanical unloading of PDL fibroblasts in the free floating gel model was shown to decrease the collagen content and increase the activity of MMP-2 and MMP-9.^[46]

MECHANO-REGULATION IN TISSUE ENGINEERED CONSTRUCTS

As in native tissues such as tendons and ligaments, mechanical forces also regulate the functionality of

tissue engineered constructs.^[47] In cardiac cells in gelatin-matrix scaffolds, for instance, the application of cyclic stretching stimulated the formation and organization of the ECM.^[48] Also, the application of unidirectional mechanical stretching generated highly differentiated cardiac tissue constructs from neonatal rat cells.^[49,50]

Furthermore, in collagen gels seeded with dermal fibroblasts, the application of cyclic strain, superimposed on a preload, can have both anabolic and catabolic effects on cells.^[29,30] Cyclic strain superimposed on preloads of 2 and 10 mN increased cell proliferation compared with that of the just preload alone. However, enhanced collagen synthesis in response to cyclic strain was observed only in collagen gel constructs preloaded at 2 mN, implying that the preload level is an important factor to be considered in engineering functional tissue constructs. In addition, the cyclic strain on the cell-seeded constructs induced both active and latent MMPs on a 10 mN preload, but not on 2 mN. The data demonstrate that cyclic strain can shift fibroblasts to a more active catabolic state, depending on the level of the initial preload.

Tendons and ligaments are two other prime candidates for the development of engineered tissue constructs. A novel system for engineering bioartificial tendons (BATs) via the application of mechanical loading on cells cultured on collagen gels has been developed.^[51] The application of mechanical strain greatly enhanced the mechanical properties of BATs by increasing the deposition of ECM components such as collagens I, III, and XII, as well as aggrecan, fibronectin, and tenascin. Furthermore, cells in BATs aligned with the principal strain direction assumed the morphology of fascicles of the whole tendon. In addition, mechanically loaded BATs gained an ultimate tensile strength that was three fold greater than that of unloaded BATs. Similarly, using a bioreactor system to engineer ligaments from mesenchymal stem cells,^[52] mechanical loading for two weeks was found to induce cell alignment in the direction of the force and increase the expression of ligament specific markers such as collagens I, III, and tenascin-C. Taken together, these studies show that mechanical loading regulates specific phenotype expression of cells in tissue engineered constructs, and that dynamic forces may be essential to the engineering of tissue constructs with mechanical properties suitable for implantation.

CELLULAR MECHANO-TRANSDUCTION

The effects of mechanical forces on fibroblasts are now well recognized; however, the cellular mechano-transduction mechanisms (Fig. 4) by which cells sense and respond to mechanical forces to undergo a cascade

Fig. 4 A conceptual illustration of cellular mechano-transduction mechanisms. Mechanical forces can induce signal transduction by directly transmitting forces to the cytoskeleton and nucleus. As a result, transcription and translation occur. Also, mechanical forces can unfold a domain of the extracellular protein (M) and expose a cryptic site that may serve as an activating ligand for a cell surface receptor, which results in a series of signaling events. Also, mechanical force applies to a “force receptor” (FR), such as integrins and G proteins, and then initiate signal transduction, which results in transcription, followed by translation. This may result in the secretion of soluble factors into ECM, and a soluble factor in turn acts on the receptor (R) and then initiates a cascade of signaling events.

of cellular and molecular events (e.g., ECM synthesis and cell differentiation) are only beginning to be understood. One model of cellular mechano-transduction mechanisms is “hard wired.”^[53,54] In this model, mechanical forces applied to the cell membrane are directly and immediately transmitted to the nucleus through the interconnected cytoskeleton composed of actin filaments, microtubules, and intermediate filaments. Previous studies with various cell types have shown that the application of a mechanical stress to integrins can alter the cytoskeleton and activate signal transduction and gene expression in a stress-dependent manner.^[55–57] Therefore, integrins are likely the force receptors and transducers.^[58] Cellular mechano-transduction, however, may also involve intracellular second messengers that are similar to those from chemical stimuli.^[59] Mechanical stresses, for instance, elevate cytoplasmic Ca^{2+} concentration,^[60,61] which is known to activate Ca^{2+} -responsive proteins, such as protein kinase C, CAM kinase (calcium/calmodulin-dependent kinase), and their downstream transcription factors [e.g., cyclic adenosine monophosphate response element-binding protein (CREB)].^[62]

While many intracellular molecules such as Ca^{2+} and protein kinases^[63] for cellular mechano-transduction have been identified, how mechanical force is initially sensed is still not clear. Candidates for the “force sensor” may include extracellular proteins. In response to mechanical stress, a domain of the extracellular protein might unfold and expose a cryptic site that may serve as an activating ligand for an adjacent

receptor.^[59] This possibility is supported by the fact that a smaller force (80 pN) and a larger force (200 pN) unfold the weakest domain and the most stable domain of fibronectin, respectively.^[64] Also, the direct activation of a transmembrane protein such as an integrin by force can occur, where the transmembrane protein may undergo a conformational change when the force is transmitted from the ECM to the protein. A mechanical force can then be transmitted via cytoskeleton to the nucleus, inducing the transcription and synthesis of a nuclear factor that transactivates a specific ECM gene.^[65] For example, the transcription factor early growth response-1 (EGR-1) and growth factor PDGF-B are regulatory genes that can be directly activated by mechanical stress.^[66,67] All ECM genes with EGR-1 binding sites in their promoters are targets for activation.

Mechanical forces, however, may also indirectly induce synthesis and secretion of growth factors (e.g., TGF- β), which in turn bind to a cell surface receptor, ultimately regulating ECM gene and protein expression, just as chemical stimuli act on a cell. Cyclically stretched fibroblasts, for instance, secrete active TGF- β , which then induces the expression of the procollagen α_1 (I) gene.^[34] Similarly, tensile stress regulates CTGF transcription and secretion.^[35] Other examples of autocrine feedback loops in response to mechanical stress include PDGF,^[68] IL-4,^[69] and adenosine triphosphate.^[70] All these factors may exert their effects on the cell through ligand-receptor binding and result in multimolecular events in an autocrine fashion. Thus, cellular mechano-transduction likely involves a mechano-electrochemical sensory system,^[32,33] including integrin-cytoskeleton machinery, load-conformation sensitive receptors, and mechanically sensitive ion channels.

Note that the description given here is meant to provide a general discussion of cellular mechano-transduction. For a detailed, more in-depth discussion of mechano-transduction in fibroblasts, interested readers should consult existing excellent reviews.^[60,71,72]

CONCLUSIONS

Fibroblasts in cardiac, lung, and connective tissues such as skin, tendons, and ligaments are mechano-responsive cells. In response to mechanical loads, these cells change gene expression and secrete proteins into the ECM, thereby maintaining, repairing, and remodeling these tissues. Determining the mechano-effects of fibroblasts is essential for a better understanding of the physiology and pathology of the various tissues, not to mention their wound healing mechanisms. In addition, the combined effects of

mechanical forces with soluble factors on fibroblasts should be further investigated, because the findings may provide clues to positive and negative cellular responses that are physiological under one set of mechanical loading conditions, but pathophysiological under another. It should be noted that while this review emphasizes the common mechano-responses of fibroblasts, these cells are actually a heterogeneous group,^[73] and their response to mechanical loads likely depend on species, tissue type, and anatomic location.^[74]

More importantly, however, it is necessary to further our understanding of cellular mechano-transduction mechanisms by which these cells sense and respond to mechanical forces. To this end, researchers in the area of fibroblast mechano-biology will face the challenge of developing novel experimental techniques and theoretical models to determine the type and magnitude of forces experienced at the cellular and subcellular levels. It is equally challenging to identify specific “force receptors” or “force sensors,” of which specific proteins at the membrane-cytoskeletal interface (e.g., integrins^[53,58] and G proteins^[75,76]) are good candidates. Ultimately, additional research in the area of fibroblast mechano-biology will aid in designing new approaches to engineer tissue constructs as well as to develop new therapeutic strategies for enhanced tissue repair.

Wallace H. Coulter Department of Biomedical Engineering, Georgia Institute of Technology
and Emory University, Atlanta, Georgia, U.S.A.

INTRODUCTION

Medical imaging technology has come a long way since its beginnings in 1895 with Röntgen's discovery of X rays and their ability to image structures in two dimensions within the body. Many modern imaging technologies are capable of acquiring, displaying, and manipulating imagery in three dimensions to aid in the diagnosis and treatment of disease and injuries. This article describes the instrumentation of a number of three-dimensional (3-D) imaging technologies commonly used in the practice of medicine, together with a description of the image processing and analysis techniques that aid in the interpretation of the imagery produced by these technologies.

MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging (MRI) is an imaging technique used to produce images of structures inside the body. It is based on the principles of nuclear magnetic resonance (NMR), a standard spectroscopic technique used to obtain chemical and physical information about molecules.^[1] The nucleus of atoms with an odd atomic number or an odd number of neutrons can be detected using NMR techniques. There are many such atoms in the body, but for the purposes of MRI, the hydrogen atom (which consists of a single proton) is of primary interest due to its large magnetic moment. Largely inspired by Lauterbur's development in 1972^[2] of the spatial encoding principles used to form images from NMR data, Kumar, Welti, and Ernst devised a two-dimensional (2-D) Fourier transform approach using field gradient pulses and phase encoding to form the modern foundation for MRI instrumentation.^[3] Such instrumentation is used to acquire multidimensional image data sets in which the contrast is a function of the density, distribution, and relaxational properties of hydrogen protons within the region of the body being imaged. MRI is used to image both structures and function within the body.

Magnetic resonance imaging systems in clinical use today consist of the following components: 1) a magnet

and shim coils to generate a static homogeneous magnetic field with a field strength typically in the range of 0.2 to 3 T; 2) a coil to transmit radiofrequency (RF) signals into the body; 3) a receiver coil to detect the RF signals transmitted by the hydrogen nuclei; 4) gradient coils to provide spatial localization of the RF signals; 5) a computer to control the system timing and reconstruct the RF signals into the image; and 6) a video display system. An example of such a system is illustrated in Fig. 1.

Magnetic resonance imaging systems have a number of attractive features for medical imaging applications. They can generate 2-D sectional images at a variety of orientations, 3-D volumetric images, or four-dimensional (4-D) images representing spatial-spectral distributions, all without any mechanical movement of the instrumentation.^[4] Unlike single photon emission computed tomography (SPECT) and positron emission tomography (PET), MRI does not require injection of radioisotopes. In addition, the imaging process involves the use of RF energy that lies in the nonionizing region of the electromagnetic spectrum.

X-RAY COMPUTED TOMOGRAPHY

The introduction of X-ray computed tomography (CT) in the early 1970s was one of the most profound developments in the field of medical imaging since the time of Röntgen.^[5,6] X-ray CT involves generating X-ray photons, exposing the body to them, detecting and digitizing those photons that are transmitted through the body, and tomographically reconstructing the digitized data to form an image. The function being imaged is the distribution of the linear attenuation coefficient within the body. The logarithm of the ratio of intensities of the generated and transmitted photons is proportional to the integral of the attenuation coefficient along the path. Contrast in X-ray CT is thus dependent on the spatial differences in the attenuation coefficient, which is strongly correlated to tissue density. X-ray CT is primarily used to image structures within the body. However, with high-speed systems and the introduction of contrast agents, it may also be

Fig. 1 Varian 3T magnetic resonance imaging system.

used to image functional changes in organs, such as blood flow rate.

X-ray CT systems in clinical use today typically consist of the following components: 1) a gantry containing a fan-beam X-ray source and a circular array of 600 to 4800 (depending on the manufacturer) independent X-ray detectors that surrounds the patient; 2) a table on which the patient lies that may be translated through the hole in the center of the gantry; 3) a computer for controlling the image acquisition parameters and for reconstructing the image; and 4) a video display system. In fourth-generation systems, the X-ray source is an X-ray tube that is rotated 360 degrees around the patient to acquire multiple projections needed to reconstruct the image. In fifth-generation systems, a high-energy electron beam is electronically scanned along a tungsten strip anode to produce the fan beam of X-rays without mechanical rotation of any component. With these fifth-generation systems, projection data can be acquired fast enough to image the beating heart without significant motion artifacts. Spiral scanning systems, consisting of fourth-generation systems that acquire projection data while the patient is translated through the gantry in a continuous motion, also can be used to image moving structures. An example of an X-ray CT system is shown in Fig. 2.

NUCLEAR TOMOGRAPHIC IMAGING

This is a class of nuclear medicine imaging techniques that utilize tomographic reconstruction methods to image the nuclear radiation emitted from radiopharmaceuticals that have been ingested, inhaled, or

Fig. 2 GE CT/i™ x-ray computed tomography system.

injected into the body. This radiation is in the form of either high-energy gamma rays or positrons, which travel very short distances before they annihilate to produce two 511 KeV photons. This differs from X-ray CT in that the emission source, not the attenuation, is measured. There are two different types of nuclear tomographic imaging techniques: single photon emission computed tomography (SPECT) and positron emission tomography (PET). Both of these techniques are used to image function, not structure. For example, in cardiology applications, with the appropriate radiopharmaceutical (e.g., ^{99m}Tc and FDG) these techniques can be used to measure perfusion in the myocardium.

Single Photon Emission Computed Tomography (SPECT)

The SPECT method was initially investigated by Kuhl and Edwards in 1963 prior to the development of X-ray CT, PET, or MRI.^[7] In a manner similar to X-ray CT, SPECT requires the rotation of a gamma-ray photon detector array around the body to acquire projection data from multiple angles. SPECT systems in clinical use today typically consist of the following components: 1) single or dual photon detector arrays (aka gamma cameras), each with its own collimator; 2) gantry for rotating the camera(s); 3) table on which the patient lies that is positioned in the center of the gantry; 4) computer for controlling the image acquisition parameters and for reconstructing the image; and 5) video display system.

The image reconstruction task for SPECT is far more challenging than for X-ray CT because the emission sources are at unknown positions and densities inside the body. The problem is compounded by the need to use a collimator to acquire projection data, which rejects all photons that are not at a particular

Fig. 3 (top) ADAC Vertex™ dual-head SPECT imaging system; (bottom) normal SPECT myocardial perfusion images.

trajectory angle, thus resulting in a low detection efficiency. Losses due to attenuation of the photons in the body further reduce the obtainable resolution. The latter losses can be partially compensated for during the reconstruction process.^[8] The typical resolution achievable by SPECT systems is on the order of 7 to 15 mm. An example of a SPECT system and typical images are shown in Fig. 3.

Positron Emission Tomography (PET)

The development of computed tomography concepts in the early 1970s spurred the development of the early PET systems.^[9] PET has several inherent advantages over SPECT. First, no collimator is required because the pair of detected 511 KeV gamma-ray photons produced when the positron is annihilated travel along the same line and thus can be traced back to their origin. Second, higher energy photons experience less attenuation, and the attenuation that does occur can

be more easily corrected for compared to SPECT. Third, PET does not require the mechanical rotation of gamma cameras around the patient. Instead, modern PET systems encircle the patient with photon detectors that are electronically coupled in such a manner as to discriminate the coincident detection of the two photons from individual annihilation events. The resolution achievable by this detector system is limited primarily by the uncertainty associated with the path length of the positron prior to annihilation. These advantages are the primary reasons why PET is capable of achieving resolutions three to four times better than SPECT. Although SPECT imaging resolution is inferior to that of PET, the cost of a typical SPECT imaging procedure is currently a factor of two to three times lower than the cost of similar PET procedures. In addition to its higher cost, PET requires the use of radiopharmaceuticals with extremely short half-lives, requiring a close proximity to a particle accelerator. An example of a PET system and typical images are shown in Fig. 4.

Fig. 4 (top) GE Medical Systems Discovery LS™ with PET and CT imaging capabilities; (bottom) PET whole-body images.

Fig. 5 Philips Integris™ 3-D rotational angiography system.

OTHER CLINICAL 3-D IMAGING TECHNOLOGIES

Although MRI, PET, SPECT, and X-ray CT are the most pervasive 3-D imaging technologies used in clinical settings today, a number of others are worth noting. Three-dimensional imaging can be performed with ultrasound using either mechanical scanning of one-dimensional (1-D) array transducers or through electronic scanning of 2-D array transducers.^[10] Electrical impedance tomography has received considerable attention in the research community, but has found only limited clinical utility to date.^[11] Angiography systems have been developed with solid-state digital X-ray detectors mounted on rotating C-arms, as shown in Fig. 5, to provide 3-D insight into vascular pathologies.^[12]

MEDICAL IMAGE PROCESSING AND ANALYSIS

The development of medical image acquisition techniques has provided some of the most effective diagnostic tools in medicine. These systems are also used for surgical planning and navigation, as well as for imaging in biology. Two-, three-, and higher-dimensional images contain vast amounts of data that need to be interpreted in a timely, accurate, and meaningful manner to benefit clinical and research applications. To assist in interpretation of biomedical images, a number of automated and semiautomated image processing and analysis techniques have been developed.^[13] This overview presents the most standard methods used in interpretation of 3-D medical images: segmentation, registration, and visualization. In addition, a brief summary of other methods is given at the end.

SEGMENTATION

Image segmentation is the partitioning of an image into regions that are homogeneous with respect to one or more characteristics or features.^[13,14] In medical applications, image segmentation is important for feature extraction, shape analysis, image measurements, and image display. There is no one standard segmentation method that can be successfully used in all imaging applications. Rather, a variety of segmentation techniques have been proposed, many of which are application-specific.^[17-19] A recent overview of medical image segmentation methods has been published.^[33] An example of 3-D medical image segmentation is illustrated in Fig. 6.

Image segmentation methods can be classified in several ways:^[13]

- Manual, semiautomatic, and automatic.
- Pixel-based (local methods) and region-based (global methods).
- Manual delineation, low-level segmentation, and model-based segmentation.
- Classical (thresholding, edge-based, and region-based techniques), statistical, fuzzy, and neural network techniques.

Furthermore, most segmentation techniques can be classified as region-based (techniques that look for regions satisfying a given homogeneity criterion) or boundary-based (techniques that look for edges between regions with different characteristics). Most image segmentation methods use one image modality (MRI, CT, ultrasound, PET, SPECT, etc.). Their performance can be enhanced by combining images of different modalities (multispectral segmentation^[26,27]) or images acquired over time (dynamic, motion, or temporal segmentation^[20,28,29]).

Among region-based segmentation methods, the most common ones are thresholding, clustering, region splitting and merging, and region growing.^[13,20] Thresholding is the simplest region-based segmentation method.^[19-21] In this technique a threshold is selected and an image is divided into two groups of pixels: one having values less than the threshold and the other with values greater or equal to the threshold. The threshold can be set globally for the entire image, or can be locally adjusted in an adaptive manner. In addition, methods have been proposed for automatic setting of an optimal threshold value.^[20] Segmentation approaches based on thresholding can produce acceptable results only in simple situations. One of the rare cases in which thresholding is successfully used in medical applications is the segmentation of bony structures from CT images (see Fig. 7 for an example). Thresholding approaches can be enhanced with

Fig. 6 Example of 3-D medical image segmentation showing a) three orthogonal sections through a 3-D MR image of the human head; b) the same image segmented into the left hemisphere (red), right hemisphere (green), cerebellum (blue), and brain stem (yellow); and c) the 3-D surface models generated for each of the four segmented regions.

mathematical morphology.^[20] Such algorithms, although usually simple, can provide effective and computationally efficient ways to segment complex medical structures. An example of the output of such an algorithm^[32] is illustrated in Fig. 8. Clustering segmentation methods partition the image into clusters of pixels that have strong similarity in the feature space.^[13,22-24] Each pixel is examined and assigned to the cluster that best represents the value of its characteristic vector of features of interest. Region splitting and merging is another region-based segmentation method.^[20] The image is subdivided initially into a set of arbitrary disjointed regions that are then merged and split in an attempt to satisfy certain conditions. Region growing starts from a set of “seed” points and assigns adjacent pixels or regions to the same group if their image values are similar enough, according to some predefined criterion.^[13,20] A typical representative of region growing methods is watershed segmentation.^[20] The idea behind boundary-based segmentation methods is to extract object boundaries and to segment regions enclosed by the

Fig. 7 Skull segmentation b) from a CT image a) of the head by global thresholding (an axial slice through the 3-D volume is shown).

boundaries.^[13,20,25] These algorithms typically rely on an edge detector, such as Sobel, Prewitt, Roberts, or Canny.^[20] One of the most successful classes of boundary-based segmentation strategies are methods based on active boundaries. This line of work was inspired by the pioneer work on active contours (also known as snakes),^[34] which is a 2-D version of the approach. The idea is that the object contours are modeled as deformable curves that automatically deform and attempt to align with image edges, at the same time preserving certain predefined properties (e.g., smoothness, proximity to certain landmarks, sharp corners, etc). The work was extended to 3-D and applied to medical images.^[35-37]

Often, the complexity of medical structures requires the design of application-specific segmentation methods that embody concepts from both region-based and boundary-based approaches. For example, an algorithm for the segmentation of the cortex is described^[38] that, in addition to using image information, restricts the cortical thickness to be within a predefined range, which greatly improves its performance. A more general way to incorporate prior knowledge into segmentation algorithms is by statistical approaches. The idea is to segment a number of objects from a certain class, learn the statistics of the shape variability of each object, and then use each to constrain the segmentation of a new object from the same class. Such an approach has been used to segment the corpus callosum from 3-D MR images of the head.^[39]

REGISTRATION

Image registration is the process of aligning images so that corresponding features can be easily related.^[15] The inputs to an image registration algorithm are the two images to be registered; the output is the geometric

Fig. 8 3-D brain segmentation from MR images using thresholding and mathematical morphology. Contours of the segmented brain are shown in axial a), coronal b), and sagittal c) sections through the 3-D MR image of the head.

transformation that maps points in one image to points in the other.^[14] Many image registration methods have been proposed, and they may be classified in a number of ways.^[30,31] Medical image registration has a wide range of applications that include, but are not limited to: combining information from multiple imaging modalities (e.g., combining images that show function and images that show anatomical structures); monitoring changes in size, shape, location, or image intensity over time; relating preoperative images to the data acquired intraoperatively or during therapy; and relating an individual's anatomy to a standardized atlas.^[15]

Medical image registration methods can be classified based on the following classification criteria: image dimensionality, registration basis, geometric transformation, degree of interaction, optimization procedure, modality, subject, and object.^[14] Each of the criteria is briefly discussed in the remainder of the section.

Medical image registration typically involves 3-D images (3-D to 3-D), but sometimes 2-D images (2-D to 2-D) or images of different dimensions (3-D to 2-D) need to be registered. Figures 9 and 10 illustrate the 3-D to 3-D case, in which functional and anatomical 3-D images are registered and fused.^[40] An

example of the 2-D to 2-D case is the registration of temporal mammograms, which are 2-D images.^[41] Registration of 3-D computed tomography images and 2-D portal images,^[42] which is an example of the 3-D to 2-D case, is often needed in prostate radiation therapy. Portal images are the X-ray images obtained with a radiation treatment beam during the prostate radiation therapy.

Registration basis refers to the underlying mechanics of the registration. By this criterion, image registration algorithms are classified as feature-based, intensity-based, or hybrid. Feature-based algorithms use various features (usually points, curves, and surfaces that are manually or automatically extracted from the two images) to determine the geometric transformation necessary to register the two images.^[43-45] Image-based algorithms use image intensity as the only information to register the images,^[46] and hybrid methods combine both approaches.^[47]

Geometric transformation is the characteristic of image registration algorithms that determines the mathematical form of the geometric mapping used to align the two images. Geometric transformations used in practice range from rigid^[48] to affine^[49] to

Fig. 9 Rigidly registered and fused SPECT and anatomical MR 3-D images.

Fig. 10 Rigidly registered and fused functional MR and anatomical MR 3-D images.

nonrigid.^[46] Rigid transformation models (composed of translation and rotation) are used in applications where there is no deformation between the two images except for a change in the location and orientation. For example, in the case of registration of 3-D images of the head of the same patient, the skull, falx, and tentorium provide almost perfectly rigid support for the soft brain tissues, and one can assume a rigid transformation between the two (see Figs. 9 and 10). Affine transformation, in addition to translation and rotation, can account for global scale and shear between the two images. Nonrigid transformation models are needed in cases where the deformation between two images is more complex than affine, e.g., in cases with soft-tissue deformation (cardiac images, pre- and postoperative images, etc.) or in aligning a patient's anatomy to that in an atlas.

Degree of interaction refers to the amount of manual interaction needed by a human operator in performing image registration. The manual interaction may range from no interaction in a fully automated algorithm, which is the ideal situation, to simple initialization of certain parameters or to manual adjustments needed throughout the registration process.

Optimization procedure refers to the approach employed to determine the geometric transformation, i.e., its parameters. Usually, a function of the two images and the mapping between them is used to measure the quality of the registration, and the goal is to optimize (minimize or maximize) the function with respect to the parameters of the transformation. Ideally, the algorithm is based on a closed-form solution that is guaranteed to produce the global extremum of the function. The global extremum can also be determined by an exhaustive search, which in most cases is computationally too expensive, and in some cases it can be determined by means of dynamic programming. In cases in which it is computationally prohibitive to compute the global extremum, iterative optimization schemes are used. Their main disadvantage is that they might find a local extremum that is not the global one,

but they are computationally less expensive and for this reason widely used in practice.

Modality refers to the type of images to be registered. When the two images are of the same modality (e.g., MRI–MRI or CT–CT), the registration is called intramodality or single-modality or monomodality. When the two images are of different modalities (e.g., MRI–SPECT as in Fig. 9 or MRI–fMRI as in Fig. 10), the registration is called intermodality or multimodality.

Medical image registration algorithms based on the subject imaged are classified as: inpatient (the two images are of the same patient), interpatient (the two images are of different patients), and patient-to-atlas (an image of a patient needs to be registered to an atlas image, which itself is typically based on one or more images of different patients).

VISUALIZATION

Three-dimensional visualization generally refers to transformation and display of 3-D objects so as to effectively represent the 3-D nature of the objects. Although an extensive discussion of various visualization techniques for 3-D medical imaging has been published,^[16] here we briefly present the most commonly used ways to display data from 3-D medical images.

Sections through 3-D image volume can be displayed as individual 2-D images (e.g., Fig. 7a, Fig. 8a–c). These 2-D image sections can be displayed together in a 3-D coordinate system as texture-mapped rectangular plane sections (e.g., Fig. 6a–b, Fig. 9, Fig. 10). Such displays provide a better insight about spatial relationships between image structures compared to the case of individually displayed 2-D sections. Usually, the displayed 2-D sections are orthogonal to the three main axes, but sometimes oblique 2-D sections are used.

Fig. 11 Examples of surface-rendered models displayed together with orthogonal sections through an MR 3-D image of the human head. Models of the right (green) and left (red) cerebral hemisphere are displayed as transparent surfaces, and models of the cerebellum (blue) and brain stem (yellow) are displayed as opaque surfaces.

In order to provide even better appreciation for the spatial relationships between objects in the 3-D image, the objects of interest are segmented and a surface model is generated around each object, which tessellates the surface with polygons allowing for rapid computer manipulation. These models are then surface-rendered, often combined with other visualization techniques. One can control the color, transparency, visibility, smoothness, complexity, and other properties of these models. Examples of surface-rendered objects are given in Figs. 6c, 11, and 12b–c.

Another way to display 3-D images is volume rendering, during which the entire image is displayed and transparency values are assigned to each voxel in the data set. Ray tracing techniques then give the sense of depth perception without the need for a priori segmentation. Typically only a part of the image volume is shown by using clip planes. Examples are shown in Fig. 12, where Fig. 12b–c illustrates a way to combine surface and volume rendering techniques for visualization of medical 3-D image data.

Note that more complex displays usually require a number of image processing methods to prepare the data for visualization. For example, in order to generate the displays in Fig. 12b–c, the head was segmented, its surface model (which represents the skin)

was generated, and the anatomical MR and functional MR images were (rigidly) registered.

OTHER TECHNIQUES AND VALIDATION

Although segmentation, registration, and visualization are the most widely used techniques for interpretation of 3-D medical image data, a number of other methods have been developed. These methods include image enhancement and restoration, feature extraction, statistical analysis, biomechanical modeling, and quantification.^[13,14,16]

A critical component of every medical image interpretation technique is its validation, because its clinical application affects the health and sometimes the life of the patient. Abnormalities, pathological cases, variability of normal human structures, limited image quality, and image artifacts are among the factors that make automated medical image interpretation difficult. On the other hand, even small errors in interpretation of medical images can negatively and sometimes fatally affect the patient's health. For this reason, any medical image interpretation technique that is intended to be used clinically needs to be validated on a large number of subjects under various conditions. An ideal

Fig. 12 Examples of visualization of 3-D medical image data. In a), a purely volume-rendered MR 3-D image of a human head is shown cut with an oblique clip plane; in b) and c), volume-rendered fused anatomical MR and functional MR images are displayed together with a surface-rendered skin model.

validation study involves comparison of the output of the medical image interpretation method against ground truth. However, ground truth is rarely available and other nonideal validation approaches need to be used. These include simulations, phantom studies, and qualitative and quantitative comparisons of expert-generated output to the output produced by the medical image interpretation method.

CONCLUSION

Modern imaging technologies are capable of acquiring, displaying, and manipulating imagery in three dimensions to aid in the diagnosis and treatment of disease and injuries. There is no single imaging technology available to satisfy the needs of the entire spectrum of clinical diagnostic procedures employed. Rather, a collection of technologies is available for clinicians to select from in order to achieve the best possible contrast and resolution for a particular imaging procedure.

Image processing and analysis techniques, ranging from simple thresholdbased segmentation to more sophisticated methods, including deformable models, statistical methods, and multimodality image registration, are available for use with the imagery produced with these technologies. The goal of these techniques is to enhance medical procedures by improving their accuracy and reducing the length and cost. The complexity of medical problems often requires application-specific solutions, which need to be extensively validated in order to be acceptable for clinical use. Finally, the 3-D nature of these problems requires advanced visualization techniques in order to properly display the data and allow for an easier interpretation.

Medical Robotics

John E. Speich

Mechanical Engineering, Virginia Commonwealth University, Richmond, Virginia, U.S.A.

Jacob Rosen

Electrical Engineering, University of Washington, Seattle, Washington, U.S.A.

INTRODUCTION

Today, robotic devices are used to replace missing limbs, perform delicate surgical procedures, deliver neuro-rehabilitation therapy to stroke patients, teach children with learning disabilities, and perform a growing number of other health related tasks. According to the Robot Institute of America, a robot is “a reprogrammable, multifunctional manipulator designed to move material, parts, tools, or specialized devices through various programmed motions for the performance of a variety of tasks” (1979). Given this definition, medical robotics includes a number of devices used for surgery, medical training, rehabilitation therapy, prosthetics, and assisting people with disabilities.

REHABILITATION ROBOTICS

The most extensive use of robotic technology for medical applications has been in rehabilitation robotics, which traditionally includes assistive robots, prosthetics, orthotics, and therapeutic robots. Assistive robots provide greater independence to people with disabilities by helping them perform activities of daily living. For example, robot manipulators can assist individuals who have impaired arm or hand function with basic tasks such as eating and drinking, or with vocational tasks such as opening a filing cabinet. Assistive robotics also includes mobility aides such as wheelchairs and walkers with intelligent navigation and control systems, for individuals with impaired lower-limb function. Robotic prosthetics and orthotics have been developed to replace lost arms, hands, and legs and to provide assistance to weak or impaired limbs. Therapeutic robots are valuable tools for delivering neuro-rehabilitation to the limbs of individuals with disabilities following stroke. An insightful summary of rehabilitation robotics from the 1960s to 2003, can be found in the commentary by Hillman.^[1]

Assistive Robots

A number of robotic systems for assisting individuals with severe disabilities are commercially available. The most widely used is the Handy 1 (Rehab Robotics Limited, UK), which was developed by Topping in 1987.^[2,3] This device enables people with little or no hand function to independently complete everyday functions such as eating, drinking, washing, shaving, and teeth cleaning. MANUS (Exact Dynamics, Netherlands) is a wheelchair-mounted, general-purpose manipulator with six degrees of freedom (DOF) and a two-fingered gripper. It was also designed to assist people with disabilities in completing tasks of daily living.^[4] More than 100 people have used MANUS in their homes in the Netherlands, France, and other countries. The Raptor (Applied Resources Corporation, U.S.A.) is a 4-DOF wheelchair-mounted robot that allows individuals with disabilities to feed themselves and reach objects on the floor, on a table, or above their heads.^[5]

Mobility assistance devices

Robotic technology can be used to equip mobility aides such as wheelchairs and walkers with intelligent navigation and control systems. Such mobility aides are commonly used by the elderly and people with impaired lower limb function or impaired vision. For example, Wasson et al. at the University of Virginia Medical Automation Research Center have developed an intelligent wheeled walker that can assist the user with obstacle avoidance and drop-off detection, and provide minor corrections to the user's steering input.^[6,7] Prassler et al. at the University of Ulm (Germany) have designed a robotic wheelchair called MAid (Mobility Aid for Elderly and Disabled People) with an intelligent navigation and control system for people with limited motor skills.^[8,9]

Vocational assistance devices

Recent studies have shown that robotic technology can greatly benefit motion-impaired individuals during the

performance of vocational tasks. In one study, nine people with manipulation disabilities used a robotic workstation to perform manipulation tasks that they would have been unable to perform otherwise.^[10] In another study, impaired individuals used a force-reflecting PHANToM (SensAble Technologies, Inc., U.S.A.) haptic interface to control a robot manipulator and to perform occupational tasks used in manual dexterity tests.^[11] The results showed that the assistance provided by the force-feedback device improved task performance and decreased task completion time. These studies show that robotic technology has the potential to provide people with disabilities with much greater access to vocational opportunities. ProVAR (Professional Vocational Assistant Robot) is a 7-DOF desktop robot system, currently being developed by Van der Loos et al. at Stanford University and the Veterans Affairs Palo Alto Health Care System, that will be used in vocational environments by individuals with high-level spinal cord injuries.^[12]

Prosthetics

A prosthetic is a mechanical device that substitutes for a missing part of the human body. These devices are often used to provide mobility or manipulation abilities when a limb is lost. The Utah Arm (Motion Control, Inc., U.S.A.) is a computer-controlled, above-the-elbow prosthesis developed by Jacobsen at the University of Utah in the 1980s.^[13] This commercially available arm is controlled using feedback from electromyography (EMG) sensors that measure the response of a muscle to nervous stimulation (electrical activity within muscle fibers). Motion Control, Inc. also makes a two-fingered prosthetic hand that is controlled using myoelectric signals from the remnant limb. Another prosthetic hand is currently being developed at the Scuola Superiore Sant'Anna, Italy,^[14] and Rutgers University^[15] is creating a robotic prosthetic hand with five fingers and twenty DOF using shape-memory alloys as artificial muscles (Fig. 1).

Fig. 1 Photograph of a robotic prosthetic hand under development at Rutgers University. (Photo courtesy of Kathryn De Laurentis and Constantinos Mavroidis, Rutgers University.)

Robotic prosthetics can also be used to replace lower limbs. The MIT LegLab is testing an intelligent prosthetic knee that enables above-the-knee amputees to walk and climb stairs more naturally by adapting the swing rate of the knee accordingly.^[16]

One challenging area of prosthetics research is determining the intended action of the human so that the prosthetic device can be properly controlled. Mussa-Ivaldi at Northwestern University has developed a fish-machine interface that allows a robot to be controlled by the brain of a fish.^[17] Nicolelis et al. at Duke University Medical Center have developed a system that uses implanted electrodes to measure the brain signals in an owl monkey and enables the monkey to control a robot arm to reach for a piece of food.^[18] This research may eventually lead to brain-machine interfaces that can control prosthetic limbs.

Orthotics

An orthotic is a mechanism used to assist or support a weak or ineffective joint, muscle, or limb. Many orthotics utilize robotic technology, and they often take the form of an exoskeleton—a powered anthropomorphic suit that is worn by the patient. Exoskeletons have links and joints that correspond to those of the human and actuators that assist the patient with moving his or her limb or lifting external loads. For example, the Wrist-Hand Orthosis (WHO) uses shape memory alloy actuators to provide a grasping function for quadriplegic patients.^[19] In ongoing research, Rosen et al. at the University of Washington are developing the exoskeleton shown in Fig. 2, which can be controlled by myosignals from the wearer's arm.^[20]

Robot-Assisted Rehabilitation Therapy

Robots have the potential to be valuable tools for rehabilitation therapy. They may enhance traditional treatment techniques by enabling more precise and consistent therapy, especially in therapies that involve highly repetitive movement training. New therapy techniques may be developed using robotic devices that can actively assist and/or resist the motion of the patient. Therapeutic robots can also continuously collect data that can be used to quantitatively measure the patient's progress throughout the recovery process, enabling therapists to optimize treatment techniques. In addition, robot-assisted therapy systems have the potential to provide extended periods of unsupervised therapy, which could increase efficiency and reduce cost by decreasing the amount of one-on-one time that a therapist must spend with a patient.

Fig. 2 Photograph of an exoskeleton for assisting arm movement under development at the University of Washington.

Upper-limb devices

Preliminary research indicates that robotic devices have the potential to greatly enhance the neuro-rehabilitation therapy of stroke patients.^[21–27] Burgar, Lum et al.,^[21,22] Krebs et al.,^[23–25] and Reinkensmeyer et al.^[26,27] have demonstrated that the use of robot-aided therapy can yield positive results in the rehabilitation of forearm movement in stroke patients.

Burgar, Lum et al. at Stanford University and the Veterans Affairs Palo Alto Health Care System have conducted clinical trials using the Mirror-Image Motion Enabler (MIME) robot system shown in Fig. 3, which uses a 6-DOF PUMA 560 robot to interact with the impaired arm.^[21,22] This system can operate in three unilateral modes and one bilateral mode. The unilateral modes are passive, in which the patient remains passive while the robot moves the arm along a preprogrammed path; active-assisted, in which the patient initiates movement and the robot assists and guides the motion along the desired path; and active-constrained, in which the robot resists motion along the path and provides a restoring force in all other directions. This system was used in clinical trials to compare robot-assisted therapy to traditional therapy in stroke patients, and the results

showed greater improvements in the robot group than in the control group.^[21,22]

Krebs et al. at MIT and the Burke Medical Research Institute have conducted clinical trials with the MIT-MANUS, a backdrivable robotic system for delivering upper-extremity neuro-rehabilitation therapy.^[23–25] This system can move and/or guide a patient's arm within a horizontal planar workspace, while recording the motion and applied forces. Clinical trials conducted with the MIT-MANUS have found who patients who underwent robot-aided rehabilitation improved more than patients in the control group.^[24]

In other research, Reinkensmeyer et al. at the University of California at Irvine developed the ARM Guide (Assisted Rehabilitation and Measurement Guide) to evaluate and treat arm impairment following stroke, using linear reaching movements.^[27] The ARM Guide has a single actuator, and the motion of the patient's arm is constrained to a linear path that can be oriented within the horizontal and vertical planes. Initial results with the ARM Guide show that the system produces quantifiable benefits in the neuro-rehabilitation of stroke patients.^[27]

Robotic therapy devices have also been developed for rehabilitating the hand and fingers. Jack et al. have performed preliminary tests indicating that rehabilitation of the hand and fingers may be enhanced using the Rutgers Master II-ND (RMII) force-feedback glove.^[28] This glove has four pneumatic actuators, located in its palm, which interact independently with the index, middle, and ring fingers and the thumb of the right hand. This system provides force feedback and allows the user to interact with a virtual environment. In a pilot clinical trial, three stroke patients used the system daily for two weeks and showed improved hand parameters at the end of the study.

Lower-limb devices

The NASA Jet Propulsion Laboratory and UCLA are developing a robotic stepper for lower-limb rehabilitation.^[29] This device uses a pair of robotic arms that resemble knee braces to guide the patient's legs while they move on a treadmill. The system uses a harness to support the patient's weight and several sensors to measure the patient's force, speed, acceleration, and resistance. Astronauts may eventually use this system in microgravity as they exercise to help maintain normal locomotion skills, muscle mass, and calcium levels in bones. In other research, Colombo et al. at the University Hospital Balgrist (Switzerland) have implemented a robotic orthosis to move the legs of spinal cord injury patients during rehabilitation training on a treadmill.^[30] Reinkensmeyer et al. at the University of California at Irvine have also developed a robotic device for measuring and manipulating stepping on a treadmill.^[31] Van Der Loos et al. at the Veterans Affairs Palo Alto Health Care System are studying lower-limb biomechanics using a servomotor-controlled bicycle that can provide both assistance and resistance independently to each leg.^[32]

SURGICAL ROBOTICS

In the last decade, surgery and robotics have reached a maturity that has allowed them to be safely assimilated to create a new kind of operating room. This new environment includes robots for local surgery and telesurgery, audiovisual telecommunication for telemedicine and teleconsultation, robotic systems with integrated imaging for computer-enhanced surgery, and virtual reality (VR) simulators enhanced with haptic feedback, for surgical training. According to Satava, "the operating room of the future will be a sophisticated mix of stereo imaging systems, microbots, robotic manipulators, virtual reality/telepresence workstations, and computer integrated surgery."^[33]

Human–Machine Interfaces in Surgery

Performing a surgical task involves three primary entities: the surgeon, the medium, and the patient. The medium is the means through which the surgeon sees, interacts, and communicates with the patient. It may include standard surgical instruments, an endoscopic camera system, laparoscopic instruments, a robotic surgery system, and/or various other technologies. Figure 4 schematically depicts the human–machine interfaces for various surgical setups. As the physician is moved farther away from the patient, the medium introduced between the surgeon and the patient

becomes more complex and places more constraints into the audio, visual, and physical communication/interaction channels between the surgeon and patient. Nevertheless, in some setups this complex medium may introduce valuable information by providing force feedback, enhancing vision, or enhancing the surgeon's kinematic capabilities by scaling down motion and filtering out hand tremor.

In conventional open surgery, the surgeon interacts with the internal tissues through a relatively large open incision, using direct hand contact or surgical instruments (Fig. 4a). There is no mediator in any of the communication channels: audio, visual, motion, or haptic (force feedback). In the absence of constraints on the surgical tool, the surgeon can translate and orient it anywhere in the surgical scene, using six DOF. In a minimally invasive surgery (MIS) setup, the tools and endoscopic camera are inserted through ports into the body's cavity (Fig. 4b). The port/tool and port/camera interfaces introduce a fulcrum, while decreasing the number of available DOF from six in open surgery to four in MIS, allowing only one (in/out) tool translation. The MIS setup requires at least two operators: the surgeon who is controlling the endoscopic tools and an assistant who is manipulating and positioning the endoscopic camera. The human assistant can anticipate the surgeon's intentions and reposition or track the surgical tools with the endoscopic camera, using minimal directions from the surgeon. However, the assistant is subject to fatigue from holding the camera in one position for long time segments. The assistant can be replaced by AESOP (Computer Motion Inc., U.S.A.), a voice-activated 7-DOF robotic arm that automates the critical task of endoscopic camera positioning and provides the surgeon with direct control over a smooth, precise, and stable view of the internal surgical field.^[34] Broderick, Merrell, et al. have demonstrated that AESOP can also provide improved visibility during open surgery.^[35]

In the United States, robotic surgery can now be performed by the two commercially available systems shown in Fig. 5: ZEUS by Computer Motion^[34] and da Vinci by Intuitive Surgical,^[36,37] which are FDA (Food and Drug Administration) approved for specific cardiac and thoracic surgical procedures. As of July 2003, these two companies have merged into a single company known as Intuitive Surgical. The typical surgical robot architecture follows a classical master/slave teleoperation setup (Fig. 4c,d). This setup consists of two modules: the surgeon console (master) and the robot (slave). The surgeon console includes a set of handles, a vision system, and in some cases voice command components. The robotic system interacting with the patient includes at least three robotic arms: two to manipulate the surgical instruments and a third to control the endoscopic camera. The surgeon controls

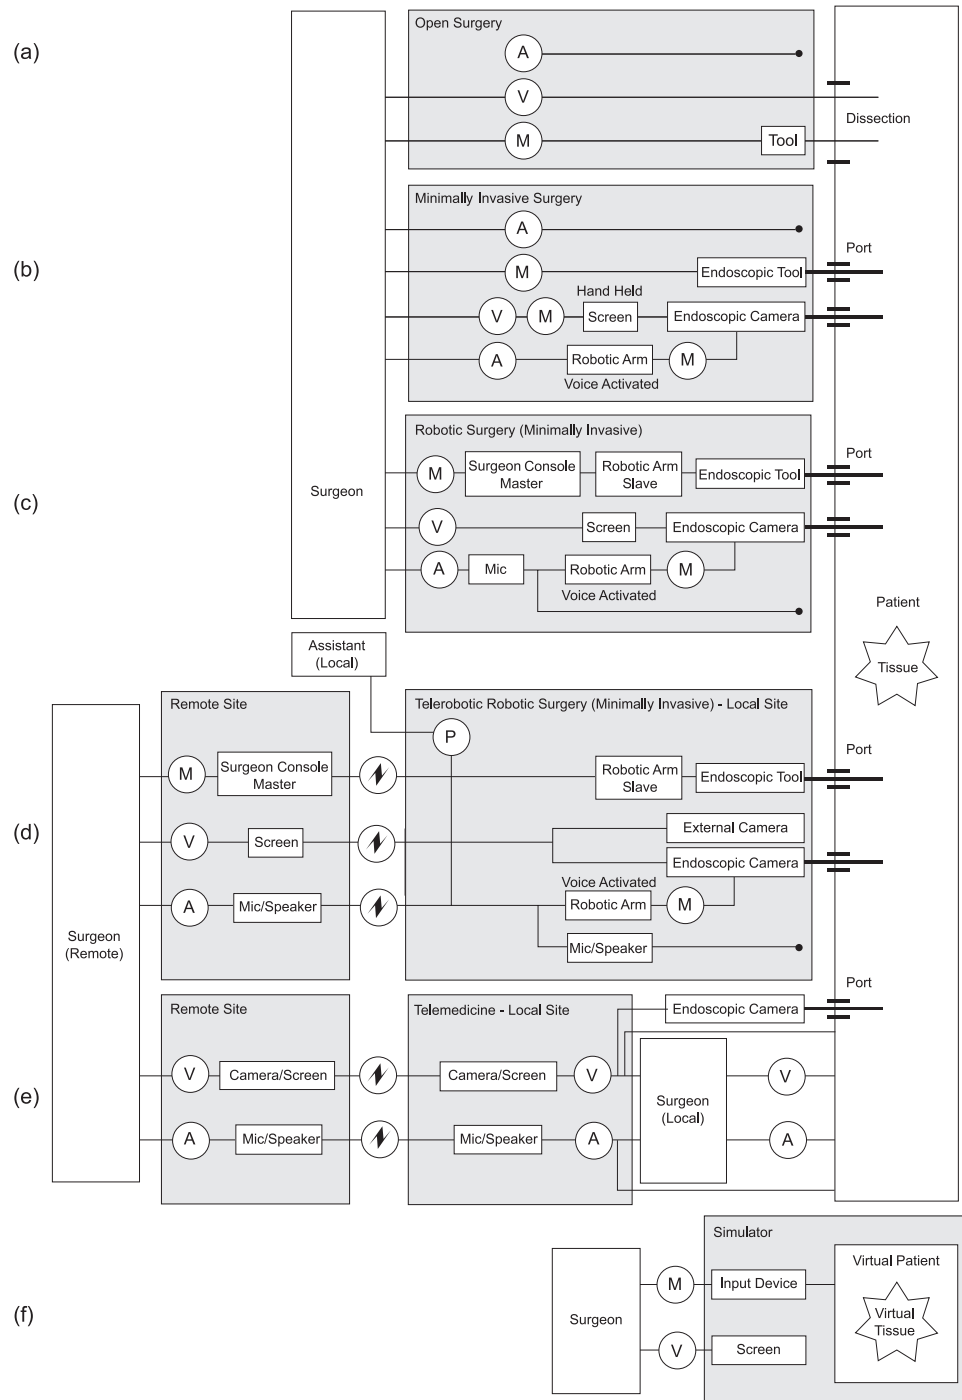

Fig. 4 Modalities used in different configurations for performing surgery: (a) open surgery; (b) minimally invasive surgery; (c) robotic surgery; (d) telerobotic surgery; (e) telemedicine or teleconsultation during surgery; (f) surgical simulation. The type of information being transferred is denoted by (A)–Audio; (M)–Motion, Haptics or Force Feedback; (V)–Vision; and (P)–Positioning.

the position of the robot arms by manipulating the two handles at the console. The endoscopic camera arm is controlled by voice commands from the surgeon, and the view is transmitted back to the surgeon console. None of the currently available surgical systems incorporate force feedback, but the Black Falcon,^[38]

which was used in part as the foundation for the da Vinci system, and other surgical systems^[39] have experimentally tested force feedback. This feedback allows the surgeon to feel the forces generated as the surgical tools interact with the tissue, using a bilateral (position and force) teleoperation mode. Currently, the

Fig. 5 Commercially available surgical robots: (a) ZEUS by Computer Motion (www.computermotion.com) and (b) da Vinci by Intuitive Surgical (www.intuitivesurgical.com).

FDA has approved only robot-assisted surgical procedures in which the entire robotic system (master/slave) is located in the operating room. However, the same robotic system has been used to perform a surgery telerobotically across the Atlantic Ocean.^[40]

In telemedicine and teleconsultation (Fig. 4e), the remote physician communicates with either the local physician or the patient through audiovisual telecommunication channels. Using systems like SOC-RATES and HERMES by Computer Motion, the remote surgeon can control an external camera, share the view from the endoscopic camera with the local surgeon, and use it as a whiteboard to draw graphics on the image seen by both surgeons.^[34]

For training purposes, the patient, tissue, instruments, and robotic arms can be replaced using computerized simulations (Fig. 4f). The surgeon can practice specific surgical tasks or full clinical procedures by interacting with virtual tissue. Haptic technology can be used to allow the physician to feel the forces generated as a result of the interaction between the virtual tools and the virtual tissue.

One element that all the modalities in Fig. 4 have in common is a human-machine interface, in which visual, kinematic, dynamic, and haptic information are shared between the surgeon and the various modalities. This interface, rich with multidimensional data, is a valuable source of information that can be used to

objectively assess technical surgical skills. Algorithms that are developed for objective skill assessment are independent from the modality being used; therefore, the same algorithms can be incorporated into any of these technologies.^[41–44]

Surgical Robots

The recent evolution of surgical robotics is the result of profound research in the field of robotics and tele-robotics over the past four decades.^[45] By examining the list of strengths and weaknesses of humans and robots in Table 1, it is apparent that combining them into a single system may benefit the level of health care delivered during surgery. The combined system allows the human to provide high-level strategic thinking and decision making while allowing the robot to deliver the actual tool/tissue interaction, using its high precision and accuracy. Because of these characteristics, robots have emerged in the field of surgery and other fields of medicine almost naturally. A number of authors have written reviews of the state of the art in surgical robotics, including Green et al.,^[46] Taylor et al.,^[47,48] Howe,^[49] Buess et al.,^[50] Cleary et al.,^[51] Ballantyne,^[52] and Li et al.^[53]

Surgical robots can be classified into three categories: class i)—semi-autonomous systems; class ii)—guided systems; and class iii)—teleoperation systems. Special robotic arms have been designed in one or more of these categories to meet the requirements of various surgical specialties, including neurological, orthopedic, urological, maxillofacial, ophthalmological, cardiac, and general surgery. Each discipline in surgery has a special set of requirements, dictated by the anatomical structure and the surgical procedure, that necessitate special design and configuration of the robotic system. However, some robotic arm configurations (e.g., ZEUS and da Vinci) are equipped with specially designed sets of tools and may be used for various types of procedures across different surgical disciplines.

Similar to industrial robotics, the tool path of a surgical robot operating in a semi-autonomous mode (class i) is predefined based on a visual representation of the anatomy acquired by an imaging device (e.g., CT, MRI) and preoperative planning. Once the path is defined, the relative locations of the anatomical structure and the robot are registered, and the robot executes the task using position commands without any further intervention on behalf of the surgeon. For obvious safety reasons, the surgeon can stop the action, but altering the path requires replanning. Semi-autonomous robotic systems are suitable for orthopedic or neurological surgical procedures with well-constrained anatomical structures such as hard

Table 1 Characteristics of human and robotic systems

Characteristic	Human	Rank	Robot	Rank
Coordination	Visual/Motor—limited	–	Geometry—Highly accurate	+
Dexterity	High within the range of sensor information	+	Limited by the number and types of sensors—Range exceeds human perception	+
Info. integration	High level—High capacity	+	High level—Limited by AI algorithms	–
	Low level—Limited (info. overload)	–	Low level—High capacity	+
Adaptability	High	+	Limited by design	–
Stable performance	Degrades fast as a function of time	–	Degrades slowly as a function of time	+
Scalability	Inherently limited	–	Limited by design	+
Sterilization	Acceptable	+	Acceptable	+
Accuracy	Inherently limited	–	Designed to exceed human capacity	+
Space occupation	Limited to the human body space	+	Currently exceeds the volume needed to replace the human operator (surgeon)	–
Exposure	Susceptible to radiation and infection	–	Unsusceptible to environmental hazards	+
Specialty	Generic	+	Specialized	–

tissues and bones or with soft tissue such as the brain, confined by the skull.

Surgical robots can be used as guided systems (class ii) in cases where high precision is required, such as in microsurgery, microvascular reconstruction, ophthalmology, or urology. The surgeon interacts directly with the robotic arm and moves the tool in space. The surgical arm provides stable, steady, and precise tool movements, using an impedance control. Forces and torques applied on the system by the surgeon's hand are sensed by a force/torque sensor and translated into a velocity command to the robot.

The architecture of a teleoperated surgical robot (class iii), as previously explained, consists of three fundamental components: the surgical console, the robotic arms, and the vision system. Using the bilateral (motion and force) mode of operation depicted in Fig. 6, the surgeon generates position commands to the robot by moving the input devices (the master) located at the surgeon's console. The position commands are

transferred through a controller to the surgical robotic arms (the slave), which have actuators that move the arms and the surgical tools to the proper positions. In some systems, force feedback may be generated by actuators attached to the master input device, enabling the surgeon to feel the forces between the tool and the tissue. The force-feedback command in a bilateral mode of operation is defined as the difference between the position command generated by the operator and the actual position achieved by the robot.^[37,38] As the difference between the position command and the actual position increases, the force feedback to the operator increases proportionally. Although the bilateral mode of operation does not require additional sensors for generating the force feedback, the high level of friction due to the use of non-direct-drive actuators and the high inertia due to large robotic arms impair the quality of the force-feedback signal using this algorithm. A different approach for incorporating force feedback requires the use of force/torque sensors

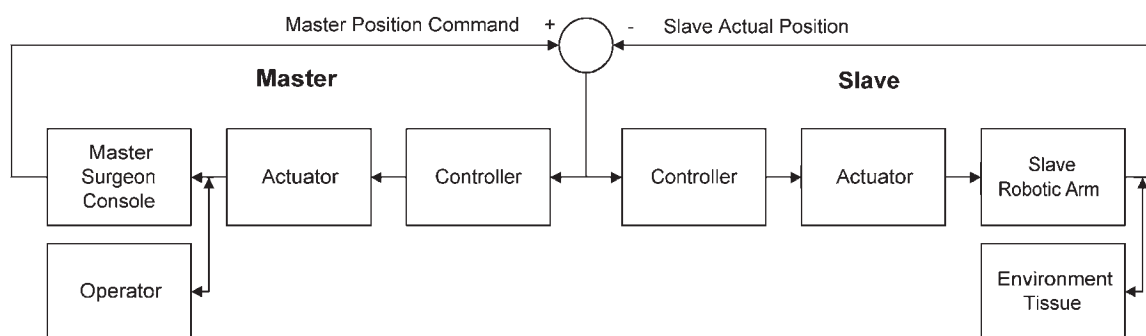

Fig. 6 A block diagram of a typical bilateral teleoperation system used in class iii robotic systems. The actuators and controllers on the master console are eliminated if force feedback is not incorporated into the system.

as close as possible to the end-effector to diminish the mechanical and dynamic interference. Given the harsh environments associated with the tool sterilization and operation, attaching force sensors to the tool and protecting them is still a technological challenge. For MIS, placing force sensors at the distal end of the tool is further limited by the 5–10 mm diameter of the port.

Surgical Training Simulators and Haptics

Training surgical residents adds substantial cost to medical care, including costs associated with inefficient use of operating room time and equipment. Residents are currently trained on a variety of modalities, from using plastic models to operating on live animals and human patients. A resident is more likely to make a mistake than an expert surgeon, and these mistakes can have dire economic, legal, and societal impacts. Ever-increasing costs and louder demands for efficiency have brought surgical simulators to the forefront of training options as a cost-effective and efficacious methodology. Medical simulators are inspired by the aviation simulators used by airline and military pilots to train in virtual reality. Realistic virtual reality surgical simulators allow more comprehensive training without endangering patients' lives. Residents can train for difficult scenarios or anatomy, and they can practice repairing mistakes. In addition, simulators also reduce the need to use animals and cadavers, with obvious ethical and financial benefits.

A typical virtual reality surgical simulator includes both hardware and software. Some input devices include only position sensors and thus provide only the positions of the tools as inputs to the simulator. More advanced input devices, called haptic interfaces, incorporate actuators in addition to position sensors. These actuators generate the appropriate force feedback as the tools are interacting with the virtual medium. Due to the wide variety of surgical procedures, there is no generic input device. Specific input devices are usually developed to match the actual human–machine interface associated with a specific medical procedure as realistically as possible. However, some generic input devices do exist for MIS, including the Laparoscopic Surgical Workstation by Immersion^[54] or a modified version of the PHANTOM by SensAble Technologies.^[55] For an extensive review of medical input devices, see the reference by Chen.^[56] In addition to input devices that are specifically designed for surgical simulators, any surgeon console (master) of a robotic system can be used as an input device, while the patient is replaced by a virtual model. Connecting two or more consoles together may allow two surgeons to share both the visual view and the haptic sensation of

the surgical scene, either in real surgery or in a VR simulation. This will allow the surgeons to regain the collaborative capability that exists in open surgery, but is somewhat lost in MIS. The ability to collaborate may enable a local surgeon to assist an expert surgeon operating from a remote location. In addition, this mode of collaboration may be used during training sessions, where the same tool is controlled by both a trainee and a senior surgeon with overruling authority.

A variety of simulators for surgical training and preoperative planning have been developed by the National Capital Area Medical Simulation Center at the Uniformed Services University of the Health Sciences,^[57] and by the National Center for Biocomputation, a collaboration between Stanford University and the NASA Ames Research Center.^[58] At the heart of a simulator is its computational engine, which accepts the tool positions as inputs and is responsible for presenting the graphical representation of the surgical scene along with generating force feedback as outputs based on a model of the virtual material. Both mass-spring and finite element models are in use for simulating soft tissues. These models are considered to be an oversimplification of real soft tissue, which exhibits nonlinear, heterogeneous, viscoelastic behavior. Measuring the biomechanical characteristics of soft tissue *in vivo* is the subject of active research.^[39,59] Most of the data currently available were acquired *in situ* or under postmortem conditions, which alters the fundamental characteristics of the tissue.

Developing objective methodologies for surgical competence and performance is of paramount importance to superior surgical training. The methodology for assessing surgical skill as a subset of surgical ability has gradually shifted from subjective scoring, based on expert and certainly biased opinion using fuzzy criteria, toward more objective, quantitative analysis. This shift has been enabled by the incorporation of surgical simulators and robots into the surgical training curriculum, in addition to using these tools for demonstrating continued competency among practicing surgeons. The kinematics and dynamics of the surgical tools are fundamental sources of data for objective assessment of surgical skill, regardless of the modality being used. Simple measures like completion time, tool tip path, forces, and torques are currently used as objective criteria, but they fail to provide an integrated approach for analyzing surgery as a multi-dimensional process. Markov modeling can be used to decompose the surgical task and analyze its internal hierarchy, using the kinematics and dynamics of the tools. This technique holds the promise of providing an integrated approach and objective means for quantifying training and skills acquisition prior to clinical implementation.^[43,44]

The Future of Robot-Assisted Surgery

Analysis of the surgical robot's role in the currently available operating room (OR) setup demonstrates that the surgeon can be safely removed from the immediate surgical scene and still maintain interaction with the patient in a teleoperational mode. Although this revolutionary mode of operation may have benefits for the patient, it is far from being efficient because of the lack of supporting technologies. The increased setup and operational time of the current robotic systems is due to lack of automation and the presence of sophisticated interfaces. As a result, the simple act of changing tools or readjusting the robot's position produces inefficient interactions between the clinical staff and the technology. These examples demonstrate the incomplete integration of surgical robotic systems into the OR.

The OR of the future has been envisioned as an integrated information system.^[60] Figure 7 shows a futuristic rendering of some of the subsystems that may be combined within the OR of the future. Much of the medical staff may be removed from the OR and replaced during surgery, in part by hardware in the form of supportive electromechanical devices and in part by software for documenting, assisting, and assessing the operation. The patient may be scanned by an imaging device, which will allow the surgeon to practice critical steps of the operation using the robotic console within a virtual reality environment based on patient-specific data. Then, the operation will be conducted by the surgeon utilizing the robot, tool changer, and equipment dispenser in an OR similar to a class 100 clean room. Smart tags will be incorporated into tools and

Fig. 7 A futuristic rendering of some of the subsystems that might be incorporated into the operating room of the future, including a modular operating table, surgical robotic arms, a tools changer, an equipment dispenser, and an imaging device.

equipment, and once they are used, the billing process and the inventory updates will be executed immediately. Surgical performance will be monitored in the background, and critical decisions may be made through consultation with an expert system incorporated into the system. Much of the core technology for materializing this vision already exists, but whether this vision will become common practice in the next few decades is still an open question.

OTHER MEDICAL ROBOTICS APPLICATIONS

Training

Robotic mannequins have been developed for simulated medical training. The commercially available Medsim-Eagle Patient Simulator developed at Stanford University and the Veterans Affairs Palo Alto Health Care System has several computer-controlled electromechanical features, including eyes that open and close, arms that move, arms and legs that swell, and lungs embedded in the chest that breathe spontaneously.^[61]

Tele-echography

A French consortium has developed a telerobotic echography system consisting of a slave robot, with a real probe as its end-effector, and a master interface with a virtual probe.^[62] This system transmits motion and force information bidirectionally, allowing an expert interacting with the master interface to perform an examination at a remote location, using the slave robot.

Robots for Special Education

AnthroTronix has developed JesterBot™ and CosmoBot™ for the rehabilitation and special education of children.^[63] These robots combine therapy, education, and recreation and can be controlled using body movements, voice commands, or an interactive control station.

Robots for the Deaf and Blind

Dexter, a robotic hand communication aid for people who are both deaf and blind, uses fingerspelling to communicate information typed on a keyboard, stored in a computer, or received from a special telephone.^[64,65]

CONCLUSION

Robotic technology has successfully produced valuable tools for rehabilitation, surgery, and medical training, as well as new and improved prosthetics and assistive devices for people with disabilities. Future applications of robotic technology will continue to provide advances in these and other areas of medicine. The most significant role of medical robots will most likely be to perform tasks that are otherwise impossible, such as enabling new microsurgery procedures by providing high-dexterity access to small anatomical structures, integrating imaging modalities into the OR, providing functional replacements for lost limbs, and enabling new human-machine interfaces and techniques for delivering neuro-rehabilitation therapy.

INTRODUCTION

Several spinning techniques are used in the production of man-made fibers, including solution spinning (wet or dry), melt spinning, gel spinning, and emulsion spinning, the latter two of which are variations of solution spinning. Of these techniques, melt spinning is the oldest and most widely used. It is an economic and safe method because no toxic solvents are involved and the production rates are high. However, melt spinning by its nature limits the usable polymers to thermoplasts with suitable molecular conformations.

In order to form fibers from glass by melt spinning, glass must have wide working range properties, i.e., the viscosity changes should occur over a large temperature range to allow accurate viscosity control of the melt. Thus, glasses that devitrify easily are very difficult to melt spin into fibers. Some other ceramics and metals have been converted into fibers by melt spinning, but only the phenomena and techniques to convert polymers and glasses into fibers are discussed here.

This chapter gives an overview of the basic principles involved in melt spinning of polymer and glass fibers, as well as application areas of melt-spun biomaterial fibers in biomedical engineering. Melt spinning of polymers involves extrusion, quenching, and drawing. Within these processes, the molecular structure of the polymer changes from randomly oriented bulk melt to highly oriented molecular chains, which give fibers the significantly higher strength properties compared with bulk polymers. With glasses, the structure of the glass network does not significantly differ in bulk and in fibers, but the melt spinning causes stress distribution across the fiber, which, together with surface quality, affects the strength properties of melt-spun glass fibers.

Sutures comprise the best known application area for melt-spun biomaterials, but in recent years interest in the use of fibers in biomedical applications has widely expanded. Fibers are bringing new advantageous properties for scaffolds, especially in tissue engineering, because in many cases fibers resemble biological materials.

MELT SPINNING OF POLYMERS

Characteristics of Polymers Suitable for Melt Spinning

The polymer suitable for melt spinning must meet several requirements:^[1,2]

- It must be a thermoplast, i.e., it must be formable using an elevated temperature.
- Molecular chains of the polymer should be linear, long, and flexible; side groups should be simple, small, or polar.
- Polymer chains should be capable of being oriented and crystallized.
- The polymer should not degrade to a high extent at melting temperature.

Molecular orientation is best reached with polymers that have long, linear, and flexible chains. For practical purposes, the melting temperature of the polymer should be high enough to allow the use of fibers in moderate or high temperatures, such as fibers applied for cloth and reinforcements. Polymers that decompose at high spinning temperatures are usually not suitable for melt spinning, although for some biodegradable polymers the loss of molecular weight during melt spinning can be taken into account in processing. The glass transition temperature should not be too close to the melting range to ensure efficient orientation temperature. However, it should be high enough to retain the characteristics of fibers in their working environment.

The temperature used to melt the polymer has an effect on the rheological properties of the polymer melt. Rheological properties influence the elongational flow of the melt through the spinneret. On the other hand, the elongational flow has an effect on the molecular orientation. The molecular orientation has an effect on forming crystallization because it affects the kinetics of solidification during cooling. Solidification, which is the transformation from a molten state to a solid state, accompanied with the possibility of uniaxial orientation from the melt, is one of the most

important factors in the production of fibers by melt spinning.^[2-4]

The most important structural characteristics of polymers influencing spinnability are degree of crystallinity, crystalline orientation, and the size of the crystallites. These factors govern the spinnability of polymers and, therefore, the spinning procedure itself. Very-high-molecular-weight crystalline polymers with high melt viscosity will induce higher shear stress in the extruder compared with lower-molecular-weight polymers with lower viscosities. For the best spinning results, a wide molecular weight distribution is optimal. Spinning results can be affected, to some extent, by modifications to the machinery or by controlling the chemistry of the polymer.^[1,2,4]

The variables of melt spinning can be divided into three categories. Primary variables include material properties, melt spinning temperature, type of spinneret and orifices, mass outflow, length of spinning path, take-up velocity, and quenching parameters. Secondary variables include extrusion speed, diameter of preoriented fibers, and spin-draw ratio. Resulting variables are take-up tension, take-up stress, fiber temperature, texture, and physical properties of preoriented fibers. Figure 1 presents the scheme of a simplified melt spinning machinery.^[1,2]

Extrusion of Polymer

In the melt spinning process the polymer is melted in the extruder. In the extruder the rotating screw compresses and homogenizes the polymer, which is then farther transferred under pressure directly or via gear pump into the spinneret. Possible additives such as pigments are already mixed into the master batch or added via a separate mixing and feeding unit along the extrusion line, either to the screw or to a metering pump at the end of the extrusion line. The design of the screw and the spinning temperatures vary according to the polymers. Polymer melt is pressed through the spinneret and the filaments are formed. Spinneret type and designs vary according to the end use specifications of the fibers. It is very important that the design of the spinneret enables constant and uniform flow of the melt for every spinneret orifice with equal residence times. Not only circular cross-sections but also different kinds of symmetric and asymmetric patterns are manufactured. The number of holes in a spinneret can vary from a single hole (monofilament spinneret) to hundreds or even thousands of holes (multifilament spinneret).^[3,5]

Quenching of Fibers

After exiting the spinneret, the individual filaments are quenched (i.e., rapidly cooled down) to a solid state so

that they can be hauled off. During quenching, the speed of cooling down and the uniform controlled cooling affects the quality of the filaments as well as the drawing parameters. Orientation already occurred in the melt when the polymer exits the extruder. It should be noted that the speed of the melt exiting the spinneret is lower than the haul of the speed of the filaments, resulting in a preoriented structure. The rate of cooling has an effect on polymer crystallization. With rapid cooling the crystalline structure can be minimized if needed, and by controlled cooling the size of crystallites can be varied. For most polymers the distance from the spinneret to the beginning of the quenching area is 50 to 150 mm. Some polymers do not need quenching. One of these is poly(hydroxybutyrate) (PHB), where quenching below T_g could result in low-quality fibers, whereas drawing from the melt without quenching resulted in preoriented filaments that could be oriented to good-quality fibers.^[6] After quenching, the filaments are oriented via drawing units.^[2-5]

The formed crystalline structure of the undrawn fibers prior to drawing plays a major role in melt spinning. The optimal molecular structure of the undrawn fibers is the foundation for the optimal final structure and for the best physical properties of the drawn fibers.^[2,4]

Drawing of Fibers

In drawing units the fibers are further oriented from the preoriented state either partly or fully. Drawing of melt-spun filaments can be divided into two categories, hot-drawing and high-speed melt spinning with a spin-draw machine. In hot drawing the produced filaments are drawn through ovens, where the filaments are heated up and drawn to a higher degree of orientation. The drawing procedure can be independent from the melt extrusion process, whereas in high-speed melt spinning and the spin-draw machine the filaments are continuously taken from the spinneret through quenching onto the heated godets, where the polymer is heated and drawn. Fig. 1 illustrates how drawing happens between the godets by spinning the D2 godet faster than the D1 godet. Different drawing and relaxation procedures can be obtained by the godet placing, temperature, and speed variations. After godets the fiber is collected on the spools. For online non-woven production the winder is replaced by a staple fiber-cutting machine with possible extensions. For textile use a spin finish (oil or emulsions of oil and water) is applied to the filaments to eliminate electrostatic charge and friction prior to the winding procedure.^[2-5]

The optimum temperature for drawing is between the glass transition temperature and the melting range.

Fig. 1 Scheme of a melt-spinning machinery: (A) extruder, (B) spinneret, (C) quenching area, (D1) first drawing unit or godet, (D2) second drawing unit or godet, and (E) winding unit.

The specific drawing temperature is dependent on the polymer and the requirements of the fiber. As a result of drawing, the final orientation is achieved. Molecular orientation is the parallelization and extension of molecular chains and structural units along the fiber axis. For flexible polymers, the uniaxial orientation is carried out by unfolding the folded molecular chains. When the degree of orientation is increased by drawing, the degree of crystallinity, Young's modulus, and ultimate tensile strength are increased but the elongation (i.e., stretching capacity) is decreased. As the drawing progresses, the movement of the polymer chains becomes more difficult as a result of even closer packing and alignment of the chains. Electrical and optical behavior, as well as absorption properties of solvents, are also affected by the change in orientation. Partially drawn fibers possess the capability of further orientation. They also usually need heat setting after the drawing prior to use in the textile industry as a result of the stretching instability. If heat setting is carried out under stress, the orientation factor can still increase, but when heat setting is carried out free of load, the fibers are reheated and left to shrink longitudinally. Fully drawing the fibers avoids this instability.^[1,2,4]

Properties of Melt-Spun Polymer Fibers

The melt spinning process results in fibers that can be used for different applications. Examples are presented

in Fig. 2. The properties of these oriented fibers differ from each other, depending on the polymer used and the spinning conditions. A proper orientation of molecules gives fibers the optimal properties in the direction of the fiber axis.^[1,2] The difference between a polymer and an oriented fiber can be summarized with polypropylene. As a billet form, its longitudinal yield strength is 25 MPa and elongation at break is around 800%, whereas in a die-drawn form (deformation ratio 20) it has a fiber axis tensile strength of 312 MPa and elongation at break of only 11%.^[7] After melt spinning tensile strength of absorbable polylactide multifilament fibers is generally around 350 to 500 MPa, elastic modulus of 6 to 8 GPa and strain at yield of 25 to 30%.^[8] In comparison, the commercial synthetic absorbable sutures have a tensile breaking strength of 450 to 920 MPa and non-absorbable sutures from 370 to 1060 MPa.^[9]

MELT SPINNING OF BIOACTIVE GLASS

Manufacturing of glass fibers by melt spinning is an important branch of the technical glass industry and technical glass fibers are used, for example, for insulation, as reinforcement of polymers, in special textiles, and as optical fibers. Bioactive glasses were introduced by Hench and colleagues in the late 1960s and since then bioactive glasses have created a great deal of interest for the biomedical society as well as clinicians. Bioactive glass is an amorphous solid that is capable of forming a cohesive bond with both hard and soft tissue when exposed to appropriate *in vivo* or *in vitro* environments, such as simulated body fluid, by developing a surface layer of hydroxycarbonate apatite by release of ionic species from the bulk material. However, in the biomedical field only results from research experiments utilizing bioactive glass fibers have been reported. As bioactive glass fibers present new possibilities to the biomedical materials field they will likely be utilized much more widely within the coming years in the biomedical field as well.

Compositional Dependence of Bioactive Glass Fiber Spinning

The ability of a substance to form glass does not depend upon any particular chemical or physical property. Any liquid, in principle, can be transformed into glass if cooled sufficiently quickly and brought below the crystal transformation range. A good glass-forming material is one for which the rate of crystallization is very slow in relation to the rate of cooling. B_2O_3 , SiO_2 , GeO_2 , and P_2O_5 all readily form glasses on their own and are commonly known as glass

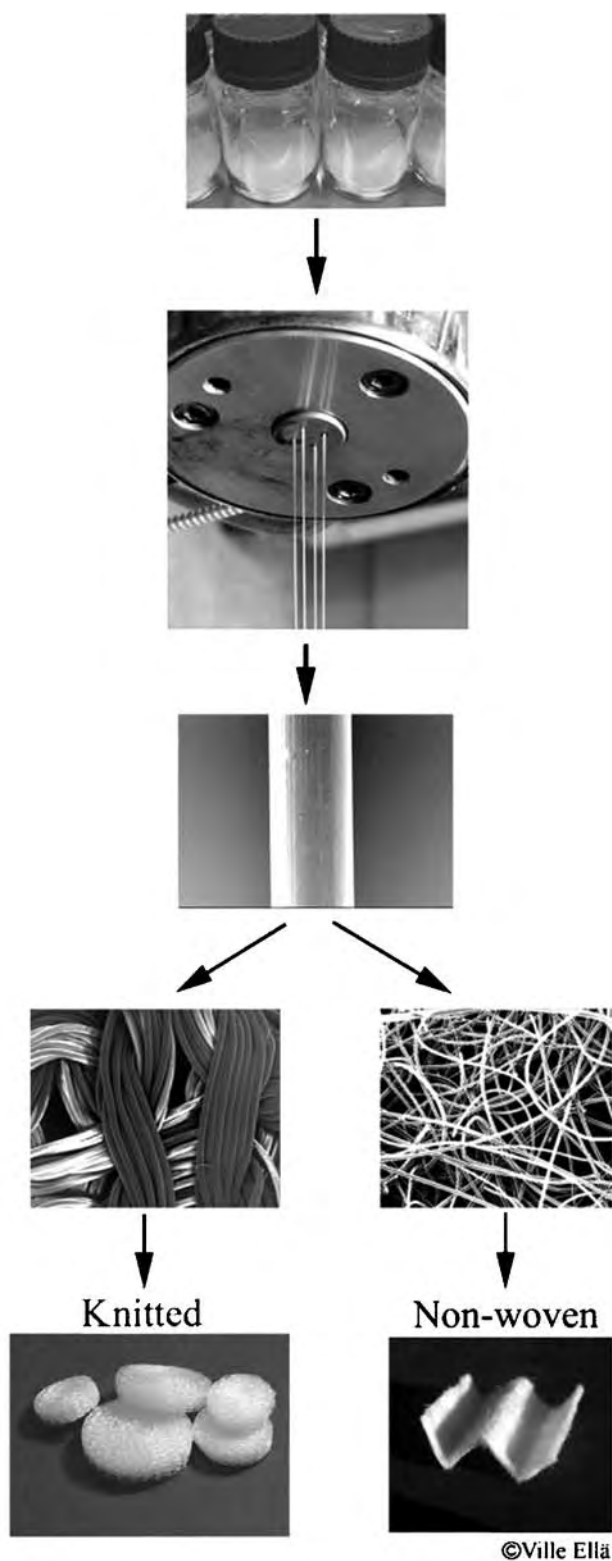

Fig. 2 Melt-spinning steps from a raw material to a product.

formers or network formers because they provide the backbone in other mixed-oxide glasses. With so-called network modifiers (Na^+ , Ca^{2+} , K^+ , Mg^{2+} , etc.), glass properties like degradation rate, bioactivity,

viscosity–temperature dependence, and crystallization behavior can be modified and optimized.

The form of bioactive glasses in clinical use has been limited mainly to the use of glass in the form of crushed particulates. The ability of most of the early bioactive glasses to crystallize when heated renders further heat treatments with these bioactive glasses difficult. Another important feature to enable fiber formation from glass is the viscosity–temperature dependence, or the “working range” of glass. A glass has a narrow working range if the viscosity is significantly changed within a relatively narrow temperature region and it has a large working range if the viscosity changes over a large temperature region. Because in melt spinning viscosity control of the glass melt is a prerequisite for successful controlled manufacture, glass compositions with a large working range are significantly easier to manufacture by melt spinning compared with glasses with a narrow working range. Currently both phosphate- and silicate-based bioactive glasses can be melt spun into fibers.

The most commonly used phosphate glasses are composed of phosphate and calcium, but other network modifiers such as sodium can be added. The first proposals regarding the use of phosphate-based glass fibers for biomedical purposes are from the mid-1980s. One of the limitations of the use of phosphate-based glasses is their rapid degradation. This property can be controlled to some extent by modifying the composition and structure of the glasses.

The first report of the manufacture and osteoconductivity of melt-spun silicate-based bioactive glass fiber was by Pazzaglia and coworkers in 1989.^[10] The composition of the used glass was as follows: 46–53 wt% SiO_2 ; 4–8 wt% P_2O_5 ; 9–20 wt% CaO ; 7–24 wt% Na_2O ; 2.8 wt% K_2O ; 1.11 wt% MgO ; and 0.12 wt% Al_2O_3 . Vita Vinzi Zalman et al.^[7] reported that bioactive glass can be formed into fiber without devitrification when it has the following composition: 40–55 wt% SiO_2 ; 5–8 wt% P_2O_5 ; 20–40 wt% CaO (MgO); 20–30 wt% Na_2O (K_2O); 2–9 wt% K_2O ; 0.5–2.5 wt% Al_2O_3 .

Brink^[11] further studied different glasses in a system containing boron, sodium, potassium, magnesium, calcium, phosphorus oxides, and silica. Brink carried out an extensive study of the crystallization, viscosity, and biological activity of different glass compositions in this system. Bioactivity occurred when the glass contained 14–30 mol % of alkali, as well as alkaline earth oxides, and <59 mol % of silica. The forming properties of bioactive glasses were improved when the content of silica in the glass was increased to 53–56 mol %. Brink also reported that the amount of alkali oxides should be decreased and the amount of alkaline earth oxides increased in glass compared with

the early bioactive glass compositions (e.g., Bioglass[®]) to achieve a large working range.

The Physics of Glass Fiber Drawing

The viscosity of molten glass is very important for manufacturing success. During drawing the viscosity should be relatively low. If it is too high the fiber will break during drawing; however, if it is too low the glass will form droplets rather than be drawn out into a fiber. The optimal viscosity range for fiber spinning is typically between 500 and 1000 dPa sec. The critical time (t) in which a very viscous (η = viscosity) circular jet of radius a leaving an orifice would break up is

$$t = 5\eta a / \sigma$$

if σ is the surface tension. However, fiber is drawn from the nozzle at such speed that its radius is much decreased immediately after the orifice and its radius is so small that it cools and becomes rigid in less than the critical time.

Under the conditions used in making glass fibers it may be assumed that the flow through the nozzle is governed by Poiseuille's law, so that the mass rate of flow M through an orifice of radius a is

$$M = \rho \pi \Delta P a^4 / (8\eta L),$$

where ΔP is the pressure difference causing flow (the hydrostatic head), ρ is the density of the glass, and L is the length of the nozzle. Drawing the fiber more quickly reduces its final diameter without increasing the mass flow rate.^[12]

Glass Fiber Melt Spinning Machinery

In the direct melt process, which is used mainly in technical glass fiber manufacturing, the molten glass in the furnace goes right to the bushing after glass formation. The temperature of the bushing plate is controlled to keep the glass at the correct temperature for fiber formation. The bushing plate normally contains 200 to 4000 nozzles with a diameter of approximately 0.5 mm and is made of platinum alloyed with rhodium for durability. Platinum is used because the glass melt has a natural affinity for wetting it.

Laboratory scale melt spinning can be carried out from the previously manufactured glass block using a simple platinum crucible. The glass block is heated to the desired temperature in a platinum crucible, which has holes as nozzles at the bottom of the crucible. Because the hydrostatic pressure resulting from the glass melt is lower in the small-scale method than in the direct melt process, the required nozzle diameter is larger (approximately 4 mm).^[13] Fig. 3 presents a

Fig. 3 Scheme of laboratory-scale machinery for bioactive glass melt spinning, including a coating unit.

schematic diagram on laboratory-scale melt spinning machinery, including a coating unit.

As glass flows through the nozzle it forms a drop, which is suspended from the end. As it falls, it leaves a thread attached by the meniscus to the nozzle as long as the viscosity is in the correct range for fiber formation. The formed threads are drawn and attached, e.g., to the rotating coil in order to collect the formed fibers. With controlled drawing speed the diameter of the formed fiber can be adjusted to the desired level.

In technical-scale glass fiber melt spinning the fibers are rapidly cooled right after formation by spraying water or water together with a sizing agent onto the formed fibers before they are wound onto a roll. Sizing agents act as a surface lubricant to minimize damage caused by glass-to-glass abrasion during drawing and winding but their use as a keying agent is also common when the fiber is to be used in some kind of polymer composite.

Structure and Strength of Melt-Spun Glass Fibers

Glass and melt-spun glass fibers are identical with regard to their chemical composition, but have structural differences caused by the manufacturing process and the larger surface area of the fiber. The rapid cooling of glass fiber in melt spinning causes stress distribution to fibers, resulting in compression stress on the surface parts and tensile stress in the inner parts. This toughening phenomenon is caused by the stress distribution, which is a result of the density differences in the different layers of the fiber caused by cooling. Thus, glasses bear viscoelastic behavior, which can be explained by the molecular relaxations of material, so structural changes and stress relaxations can be presumed to occur in glass fibers over long time periods.

The theoretical strength, which can be calculated from the bond energies between different ions and molecules, is about $15,000 \text{ N/mm}^2$ for technical “E” glass fiber. In a laboratory setting strength values close to the theoretical value have been achieved with very thin, faultless fibers. In practice, obtained strength values are much lower depending on the manufacturing method, the fiber diameter, and mostly the fiber surface quality. The structural defects, such as cracks, voids, and impurities on the fiber surface, significantly decrease fiber strength. Because thinner fibers have a smaller surface, there is less likelihood of flaws, which leads to higher strength values with thinner fibers. The Griffith theory is also supported by the dependency of the fiber length on the fiber strength. Because even slight abrasion of the fiber surface drastically reduces the strength of bioactive glass fibers, it is crucial to apply a sizing or coating to the fiber surfaces within fiber melt spinning to maintain the initial high strength of the formed fibers.^[13]

BIOMEDICAL APPLICATIONS OF MELT-SPUN FIBERS

Polymer Fibers

Textiles have a long history in medicine dating back to 2000 BC. The most widely used applications are hospital textiles, such as beddings and sheets, and the largest selling product group are wound dressings. In these applications the material is temporarily and is in contact with the human body for only a short period of time; thus, materials do not need to be biocompatible (i.e., accepted by human tissues).

The most used surgical products are sutures, threads, and yarns used to close wounds. They exist in both biostable (i.e., material remains in the body unchanged) and bioabsorbable (material intentionally and at a predictable rate disappears from the body) forms. The first man-made synthetic bioabsorbable suture materials, Dexon[®] and Vicryl[®], were introduced in the 1970s when the fibers emerged as an interesting aspect in scaffold manufacturing. Bioabsorbable sutures have been extensively used in medicine for decades and new materials have also been developed. Along with new materials, new techniques and modifications of old textile manufacturing systems have emerged.^[9,14]

The main purpose of fibers in the field of biomedical applications has been wound closure operations. Much knowledge has been gained in this area of expertise. Biomaterials used for this purpose are biostable-like silk, polypropylene, nylon 6, nylon 66, polyethylene terephthalate, polybutylene terephthalate, poly(tetramethylene ether) terephthalate-co-tetramethylene terephthalate, and bioabsorbable-like regenerated

collagen, polyglycolic acid, polyglycolide-co-lactide, polyglycolide-co- ϵ -caprolactone, polyglycolide-co-trimethylene carbonate, and poly-*p*-dioxanone. These bioabsorbable sutures must have a certain degree of crystallinity for mechanical strength and in vivo retention time. The development of biomaterial fiber production also gave rise to a whole new set of products and applications. In the field of biomedical engineering the main focus at the moment is filling voids, creating new tissue by creating a support for the tissue, and manufacturing 3-D scaffolds as support structures for living organisms such as bone, ligaments, tendons, veins, and body walls. By manufacturing the scaffold from fibers it is possible to create open and porous networks that still have suitable strength and endurance capabilities. Different processing methods can be utilized with fibers depending on their application. The most commonly used methods with polymeric fibers are weaving, knitting, and braiding.^[9,14]

Wovens and non-wovens

Fabrics weaved from fibers are called woven fabrics. These products are generally used as cloths and drapes in hospitals. In an atmosphere where sterility is a key issue, some fabrics are meant for single use. For these applications non-woven fabrics are the most economic solutions because of their lower manufacturing costs and prices. Several methods for producing non-wovens from staple fibers exist, such as air laying, needle punching, thermal bonding, and wet laying. A non-woven production method for continuous fibers is a spun-laying technique. Manufacturing methods can change the porosity of the fabric. High-porosity fabrics, where the porosity is around 90%, can be manufactured, although increased porosity results in decreased mechanical strength and fabric stability. When comparing the non-woven method with other methods of production, the structure of the non-woven fabric is always random because of the method used, whereas manufacture by weaving, knitting, and braiding results in a well-organized structure. Non-wovens are used for applications such as non-degradable condensed poly(tetrafluoroethylene) PTFE hernia meshes and surgical drapes. Non-wovens produced from melt spun polylactide fibers for cell carrier scaffolds (Fig. 2) have been studied by Sittinger et al.^[15] and Ellä et al.^[8] and some products made from biodegradable non-wovens are already on the market.

Knitting

Knitting is a manufacturing method that includes styles like weft knitting and warp knitting. In knitting

there is continuous feed of the fiber to the fabric for every layer. Both techniques have the capability to produce flat or tubular structures, of which weft knitted are more deformable. Using warp knitting it is possible to manufacture tricot and raschel knits, among other structures. These structures can be used as core structures in engineering composites and implantable device manufacturing or as scaffolds for tissue engineering purposes. The needles used in the machines make loops in the knit and, depending on the fiber and the loop geometry, the loop is the weakest point, thus lowering the maximum possible strength of the knit.^[16] Knitting has been used to manufacture stents and vascular grafts for use in the human body.^[14] As a more engineered implant, Honkanen et al.^[17] studied a knitted circular implant made from polylactic acid fibers as a joint scaffold arthroplasty in metacarpophalangeal joints (Fig. 2).

Braiding

As a manufacturing method, braiding differs from knitting because the fibers are fed from every spool while the spools are spinning around each other, making a criss-cross pattern. This method is used for everyday applications such as shoelaces and cords. Some commercial surgical sutures are manufactured using braiding. Compared with a monofilament, multifilament braiding increases knot break strength, permeability, and flexibility. Knot break strength is the most important factor for a suture material: if a knot breaks during suturing, it cannot be fastened. Braiding is also used to manufacture stents and vascular conduits. The suitability of the method was also studied for use in reinforcement for implantable products and as artificial ligaments. The main interest in braided products lies in their good pulling strength along the braiding axis compared with other manufacturing methods.^[9,14]

Bioactive Glass Fibers

The medical field, and especially the field of tissue engineering, continues to set new challenges for biomaterials engineering. Despite dramatic progress in the field, there is still a need to further enhance the properties of these materials. One fruitful area of research in biomaterials is the use of melt-spun bioactive glass fibers in raw form or as part of biomaterial composites, because bioactive glass fibers are well tolerated by living tissues. Advantageous properties can be achieved, for example, when strong bioactive glass fibers are used as reinforcement in biomedical polymer matrixes.

Sintered porous scaffolds

Bioactive glass is proposed as a good option to achieve repair of bone tissue because of its resorbability and its osteostimulating effect. With the sintering method, in which chopped bioactive glass fibers are connected to each other using heat to form a structure, a scaffold with porous network is obtained. The network has highly interconnected pores, as illustrated in Fig. 4. The porosity, pore size, scaffold architecture, mechanical properties, and degradation rate of the material of the scaffold can all be optimized using this method. The preliminary in vivo and in vitro results indicate that this material bears advantageous properties in use as synthetic bone grafting material and bone tissue engineering applications.^[18]

Reinforcement for bioabsorbable composite structures

Using strong bioactive glass fibers as part of a polymer-based composite, the properties of the plain polymer can be enhanced: 1) bioactive glass fibers reinforce the polymer and the mechanical properties of the obtained composite may reach the level of hard bone tissue; and 2) bioactive glass imparts osteoconductive characteristics to the composite.

The advantage of fiber-reinforced composite materials is the ability to tailor the mechanical or physical properties of the material. For example, the modulus of a unidirectional fiber composite correlates closely with a rule of mixtures,

$$E_{\text{composite}} = fE_{\text{fiber}} + (1 - f)E_{\text{matrix}},$$

Fig. 4 Scanning electron microscopy image of a porous bioactive glass scaffold manufactured by sintering the melt-spun bioactive glass fibers. Scale bar = 100 μm .
