Osteocytes are the prominent cells of the adult skeleton. They are the only bone cells that actually lie *within* the hard bone ECM. On the surface of adult bone a thin sheath of lining cells is found that covers all bony surfaces, i.e., the periosteum, the trabecular surfaces, and the Haversian channels. Lining cells are only absent from those surfaces where osteoclasts and osteoblasts are active. Both osteocytes and lining cells represent the end stage of differentiation of osteoblasts, the cuboidal cells that produce the bone ECM (see Fig. 3). Osteocytes are left in the mineralizing bone matrix during the process of bone formation, and are therefore the only cells that are truly embedded in the bone ECM. Lining cells are formed when bone formation has finished at a certain surface and the last remaining osteoblasts flatten out to become lining cells (Fig. 3). Osteocytes keep contact with other osteocytes and with lining cells via long, thin, fingerlike processes that run through the ECM and connect to other osteocyte processes by means of gap junctions. Calcification of the ECM always stops before the osteocyte cell body or cell processes are reached. As a result, osteocytes are completely surrounded by a thin sheath of nonmineralized ECM. In deproteinized preparations of bone, the osteocyte cell bodies and their surrounding sheath show up as small holes called lacunae, while the cell processes plus their sheaths show up as tiny canals, the canaliculi of bone. Bone canaliculi are approximately 0.2 micrometer in diameter, about 250 times smaller than the Haversian channels (which are about 50 micrometer in diameter and contain blood vessels). Osteocytes may have up to 80 cell processes (and therefore 80 canaliculi); via these processes they keep contact with neighboring osteocytes as well as with bone lining cells. Therefore, compact as well as trabecular bone may be considered as a three-

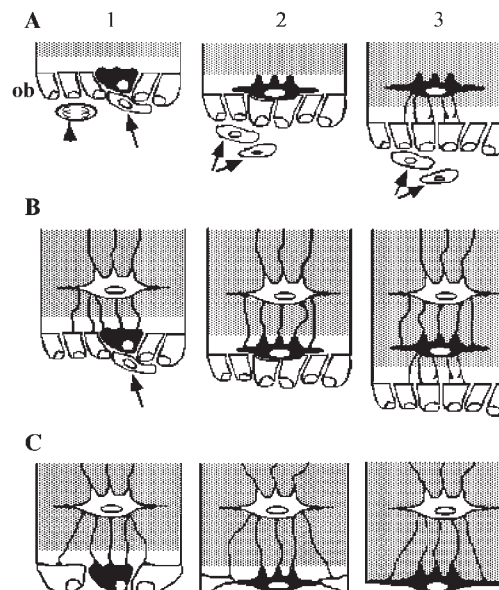

Fig. 3 Schematic presentation of the growth of bone tissue. In A and B, a quiescing osteoblast (black cell) turns into an osteocyte because its neighbors continue to produce bone ECM. Note that during rapid growth (A), proliferation of osteoblast progenitor cells (arrows) ensures that new osteoblasts can be recruited. In B, bone growth slows down as cell proliferation stops. In C, bone growth has stopped completely. The last echelon of osteoblasts stops producing ECM and turns into a layer of lining cells. No new osteoblasts are recruited at this site. Note that when the ECM mineralizes (indicated by gray stippling), the osteocytes remain in contact with the bone surface by means of thin cell processes in canaliculi (thin black lines). (Figure reproduced with permission from Ref. [12].)

dimensional network of osteocytes with bone ECM in the interstices and lining cells on the surface. The function of this cellular network throughout a piece of bone was until recently unclear; recent studies, however, suggest that it functions as the mechanosensory system that regulates and orchestrates adapted bone remodeling. First, the anatomical location of the osteocytes is perfect for sensing strains throughout the tissue. Animal studies have shown that mechanical loading activates several cellular processes in osteocytes, including energy metabolism, gene activation, growth factor production, and matrix synthesis.^[10-12] In addition, comparative studies of the responsiveness of isolated osteocytes, osteoblasts, and periosteal preosteoblasts to mechanical strain in-vitro, showed that osteocytes were most responsive. Of the other two cell types, osteoblasts were more responsive than preosteoblasts.^[13-15] Thus, in the course of differentiation from immature preosteoblast via osteoblast to osteocyte, bone cells increase their sensitivity to mechanical strain; this development is suggestive of a specific role for osteocytes in mechanosensing. Even so, the manner

Fig. 4 Effect of pulsating fluid flow (5 Hz sigmoidal pulses, 0.6 ± 0.03 Pa shear stress) on NO production by cultured human bone cells obtained from a transiliac bone biopsy. After 1 hr with or without flow, the cell culture medium was assayed for NO (measured as NO₂). Black dots are stressed cells; white dots are nonstressed controls. Note that after 15 minutes the initial rapid stimulation of stressed cells stopped. (Figure reproduced with permission from Ref. [25].)

whereby osteocytes sense the strains of the mineralized matrix remained obscure because of the very small strains in bone during daily loading (as compared to, e.g., muscle tissue). In healthy bone, the strains resulting from physiological loading do not exceed 0.3%, and are usually of the order of 0.05%,^[16] whereas cultures of isolated bone cells need strains of the order of 1 to 10% to evoke a response.^[17] This apparent contradiction was overcome by the concept of strain-derived canalicular fluid flow as the physical mediator of mechanosensing by osteocytes in bone tissue.^[18,19] According to this view, the osteocytes of loaded bone are activated by the flow of extracellular fluid through the network of canaliculi and lacunae. When bone is loaded, extracellular fluid is squeezed through the thin layer of nonmineralized matrix surrounding the osteocytes toward the bone surface. This flow, rather than the small bulk strain of the loaded bone, produces fluid shear stress at the osteocyte membrane that activates the osteocyte. Several biological studies support this concept. Animal studies show that bone formation in response to loading is sensitive to strain rate, and that large strains alone are not sufficient to activate bone cells, suggesting that interstitial fluid flow is the physical stimulus involved.^[20,21] In cell culture studies, osteoblasts are more responsive to fluid forces than to mechanical strain.^[22] Isolated osteocytes show strong responses to fluid flow of the order of 0.5 pascals (Pa), the magnitude predicted by the studies of Weinbaum and colleagues,^[18,23] responses include rapid release of nitric oxide (NO) (Fig. 4) and prostaglandin E₂ (PGE₂).^[13-15,24-26] Together, these findings suggest that the osteocyte network, with its accompanying lacuno-canalicular porosity, is the site of mechanosensing in bone tissue. Mechanotransduction then

includes translation of canalicular fluid shear stress into signals in osteocytes that can recruit osteoclasts and osteoblasts. The following sections discuss how this concept fits into a cellular mechanism of strain-adapted remodeling. (See the article titled *Histogenesis* in this encyclopedia.)

STRAIN-INDUCED CANALICULAR FLUID FLOW AROUND A BMU

Assuming that osteocytes regulate adaptive bone remodeling, the very local strain fields around a progressing BMU become important, because they could activate the local osteocytes to recruit first osteoclasts, and subsequently osteoblasts. Finite Element (FE) analysis of remodeling (hemi-)osteons, performed on a microscopic, supracellular level, found opposite strain fields around the tip and the tunnel of a progressing BMU.^[6] Equivalent strain was used as a measure for the deformation of the tissue. In the FE model of a tunneling osteon, a region of decreased strain appeared in front of the tunnel tip or cutting cone (Fig. 1) when the model was loaded naturally (i.e., in the longitudinal direction) (Fig. 5). Behind the tunnel tip, however, elevated strains appeared in the tunnel wall in the area known as the closing cone where new bone is formed by osteoblasts (Fig. 5). The bone tissue around the site where osteoclasts are active (the cutting cone) is thus understrained, while the tissue around the site where osteoblasts are active (the closing cone) is overstrained. A similar relation was found for (hemi-)osteons of

Fig. 5 Equivalent strain field in compact bone around the resorption tunnel of a tunneling BMU (half model). Loading occurred in the longitudinal direction. Reduced strains are present in front of the cutting cone tip where osteoclasts are active (blue or dark grey). Elevated strain levels are present directly after the cutting cone, where osteoblasts are recruited to refill the tunnel (yellow or white band). (Figure reproduced with permission from Ref. [6].)

remodeling trabecular bone (Fig. 6). Here the initial stage of remodeling was modeled as a resorption lacuna in a trabecula. Loading of the trabecula in the longitudinal direction produced increased strain at the bottom and transverse border of the lacuna, the sites where further osteoclast activity is inhibited while osteoblasts are actively filling up the gap. Reduced strain levels appeared, however, along the longitudinal border and surface of the trabecula just where resorption continues (Fig. 6). This study therefore concluded that subsequent activation of osteoclasts and osteoblasts during remodeling may be a strain-regulated phenomenon.^[6]

The opposite strain fields around cutting and closing cones were subsequently linked to fluid flow patterns in the lacuno-canalicular network around the cutting and closing cones.^[7,8] Biot's theory of poroelasticity was used to calculate the interaction between bone deformation and extracellular fluid flow in a finite element model of a tunneling osteon.^[8] Remodeling was considered to occur within the diaphyseal cortex of a human femur; the force pattern applied was a typical loading curve recorded from a walking person. As expected, the pattern and magnitude of flow were very different around the cutting and closing cones. At maximum load during the heel strike phase, a high fluid outflow was found at the bone surface of the closing cone that dampened out at a depth of some 100 micrometers within the bone tissue (Fig. 7). Along the cutting cone, however, a much lower fluid inflow at the bone surface reversed to a very low outflow at a

Fig. 6 Equivalent strain field around the initiation of a resorption trench along a remodeling trabecula (half model). Elevated strains are found at the bottom and transverse border of the resorption pit, where further osteoclast activity is inhibited and osteoblasts are recruited (yellow or white area). Reduced strain levels appear along the longitudinal rim and the trabecular surface (blue or dark grey), just where resorption will continue. (Figure reproduced with permission from Ref. [6].)

Fig. 7 Fluid flow within the lacuno-canalicular porosity around the cutting and closing cones of a remodeling resorption tunnel, in the human femoral diaphysis at maximum load during the walking cycle. Along the closing cone, fluid outflow (indicated by negative values) is high at the surface and dampens out at a depth of some 100 micrometers. Along the cutting cone, low fluid inflow (indicated by positive values) is reversed to low fluid outflow (negative values) at a depth of some 10 micrometers. (Figure reproduced with permission from Ref. [8].)

depth of some 10 micrometers within the bone tissue (Fig. 7). This led to a situation of almost complete fluid stasis in front of the cutting cone during the entire walking cycle (Fig. 8). The bone tissue layer immediately in front of the cutting cone is therefore an area that lacks fluid flow, whereas the bone tissue layer around the closing cone is an area of enhanced fluid flow.^[8] Assuming that unloaded osteocytes attract osteoclasts while overloaded osteocytes attract osteoblasts, this study is the first to link the progress of a BMU, and the coupling of bone formation to bone resorption, to the mechanical strain of osteocytes around a loaded remodeling site. Speculation is now in order about the cellular mechanisms by which unloaded osteocytes attract osteoclasts and overloaded osteocytes attract osteoblasts.

OSTEOCYTE APOPTOSIS AND REMODELING IN THE DIRECTION OF LOADING

The studies in the foregoing discussion^[6-8] provide evidence for mechanical regulation of osteoclast and osteoblast recruitment during bone remodeling. Osteoblast recruitment to loaded bone is generally believed to involve growth factors such as insulin-like growth factor^[11] as well as prostaglandins,^[27] but the pathway by which overloaded osteocytes recruit osteoblasts to the bone surface is largely unknown.^[28]

Fig. 8 Fluid flow at three levels of depth around the cutting cone tip of the remodeling resorption tunnel of Fig. 7. At a depth of about 10 micrometers, a situation of almost complete fluid stasis occurs during the whole walking cycle, leading to absence of fluid flow in the canaliculi during normal loading. (Figure reproduced with permission from Ref. [8].)

A cellular mechanism by which osteoclasts may be recruited by underloaded osteocytes has recently been proposed.^[9] This cellular mechanism is based on osteocyte apoptosis (or programmed cell death) as the steering mechanism for attracting osteoclasts.^[29] In the proposal by Burger, Klein-Nulend, and Smit, apoptosis of underloaded osteocytes results from lack of NO production due to lack of canalicular fluid flow. Production of low levels of endogenous NO is important for preventing apoptosis in many cell types, including the endothelial cells that line blood vessels.^[30] The example of endothelial cells is particularly important because these cells need a certain amount of fluid shear stress (provided by the blood stream) to produce enough NO to prevent the cells' apoptosis.^[31] The shear stress-dependent NO is produced by a specific enzyme, endothelial cell-NO-synthase (ecNOS), that is found in osteocytes as well as in endothelial cells.^[25,32] Because osteocytes rapidly produce low levels of NO by this enzyme in response to shear stress,^[24] it is therefore likely that NO plays a role in preventing their apoptosis similar to the role it plays with endothelial cells.^[9] Fluid shear stress has been reported to inhibit experimentally induced apoptosis in osteoblasts.^[33] The Burger/Klein-Nulend/Smit hypothesis proposes that, under normal mechanical loading conditions, osteocytes are protected against apoptosis by a basal amount of NO and probably by PGE₂ production under normal canalicular shear stress. At the tip of the cutting cone of a BMU, however, osteocytes enter apoptosis as a result of insufficient fluid flow and, therefore, insufficient NO (and PGE₂) production. These apoptotic

osteocytes attract osteoclasts (Fig. 9) that behave as macrophages by phagocytosing the dying osteocytes.^[29,34] By contrast, at the base of the cutting cone where the osteocytes become overloaded, NO production is higher than normal. Because released NO can cause retraction of osteoclasts from a resorbing bone surface,^[35] it is proposed that the osteoclasts of a BMU move in a treadmill: attaching at the tip of the cutting cone, detaching at the base, and reattaching again at the tip (Fig. 10).^[9] While osteoclasts further excavate the cutting cone, the front of low fluid flow and osteocyte apoptosis also moves along, steered by the strain fields in the correct (i.e., strain-oriented direction). This process will lead to secondary osteons and (hemi-)osteons that run in the direction of mechanical loading.

OSTEOCYTE APOPTOSIS, ACTIVATION OF REMODELING, AND UNWANTED BONE LOSS

Osteoclast recruitment by apoptotic osteocytes has been demonstrated experimentally in adult rat long bones after fatigue loading^[36] and after damage applied by inserting an orthopedic screw.^[37] Both studies linked local osteocyte apoptosis to rapid recruitment of osteoclasts and resorption of damaged bone surfaces.

Fig. 9 Schematic illustration of the proposed relation between canalicular fluid flow stasis, osteocyte apoptosis, and osteoclast recruitment. White ovals are vital osteocytes (OCY); black ovals are apoptotic osteocytes. Black interconnecting lines represent canaliculi. OCL is an osteoclast in the cutting cone (white void) that is attracted to the cutting cone surface by apoptotic osteocytes. Longitudinal loading causes fluid stasis (indicated by white background) in front of the cutting cone, which in turn causes osteocyte apoptosis. Apoptotic osteocytes (black ovals) attract osteoclasts, possibly by expressing apoptosis-specific markers on the surface of their cell processes (indicated by asterisks). (Figure reproduced with permission from Ref. [9].)

Fig. 10 Schematic illustration of how overloaded osteocytes around the base of the cutting cone may suppress further osteoclastic resorption by producing enhanced amounts of NO. White ovals are vital osteocytes, black ovals are apoptotic osteocytes, and interconnecting lines are canaliculi, similar to Fig. 9. Osteoclasts (large cells with several nuclei, indicated by black dots) are attracted by apoptotic osteocytes to attach to the cutting cone surface and resorb bone. Behind the cutting cone, where the wall of the tunnel is overloaded (indicated by dark gray background), the vital osteocytes are mechanically overstimulated (indicated by long arrows) to produce enhanced amounts of NO. High levels of NO cause retraction of the osteoclasts from the bone surface, so that osteoclasts now appear as round cells. A retracted osteoclast can only reattach at the cutting cone tip where no NO is produced, which leads to a treadmill of osteoclasts that continue to dig a tunnel along the direction of mechanical loading. (Figure reproduced with permission from Ref. [9].)

Osteocyte apoptosis thus served to start remodeling—a process called activation—rather than continuing it, as discussed in the previous section.^[9] However, many authors assume that in physiological bone remodeling, microdamage due to tissue fatigue is also a signal for activation of remodeling.^[38,39] Microdamage due to fatigue of the ECM can easily lead to osteocyte apoptosis by disrupting canaliculi and severing osteocyte processes.^[12] Osteoclast recruitment by apoptotic osteocytes will therefore also explain remodeling activation. A single mechanism—programmed cell death of local osteocytes—may thus cause first activation and subsequently adaptation during bone remodeling. The only difference is the cause of osteocyte apoptosis: ECM fatigue and damage for activation; strain-oriented disuse and lack of canalicular flow for (hemi-)osteon formation and alignment. Interestingly such a mechanism also explains the clinically observed unwanted loss of bone that occurs around orthopedic joint-replacing implants and in the edentulous jaw. Both cases may be seen as the outcome of the biological response

to bone disuse. In the edentulous jaw, the processus alveolaris of the jaw that carried the teeth completely loses its function after tooth extraction. In the case of the replaced hip joint, the femoral diaphysis is shielded against stress by the pin of the prosthesis. In both cases the resulting disuse of bone tissue may lead to lack of strain-derived fluid shear stress, and therefore to osteocyte apoptosis. These events will lead to untimely activation of remodeling, and unlimited progress of the osteoclastic attack. In addition, the space created by the resorptive action of osteoclasts is not refilled, because resorption does not lead to overstraining of the surrounding osteocytes, again due to generalized disuse of the surrounding bone tissue. Trabecularization of the femoral diaphysis and resorption of the processus of the jaw are the final result of this process.

CONCLUSION

Recent experimental and theoretical studies have for the first time provided an explanation for the strain-oriented remodeling of bone tissue. The histological structure of bone, with its three-dimensional network of osteocytes and lacuno-canalicular porosity, seems to provide the intrinsic mechanosensory system whereby bone tissue can renew itself in relation to the direction and magnitude of its daily mechanical loads. Although many details of this process remain to be unraveled, a cellular explanation of Wolff's Law now exists.

Burn Dressing

Andrew Burd

Department of Surgery, The Chinese University of Hong Kong, Prince of Wales Hospital, Shatin, Hong Kong

INTRODUCTION

The concept of burn dressings is undergoing radical change. Traditionally, the goal was to protect the wound and promote natural healing. Now we are revisiting the concept of dermal healing, a process of repair resulting in unwanted scars. The focus has shifted toward preventing repair and promoting regeneration. A burn is a specific type of wound caused by a pathological change in energy within a tissue, resulting in the loss of functional and structural integrity. All of this energy—thermal (hot), chemical, electrical, or radiation—destroys cells and denatures proteins. In thermal (cold), proteins will not be denatured and a different outcome will result. Healing is the process whereby wounded tissues respond and attempt to restore functional and structural integrity. In the skin there are two major mechanisms of healing; regeneration and repair.

This article begins with a brief overview of the structure and function of skin and the effects of burn injury. Burn injury represents a wide spectrum of trauma, and treatment strategies are varied. Burn dressings provide an essential part of treatment. They may be all that is required in a superficial wound, or they may be used as adjuncts to surgical treatment. In this latter context there has been a surge in the development of tissue-engineered products incorporating biological interactions.

STRUCTURE AND FUNCTION OF SKIN

Skin is the largest immunologically competent organ in the body.^[1,2] It extends to over 1.6 square meters in the adult and weighs approximately 3000 gm. The skin has two layers: epidermis and dermis (Fig. 1). The epidermis is rich in cells and is of ectodermal origin. The cells are specialized in the formation of keratin and are called keratinocytes. The basal keratinocytes adhere to the basement membrane, which forms part of the zone between epidermis and dermis: the dermo-epidermal junction. Basal keratinocytes are unique in that they are capable of proliferating to form either new basal cells or terminally differentiating keratinocytes. The terminally differentiating keratinocyte moves up

through several layers and undergoes certain changes: the cytoplasm becomes increasingly packed with keratin and the nucleus shrinks. The outermost layer—the stratum corneum—contains dead keratinocytes packed with keratin, forming a barrier between the living tissues and the external environment.

The area of the basement membrane far exceeds that of the surface of the stratum corneum, because multiple dermal papillae project from the surface of the dermis. These papillae are formed by loose approximations of collagen bundles referred to as the papillary dermis, which lies on the relatively much thicker reticular dermis. Collagen bundles in the reticular dermis are thicker and more condensed.

Between the organized structure of elastin and collagen fibers is a thick, viscous fluid made up of glycosaminoglycans and hyaluronan. This arrangement of the dermis gives the skin its major biomechanical properties, allowing stretching and recoil and deformation without destruction.

The dermis contains a complex vascular arrangement of capillary and venous plexuses. Within the dermis are adnexal structures of ectodermal origin—hair follicles, sweat glands, and sebaceous glands—which are lined with keratinocytes. This arrangement becomes particularly important when considering the mechanisms of burn wound healing.

Multifunctional Langerhan's cells found in the epidermis have an important role as antigen-presenting cells in cutaneous immune reactions. Skin color is determined principally by the pigment melanin, produced by melanocytes. These cells package the melanin into melanosomes, which are then transferred to keratinocytes.

The skin is richly endowed with sensory nerve endings that enable the skin to play its vital role as a tactile interface between the body and the environment. Other sensory functions provide important stimuli for behavioral modification, e.g., the withdrawal reflex associated with pain or excessive temperature.

THE BURN INJURY

The damage caused by a burn is a function of the amount and the speed of the energy change within the

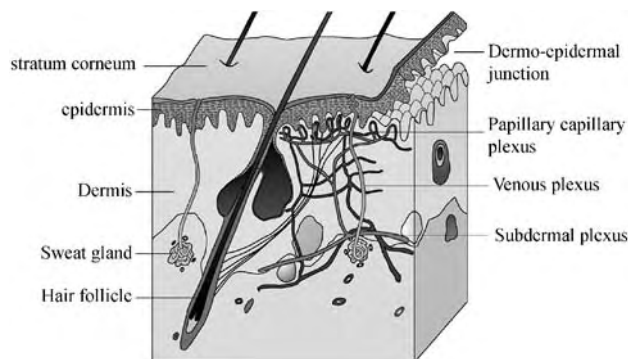

Fig. 1 A diagrammatic section of skin showing bilaminar structure, vascularity, and appendageal elements.

system.^[3] In a burn from hot water, for example, two major factors that influence the potential damage are the temperature of the water and the duration of contact with the skin. Prompt cooling can reduce this damage. The actual damage will be influenced by other factors, however, including the anatomical location of the burn, the local blood supply, and the treatment.

Following the burn the immediate damage will be to the keratinocytes. The integrity of the cell membrane is lost and the cell contents are released. This results in an uncontrolled series of devastating chemical interactions that produce a range of biologically active substances with wide-reaching systemic effects. Capillary permeability increases, resulting in a fluid shift from the vascular to the extravascular compartment. Edema develops in the tissues and the patient suffers from increasing hypovolemia that can lead to renal failure and death, if not treated. For the uncomplicated burn injury, the immediate concern is to treat the potential fluid imbalance by a prospective infusion of intravenous fluids. Once the acute resuscitative needs of the patient have been addressed, attention is then focused on the burn wound.

A number of factors influence the management of the burn wound:

- the percentage of body surface area (BSA) involved, affecting logistics
- the depth of the burn, affecting surgical strategy
- the resources available
- the ability to utilize the resources
- the preburn condition of the patient

The depth of injury is classified by descriptive terminology. The skin may be either partially or completely destroyed; partial destruction may be superficial, intermediate, or deep. Most burn injuries will contain areas of varying depth of tissue damage, and the depth of burn determines the capacity of the wound to heal.

BURN WOUND HEALING, REGENERATION, AND REPAIR

Regeneration is the capacity of a tissue to renew itself so that the end result is indistinguishable from the preinjured tissue.^[4] Regeneration is a feature seen in superficial partial-thickness burns, in which the injury involves the loss of epidermis and basement membrane and the papillary dermis. There may be a highly exudative and painful wound.

The exudative phase persists for several days, and as it decreases the nature of the exudates changes. The viscosity and relative protein content increase, and eventually a fibrin layer seals the wound. In the meantime, the basal keratinocytes at the margin of the wound begin to undergo mitosis. In the normal resting state only approximately 12% of basal keratinocytes are proliferating at any time, giving the skin a tremendous reserve capacity. Re-epithelialization begins not just at the wound margin, but also from the appendageal structures. The rate of keratinocyte proliferation and migration is extremely high, and when the exposed dermal surface is recovered, contact inhibition abruptly stops migration and redirects the cells to stratification. A superficial partial-thickness burn will heal with a stratified squamous epithelial in a matter of days. Disturbance in normal pigment expression can occur, even with no scarring. In people with darker pigmentation, areas of absent pigment can have major social and psychological sequelae.

As the burn becomes deeper, the nature of the wound changes. With an intermediate partial-thickness burn the epidermis is destroyed (as with the superficial partial-thickness burn) and there is more dermal damage. The damage to the dermis involves an irreversible denaturation of the collagen. The inert collagen has to be removed for re-epithelialization to take place. Removal involves an autolytic process with enzymatic degradation and phagocytosis, augmented by an inflammatory response. Healing takes longer. As the depth of burn increases through the thickness of the dermis the phenomenon of inflammation plays an even more important role in the healing process. Typically, inflammation initiates a cascade of events, with polymorphonuclear leucocytes being attracted to the wound site. Their principal role is proteolysis and phagocytosis of debris. These leucocytes signal to macrophages which, when activated, enter the wound site to undertake a more detailed assessment of the damage. Through a cytokine-mediated signaling process, they recruit fibroblasts to begin the process of replacing the damaged collagen. Fibroblasts involved in wound healing have the capacity to produce abundant amounts of collagen, but they have lost the capacity to place and organize it in a highly structured way. The end result of dermal repair is the deposition

of disorganized collagen, which is physically apparent as scar tissue. Scarring represents a very complex biological phenomenon. Hypertrophic and keloid scars represent clinical descriptions of a heterogeneous group of disorders with various etiologies and pathological mechanisms that result in the production of a disorganized connective tissue. The duration of the phase of wound closure (i.e., re-epithelialization) and the incidence of adverse scarring increase as the depth of burn increases.

Scarring is the major cause of long-term morbidity after a burn. It can result in physical disability when function is impaired and psychological and social isolation when deformity distorts features, particularly on the face and other regions of high aesthetic impact.

Burn wounds and their treatment vary widely, and there are few universal standards. The most widely accepted surgical principles are that superficial partial-thickness wounds *do not* require surgery and that full thickness wounds *do* require surgery. There is the qualification that a full-thickness wound of no more than 2–3 cm in diameter in a nonvital part of the body can close by the natural process of wound contraction. Debate revolves around the role of surgery for the intermediate and partial-thickness burns.

The goals of burn treatment have evolved, and the major outcomes are no longer described in simple actuarial terms of death, survival, or time-to-healing but in more qualitative terms that relate to the degree, effects, and influence of scarring.

THE IDEAL BURN DRESSING

Properties of the ideal dressing for burns are listed in Table 1. In addition, the dressing should be easy to apply and readily available.

Protects

The skin provides a number of protective functions. The stratum corneum acts as a barrier that prevents invasive infection, and sebum secreted by sebaceous glands has an antibacterial action. The burn wound is vulnerable to bacterial colonization and invasive

bacterial contamination and sepsis. As burn depth increases the potential reservoir for bacterial invasion increases before viable tissue and host defenses are reached. Burns dressing should have either an antibacterial barrier function or a bactericidal/bacteriostatic function or, ideally, both. The dressing also should protect the regenerating epidermis from further mechanical injury.

Proteolytic

Except for the most superficial injuries, the wound is going to produce a layer of dead tissue. The natural process of removing this tissue involves proteolysis and phagocytosis. The deeper the wound the more tissue has to be removed, and the longer it will take for healing to occur. The ideal dressing would either support or augment the natural autolytic process or, even better, have an intrinsic enzymatic action.

Promotes Healing

The ideal dressing would promote healing through regeneration. Regeneration occurs when the epidermis is damaged, but repair is the mechanism for dermal wound healing. Repair is a macrophage-driven fibroproliferative process in which collagen is rapidly but randomly deposited. The fibroblasts involved are recruited by the macrophages, but their origin remains a subject of controversy. They are mesodermal cells, and one possibility is that they are derived from a differentiated endothelial cell at the front end of sprouting capillary buds. Whatever their origin, they seem to have lost the blueprint for the original dermal architecture.

Apart from the selective promotion of specific cell behavior, the ideal wound dressing would also provide an environment that would be more conducive to healing. In this respect the healing wound performs better in a moist healing environment, but not a macerated healing environment. Accordingly, the dressing should have the physical ability to deal with the exudates produced by the wound, but at the same time not allow the wound to dry out and the tissues to desiccate.

Pain Relieving

Partial-thickness burns can be extremely painful, and one aspect of pain control is the nature of the dressing applied to the wound. In addition, when the dressing needs to be changed it should be possible to remove it easily from the wound prior to reapplication.

BURNS DRESSINGS—DEFINITIONS AND CLASSIFICATION

On a global scale a vast range of nonmedical materials are applied to burn wounds (Table 2).^[5]

Banana leaves could be regarded as a dressing, as well indeed could river clay, but what about curry powder or, for that matter, urine? It would appear that a distinction must lie somewhere between treatments that could be regarded as dressings and treatments that are not dressings.

The Chambers Dictionary^[6] refers to a dressing as being “material applied to a wound.” Material, in turn, is described as relating to matter, and matter is defined as “that which occupies space and with which we become acquainted by our bodily senses”! On the face of it, then, chili powder is a dressing, as indeed is urine. Using such simplistic logic, even air can be described as a dressing. Indeed, facial burns are routinely left exposed, and more extensive burns also can be

treated by exposure to filtered, warm laminar-flow air in individualized cubicles. The wound exudate dries within a few days to form a thin eschar, which acts as a protective dressing for the underlying process of re-epithelialization (Fig. 2).

How then to classify burns dressings? We could consider the type of material—solid, liquid, or cream—or the complexity of the dressing with single or multiple components. There is a tendency toward developing more complex dressings that serve a number of functions, e.g., antibacterial and exudate control and/or wound protection. Another classification is to consider the range of available treatment options and develop groupings of similar types of dressing. Table 3 lists a range of treatments for partial-thickness burns, and Table 4 lists the treatments for full-thickness burns. We thus arrive at the classification outlined in Table 5. This classification differs from that proposed by Quinn et al. in their seminal 1985 paper,^[7] where she proposed that burn dressings fall into three categories: conventional, biological, and synthetic. The conventional dressing was cotton wool, gauze and lint, or Gamgee (gauze and cotton tissues), which are still widely used for dressing many types of wound including burns, principally because of their absorptive capacity (Fig. 3). The biological dressings in Quinn’s classification comprise autograft, allograft, xenograft, and tissue derivatives. In turn, the allograft can be skin or amnion, and the tissue can be used fresh, frozen, or lyophilized. The third category in Quinn’s classification—synthetic—is divided into films, gel, foams, and composites. There are a number of limitations in Quinn’s classification, notwithstanding the fact that it was published at a time when there was an exponential growth in the concept of tissue engineering. That growth resulted in a new category of biological skin substitutes that also have synthetic elements and are known as biological composites.

Skin Substitutes: Biological and Synthetic

There have been a number of more recent reviews of skin substitutes, both biological and synthetic. These act as a temporary dressing and may incorporate elements that modulate the healing response (Table 6). Pruitt gives an excellent review of the evolutionary development of biologic dressings and skin substitutes, ranging from rubbing frogs dipped in warm oil onto a burn wound (as described in the Ebers Papyrus dated 1500 B.C.) to the use of chimeric allogenic tissue proposed over three thousand years later.^[8] An increasing number of new products on the market could be grouped together under the heading of biological skin substitutes,^[9,10] and the majority of these (except for cadaveric allograft) are engineered (Table 7). The

largest not-for-profit skin bank is the Euroskin bank, based in Holland, which provides glycerolized cadaver skin.^[11]

Skin substitutes vary widely in concept and application, but Integra sets the standard in addressing the problem of dermal repair. Integra is a bilaminar material; the outer layer—silicone—is synthetic (Fig. 4). The inner layer is derived from bovine type I collagen and shark-derived chondroitin sulphate, combined in a tissue-engineering process to produce a biodegradable matrix. The design of this matrix is such that the process of degradation results in the formation of a highly organized autocollagenous replacement. With

concurrent vascularization the new dermis can be covered with autologous keratinocytes after the silicone outer layer is removed. The concept and practice come close to being realized in terms of permanent skin replacement. The process is influenced by many factors, however. Whereas the best results compare extremely favorably with autologous full and thick-split thickness grafts, there is still a considerable range in outcomes that suggests more work needs to be done in refining the product and defining the clinical procedures and applications. Another tissue-engineered

B

product, Apligraf, adopts an alternative approach. Apligraf has been described as “the nearest thing to living skin” that is produced in a laboratory. It has a bilaminar structure with a collagen matrix populated with allogenic neonatal fibroblasts, over which there is a stratified layer of neonatal keratinocytes. This living dressing is applied to the wound and begins a complex interaction. The cytokine profile of the wound bed is detected and modulated by cytokine expression by the neonatal cells. The nature of the wound changes, and the process and outcome of the healing are modified.

In a review of the clinical application of tissue-engineered skin substitutes, Kearney provides a useful categorization:^[12]

	<i>Synthetic</i>	<i>Biological</i>
Cell-free	e.g., Integra	e.g., Alloderm
Cell-containing (or cell-conditioned)	e.g., Dermagraft	e.g., Apligraf

Kearney also describes the therapeutic strategies of the various products:

1. Materials that are applied for short intervals and then removed or replaced at intervals. Function: to stimulate autologous healing.
2. Cell-free materials that encourage colonization by autologous cells and/or biodegradation and remodeling. Function: to stimulate neo-skin function.
3. Cell-containing skin substitutes. Function: to provide an immediate functional skin replacement.

A major problem with these new concepts in biointeractive, tissue-engineered burn wound dressings is cost. Other factors that affect the availability of biologically derived dressings are regulatory approval and legislation. One of the major reasons for the considerable interest in tissue-engineered skin substitutes is the lack of availability of what many consider to be the gold standard for temporary biological burn wound dressing: viable cutaneous allograft.^[13] The beneficial properties of viable cutaneous allograft are

Fig. 3 This patient has been treated with the closed method. The extensive burns are covered with antibacterial dressings adjacent to the skin and with absorbent Gamgee and retaining dressings. The dressings require daily changing, and the process is extremely time consuming.

listed in Table 8, but there are several problems associated with its use that are independent of its biological effects. The principal concerns are donor availability, effective processing, and safety in regard to disease transmission.^[14,15] Allograft skin can be either viable or nonviable. Viable skin, which can be fresh or frozen in liquid nitrogen, has advantages in providing cytokine release into the wound bed and also providing temporary vascular connection. With appropriate immunosuppression, viable allograft can be considered a transplant, but such clinical application is rarely indicated or justified. Nonviable cadaver skin has certain advantages in terms of increased safety, and it also has a longer shelf life. The most common ways to render skin nonviable are either gamma irradiation, glycerolization, or lyophilization.

There are three principal uses for cadaver skin:

1. Both viable and nonviable cadaver skin are used as temporary skin substitutes after the excision of full-thickness cutaneous burns. Rejection will occur in both, but the period of take can be extended by the use of immunosuppression.

Table 7 Tissue engineered skin substitutes

Trade name	Source	Layers	Purpose
Alloderm	Lifecell corporation	1) Acellular de-epithelialized cadaver dermis	Permanent dermal replacement.
Apligraf	Organogenesis corporation	1) Neonatal keratinocytes 2) Collagen seeded with neonatal fibroblasts	An 'intelligent' bio-interactive wound healing modulator.
Biobrane	Dow Hickman/Bertek Pharmaceuticals	1) Silicone 2) Nylon mesh 3) Collagen	A temporary dressing for partial-thickness burns and a temporary skin substitute for excised burn wounds.
Comp Cult Skin	Ortec International, Inc.	1) Allogenic keratinocytes 2) Allogenic fibroblasts and collagen	A temporary bio-interactive wound dressing.
Dermagraft	Advanced Tissue Sciences	1) Polyglycolic acid (Dexon) or polyglactin-910 (Vicryl) seeded with neonatal fibroblasts.	When covered with autologous keratinocytes, this can be a permanent skin substitute.
Epicel	Genzyme Biosurgery	Cultured autologous keratinocytes	Permanent epidermal replacement.

Laserskin	Fidia Biopolymers (Italy)	1) Culture autologous keratinocytes 2) Hyaluronic acid membrane with laser drilled perforations.	Keratinocyte delivery system for permanent epidermal replacement.
Polyactive	HC Implants (Netherlands)	1) Polyethylene oxide and Polybutylene terephelate with autogenous human fibroblasts.	Covered with autologous human keratinocytes to give a permanent skin replacement.
Transcyte	Advanced Tissue Sciences	1) Silicone 2) Nylon mesh 3) Collagen seeded with neonatal fibroblasts.	Temporary, bio-interactive, skin substitute.

Fig. 4 Integra dermal regeneration template is being stapled to the excised burn wound of this young patient.

B

2. A more common use of nonviable allogenic skin is to act as a temporary cover to widely meshed autograft, which is placed on a bed of viable tissue after the excision of a full-thickness or very deep partial-thickness burn. The autograft will take and the interstices of the mesh will close, but this process takes time. The allogenic skin prevents desiccation from occurring in the viable exposed graft bed in the interstices of the meshed autograft. Once re-epithelialization has occurred, the allograft (the nonviable allogenic skin) falls off. It has acted as a temporary dressing.
3. The third use for nonviable allograft is as a dressing for intermediate-depth partial-thickness burns. The burn is not excised, but it is cleaned and dressed with the allogenic skin. The cadaver skin adheres to the wound and protects it while healing occurs underneath. When the underlying skin heals the allogenic skin desiccates and falls off.

Allogenic skin can also run into problems with regulatory authorities, and the classification of allogenic skin as a transplant or a dressing does have medical/legal implications. Figure 5 shows a scheme for determining the nature of allogenic skin.^[16]

The other allogenic material used as a burn wound dressing is amniotic membrane. Where alternatives do not exist and risks of use are otherwise minimized and justified, it can provide an effective, temporary, biologically interactive dressing.

The other principal category of biological dressing includes xenogenic dressings. Pruitt describes the evolution of the use of xenograft tissue, identifying Canaday as being among the pioneers when he reported the use of water lizard skin in 1692.^[8] It is interesting to note that Dr. Nelson Piccolo in Brazil regularly uses frog skin dressings to good effect on burn wounds today. The skins of guinea pigs, rabbits, chickens, and dogs have all been tried, but it is porcine xenograft that finds the widest clinical application in contemporary burn care. Like human allograft, porcine xenograft can be used fresh, frozen, irradiated, or lyophilized. Availability depends on local resources, although a lyophilized preparation is commercially available. In most cases, pig skin is used as a temporary dressing for superficial burns. Typically applied after the exudative phase has passed, it provides a protective barrier dressing that relieves pain, allows movement, and promotes healing. Porcine skin can also be used as a biological dressing for a debrided partial-thickness

burn. There are cultural limitations to the use of certain xenografts; porcine sources are not acceptable among Muslim patients, for example.

Autologous tissue has another role in dermal replacement. This involves the strategy to reduce scar formation by reducing the need for repair. The source may be acellular, highly processed dermis such as Alloderm, or it could be the incorporated dermis from either viable or nonviable cadaver skin. Cuono has described a strategy of using this dermal bed and shaving off the allogenic epidermis, replacing it with autologous keratinocytes.^[17] The nature of autologous applications is changing, however, particularly with regard to the keratinocytes. Autologous keratinocytes are the key cells for survival of the patient because of the essential nature of the protective function of the stratum corneum.

In 1975, when Rheinwald and Green first described the technique of producing keratinocyte cultures in vitro, it appeared that a new era of burns management was about to commence.^[18] Indeed it has, but the expectation of rapid wound closure with laboratory-produced cultured epithelial cell autografts (CEAs) has not been fulfilled in clinical practice. The process of preparation is expensive. Although it takes only a few weeks to create enough CEAs from a few square centimeters of original biopsy to cover the entire body, the actual take and survival of the CEAs on the body has been a disappointment. Keratinocyte delivery vehicles have been developed to facilitate the process and improve the rate of successful engraftment, but this has further increased the costs of this strategy while not significantly increasing the success.^[19]

There has been a tremendous amount of research and development in keratinocyte preparation and application, and there has been a parallel development in the area of dermal replacement and/or regeneration. One major problem that has faced workers in this field is how to combine the two layers of the skin. The dermo-epidermal junction (DEJ) is extremely complex.

It is a combined unit with structural components produced by both keratinocytes and by dermal fibroblasts. In nature, a new DEJ is formed when proliferating keratinocytes migrate across the dermal collagen. This occurs in all superficial wounds and in healing donor sites. There is no problem in the function of a DEJ in these situations, and this has focused attention on the role of the undifferentiated, proliferating keratinocyte cell suspensions in burn wound coverage. Fiona Wood, a pioneer in this field, has used cell suspensions of keratinocytes to treat burns in an increasing number of clinical applications, including dermal collagen remodeling, pigment expression, and keratin expression.^[20] Thus, the interaction between the products of the keratinocytes and the dermal fibroblasts becomes as important as the speedy regeneration of the lost epidermis.

Antimicrobial Dressings

Biological dressings will not be effective in the presence of infection. The treatment and prevention of infection encompasses another vast range in the field of burn dressing. The most common topical antimicrobial agents currently used in burns care are silver based. The history of the use of silver in burn wound care has been extensively reviewed by Klasen.^[21,22]

The contemporary use of silver really dates from 1965, when Moyer described his observations on silver nitrate solution. Through clinical observation, Moyer determined that a 0.5% solution topically applied to burn wounds did not impede the process of re-epithelialization, but this concentration was quite toxic to bacteria when evaluated in in vitro studies. Silver nitrate solution had to be reapplied at frequent intervals to maintain an effective local concentration of silver; it was thus labor-intensive and also very messy. Nevertheless, it was associated with a major reduction in lethal infection.

A significant development in topical silver preparation was the introduction of silver sulphadiazine cream. This combination of silver with a sulphonamide, in a cream formulation, heralded a dramatic reduction in the once-feared *Pseudomonas septicemia*. The cream was liberally applied to the wound and then covered with a paraffin gauze layer, several layers of absorbant gauze or Gamgee, and a retaining crepe bandage. This became and remains the standard burn dressing in many centers world-wide. Silver sulphadiazine is an excellent dressing where surgical expertise is limited and facilities are poor. It promotes desloughing of the burn wound, initially by maceration. As this process becomes established in the burn wound there is considerable exudate, and the process of dressing change becomes more demanding on nursing staff. Breakthrough requires repadding of dressings or twice daily changes. The mechanism of action involves stimulating the autolytic process through an enhanced inflammatory response. The viable tissue below the eschar demonstrates increased leucocytosis. As observed earlier, when healing is associated with inflammation there is liable to be more scarring.

A further concern about silver sulphadiazine cream is that when surgery is performed the macerated, hyperemic tissue is more hostile for the surgeon. As the trend toward a more aggressive surgical management of the burn wound developed, surgeons became more critical of silver sulphadiazine cream. At the same time, a new generation of nurses who had not experienced the devastating pseudomonas septicemia began to express dissatisfaction with the “messy” application of silver sulphadiazine. A new topical preparation of silver—flammacerium—appeared to address both of these concerns.^[23]

Flammacerium is a combination of flammazine, the silver sulphadiazine combination, and cerium nitrate. The effect of this formulation was to provide the antibacterial properties of the flammazine along with improved handling properties due to the tannalizing effect of the cerium nitrate. Cerium acts on nonviable collagen, and instead of creating a macerated eschar, the burn wound develops a crust like eggshell. It is dry and favorable for the surgeons, and once formed the dressing requirement is reduced. A further advantage of flammacerium is that there is less inflammatory response in the subeschar tissue and thus less bleeding at surgery—and more importantly from the patient’s perspective, less hypertrophic scarring.

The development of silver-based dressings continues, and new products are emerging in which the silver is incorporated into a material. One such product is Acticoat, developed by Burrell, which heralds a new concept of dressings in the era of nanotechnology.^[24] Acticoat is a nonadherent, trilaminar dressing

comprising a core of polyester and absorbent rayon with polyethylene mesh on either side. This mesh is coated with nanocrystalline silver, using a physical vapor deposition. When applied to a wound and activated by moistening with water, Acticoat delivers a controlled, sustained, antimicrobial dose of 50–100 mg/ml of silver ions (0.005–0.01% silver). The dressing can remain intact for three to four days, and newer preparations can remain unchanged for even longer (Fig. 6). This makes Acticoat an extremely attractive dressing from the perspective of the nursing management of burns patients.

Another approach to delivering silver to the wound has been pioneered by Dr. A. B. Flick, the Silverlon range of products manufactured by Argentum Medical is based on silver-plated fabric. This product range includes elastic burn wraps as well as absorbent burn dressings. Silver-impregnated dressings have another interesting aspect regarding wound healing: The silver is highly conductive. Using a current density of $0.6 \mu\text{A}/\text{cm}^2$, Chu and McManus at the Army Surgical Research Center at Fort Sam Houston studied the effect of using silver-coated fabrics as anodes. The biological effects observed were increased antibacterial effects, modified vascular permeability, enhanced dermal blood flow, and enhanced rate of donor site wound healing.^[25]

Yet another silver-impregnated product to be promoted for burn dressing is Aquacel Silver, produced by Convatec. Aquacel is a hydrofiber dressing promoted for its absorbent properties. The incorporation of silver gives an antibacterial dimension to the product.

There are many other wound dressings that have antibacterial properties by virtue of medical additives. Such products include chlorexidine-impregnated paraffin gauze, and povidone-iodine impregnated gauzes.

Nonbiological, Nonmedicated Dressings

The final category of dressings to be discussed includes nonbiological, nonmedicated materials developed from the classic concept of wound dressings. Natural fabric derived from wool contains lanolin and is thus poorly absorbent. Lawrence describes wound dressings prior to the latter half of the nineteenth century that were often based on well washed old rags and spent cloth that were more absorbent than new cloth.^[26] Cotton wool in its natural state is also nonabsorbent, because of natural greases.

In 1880 the surgeon Joseph Sampson Gamgee discovered that bleaching cotton wool rendered it highly absorbent. Gamgee tried to contain the wool in an open-weave gauzelike material. The resultant dressing, known epinonymously as Gamgee, is still in widespread use today. One of the main disadvantages of

Fig. 6 This child is a septic burn patient being nursed in the ICU. The dressing is Acticoat, which is applied to the wound with no absorbent or retention dressings. The Acticoat needs to be kept moist to activate the silver it contains.

using the cotton wool is its adherence to the burn wound. During the First World War, Lumiere devised the wide-meshed cotton-weave gauze impregnated with soft, medical-grade paraffin. This dressing alone and its medicated versions referred to earlier are commonly applied to small and superficial burns.

In 1962 Winter published the classic paper in the journal *Nature* describing the process of healing in wounds dressed with nonocclusive dressings and in those dressed with occlusive dressings.^[27] This observation in a porcine model, subsequently verified in human experiments, led to the development of new dressing materials based on film technology.

Films represent the most extensive group of synthetic material dressings, and the therapeutic strategy is to cover the wound to prevent bacterial invasion while allowing for some water loss. Clingfilm is possibly the most common film dressing used in burns care. A polyvinylchloride film widely used in food preparation and storage, its principal application is in the emergency treatment of burns to cover and protect burn wounds and later, in the burns unit, to cover wounds between dressing changes to allow for clinical inspection. Clingfilm and other commercially available polyvinylchloride films have excellent flexibility and mechanical properties, but their low rate of water vapor transmission leads to pooling of exudates under the dressing with prolonged use.

The discovery of a methyl methacrylate film called Hydron was a major advance in film technology. It had a high permeability to water vapor and yet was occlusive to bacteria. It was thus capable of creating the optimum environment for re-epithelialization, but it avoided the buildup of bacteria associated with earlier film dressings. This initial material was subsequently

modified to a vapor-permeable polyurethane, Opsite, that had similar properties but was more flexible. Trials indicated it considerably enhanced the rate of re-epithelialization of burns. Another interesting feature concerned the nature of the exudate that collected under Opsite dressings. It was rich in leucocytes, and the dressing appeared to exert an *in vitro* antibacterial effect.

Another polyurethane dressing that has widespread clinical application is Tegaderm. Nonadhesive coated films are also available. Omiderm is a highly vapor-permeable polyurethane that adheres to superficial wounds without the need for additional retention.

Film dressings have been medicated are also available. It should be pointed out that films can also be used in conjunction with other medicated dressings, as well as topical antibacterial preparations.

Gel dressings have an established place in the spectrum of burn dressings. The advantage of gels is that they are highly conformable and impermeable to bacteria, but are permeable to water and oxygen. They can also act as carriers for antimicrobial agents. They lack durability, however, but are useful for short-term application. One example is Geliperm, a hydrophilic gel composed of agar and polyacrylamide that is an excellent dressing to protect eyelid skin in the ventilated burn patient. Further advances in developing gels for dressings, using nanotechnology, are anticipated.

Foams and sponges have particular advantages as dressing materials. They are absorbent, their thickness provides protection to the wound, and they are relatively inexpensive and easy to apply. Lyofoam is a polyurethane foam manufactured from a soft polyether foam subjected to further processes of heat and pressure to form a smoothly hydrophilic, porous

surface membrane. It has been targeted at the burns market. Another foam product is Allevyn, produced by Smith and Nephew and marketed as a donor site dressing. This product has been shown to be clinically effective and is widely used.

Hydrocolloid dressings have an established place in burns treatment. One example of a hydrocolloid is Granuflex/Duoderm, marketed by Convatec. This dressing has an outer layer of polyurethane foam bonded to an inner adhesive layer of pectins, methyl cellulose, and other materials. The hydrocolloid liquefies on the wound, and the enclosed environment promotes re-epithelialization while suppressing bacterial colonization.

The final dressings to be described are the alginates, derived from seaweed. The common preparation is calcium alginate, which forms a gel when moistened. The calcium does have a hemostatic effect, and the gel-like alginate does appear to promote epithelialization. For this reason, calcium alginate is a popular dressing for skin graft donor sites.

This overview of burn dressings does not attempt to be an exhaustive list; the range of commercially available products is vast. Examples have been given of different types of dressing, but this is not meant as a recommendation. New dressings will continue to be developed and older methods rediscovered.

THE FUTURE

The spectrum of burn dressings is vast, but this is in part due to the spectrum of burn injury. The principles remain, though:

1. Promote healing
2. Prevent infection
3. Protect from further injury
4. Pain relief

As we move ever further into the era of regenerative medicine, the nature of burn dressings is going to change to reflect an increasing focus on the ultimate goal—skin regeneration.^[28] The previous philosophy of burn dressings has been to optimize the natural process of repair and prevent infection. The natural process of repair is not good enough, however. The result of repair is scar, and scar is the enemy. The burn dressing of the future must modulate healing. It must, in fact, prevent repair and promote regeneration. As our understanding of the biology of wound healing increases, we may well have to confront some paradoxes. Our present strategy is to speed up healing and to promote re-epithelialization. It may be that we should be paying more attention to the dermis, stimulating the mesodermal stem cells and keeping our

window of opportunity—the defect in the epidermis—open for a little longer.

INTRODUCTION

Many types of calcium phosphate biomaterials are clinically used in Japan, including calcium phosphate ceramics, calcium phosphate cements (CPCs), and composites. The first calcium phosphate biomaterial to be officially approved for clinical use was dense hydroxyapatite [HA: $\text{Ca}_5(\text{PO}_4)_3\text{OH}$] in the form of a dental implant in 1983. Although the application of dense HA to a dental implant was unsuccessful, a variety of dense and porous calcium phosphate ceramics have been developed as bone grafting materials since then: five HA, one tricalcium phosphate, and one biphasic calcium phosphate products have been officially approved and are commercially available. They vary widely in porosity, porous structure, mechanical strength, surface chemistry, and biological reaction. Calcium phosphate cement is an injectable paste-like material that hardens in the body. Two different classes of CPC have been developed; one has been officially approved and the other is pending approval. The calcium phosphate composites described in this entry are the recently developed, calcium phosphate/collagen, calcium phosphate/gelatin, and calcium phosphate/poly L-lactic acid composites, all of which have distinctive features. Two of the composites are pending approval and the rest have been officially approved. All these calcium phosphate biomaterials are described in this article with a brief introduction to the calcium phosphate family to help understanding of calcium phosphate biomaterials.

The addition of an osteogenic ability or osteoinductive property to calcium phosphate biomaterials holds great promise for treating patients with diminished bone forming ability. The calcium phosphate biomaterials are osteoconductive materials that only allow the formation of bone on their surface by serving as a scaffold. In patients with diminished bone forming ability, bone tissues do not necessarily bond to calcium phosphate biomaterials at a clinically satisfactory level. If the calcium phosphate biomaterials possess osteoinductive properties, the expansion of clinical applications for the

ceramics is certain. In this context, the addition of bone marrow cells to calcium phosphate biomaterials is promising. The present article also describes this tissue engineering approach in which bone marrow cells are added to calcium phosphate biomaterials.

NEW GENERATION OF CALCIUM PHOSPHATE CERAMICS PRODUCED IN JAPAN

Calcium Orthophosphates

There are many types of calcium orthophosphates (Table 1). Calcium orthophosphate is simply termed calcium phosphate in this article. Calcium phosphates are conventionally classified according to their Ca/P molar ratio, which varies from 0.5 to 2.0. Monocalcium phosphate anhydrous [MCPA: $\text{Ca}(\text{HPO}_4)_2$] and monocalcium phosphate monohydrate [MCPM: $\text{Ca}(\text{HPO}_4)_2 \cdot \text{H}_2\text{O}$] are soluble calcium phosphates, unlike all the rest of the calcium phosphates. Dicalcium phosphate dehydrate (DCPD: $\text{CaHPO}_4 \cdot 2\text{H}_2\text{O}$) and dicalcium phosphate anhydrous (DCPA: CaHPO_4) are used as powder components of CPCs. Octacalcium phosphate [OCP: $\text{Ca}_8\text{H}_2(\text{PO}_4)_6 \cdot 5\text{H}_2\text{O}$] is a transient intermediate phase formed in the precipitation of the thermodynamically more stable HA or calcium-deficient HA. Amorphous calcium phosphate (ACP) is an amorphous phase with a typical Ca/P molar ratio of 1.50. Amorphous calcium phosphate is precipitated in moderately or highly supersaturated calcium phosphate solutions at or above neutral pH. It tends to convert into thermodynamically more stable OCP or calcium-deficient HA. Tricalcium phosphate [TCP: $\text{Ca}_3(\text{PO}_4)_2$] has three polymorphs β , α , and super α , with transition temperatures $\beta \rightarrow \alpha$ at 1125°C and $\alpha \rightarrow \text{super } \alpha$ at 1430°C . The β phase (β -TCP) powder is converted into a dense solid, thus sintered into a ceramic body, when the powder is compacted followed by heating at a temperature in the range of $700\text{--}1125^\circ\text{C}$. The α phase (α -TCP) powder is

Table 1 Calcium orthophosphate family

Ca/P	Abbreviation	Composition	Feature or application
0.50	MCPA	Ca(HPO ₄) ₂	Soluble in water
0.50	MCPM	Ca(HPO ₄) ₂ · H ₂ O	Soluble in water; cement powder
1.00	DCPD	CaHPO ₄ · 2H ₂ O	Cement powder
1.00	DCPA	CaHPO ₄	Cement powder
1.33	OCP	Ca ₈ H ₂ (PO ₄) ₆ · 5H ₂ O	Transient intermediate phase; reaction product in cement setting
1.50	ACP	—	Amorphous; transient intermediate phase
1.50	β-TCP	Ca ₃ (PO ₄) ₂	Resorbable; sintered into ceramics
1.50	α-TCP	Ca ₃ (PO ₄) ₂	Cement powder
1.50	α'-TCP	Ca ₃ (PO ₄) ₂	Appears only at above 1430°C
1.50–1.67		Calcium deficient HA	Low or moderately crystalline; decomposes above approx. 700°C; low crystalline material is resorbable
1.67	HA	Ca ₅ (PO ₄) ₃ OH	Low to highly crystalline; sintered into ceramics; low crystalline material is resorbable; highly crystalline material is nonresorbable and osteoconductive
2.00	TeCP	Ca ₄ (PO ₄) ₂ O	Cement powder

MCPA, monocalcium phosphate anhydrous; MCPM, monocalcium phosphate monohydrate; DCPD, dicalcium phosphate dehydrate; DCPA, dicalcium phosphate anhydrous; OCP, octacalcium phosphate; ACP, amorphous calcium phosphate; TCP, tricalcium phosphate; HA, hydroxyapatite; TeCP, tetracalcium phosphate.

hardly sintered. The α-TCP powder is used for CPCs. The super-α phase is unable to survive quenching to room temperature. Hydroxyapatite is the most stable, and hence the most insoluble, among the calcium phosphates in neutral and alkaline solutions. Hydroxyapatite powder compact is sintered into a ceramic body by heating at a temperature in the range of 700–1200°C. Hydroxyapatite decomposes at temperatures higher than 1200°C. Hydroxyapatite with a Ca/P molar ratio lower than 1.67 is termed calcium-deficient HA. Calcium-deficient HA is formed without difficulty by aqueous reactions between calcium ions and phosphate ions. Calcium-deficient HA powders can be sintered into a biphasic ceramic body consisting of β-TCP and HA. Tetracalcium phosphate [TeCP: Ca₄(PO₄)₂O] is used for CPCs.

Biological reactions to HA and calcium-deficient HA depend on their crystallinity. Hydroxyapatite and calcium-deficient HA have low crystallinity when they are precipitated in aqueous solutions. Such low-crystallinity HA or calcium-deficient HA has an extremely small particle size (usually some tens of nanometers), and thus a large surface area, high reactivity, high dissolution rate, and high adsorption property. Low-crystallinity HA or calcium-deficient HA can be resorbed in bone tissue. When powders or powder compacts of these low-crystallinity materials are heated, there is an increase in crystallinity, and in particle or grain size. Moreover, calcium-deficient HA decomposes into β-TCP and highly crystalline HA upon being heated.

The highly crystalline HA, typically a ceramic HA, is a nonresorbable and osteoconductive material.

CALCIUM PHOSPHATE BIOMATERIALS PRODUCED IN JAPAN

Hydroxyapatite

The crystalline phase of natural bone is basically HA and thus HA ceramics have extensively been used as a bone graft substitute. Dense or porous ceramic bodies as well as granules are available. There is diversity in pore size, porosity, interconnectivity of pores, and mechanical strength depending on manufacturers.

Bonfil[®] (Pentax Co.)

Porous blocks and granules have been officially approved for orthopedic use. Bonfil[®] is sintered at 900°C, which is the lowest sintering temperature among the commercially available HA ceramic bodies in Japan. The sintering temperature is selected so that the porous ceramic has the maximum bone ingrowth. Bonfil[®] has compressive and bending strengths of 15 MPa and 2–3 MPa, respectively. All the pores are of irregular shape with a size of 200–300 μm, and have interconnectivity. The porosity is 60–70%. The previous manufacturer of Bonfil[®] was Mitsubishi Materials Co. The

Biomaterial Business Center of Mitsubishi Materials Co. has merged with Pentax Co. since October 2004.

Bonetite[®] (Pentax Co.)

Porous blocks and dense granules have been officially approved for dental use. Bonetite[®] is sintered at 1200°C. The pores of the porous block are of irregular shape with a size of 200 μm and a porosity of 70%. The previous manufacturer of Bonetite[®] was Mitsubishi Materials Co. The Biomaterial Business Center of Mitsubishi Materials Co. has merged with Pentax Co. since October 2004.

Bonoceram[®] (Sumitomo Osaka Cement Co., Ltd.)

Porous blocks, porous granules, and dense bodies, all sintered at 1150°C, have been officially approved for orthopedic use. The porous bodies are termed Bonoceram-P[®] while the dense bodies are termed Bonoceram-K[®]. The porous body has a compressive strength of 44.1–68.6 MPa and a bending strength higher than 8.33 MPa. The pores are spherical in shape with a size of 50–300 μm. The porosity is 35–48%. The dense body has a bending strength higher than 58.8 MPa.

Apaceram[®] (Pentax Co.)

Porous blocks, porous granules, and dense bodies have been officially approved for dental, orthopedic, and brain surgery uses. The porous blocks are applied to dental and orthopedic cases as well as to filling the bone defects formed in brain surgery. The granules are applied to dental and orthopedic cases, and the dense bodies are used as plugs to fill the hole formed in brain surgery.

The porous blocks and granules, sintered at 1200°C, have a porosity of 15–60%. The compressive and bending strengths vary from 16 to 250 MPa and from 8 to 47 MPa, respectively, depending on the porosity (Table 2). The porous bodies have an interconnected bimodal pore configuration consisting of spherical macropores about 300 μm in size and micropores about 2 μm in size with irregular shapes. The dense body, sintered at 1200°C, has a porosity of less than 0.8%. The compressive and bending strengths of the dense body are 750 and 210 MPa, respectively.

Neobone[®] (Toshiba Ceramics Co., Ltd.)

Porous blocks and granules have been officially approved for orthopedic use. Neobone has fully interconnected pores. The interconnected pores are produced by sintering foamed and solidified hydroxyapatite slurry.

Table 2 Mechanical strength of Apaceram[®]

Porosity (%)	Three-point bending strength (MPa)	Compressive strength (MPa)
0	210	750
15	47	250
30	25	180
40	16	66
50	11	30
55	9.5	21
60	8.0	16

(Courtesy of Mr. T. Ogawa, Pentax Co.)

The slurry contains hydroxyapatite and a polyethyleneimine aqueous solution, and is foamed with the addition of polyoxyethylenelaurylether. For solidification, a polyfunctional epoxy compound is used. The solid and foamy body is dried and sintered at 1200°C.

Neobone has a porosity of 72–78% and a compressive strength of 8–10 MPa. All the pores are spherical in shape and approximately 100 μm in diameter with uniform interconnections among adjacent pores. The interconnecting pores are 10–80 μm in diameter. The pore walls are densely sintered, which leads to the relatively high compressive strength.

Bone ingrowth throughout the pores has been observed in Neobone: new bone with vessels and abundant bone marrow entered the pores located at the central part of the cylindrical body 6 mm in diameter and 15 mm in length implanted in the femoral condyles of rabbits for 6 weeks. Owing to the dominant bone ingrowth, the compressive strength of Neobone gradually increased from its original value (10 MPa) with increasing implantation period, and finally reached about 30 MPa 9 weeks after the implantation.^[1]

β-Tricalcium Phosphate

In contrast to HA ceramics, a β-TCP ceramic is gradually degraded with time in bone tissue. A β-TCP ceramic is called “resorbable ceramic,” which means that the β-TCP ceramic has the ability to be replaced by new bone tissue during the process of degradation.

Osferion[®] (Olympus Optical Co., Ltd.)

Porous blocks and granules have been officially approved for orthopedic use. Osferion has a porosity of 75% with a sponge-like interconnected bimodal pore configuration. The macro- and micropores, both irregular in shape, are 100–400 μm and 1 μm in diameter, respectively. The sintering temperature is 1050°C. The

compressive strength is very low (2 MPa). Owing to the low strength, additional grafting of cancellous bone together with cortical bone with internal fixation may be required when the ceramics are used in high load-bearing areas including those just beneath the knee joint. Furthermore, a long period is required before the start of load bearing compared with the use of other types of ceramic. Osferion is completely resorbed in a period ranging from 6 mo to a few years, with replacement by regenerated new bone tissue in many cases.

Osferion has a distinctive feature in its powder preparation method.^[2] Unlike the conventional aqueous precipitation methods, β -TCP powder is prepared by mechanochemical reaction between DCPD and calcium carbonate powder in water. In this method, DCPD and calcium carbonate are mixed with a Ca/P molar ratio of 1.50 with the addition of water followed by grinding. During the wet grinding, a chemical reaction takes place between DCPD and calcium carbonate. The reaction product is calcium-deficient HA with a Ca/P molar ratio of 1.50. Pure β -TCP is obtained by heating the reaction product. This method is superior to the conventional precipitation methods in its simplicity of powder separation from water and in the control of Ca/P molar ratio.

Biphasic Ceramic

Ceratite[®] (NGK Spark Plug Co., Ltd.)

Porous blocks, porous granules, and dense bodies have been officially approved for orthopedic and brain surgery uses. Ceratite consists of 70% HA and 30% β -TCP. Ceratite is a nonresorbable material. Ceratite supports the osteogenic action of host bone tissue near the implantation site, resulting in new bone formation around the implant. Ceratite bonds directly to the newly formed bone. The porous Ceratite has two different classes: one is a microporous ceramic body with a pore diameter of 1–10 μm and a porosity of 35–40 %, and the other is a macroporous ceramic body with a pore diameter of 150–250 μm and a porosity of 45–55%. The microporous ceramic body, sintered at 1100°C, has compressive and bending strengths of 120–160 MPa and 30–40 MPa, respectively. The macroporous ceramic body, sintered at 1300°C, has compressive and bending strengths of 20–30 MPa and 7–10 MPa, respectively. The macroporous ceramic body has a bimodal pore size distribution: many micropores are present in the matrix surrounding the macropores. The macropores are fairly well connected three dimensionally to adjacent pores with interconnecting pores with a size of 60–80 μm . A dense Ceratite ceramic body, sintered at 1300°C, has

compressive and bending strengths of 600–700 MPa and 140–170 MPa, respectively.

Two clinical cases treated with granular and dense Ceratite are detailed below:

Case 1: Twenty-five-year-old male case (benign bone tumor at tibia side) Ceratite granules were mixed with autogenous bone chips and implanted in the excised bone tumor area. Six months after the operation, a radiograph showed the homogenous appearance of the implants.

Case 2: Fifty-three-year-old male case (cerebral aneurysm) Dense Ceratite buttons were implanted for a burr hole skull defect. The postoperative x-ray showed bone integration around the ceramic buttons.

Calcium Phosphate Cement

A CPC consists of aqueous liquid and finely pulverized calcium phosphate powders. Calcium phosphate cements date from the discovery of hardening of α -TCP in water reported by Monma and Kanazawa.^[3] Calcium phosphate cements are of considerable interest in orthopedics owing to their ability to be shaped easily during surgical operations, their ability to be injected with low operative invasion, their ability to harden in the body, and their good osteoconductivity. Calcium phosphate cements are used to fill bony defects and to augment bone tissue. The calcium phosphates used in the cement powder are precursors of calcium-deficient HA. The precursors convert into calcium-deficient HA or OCP by hydrolysis reactions in aqueous solutions. Such precursors include α -TCP, DCPD, DCPA, and TeCP. During the hydrolysis reaction, the calcium-deficient HA and OCP become tangled and join together, which leads to hardening of the cement (Fig. 1).

Fig. 1 Microstructure of hardened Biopex-R. (Courtesy of Dr. M. Hirano, Pentax Co.)

Biopex-R[®] (Pentax Co.)

Biopex-R has been officially approved for: 1) repairing bone defects; 2) repairing and strengthening/supporting broken bones; 3) reinforcing orthopedic screws and implants; and 4) filling gaps between cement-less artificial joints and bones. The previous manufacturer of Biopex-R was Mitsubishi Materials Co. The Biomaterial Business Center of Mitsubishi Materials Co. has merged with Pentax Co. since October 2004. Biopex-R contains α -TCP as the major powder component. Other powder components include TeCP, DCPD, HA, and magnesium phosphate. The aqueous liquid contains sodium chondroitin sulfate, sodium succinate, and sodium hydrogensulfite. The cement hardens in 6–10 min at 37°C when the powder and liquid are mixed at a powder/liquid (P/L) ratio in the range from 3.3 to 4. The ideal hardening reactions can be described as follows:

However, in practice the HA finally formed is either calcium-deficient HA or HA containing sodium and carbonate ions instead of stoichiometric HA.

The hardening speed and final mechanical strength depends on the temperature and P/L ratio.^[4] The higher the temperature and P/L ratio, the higher the hardening speed and strength. A hardened body, which was set at 37°C for 1 hr with the P/L ratios of 2.5, 3.0, and 3.5, was subjected to four-point bending and compression tests after immersion in a phosphate buffer solution for 7 days. The maximum bending and compressive strength were 10.5 ± 1.1 MPa and 50.2 ± 4.3 MPa, respectively, which were attained at a P/L ratio of 3.5. The compressive strength is higher than that of human tibial cancellous bone (1.9 ± 4.3 MPa), morselized bone graft (1–2 MPa) and porous hydroxyapatite ceramic with a porosity of 60% (15 MPa) although the bending strength is low. The cement paste was inserted and hardened in a hole 5.2 mm in diameter and 15 mm in depth at femoral condyle of rabbit. After 1 day, 3 weeks, and 6 weeks, the push-out test was performed. The push-out strength was 1.4 MPa after 1 day and

2 MPa after 6 weeks at a P/L ratio of 3.5. All these mechanical strength data indicate that the cement is applicable only to non-load-bearing sites.

Biopex-R[®] is used to maintain normal bone architecture after reduction of fractures such as radius (metaphyseal areas), tibia plateau, calcaneus, and vertebral body (compressioned types) fractures.^[5–8] Biopex-R is also used for unstable femoral intertrochanteric fractures with hip screw fixation devices, and for fixation of cementless artificial hip joints.^[9,10]

Using the cement, percutaneous transpedicular vertebroplasty procedures were performed in patients having thoracic or lumbar osteoporotic vertebral fractures to obtain early pain relief and improve the integrity of the osteoporotic vertebral body (VB). Following repositioning and curettage of the pathological soft tissues, cement-assisted vertebroplasty was percutaneously performed in four patients with osteoporotic burst fractures and pseudarthrosis (Procedure A). In situ cement-assisted vertebroplasty was performed in 12 patients with fresh vertebral compression fractures due to osteoporosis (Procedure B). Back pain and low-back pain were evaluated using a visual analog scale (VAS). The deformity index of the VB was measured on a lateral radiograph as the ratio of the VB's height (sum of measurements at anterior, middle, and posterior regions) to its longitudinal diameter. On the basis of VAS scores, pain was decreased in all patients immediately after surgery, and pain relief was maintained at the last follow-up. The mean preoperative deformity index score of the VB was 1.43 in Procedure A and 1.67 in Procedure B; postoperative scores improved to 1.59 and 1.93, respectively. At the 6 mo follow-up examination, the mean deformity index score rebounded to 1.52 in Procedure A and 1.79 in Procedure B. Bone union was documented in all patients. Complications, such as a temporary respiratory insufficiency and a small amount of cement leakage into the spinal canal, were observed in patients. It is concluded that percutaneous transpedicular cement-assisted vertebroplasty is a minimally invasive procedure that provides early relief of pain and prevents vertebral collapse and pseudarthrosis in patients with osteoporotic vertebral fractures.^[11]

TeCP-DCPA cement

A new TeCP-DCPA cement is pending approval. The cement uses an equimolar mixture of TeCP and DCPA as the powder. The liquid is a 50% solution of dextran sodium sulfate that effectively prevents the cement from absorbing excess water, and hence from disintegrating during the hardening reaction. The ideal hardening reaction is described as:

However, the HA finally formed contains sodium and carbonate ions in practice.

The cement reached the maximum compressive strength of 48 MPa in 8 hr; it was hardened at 37°C and 95% relative humidity after mixing the powder and the liquid. The cement was implanted in a rabbit femoral condyle for up to 52 weeks. A greater amount of new bone formation was observed around the cement than around sintered HA. The cement was considerably resorbed without inflammation: the cross-sectional area of the implanted cement decreased to as low as two-thirds of the initial area at 24 weeks as demonstrated by microcomputed tomography.^[12]

Composite of HA and Poly-L-Lactic Acid

SuperFIXSORB30[®] (Takiron Co., Ltd.)

SuperFIXSORB30 is the screw fixation device consisting of 30% HA and 70% poly-L-lactic acid (Fig. 2). SuperFIXSORB30 has been officially approved and commercialized since August 2003. SuperFIXSORB30 has the bending strength of 270 MPa and Young's modulus of 7.6 GPa.

SuperFIXSORB30 is osteoconductive and bioresorbable material. The HA used in SuperFIXSORB30 is low-crystallinity HA that is precipitated by a wet method without being subjected to any heat treatment. The HA, therefore, can be well resorbed. SuperFIXSORB30 bonds directly to the surrounding bone tissue without intervening fibrous tissue, and is gradually resorbed and totally replaced by newly formed bone tissue.

HA-Collagen Composite

Bonject[®] (Koken Co., Ltd.)

Bonject is a viscous and injectable bone filling material that has been officially approved for use in dentistry.

Fig. 2 SuperFIXSORB30[®] screw fixation devices. (Courtesy of Mr. R. Kashiwadani, Takiron Co., Ltd.)

Bonject is a mixture of HA granules and atelocollagen solution. The HA granules are synthesized by heating cattle bone at 1100°C. Two classes of particle size, 300–600 μm or 600–1000 μm, are available for the HA granules depending on clinical cases. The atelocollagen is derived from the dermis of cattle by enzymatic treatments and is highly purified. The HA to atelocollagen ratio is 3:2. The atelocollagen solution is sufficiently viscous to prevent the HA granules from leaking from the implanted site. Bonject is applicable to the bony defects caused by marginal periodontitis, radicular cysts, and resection of benign bone tumors.

Composite of HA and collagen type I

A novel composite of HA and collagen type I has been recently developed. The HA-collagen composite is synthesized by reaction between a collagen-containing phosphoric acid solution and a calcium hydroxide aqueous suspension followed by removal of excessive water. The collagen-containing phosphoric acid and the calcium hydroxide suspension are mixed at pH 7–9 and 25–40°C at a Ca/P molar ratio of 1.67 that corresponds to that of HA. The excessive water is removed by either high-pressure squeezing (200 MPa) or freeze-drying. The high-pressure squeezing is used to make solid HA-collagen composite while the freeze-drying is used to make highly porous and sponge-like composites. The solid HA-collagen composites contain different amounts of collagen depending on the reaction pH: 7–14 wt% at pH 7–8 and 17–19 wt% at pH 9. Water content is 10–20 wt%. The solid HA-collagen composite shows mechanical properties that are similar to those of cancellous bone: a three-point bending strength of 39.5 ± 0.9 MPa and Young's modulus of 2.54 ± 0.38 GPa.

The HA-collagen composite is an intertwined assembly of fibers 20 μm in length or longer. Each fiber consists of HA nanocrystals 50 nm in diameter bound to collagen fibrils 300 nm in length. The fibril axis and the crystallographic *c*-axis of HA aligned at an angle within 30°. This alignment of HA and collagen fibrils is very similar to that in bone tissue. The HA *c*-axis is best aligned when the composite is prepared at pH 9 and 40°C.

The solid HA-collagen composite is a resorbable material and can be used as the carrier of bone morphogenetic protein-2 (BMP-2). A composite 5 × 5 × 10 mm³ in size adsorbing 40 and 80 μg recombinant human BMP-2 (rhBMP-2) implanted in holes 6 mm in diameter in a beagle radius or ulna led to significant callus formation on the grafted composite as early as 2 weeks after the implantation. The average time needed until bone union was 9.2 ± 2.3 weeks for the 0 rhBMP-2 μg group, 7.6 ± 0.9 weeks for 40 rhBMP-2 μg, and 5.6 ± 0.9 weeks

for the 80 rhBMP-2 μg group. The time until bone union for the 80 rhBMP-2 μg group was significantly shorter than that for the 0 rhBMP-2 μg group ($p < 0.05$). The solid apatite–collagen composite $5 \times 5 \times 10 \text{ mm}^3$ in size adsorbing 80 μg rhBMP-2 used in anterior interbody fusion of the cervical spine of a beagle dog led to the enhancement of callus formation and bone bridging as well as a reduction in the intervertebral distance within 13 weeks, indicating the efficacy of this material in anterior interbody fusion of the cervical spine.^[13]

The sponge-like HA–collagen composite has a structure similar to that of cancellous bone. Owing to its highly porous nature, the sponge-like HA–collagen composite has sufficient internal spaces for osteoblasts and osteoclasts to enter. The sponge-like HA–collagen composite easily absorbs liquids and swells when it is immersed in a liquid, which is a clinically useful characteristic for the incorporation of any medicine and growth factor. The sponge-like HA–collagen composite shows distinctive elasticity when the composite absorbs water: the sponge-like HA–collagen composite deforms in response to the applied compressive stress, and it returns to its original shape after the stress is removed (Fig. 3). The sponge-like HA–collagen composite is scheduled to be commercialized in 2006 in Japan.

APPLICATION OF CALCIUM PHOSPHATE CERAMICS TO TISSUE ENGINEERING

Adding an osteogenic ability or osteoinductive property to calcium phosphate biomaterials holds great promise for treating patients with diminished bone forming ability. The calcium phosphate biomaterials are osteoconductive materials that only allow the formation of bone on their surface by serving as a scaffold. In patients with diminished bone forming ability, bone tissues do not necessarily bond to calcium phosphate biomaterials at a clinically satisfactory level. If the calcium phosphate biomaterials possess osteoinductive properties, the expansion of clinical applications for the ceramics is certain. Bone morphogenetic protein is a protein that demonstrates osteogenesis when implanted at subcutaneous and intramuscular sites. Therefore, BMP is osteoinductive.^[14] The composite of BMP and calcium phosphate ceramic enhances the inherent osteogenic ability of BMP.^[15,16] In contrast to the utilization of the osteoinductive activity of BMP, the composites of marrow cells and porous calcium phosphates such as HA show an osteogenic response when implanted in vivo.^[17] The osteogenic capability of the marrow cells resides in not only fresh marrow cells but also in in vitro culture-expanded mesenchymal stem cells (MSCs) derived from marrow cells.^[18]

Mesenchymal stem cells residing in marrow cell population can differentiate into osteoblasts and

Fig. 3 The sponge-like HA–collagen composite. The sponge-like HA–collagen composite containing water deforms in response to the applied compressive stress (upper), and returns to its original shape after the stress is removed (lower). (Courtesy of Mr. D. Shoji, Pentax Co.)

produce mineralized bone matrix in in vitro culture conditions in the presence of dexamethasone and β -glycerophosphate.^[19,20] Although the number of MSCs in fresh marrow is extremely small, their number can be expanded without loss of their osteogenic potential by using a culture technique.^[21] When MSCs are cultured in a porous framework of HA under conditions where the stem cells can differentiate into osteoblasts and fabricate bone matrix, the porous areas of the HA are covered with a thin layer of the “in vitro bone” containing active osteoblasts.^[22] The construct can show the ability of immediate new bone formation after in vivo implantation (Fig. 4). On the basis of the fact that the construct fabricated with human cultured MSCs can

Fig. 4 Two weeks after subcutaneous implantation of HA covered with bone matrix/active osteoblasts (rat-cultured bone). Newly formed bone can be seen in the pore region of the HA ceramics. Arrows indicate the bone forming osteoblasts.

show promising osteogenic ability, we initiated clinical applications of various kinds of ceramic loaded with in vitro bone tissue/osteoblasts derived from patient's marrow cells.^[23] These techniques using patient's cultured MSCs convert the nonosteogenic materials into osteogenic materials; i.e., the osteoconductive ceramics turn to osteoinductive ceramics. These new tissue engineering approaches, therefore, can be applied to various patients with massive skeletal defects to regenerate skeletal tissues.^[24]

CONCLUSIONS

We described the current status of calcium phosphate biomaterials produced in Japan. The calcium phosphate biomaterials detailed are HA, TCP, biphasic HA/TCP, CPC, the HA–collagen composite, the HA–collagen composite, and the HA–PLLA composite. They have been officially approved or are pending approval for clinical use. All the materials show biocompatible and osteoconductive nature with a variety of characteristics in porosity, pore size, mechanical strength, and ability to be resorbed. We also focused on tissue engineering approaches using mesenchymal stem cells/ceramic composites. These tissue engineering approaches can offer new cell-based therapies to various patients who need skeletal reconstruction.

INTRODUCTION

Cardiac assist devices are designed to assist or (in some cases) replace the natural heart. These devices can be used as short-term therapy, bridge to transplantation, and as permanent cardiac support. The different types of cardiac assist devices described in this article are the roller pump, intraaortic balloon pump, ventricular assist device (pulsatile and continuous flow), and total artificial heart. In-vitro and in-vivo methods that are used to test and evaluate cardiac assist devices will also be detailed. Finally, the complications associated with cardiac assist devices will be presented.

NATIVE HEART ANATOMY, FUNCTION, AND CLINICAL NEED

Anatomy

The anatomy of the native heart is shown in Fig. 1. The heart may be thought of as two pumps (right and left side) working together. The right pump delivers blood to the pulmonary circulation, while the left pump delivers blood to the systemic circulation. Each pump consists of an atrium and ventricle making up the heart's four distinct chambers: right atrium, right ventricle, left atrium, and left ventricle. The atria act as priming chambers for the ventricles. The ventricles pump blood out of the heart to either the pulmonary or systemic circulation. Heart valves located between each atrium and ventricle and at the outlet of each ventricle maintain flow direction during pulsatile flow.

Function

Blood from the systemic circulation (the body) enters the right atrium through the superior vena cava (from

the head and upper extremities) and inferior vena cava (from the trunk and lower extremities). The blood is then pumped to the right ventricle, which then pumps blood to the pulmonary circulation (the lungs) via the pulmonary arteries. Oxygenated blood returns to the heart from the lungs via the pulmonary vein to the left atrium and is then pumped to the left ventricle. The left ventricle pumps blood to the systemic circulation via the aorta.

Table 1 lists the nominal pressures and flows in the native heart.^[1] Any cardiac pumping system must generate these pressures and flows in order to meet the needs of recipients.

Clinical Need for Cardiac Assist Devices

Cardiovascular disease was the leading cause of death for almost 1.4 million people in the United States in 1999, representing over 40% of the reported deaths. Coronary heart disease (55%) represented the majority of these deaths, followed by stroke (17%), and congestive heart failure (6%). Almost 4.8 million Americans suffer from congestive heart failure, with about 550,000 new cases diagnosed each year. According to the Framingham Heart Study, 80% of men and 70% of women with congestive heart failure under the age of 65 will die within 8 years.^[2]

One treatment for congestive heart failure is heart transplantation. It is estimated that 40,000 Americans could benefit from a heart transplant each year. However, only 2300 donor hearts are available each year (1998–2001), with over 4000 patients on the waiting list during this period. From 1988 to 2002, approximately 640 patients died each year waiting for transplant.^[2,3] These numbers clearly demonstrate the need for blood pumps that either sustain the patient until transplant or permanently assist or replace the natural heart.

Fig. 1 Natural heart. (Permission pending.)

Different types of cardiac assist devices have been developed to aid the failing heart. These devices can be divided into roller pumps, balloon pumps, ventricular assist devices, and total artificial hearts. Roller pumps provide temporary support during or immediately following cardiac surgery. Balloon pumps aid the heart during cardiopulmonary bypass and cardiogenic shock. Ventricular assist devices assist the function of either the left or right ventricle. Total artificial hearts entirely replace the human heart.

Table 1 Nominal pressures and flows in the natural heart

Pressures:

1. Left ventricle
 - a. 120 mmHg peak systolic normal (into aorta)
 - b. 10 mmHg mean diastolic (from left atrium)
2. Right ventricle
 - a. 25 mmHg peak systolic (into pulmonary artery)
 - b. 5 mmHg mean diastolic (from right atrium)

Flows:

Normal healthy adult at rest: 5 liters/minute.
Maximum flow: 25 liters/minute.

ROLLER PUMPS

Roller pumps were the first generation of cardiac assist devices. These devices are designed to allow the natural heart to rest and recuperate after the surgical procedures have been completed. Roller pumps were first used in humans in 1953.^[4] These pumps are non-pulsatile and are used during cardiopulmonary bypass (CPB). They remain an integral part of most modern extracorporeal membrane oxygenators (ECMO), supporting patients for an average of 10 days. During open heart surgery, blood is routed extracorporeally (outside the body) through arterial and venous cannulation via elastic tubing to membranes that facilitate oxygen and carbon dioxide exchange with the blood.

Roller pumps used in CPB and ECMO have resulted in extremely high levels of damage to red blood cells (hemolysis) and other blood components with increasing damage with extended support time. Patients are then required to take high dosage levels of anticoagulants that may lead to excessive bleeding. Additional complications include blood cavitation due to tubing fatigue resulting in the tubing becoming less compliant.^[5] Because of these complications, roller pumps are typically limited to pediatric patients, and those adult patients who do not require large flow rates.^[5]

INTRAAORTIC BALLOON PUMPS

Intraaortic balloon pumps (IABP), illustrated in Fig. 2, are commonly used to assist in weaning patients from cardiopulmonary bypass or when patients experience cardiogenic shock secondary to an acute myocardial infarction.^[6] Initial success in human implants occurred in 1968.^[7] The IABP is inserted through the femoral or axillary artery and placed within the descending aorta. The patient's electrocardiogram (ECG) is used to trigger the IABP in order to adequately support the native heart. A polyethylene balloon inflates with gas (helium) via a percutaneous tube during diastole and deflates during systole. This counterpulsation reduces the amount of work that the heart has to perform by supplementing cardiac output by approximately 15%.^[8]

The complications associated with IABP are predominantly due to vascular injury that occurs during insertion into the aorta. Additional complications include excessive bleeding and limb ischemia.^[6] The IABP has been used for temporary support (mean of 53 hours),^[6] for short term ventricular assistance, and bridge to transplantation (up to 70 days).^[9] The IABP is currently being adapted for permanent ventricular assistance.^[10] The IABP has been used successfully in

Fig. 2 Intraaortic balloon pump. (Permission pending.)

adult patients (regardless of size or age) and in pediatric patients.^[11]

VENTRICULAR ASSIST DEVICES

Ventricular assist devices (VADs) are designed to assist or replace the function of either the left or right ventricle. These devices are intended to provide temporary support until a donor heart has been located, myocardial recovery occurs, or as a permanent device. Ventricular assist devices can be classified as pulsatile or continuous flow devices.

Pulsatile Flow

Pulsatile flow ventricular assist devices are composed of a single ventricle that mimics the native ventricle. The ventricle is placed either within the abdominal cavity or outside the patient's body. There are two types of pulsatile flow ventricular assist devices: pneumatic and electric.

Pneumatic ventricular assist device

Figure 3 shows a pneumatic ventricular assist device that was originally developed by Penn State. The ventricle contains a flexible blood sac (of segmented polyurethane) that is housed within a rigid (polysulfone or titanium) case. The blood sac is extremely smooth to prevent the formation of clots (or thrombi). Prosthetic heart valves are placed in the inlet and outlet positions

of the ventricle to regulate flow direction. Air pulses that are generated by an external drive unit are used to compress the flexible blood sac periodically. An automatic control system varies the cardiac output by adjusting the heart rate and the time for ventricular filling in response to an increase in filling pressure.^[12]

The pump is placed extracorporeally on the patient's abdomen. The inlet cannula is inserted into the apex of the left ventricle and connected to the inlet port of the ventricular assist device. The outflow cannula is attached between the outflow port of the ventricular assist device and the ascending aorta, as an end-to-side anastomosis. Both the inflow and outflow cannulae pass through the skin below the rib cage. The first human implant of this type of assist device occurred in 1976. The Penn State pneumatic ventricular assist device was later purchased by Thoratec Corporation (Pleasanton, CA) and implanted in over 1700 patients worldwide. The pneumatic pump can also be used to assist the right ventricle by itself, or simultaneously with an additional pump that assists the left ventricle.^[13]

Other types of pneumatic devices include the ABIOMED (Danvers, MA) BVS (biventricular system) 5000 and the Heartmate (Thoratec) IP (intra-peritoneal) LVAS (left ventricular assist system). The ABIOMED BVS 5000 is an external dual-chamber device that can provide support to one or both ventricles. The chambers utilize polyurethane valves to regulate the flow direction.^[14] More than 3000 implants have been performed worldwide.^[15] The

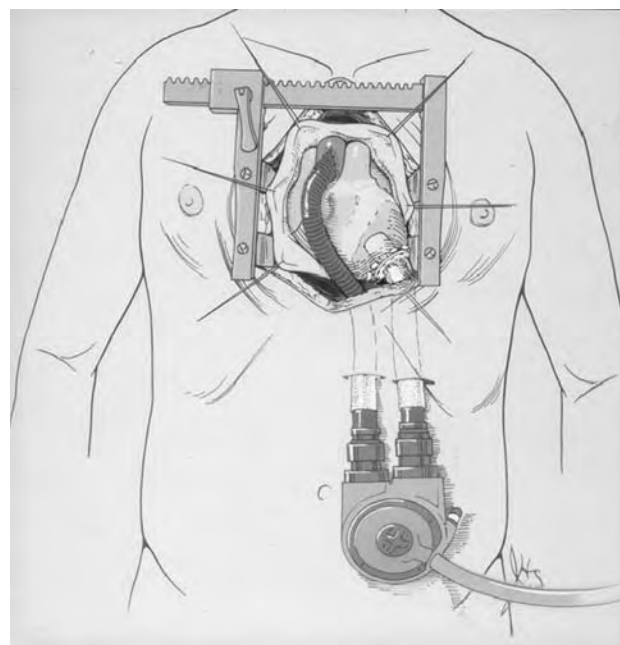

Fig. 3 Penn State/Thoratec pneumatic ventricular assist device. (Permission pending.)

Heartmate IP LVAS features an implantable blood pump that is connected to an external drive unit via a percutaneous air drive line. A unique feature of this device is the use of a textured blood surface in the ventricle that promotes the formation of a cell layer. This layer is believed to decrease thrombus formation because the layer mimics the blood contacting surface of a blood vessel. The Heartmate IP has been implanted in over 1200 patients worldwide.^[16]

Electric ventricular assist devices

Figure 4 illustrates an electric ventricular assist device developed by Penn State. Electric ventricular assist devices are typically placed within the abdominal cavity. The inlet cannula is inserted into the apex of the native left ventricle and connected to the inlet port of the device. The outlet cannula is attached between the outflow port of the device and the ascending aorta via an end-to-side anastomosis. The blood pump assembly utilizes a rollerscrew energy converter with a pusher plate. The motion of the pusher plate compresses the blood sac and ejects blood from the ventricle. The controller and internal battery supply are also implanted in the abdomen. This allows tether-free operation for approximately 30 minutes. Energy passes from the external power coil to the subcutaneous coil by inductive coupling via the transcutaneous energy transmission system (TETS). Air displaced by the blood pump housing enters the compliance chamber.

Fig. 4 Penn State/Arrow International electric ventricular assist device. (Permission pending.)

Air that diffuses out of the compliance chamber is periodically replenished by medical personnel via the subcutaneous access port. The Penn State system shown in Fig. 4 is being developed with Arrow International (Reading, PA) and is currently in clinical trials in the United States and Europe.^[17]

Other types of electric VADs include the Novacor (WorldHeart, Oakland, CA) LVAS and Heartmate VE (Vented Electric) LVAS. The Novacor LVAS contains a polyurethane blood sac that is compressed between dual pusher plates. A percutaneous power line connects the pump to an external battery pack and controller. The Novacor LVAS has been implanted in over 1350 patients worldwide.^[18] The Heartmate VE LVAS is similar to the Heartmate IP LVAS except for the use of an electric motor and pusher plate system. A percutaneous power line is also used to connect the pump to an external battery pack and controller. The Heartmate VE has been implanted in over 1600 patients worldwide.^[19]

A recent study, Randomized Evaluation of Mechanical Assistance for the Treatment of Congestive Heart Failure (REMATCH), examined the utility of ventricular assist devices. Patients with end-stage heart failure who were ineligible for cardiac transplantation were split into two groups. The first group received the Heartmate VE LVAS ($n=68$) while the second group received optimal medical management ($n=61$) consisting of angiotensin-converting-enzyme (ACE) inhibitors. The results showed a reduction of 48% in the risk of death from any cause in the LVAD group versus the medical-therapy group ($p=0.001$). The one-year survival was 52% for the VAD group and 25% for the medical-therapy group ($p=0.002$). The two-year survival was 23% for the VAD group and 8% for the medical-therapy group ($p=0.09$). Finally, the median survival was 408 days for the VAD group and 150 days for the medical-therapy group. This study clearly showed the clinical utility of ventricular assist devices.^[20]

Continuous Flow

Continuous flow ventricular assist devices deliver nonpulsatile flow and are classified as rotary pumps. There are two types of continuous flow ventricular assist devices: centrifugal or axial.

Centrifugal pumps

Figure 5 shows a centrifugal pump configuration. The inlet and outlet ports of the device are orthogonal to one another and are connected to the native ventricle and the aorta, respectively, in a similar fashion as described previously for electric ventricular assist devices. Blood entering the pump through the inlet port is

Fig. 5 Centrifugal flow ventricular assist device. (Permission pending.)

propelled towards the outer edge of the impeller due to centrifugal and lifting forces into a collecting volute. This volute is a channel carved into the housing where fluid is collected and stabilized before it exits the pump. The impeller can consist of blades, cones, or disks with the number and geometric configuration of the impeller being optimized for maximal efficiency. Typically, the impeller and housing are constructed of the same material (titanium or acrylic/plastic). Acrylic is used for some pump housings to provide optical access and examination of the impeller while in clinical use. Current centrifugal pumps serve as extracorporeal ventricular assist devices. However, newer generation pumps are being designed for implantable use with TETS.^[21]

Centrifugal pumps have several advantages over pulsatile ventricular assist devices. For example, centrifugal pumps require less energy than pusher plate designs because there is not an active load to move (piston or diaphragm). The impeller transfers its energy directly to the fluid to assist in flow. In addition, centrifugal pumps do not require valves for operation. Centrifugal pumps, however, are outlet pressure sensitive and may not produce flow should the outflow pressure be greater than the outlet pressure. In this case, the impeller will continue to spin without producing flow. To remedy this, either the outflow pressure must be reduced or the impeller speed must be increased, thus allowing the pump to operate regardless of the pressure at the inlet.

Typical motor speeds (or rotation rates) for centrifugal pumps range from 1500 to 5000 RPM (rotations per minute). This results in flow rates of 2 to 10 liters/minute. Although centrifugal pumps can be operated under steady or pulsatile flow conditions, there is debate regarding the superiority of either type

of flow.^[22] The long term effects of continuous flow on circulatory physiology and overall homeostasis remain unknown.

The Medtronic (Minneapolis, MN) Bio-Pump (Fig. 5) is the most commercially successful of all centrifugal blood pumps.^[23,24] This pump is placed extracorporeally and used during cardiac surgery for cardiopulmonary bypass, surgical recovery, and bridge to transplantation. The pump uses stacked acrylic cones as its impeller within a conical acrylic housing. The fluid enters the center of the cones, which creates swirling flow that is similar to a tornado. Flow is forced beyond the outer edge of the impeller and then exits at the bottom of the pump. A single magnetic drive unit is coupled with a magnet in the impeller. The Bio-Pump also comes in a pediatric version that can be used for assisted circulation. However, the Bio-Pump has limited use for long-term assistance because of excessive thrombus formation that has been mitigated through the use of heparin-coated circuits reducing the frequency for pump head exchange.^[24] Despite thrombus formation, the Bio-Pump has been intentionally designed so that the pump head (impeller) may be quickly replaced once thrombus has formed without detrimental effects on the patient. Clinical use of the Bio-Pump is said to be up to 1.5 million times. One clinical report from Baylor College of Medicine reported its use on 141 patients resulting in only 54% being weaned and only 22% being discharged from the hospital.^[25] An additional report from St. Louis University and Wake Forest University reported the use of the Bio-Pump on 52 patients resulting in only an 11% survival rate.^[26]

Other centrifugal pumps in use or under development include the Sarns pump (Terumo, Ann Arbor, MI),^[27] the Baylor College of Medicine's series of Gyro pumps,^[21] Ventracor's VentrAssist pump (Sydney, Australia),^[28] and MedQuest's HeartQuest pump (Salt Lake City, UT).^[29] Clinical postcardiotomy use of the Sarns pump in 91 patients resulted in 46% of them being weaned from the device but only a 21% survival rate.^[30]

Axial pumps

Figure 6 illustrates an axial flow pump, which is another type of continuous flow ventricular assist device. The flow through these pumps moves in the axial direction assisted by tangential forces and is accelerated through the device by a rotating impeller (rotor) that transfers energy from the impeller to the fluid. Stators (stationary flow straighteners) stabilize the blood as it enters and exits the rotor/impeller to prevent additional blood damage. Magnets are embedded within the rotor and are coupled with a rotating magnetic

Fig. 6 Axial flow ventricular assist device. (Permission pending.)

field on the housing to act as a brushless DC motor. The pumps are constructed of titanium or a similar metal alloy that is biocompatible.

Axial pumps are either implanted directly within the left ventricle using a sewing cuff or are attached outside of the heart near the apex like most devices. Apical cannulae and outlet grafts have been evaluated to optimize each pump's efficiency. The outlet grafts are attached to the ascending or thoracic aorta.

Axial flow pumps run at speeds of 10,000–20,000 RPM, generating flow rates of up to 10 liters/minute. Such high motor speeds do not cause excessive hemolysis because of the short residence time of blood within the axial flow pump.^[31] Like centrifugal pumps, these pumps are also outlet pressure sensitive and may not produce flow should the outflow pressure exceed the outlet pressure.

Two types of axial flow pumps are currently in clinical trials as ventricular assist devices in the United States. They are the Jarvik2000 (New York, NY) and the Micromed DeBakey VAD (Houston, TX). The Jarvik2000 pump was developed through a collaborative effort between Jarvik Heart, Inc. and the Texas Heart Institute (Houston, TX). It employs a titanium stator and rotor that uses immersed bearings in the blood.^[32] The pump is placed within the left ventricle via a sewing cuff sutured to the ventricle, eliminating the inflow cannula. The outflow cannula is attached to the thoracic aorta as an end-to-side anastomosis. In-vivo studies with calves and humans illustrate the pump's effectiveness in assisting cardiac output and myocardial recovery.^[33,34] The initial 10 cases of human implantation yielded a 70% bridge-to-transplantation success rate.^[34] Pump speeds range from 8000 to 12,000 RPM with a maximum flow rate of 8 liters/min. In order to accommodate a wide range of patients, adult and pediatric versions have been developed.

The MicroMed DeBakey VAD (Fig. 6) is a collaborative effort between MicroMed Technology, Inc. and the Baylor College of Medicine. The rotor and stator were optimized through the extensive use of computational fluid dynamics prior to the manufacturing of the first prototype.^[31,35] Studies in calves

and humans have suggested great potential as an assist device.^[36] The DeBakey VAD operates from 7500 to 12,000 RPM and is attached to the left ventricle via an inflow cannula near the apex. The outflow tract attaches to the ascending aorta via an end-to-side anastomosis.^[37] Fifty-one patients had received the MicroMed DeBakey VAD as of September 2000 with an estimated probability of survival at 30 days to be 81%.^[38]

C

TOTAL ARTIFICIAL HEARTS

The total artificial heart (TAH) is designed to support both the pulmonary and systemic circulatory systems by replacing the natural heart. Two types of artificial hearts have been developed: pneumatic and electric.

Pneumatic Total Artificial Heart

A pneumatic total artificial heart is composed of two ventricles that replace the native left and right ventricle. Each ventricle is of similar design to the Penn State/Thoratec pneumatic ventricular assist device. Both ventricles are implanted within the chest. The air pulses are delivered to the ventricles via percutaneous drivelines. An automatic control system varies cardiac output by adjusting the heart rate and the time for ventricular filling in response to an increase in filling pressure.^[12]

Pneumatic artificial hearts can be used as a mechanical bridge to transplant (until a donor heart is implanted) and as a permanent replacement. The only pneumatic TAH approved as a bridge to transplant in the United States is the CardioWest/Jarvik (Tucson, AZ) Total Artificial Heart. Since 1993, the CardioWest has been implanted in over 100 patients. Sixty-seven patients survived to receive a cardiac transplant.^[39]

Pneumatic artificial hearts have also been used as a permanent replacement device. The Jarvik-7 pneumatic TAH was implanted in four patients.^[40] Although the longest survivor lived for 620 days, all four patients had hematologic, thromboembolic, and infectious complications. This type of artificial heart is no longer considered for permanent use because of infections associated with the percutaneous pneumatic drive lines and quality-of-life issues related to the bulky external pneumatic drive units.

Electric Total Artificial Heart

The electric TAH is completely implantable and is designed for permanent use. A schematic of the Penn State Electric TAH is shown in Fig. 7. The artificial heart is composed of two blood pumps that are of similar design to the Penn State electric ventricular

assist device. However, the electric TAH uses a single implantable energy converter that drives both ventricles asynchronously. The implantable controller adjusts the heart rate in response to ventricular filling and maintains left-right balance. The Penn State electric TAH has been successfully implanted in animals for over 1 year without thromboembolic complications.^[41]

The ABIOMED AbioCor TAH uses an electrohydraulic energy converter^[42] to compress the blood sacs. The AbioCor is currently undergoing clinical trials in the United States. Seven patients have been implanted. Two patients were discharged from the hospital, with one patient surviving for over one year. No significant device malfunctions were noted.^[43]

TESTING AND EVALUATION

Cardiac assist devices are subjected to a series of in-vitro and in-vivo tests prior to implantation in humans.

Fig. 7 Penn State electric total artificial heart. (Permission pending.)

These tests are designed to demonstrate the safety and efficacy of the devices.

In-Vitro Testing

In-vitro testing permits the evaluation of a cardiac assist device under controlled conditions that simulate in-vivo conditions. A mock circulatory loop is typically used to mimic the human circulatory system by replicating the systemic arterial capacitance and resistance.^[44] The fundamental components that compose a mock circulatory loop are blood pump, aortic compliance chamber, peripheral resistance element (constricted tubing), and venous reservoir. Tests are conducted to assess the performance characteristics (pressure-flow characteristics and power consumption) of the cardiac assist device under a variety of operating conditions simulating physiologic flows and pressures.^[45]

Flow visualization studies in transparent pump models are often conducted to elucidate any potential areas of risk (high shear or flow stasis) that could lead to hemolysis or thrombus formation. Laser Doppler velocimetry and particle image velocimetry systems are two noninvasive experimental techniques that can be used to evaluate flow fields within cardiac assist devices for fluid shear stress and turbulence levels.^[46,47] These techniques can also be used to assess the inlet and outlet flow regions quantitatively.^[48]

Durability testing (bearings, seals, diaphragms, heart valves, etc.) of the cardiac assist device is also performed to determine the lifetime and failure modes of the device through individual assessment in mock circulatory loops and accelerated wear testers.^[41,49] Hemolysis testing may also be performed to determine the degree of blood damage caused by the device relative to other systems.^[50]

In-Vivo Testing

In-vivo testing is employed to demonstrate the viability of the pump design in an animal model that simulates the human patient. Typical animal models include pigs, goats, dogs, and calves. The cardiac assist pump is implanted using surgical procedures and anatomical placements that will be used in human implants. After implantation, the animal is typically subjected to an anticoagulant therapy that includes heparin, coumadin, and/or aspirin. Plasma hemoglobin levels, erythrocyte, platelet, and leukocyte counts, and additional blood parameters are monitored to determine the existence and extent of blood trauma. After sacrifice, the cardiac assist device is explanted and carefully evaluated for thrombus deposition. Histopathological

studies are also conducted on the animals' organs (liver, kidney, lung, brain) to evaluate damage.^[51,52]

COMPLICATIONS

Although cardiac assist devices fulfill a major clinical need, many device-related complications exist. Bleeding has been reported in 79% of the patients with a Biomedicus centrifugal pump.^[51] Additional complications reported in this study included high levels of hemolysis (35%), renal failure (33%), thrombus formation in the pump (23%), and infection (15%). For patients with the Thoratec pneumatic LVAD, infection was the most frequent complication (46%), followed by bleeding (44%), thrombus formation in the device (15%), renal failure (14%), and hemolysis (9%). Results from the Registry Review for 1983–1993 indicated similar complication rates. Additional complications include the response to the implanted materials and device failure.^[53] These complications are also associated with other types of cardiac assist devices.^[5,43]

CONCLUSIONS

Current cardiac assist devices are able to provide viable cardiac support successfully by either assisting or replacing the native heart. Future designs will utilize novel battery technologies to permit longer time between battery changes, new biomaterials to enhance biocompatibility, improved control schemes that enhance the response of the cardiac assist device to meet physiologic demands, and smaller electronics to decrease the size of the pumps. These designs will also incorporate features that minimize blood trauma, reduce thromboembolic complications, and eliminate the need for anticoagulants. Future pumps will also be designed in a range of sizes to fit easily in a variety of patient populations including women and infants.

Virginia Commonwealth University, Richmond, Virginia, U.S.A.*

INTRODUCTION

An electrical event—the action potential—is the signal that initiates cardiac contraction and the pumping of blood. Action potentials reflect the intrinsic bioelectricity of the heart. Electrical activity of individual cardiac myocytes (muscle cells) arises both from the characteristics of the ion channels found in the plasma membrane (sarcolemma) and the ionic gradients that exist between the cytoplasm and extracellular spaces. Individual myocytes are electrically coupled by low-resistance gap junctions, located at the intercalated disk at the end of cells and at lateral points of contact. This coupling creates an electrical syncytium and permits the electrical impulse to spread to every cell in the heart. Normal function requires a precise coordination of cardiac bioelectric activity, and the action potential propagates over the heart in a specific sequence and with specific timing. The precise coordination of cardiac electrical activity arises from both the electrical anatomy of the heart and the specialized characteristics of myocytes in each region. The distribution of ion channels and, to a lesser extent, ionic gradients is not uniform. Regional differences exquisitely tune the electrophysiological properties of myocytes for their functional requirements.

This article reviews several facets of cardiac bioelectricity, including the electrical anatomy of the heart, the ionic basis for the cardiac action potential, pacemaker activity, and excitability. These concepts form the physiological basis for understanding the electrocardiogram, stimulation of the heart by pacemakers, and defibrillation, but clinical aspects of electrophysiological function will not be covered.

CARDIAC ELECTRICAL ANATOMY

The cardiac action potential propagates to every myocyte in the heart in a specific sequence and with specific timing. This is called normal sinus rhythm (NSR). NSR requires excitation to originate at the sino-atrial node (SAN) at a regular rate of 60–100 min⁻¹ and to follow the sequence and timing described in the following section.^[1] The resulting coordination of electrical activity reflects, in part, both

the presence of myocytes with specialized bioelectric properties and the electrical anatomy of the heart, which is illustrated in Fig. 1.

Sino-Atrial Node

The SAN is the physiologic pacemaker, the site where the heartbeat originates.^[1] It is approximately 8 mm long and approximately 2 mm thick in humans and is located at the roof of the right atrium (RA) along the posterior margin of the superior vena cava, where it joins the RA free wall at the crista terminalis.^[2,3] SAN myocytes spontaneously and repetitively give rise to action potentials that propagate to the rest of the heart, a property called normal automaticity. Cardiac electrical activity does not require neural input. The SAN beats spontaneously when excised from the heart, even after blocking both the sympathetic and parasympathetic neurons that richly innervate this structure.

Autonomic neurons modulate the frequency of SAN firing and thereby modulate heart rate.^[1] Sympathetic neurons innervating the SAN arise in the superior cervical ganglion and release norepinephrine, which binds to β_1 adrenoreceptors on the myocytes and accelerates SAN automaticity. Parasympathetic neurons reach the heart via the vagus nerve and release acetylcholine (ACh), which binds to muscarinic (M₂) receptors and slows the heart. At rest, the heart is under parasympathetic control, meaning heart rate accelerates if both sympathetic and parasympathetic influences are eliminated. The two autonomic branches are regulated in a coordinated but antagonistic manner by the vasomotor center in the medulla. To increase heart rate, for example, the vasomotor center depresses the firing of parasympathetics (parasympathetic withdrawal) while simultaneously augmenting sympathetic activity. Slowing of the heart is accomplished by the converse process. These actions are termed positive and negative chronotropic effects, respectively.

Atria

Because SAN is located within the RA, RA becomes excited before the left atrium (LA). The excitation

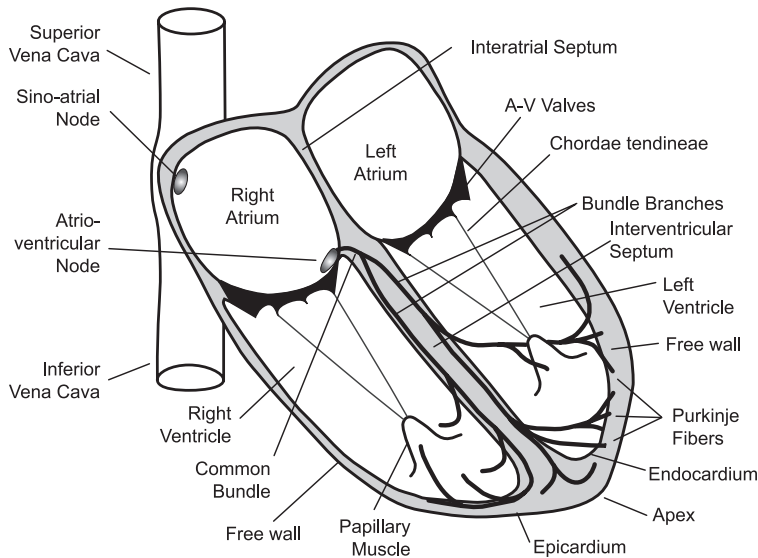

Fig. 1 Diagram of the electrical anatomy of the heart. Tissue specialized for electrical properties includes: sino-atrial node, at the roof of right atrium; atrio-ventricular node, at floor of right atrium adjacent to interatrial septum; and the His-Purkinje system, comprising the common bundle, bundle branches, and Purkinje fiber network.

wavefront conducts in all directions in atria with a conduction velocity of approximately $0.5\text{--}1\text{ m}\cdot\text{s}^{-1}$.^[1] Preferential conduction pathways—the atrial internodal tracts—have been noted. Bachmann's bundle (anterior tract) directs excitation from RA to LA, and there is evidence that its interruption slightly delays LA excitation. Wenkebach's and Thorel's bundles (middle and posterior tracts) direct the impulse from SAN to the atrio-ventricular node (AVN). These tracts are not of major functional significance, however. Preferential conduction largely reflects local fiber orientation and variations in atrial wall thickness (i.e., the pectinate muscles).

Atrio-Ventricular Node

Atria and ventricles are physically separated by connective tissue that serves to anchor the valves and electrically isolate the upper and lower chambers. Normally, the only muscular connection is the AVN, and to pass from atria to ventricles the electrical impulse must propagate through this 5 mm-long structure.^[1–3] The AVN is adjacent to the coronary sinus at the RA floor and posterior along the atrial septum (Fig. 1). AVN conduction velocity is extremely slow ($0.02\text{--}0.05\text{ m}\cdot\text{s}^{-1}$), which gives rise to the AV delay. AV delay allows time for completion of atrial contraction and ventricular filling before the initiation of ventricular contraction.

Classically, AVN is divided into AN (atrio-nodal), N (nodal), and NH (nodal-His) regions based on anatomic and electrophysiologic criteria.^[1,2] The AN and NH regions contain transitional cells. Conduction velocity is slowest in the central N region, although the majority of AV delay occurs in the AN region because

of its greater length. A more recent approach better reflecting the complex 3-dimensional AVN anatomy divides AVN into transitional cells, compact node, posterior node extensions, and the lower nodal cell bundle.

The AVN has two additional functions. First, it acts as an electrical filter. Excitability recovers slowly after the action potential in AVN, and therefore the AVN cannot follow accelerated atrial rates that occur in certain dysrhythmias, such as atrial tachycardias and atrial fibrillation. If the atrial rate is too fast, an impulse may reach AVN during the effective refractory period (ERP), when the myocytes are inexcitable.^[1,3] This can give rise to 2:1 or 3:1 AV block, where only every second or third impulse conducts through. The basis for the ERP will be discussed later. The second function of the AVN is to serve as a backup pacemaker. AVN exhibits normal automaticity, although its spontaneous rate (typically $40\text{--}50\text{ min}^{-1}$) is slower than that of SAN. Therefore, the AVN is said to be a latent pacemaker, and its automaticity is not normally expressed in the intact heart.

Occasionally, an accessory pathway (bundle of Kent) directly links the atria and ventricle.^[1,2] When functional, bypass tracts allow rapid impulse conduction from atria to ventricle and premature ventricular excitation known as Wolff–Parkinson–White syndrome, or preexcitation. Additional accessory pathways—bypass fibers of James that connect RA to the distal end of AVN and Mahaim fibers that link AVN to ventricle—sometimes are noted. Such pathways can serve as the anatomical substrate for reentrant arrhythmias and preclude normal AV delay. Recent evidence indicates that the posterior extension of the AVN also may serve as a slowly conducting pathway in reentrant arrhythmias.

AVN is highly innervated by both sympathetic and parasympathetic fibers, and each aspect of AVN function is regulated by autonomic neurons.^[1,3] Sympathetic stimulation speeds conduction velocity (positive dromotropic effect); quickens recovery of excitability (decreased ERP), which allows AVN to pass impulses at a higher frequency; and augments its spontaneous firing rate (normal automaticity). On the other hand, parasympathetic (vagal) stimulation slows conduction velocity (negative dromotropic effect), delays recovery of excitability (increased ERP), and suppresses AVN automaticity.

His-Purkinje System

The location of the aortic and pulmonic valves at the base of the heart (plane dividing atria and ventricles) presents an engineering dilemma. The electrical signal to contract reaches the ventricle via AVN at its base, whereas efficient ejection of blood requires excitation from apex to base, creating a wave of contraction that propels blood toward the valves. This dilemma is solved by the His-Purkinje system, also called the ventricular specialized conducting system. Conduction velocity in the His-Purkinje system ($2\text{--}4\text{ m}\cdot\text{s}^{-1}$) is the fastest in the heart, and it rapidly distributes the impulse to the ventricles.^[1,3] The His (common) bundle runs in the ventricular septum and subdivides into right and left bundle branches, anterior (superior) and posterior (inferior) fascicles of the left bundle, and the Purkinje fiber network, which terminates under the endocardial surface near the apex and along the free walls of the ventricles (Fig. 1).^[1,2] The detailed anatomical pattern of Purkinje network branching is highly variable. Portions of the network are free-running,

meaning they cross part of the ventricular cavity rather than adhering to the walls of the chamber. The His-Purkinje system also expresses automaticity and serves as a latent pacemaker. Intrinsic rate decreases from 40 to 20 s^{-1} from the AVN junction to terminal Purkinje fibers.

Ventricle

Within the ventricular wall, the action potential spreads in all directions with a conduction velocity of $0.5\text{--}1\text{ m}\cdot\text{s}^{-1}$,^[1] depending on fiber orientation (conduction is fastest parallel to the myocyte's long axis and slowest transversely). The first region to be excited is the ventricular septum adjacent to the left ventricular chamber. From this point, depolarization spreads across the septum toward the right ventricle and down the septum toward the apex. Then, distributed via the Purkinje network, excitation begins at multiple subendocardial sites near the apex. The excitation coalesces and spreads over the free walls from endocardium to epicardium and from apex to base.

CARDIAC ACTION POTENTIAL

Action potentials from various regions and the phases of the action potential are shown in Fig. 2. Recordings can be made either by impaling a cell in a multicellular preparation with a 3 M KCl -filled microelectrode or from isolated single myocytes using a patch electrode filled with a physiological intracellular solution. By convention, the potential difference across the membrane (membrane potential, E_m) is taken with the outside as ground.

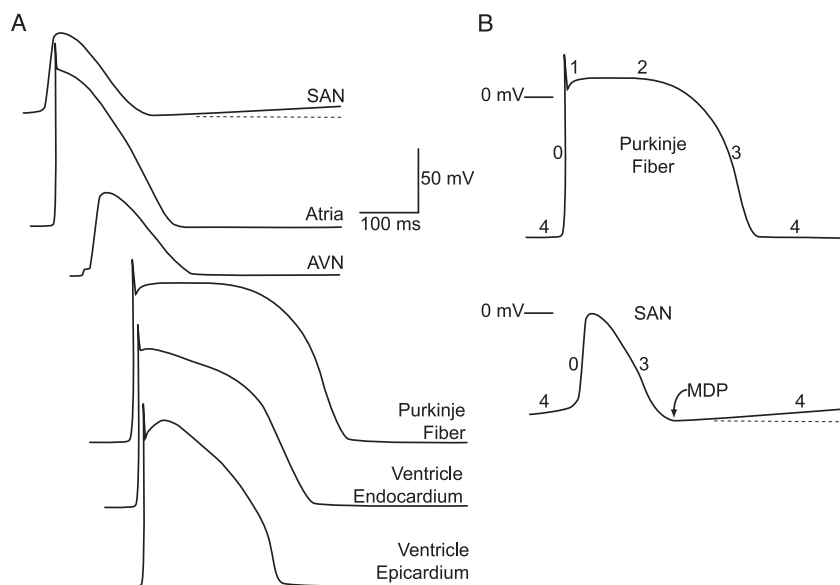

Fig. 2 (A) Action potentials from regions of the heart. Upstrokes are offset, representing the normal timing of activation. SAN undergoes diastolic depolarization (dashed line at MDP). The step in AVN upstroke is due to asynchronous arrival of action potentials via different AVN pathways. (B) Action potential phases in Purkinje fiber and SAN: 0, upstroke; 1, initial repolarization; 2, plateau; 3, repolarization; and 4, electrical diastole (or diastole). SAN action potentials do not have a distinct phase 2 (plateau) or phase 1 (initial repolarization), and they undergo phase 4 depolarization. Time and voltage calibrations apply to both panels.

Action potentials have distinct features in each region (Fig. 2A).^[1,4,5] Phase 0, the upstroke, is rapid in atrial, ventricular, and His-Purkinje myocytes (maximum $dV/dt = 150\text{--}600 \text{ V} \cdot \text{s}^{-1}$), but is much slower ($dV/dt = 2\text{--}10 \text{ V} \cdot \text{s}^{-1}$) in SAN and AVN. Action potential duration (APD) ranges from nearly 400 ms in the terminal Purkinje fibers to about 150 ms in SAN and AVN. The sequence of APD is:

terminal Purkinje fibers > His-Purkinje system
 > ventricle (midmyocardium > endocardium
 > epicardium) > atria \approx SAN \approx AVN

APD also is inversely related to heart rate.^[1,4,5] This effect is prominent in ventricle, which explains the heart-rate dependence of the Q-T interval in the electrocardiogram, as well as in the His-Purkinje system. Ventricular and Purkinje action potentials have a distinct plateau (phase 2), whereas atrial action potentials are more triangular, and phases 2 and 3 (repolarization) blend together in SAN and AVN. Finally, phase 4 (diastolic) depolarization is responsible for normal automaticity observed in SAN, whereas E_m during phase 4 (electrical diastole or diastole) typically is constant in other regions. Nevertheless, the AVN and the His-Purkinje system exhibit phase 4 depolarization under certain conditions.

Ionic Basis for Cardiac Action Potential

Ultimately, the electrical activity in the heart reflects the time- and voltage-dependent behavior of ion channels and the transmembrane ionic gradients. The heart is particularly rich in ion channels; Na^+ channels and several types of K^+ , Ca^{2+} , and Cl^- channels play key roles.^[4-6] The main types of cardiac ion channels and their localization and molecular correlates are summarized in Table 1. To understand the basis for the action potential and its distinct characteristics across the heart, we will first review the equations for ionic current and E_m , then consider a prototypic ventricular action potential, and finally discuss how heterogeneous ion channel expression is responsible for distinct functional characteristics.

Equations for ionic current and E_m

Ionic current (I) crossing the membrane is determined by conductance (g) and driving force, the difference between E_m and the Nernst equilibrium potential for the ion carrying the current. For example, we

write for K^+ current

$$I_K = g_K(E_m - E_K)$$

where the K^+ equilibrium potential, E_K , is given by

$$E_K = -RT/zF \ln[K^+]_i/[K^+]_o$$

where R is the gas constant, T is temperature (K), z is the valence, F is Faraday's constant, and the bracketed terms refer to intracellular, i , and extracellular, o , concentrations, respectively. For a monovalent ion such as K^+ , at 37°C this is equivalent to

$$E_K = -61 \log[K^+]_i/[K^+]_o$$

Measurements of intracellular ion concentrations in various parts of the heart and the resulting equilibrium potentials are reviewed elsewhere.^[7] By convention, an outward current is taken as cation efflux from the cell (or the electrical equivalent, anion influx) and will result in repolarization or hyperpolarization of E_m , whereas inward current is cation influx (or anion efflux), which causes depolarization. In terms of the sign of I , an outward current is positive and an inward current is negative, regardless of whether a cation or an anion is carrying current.

When E_m is constant ($dV/dt = 0$), the sum of the ionic currents, I_{ionic} , must be 0, and E_m is given by the chord conductance equation. For a membrane with K^+ , Na^+ , Ca^{2+} , and Cl^- channels,

$$I_{\text{ionic}} = g_K(E_m - E_K) + g_{\text{Na}}(E_m - E_{\text{Na}}) \\ + g_{\text{Ca}}(E_m - E_{\text{Ca}}) + g_{\text{Cl}}(E_m - E_{\text{Cl}}) = 0$$

and solving for E_m gives

$$E_m = \frac{g_K E_K + g_{\text{Na}} E_{\text{Na}} + g_{\text{Ca}} E_{\text{Ca}} + g_{\text{Cl}} E_{\text{Cl}}}{g_K + g_{\text{Na}} + g_{\text{Ca}} + g_{\text{Cl}}}$$

where the subscript j in g_j and E_j denotes the species, and the chord conductance for each species is taken as the chord of the current-voltage relationship between E_m and the equilibrium potential, E_j . (Note that the chord conductance, $\Delta I/(E_m - E_j)$, is different from the slope conductance, which is equal to $\delta I/\delta E$ at a selected voltage.) E_m is constant at the point at which inward and outward currents balance, and E_m approaches the equilibrium potential for the ion that has the greatest conductance. Nevertheless, the chord conductance equation as written is a simplification. It lumps all of the conductance for a particular ion into a single term, even though multiple distinct channel types may contribute, and it ignores the small contributions of electrogenic pumps and exchangers that produce a

Table 1 Major ionic currents in heart

Current	Molecular basis		Role in action potential	Localization of current
	α subunit	β subunit		
<i>Inward cation</i>				
I_{Na}	$Na_v1.5$ (SCN5A)	β_1 (SCN1B) β_2 (SCN2B)	Upstroke in A, V, PF	PF > A ~ V

Ionic basis for a prototypic ventricular action potential

The relationship between the action potential and the flow of time-dependent ionic currents is shown diagrammatically in Fig. 3. Starting with phase 4 (diastole), each phase of the action potential will be reviewed in turn. E_m in ventricle remains constant during phase 4 and is about -85 mV , which approaches the value of E_K , -95 mV , with a physiologic serum K^+ concentration of $3.5\text{--}4.5\text{ mM}$. Resting E_m approaches E_K because K^+ is the ion with the greatest conductance during phase 4. The specific K^+ channel responsible is the I_{K1} channel,^[7,8] and its conductance is termed g_{K1} (Table 1). It is important to note, however, that the constancy of E_m during phase 4 requires that inward and outward currents are exactly in balance. The outward I_{K1} is balanced by inward currents carried primarily by Na^+ . The resting Na^+ conductance, g_{Na} , is much smaller than g_{K1} because almost all of the Na^+ channels are closed at -85 mV , but E_{Na} is $+60\text{ mV}$, and the driving force for Na^+ entry, $E_m - E_{\text{Na}}$, is nearly 15-fold greater than that for K^+ efflux. As expected from this analysis, replacement of extracellular Na^+ with an impermeant cation causes E_m to hyperpolarize and approach E_K . The remaining discrepancy between

Fig. 3 Ionic currents during generic action potential. Main inward and outward currents are denoted, respectively, by arrows entering or leaving the cell and are placed at time of their activation. Currents found throughout the heart are included, although the distribution of ionic currents is heterogeneous (Table 1). For the illustrated ventricular epicardial action potential, currents in parentheses normally are not significant.

E_m and E_K is largely explained by Cl^- conductance, which carries inward current during phase 4.

Because the K^+ conductance dominates, resting E_m is sensitive to serum K^+ and will follow E_K . For example, increasing serum K^+ from 4 to 6 mM : 1) shifts E_K positively by approximately 10 mV ; 2) reduces K^+ driving force; 3) reduces outward I_K ; and thereby 4) causes a depolarization of approximately 10 mV . Elevation of serum K^+ causes the myocyte to depolarize until the inward Na^+ and outward K^+ currents are again in balance. The final value of E_m primarily reflects the restoration of the driving force for K^+ and thereby K^+ efflux, although voltage-dependent changes in conductance and the effect of E_m on the Na^+ driving force also make small contributions.

Phase 0, the upstroke, begins when a ventricular myocyte starts to depolarize. Normally, depolarization is initiated by the flow of current through gap junctions from nearby myocytes that already are depolarized, or it may be initiated by an electrical stimulus such as that provided by an implantable pacemaker. Depolarization opens Na^+ channels, giving rise to an inward I_{Na} .^[9,10] If the depolarization is sufficient to reach the threshold potential, the inward current produced is larger than the outward current, and as a result, the myocyte will continue to depolarize without a further stimulus. As it continues to depolarize, additional Na^+ channels open, producing an even larger inward I_{Na} , further depolarization, and the opening of more Na^+ channels in a positive feedback loop. Because g_{Na} is much greater than any other conductance during the upstroke, the activation of Na^+ channels elicits a large inward I_{Na} that rapidly drives E_m to about $+50\text{ mV}$ in $<2\text{ ms}$. I_{Na} is transient, however, for two reasons. First, depolarization not only activates (opens) Na^+ channels, but it also causes them to inactivate (close). Therefore, both the Na^+ channel opening and the increase in g_{Na} will be transient. Individual Na^+ channels remain open for $<1\text{ ms}$. Second, as the upstroke is inscribed, the driving force for Na^+ entry decreases. At a resting E_m of -85 mV , the driving force for Na^+ ($E_m - E_{\text{Na}}$) is 145 mV , whereas at the peak of the action potential, $+50\text{ mV}$, it is only approximately 10 mV . Thus, I_{Na} is much reduced near the peak of the upstroke.

Phase 1, initial repolarization, begins when outward currents again become larger than inward currents as I_{Na} decays. Because the driving force on K^+ at the peak of the action potential is large, one might expect an enormous outward I_{K1} . This is not the case, however. I_{K1} exhibits strong inward-going rectification, also termed anomalous rectification, and its conductance is markedly reduced almost instantaneously on depolarization.^[7,8] This decrease in g_{K1} minimizes the K^+ efflux that otherwise would occur and permits development of the remainder of the cardiac action potential. The rectification of I_{K1} is not due to an

intrinsic voltage-dependence of the channels, however. Outward current through the I_{K1} is suppressed because the pore is blocked by millimolar concentrations of intracellular Mg^{2+} and micromolar concentrations of intracellular polyamines, such as spermine and spermidine.^[8]

Other currents contribute to phase 1 repolarization. The transient outward current, I_{to} , is a K^+ current that rapidly activates upon depolarization and inactivates over roughly 100 ms, so it contributes to phase 1 and phase 2.^[4,5,11] As will be noted later, the expression of I_{to} varies in different parts of the heart. A second transient outward current, I_{to2} , also has been identified. I_{to2} is a Ca^{2+} -activated Cl^- repolarizing current due to a conductance that tracks changes in intracellular Ca^{2+} .^[6]

Ventricular action potentials have a pronounced plateau, phase 2, that constitutes most of APD. During the plateau, E_m is near 0 mV and is changing slowly, representing a near balance of inward and outward currents. The inward current during the plateau is primary I_{Ca-L} .^[4,5,10] Like the Na^+ channel, the L-type Ca^{2+} channels open on depolarization. I_{Ca-L} activates more slowly than I_{Na} , reaching a peak in about 10 ms, and inactivates slowly during the plateau. Its amplitude is about 1/50 that of I_{Na} . The inward current is balanced primarily by the outward K^+ currents, I_{Kr} and I_{Ks} .^[10-12] These currents are termed delayed rectifiers because they activate over time upon depolarization. I_{Kr} is the rapidly activating component, and I_{Ks} activates slowly. Overall, the amplitude of I_{Ca-L} and the kinetics of its inactivation and the amplitude of I_{Kr} and I_{Ks} and the kinetics of their activation are the primary factors that set the duration of the plateau, and thereby APD. During the plateau, the inward Ca^{2+} current is decaying and the outward K^+ currents are increasing. Eventually this leads to a more rapid repolarization and the onset of phase 3. The critical role of I_{Kr} and I_{Ks} in setting APD is emphasized by analysis of certain types of dysrhythmias. Forms of genetic, acquired, and drug-induced long-QT syndrome have been traced to modification of these K^+ conductances and a resulting prolongation of ventricular APD.^[13]

The transition between phase 2 and phase 3 (repolarization) is characterized by an acceleration of the rate of repolarization rather than by a distinct transition. As the membrane repolarizes, g_{K1} and I_{K1} begin to increase again. In addition, a fraction of I_{Kr} channels produce extra outward current while transiently passing through the open state as they move from the inactivated state back to the closed state.^[4,5,12] Phase 3 also has an important effect on Na^+ and Ca^{2+} channels. Repolarization is required for both Na^+ and Ca^{2+} channels to recover from the inactivated (closed) state, to the resting (closed) state, from which they can

again open.^[9,10] Recovery of Na^+ channels occurs rapidly during phase 3, and the recovery of Na^+ channels restores the excitability of the cell. Because of the high density and rapid recovery kinetics of Na^+ channels, ERP in ventricular as well as atrial and His-Purkinje myocytes ends during phase 3.

Membrane conductance is much lower (i.e., resistance is higher) during the plateau than during diastole. Therefore, although I_{Ca-L} , I_{Kr} , and I_{Ks} are most important, the potential attained during the plateau and the timing of repolarization are sensitive to several smaller currents. One is due to the Na^+-Ca^{2+} exchanger, which produces a current by coupling the efflux of one Ca^{2+} ion to the influx of three Na^+ ions. At resting E_m , Ca^{2+} is extruded and an inward current is produced, but depolarization causes reversal of the Na^+-Ca^{2+} exchanger, generating an outward current. The Na^+-Ca^{2+} exchanger current again flows inward later in the action potential because of the transient increase in $[Ca^{2+}]_i$ and, eventually, phase 3 repolarization. The exact voltage and, therefore, the timing of the reversal of the Na^+-Ca^{2+} exchanger depends on $[Na^+]_i$. A second current is due to the Na^+-K^+ pump, which extrudes 3 Na^+ while taking up 2 K^+ and contributes a small time-independent outward current to the plateau. A third is I_{to} , which contributes a decaying outward current, especially early in the plateau. Finally, at least two Cl^- currents are important.^[6] There is a background Cl^- current that has been attributed to the same channels that produce a volume-sensitive current, and a cAMP-sensitive Cl^- current that is due to the cardiac variant of the cystic fibrosis transmembrane regulator (CFTR). Both of these Cl^- currents are largely time- and voltage-independent at the plateau potential. Nevertheless, they have significant effects on APD and smaller effects on resting membrane potential.

Because of the interaction of multiple currents and their time- and voltage-dependence, control of the action potential plateau and APD is more complex than may be apparent. Ion channel kinetics are highly voltage-dependent, and in some situations, this can lead to counterintuitive outcomes. For example, an intervention that shifts the plateau positive (e.g., increased inward or decreased outward current) can, in certain situations, result in a more rapid activation of I_{Kr} and I_{Ks} and a paradoxical decrease in APD. Because of these complex interactions, computer models are useful and sometimes necessary for predicting changes in APD.^[14,15]

Recovery of excitability

The prolonged depolarization that is characteristic of cardiac action potentials has an important

consequence. It sets the maximum frequency at which action potentials can be elicited. The current required to initiate an action potential is described as excitability, and a reduction in excitability means that a greater current is required to excite the cell and give rise to another upstroke.

The recovery of excitability is time-dependent, and three periods can be defined, as illustrated in Fig. 4. During the absolute refractory period (ARP), which begins at the upstroke, myocytes are inexcitable and no stimulus can elicit another action potential. Following the ARP is the relative refractory period (RRP). An action potential can be evoked during the RRP, but a larger current is required to excite the cell than when the cell is at rest (phase 4), and therefore excitability is said to be reduced. Moreover, threshold potential during the RRP is more positive than at rest. Excitability and threshold potential return to their resting levels as phase 4 begins.

As a practical matter, the effective refractory period (ERP) is both more important for the heart and more easily measured. The ERP extends from the upstroke to the middle of the RRP and is defined as the period during which one cannot elicit a conducted action potential. Thus, the end of the ERP marks the time when a stimulus can give rise to an action potential that is robust enough to depolarize neighboring cells and spread to the rest of the heart. This definition of the ERP implies that an action potential can be elicited early during the RRP, but it will fail to conduct.

The basis for the time-dependent recovery of excitability is the recovery of the ability to generate an inward current. Depolarization during the upstroke

causes Na^+ channels to open and then inactivate.^[9,10] The Na^+ channels remain in the inactivated state until repolarization occurs during phase 3. Repolarization leads to Na^+ channels returning to their closed state, from which they can open again. This process is rapid and voltage-dependent, and more and more Na^+ channels recover to the closed state as phase 3 repolarization progresses. As a result, sufficient Na^+ channels recover to generate a net inward current and elicit an action potential by the middle of phase 3. Excitability returns as more and more Na^+ channels recover over time. The opening of Na^+ channels is voltage-dependent, so when a greater number of Na^+ channels are in the closed state, a smaller current and less depolarization are required to open a sufficient number of channels to generate a net inward current.

The recovery of Na^+ channels is responsible for the recovery of excitability in atria, ventricle, and the His-Purkinje system, and the relationship of the refractory periods and repolarization is similar in each. Certain pharmacologic agents that are useful in treating ventricular arrhythmias, such as lidocaine, act in part by trapping Na^+ channels in the inactivated state, which delays recovery of excitability. As discussed in a subsequent section, recovery of excitability also is delayed in the AVN because Ca^{2+} channels rather than Na^+ channels are responsible for the upstroke.

REGIONAL VARIATIONS IN CARDIAC ELECTROPHYSIOLOGY

Sino-Atrial Node

The most negative potential attained by SAN myocytes—maximum diastolic potential (MDP)—is about -50 mV; the upstroke in SAN is slow, $2\text{--}5 \text{ V} \cdot \text{s}^{-1}$; and spontaneous depolarization during phase 4 is responsible for pacemaker activity (Fig. 2). Earliest excitation is in the center of SAN. The precise location is not fixed, but moves in response to altered autonomic input and other interventions.^[16] The SAN is heterogeneous.^[2,3,16] Microscopic observation reveals both stellate and elongated spindle cells. Electrophysiologically, the stellate myocytes have a faster intrinsic rate, a more positive MDP, and a longer APD, and they are the primary pacemaker cells.

The expression of ion channels in SAN is different from that in ventricle, atria, and the His-Purkinje system, and these differences can explain the distinct electrophysiological properties of SAN.^[4,5,17] I_{Na} is absent in the primary pacemaker cells. L- and T-type Ca^{2+} channels ($I_{\text{Ca-L}}$ and $I_{\text{Ca-T}}$) rather than I_{Na} are responsible for the upstroke (Table 1). $I_{\text{Ca-T}}$ is particularly prominent in SAN, and it activates and inactivates more rapidly and at more negative potentials

Fig. 4 Recovery of excitability during action potential. Absolute refractory period (ARP): no stimulus can elicit action potential; relative refractory period (RRP): action potential can be elicited, but current required is greater than during phase 4, and threshold potential is more positive; effective refractory period (ERP): a conducted action potential cannot be elicited. Time-dependence of excitability reflects the state of Na^+ channels. Depolarization causes opening and then inactivation. Channels recover from the inactivated to the closed (resting) state during phase 3. C, closed (resting); O, open; I, inactivated; I \rightarrow C, inactivated to closed transition.

than I_{Ca-L} . The upstroke in SAN is very slow because I_{Ca-L} and I_{Ca-T} are much smaller than I_{Na} , and their activation upon depolarization is slower. The depolarized level of MDP in SAN is due to the absence of I_{K1} , the current responsible for the high resting K^+ conductance in other parts of the heart. SAN cells do possess I_{Kr} , I_{Ks} , and also I_{K-ACh} , a K^+ current activated by vagal stimulation. Another critical feature in SAN is a non-selective cation current called I_f , or the pacemaker current.^[17] The density of I_f is much greater in the stellate cells that serve as the primary pacemaker than it is in spindle cells. Activation of I_f upon repolarization drives phase 4 depolarization. In addition, deactivation of I_{Kr} and I_{Ks} following repolarization and activation of Ca^{2+} channels as the cell nears threshold potential contribute to SAN pacemaker activity.

Atria

E_m in atria is about -80 mV, and the upstroke is rapid (150 – 250 $V \cdot s^{-1}$). Atrial action potentials are approximately 150 ms in duration and take on a triangular configuration, because the transition from phase 2 to phase 3 is less distinct and phase 3 repolarization is slower than in ventricle. Regional differences within the atria may contribute to atrial arrhythmias.^[4,5,11] APD and ERP are longer in the crista terminalis than in the pectinate muscles in RA, and longer in RA than in LA. Atrial APD and ERP are both significantly abbreviated by parasympathetic stimulation, although the magnitude of the effect is not uniform throughout the atria. These regional differences in atrial APD, ERP, and parasympathetic responsiveness are thought to play an important role in reentry and atrial fibrillation. Recent studies have recognized that atrial myocytes grow into and form a collar in the pulmonary veins. In some cases, these atrial cells become spontaneously active and serve as ectopic foci that initiate atrial tachyarrhythmias.

The ionic mechanisms underlying atrial and ventricular activity are similar, but some differences have been noted.^[4,5,11] The density of I_{K1} is lower in atria, explaining the more positive E_m and the greater difference between E_m and E_K . The shorter APD in atria is explained in part by expression of I_{Kur} , an ultra-rapidly activating component of delayed rectifier K^+ current in atria, that is found along with I_{Kr} , I_{Ks} , and I_{to} . In addition, atria contain I_{K-ACh} , which plays a critical role in the parasympathetic-induced shortening of atrial APD but is sparse in ventricle. As in SAN, both I_{Ca-L} and I_{Ca-T} are found in atria, whereas I_{Ca-T} is observed in ventricle only after hypertrophy. Interestingly, I_f also is expressed in atrial myocytes,^[17] even though working atrial muscle does not normally

exhibit automaticity. It has been suggested that I_f may play a role in atrial ectopic beats in diseased myocytes. At normal atrial diastolic potentials, however, there is little change in the activation of I_f .

AVN

Overall, the cellular electrophysiology and ionic mechanisms in AVN resemble those of the SAN.^[3-5] The action potential shapes and durations are similar, but MDP in AVN myocytes is slightly more negative, about -60 mV; the upstroke is slightly faster, about 10 – 20 $V \cdot s^{-1}$ and the intrinsic automaticity arising in the N and NH regions is slower, 40 – 50 min^{-1} . Importantly, ERP is significantly longer than APD in AVN, because recovery of I_{Ca-L} is slow.^[10] Slow recovery of AVN excitability prevents rapid atrial rhythms from propagating to the ventricle at an excessive frequency. Ovoid-shaped cells isolated from AVN have the characteristics of N and NH regions, and rod-shaped cells appear to arise from the AN region.

I_{Ca-L} is responsible for the upstroke in the N and NH regions,^[4,5] and its small amplitude and slow activation explain the slow upstroke and slow conduction in the AVN. The presence of I_{Ca-L} without I_{Ca-T} gives rise to useful pharmacologic distinctions. L-type Ca^{2+} channel blockers, such as dihydropyridines and verapamil, can impede AVN conduction and prolong ERP with minimal effects on SAN. In contrast to N and NH cells, I_{Na} is found in transitional AN cells. I_{Kr} , I_{to} , and I_{K-ACh} are prominent in AVN, whereas I_{Ks} is less important in AVN than in SAN. As expected from the depolarized MDP, only low levels of I_{K1} are found. The N and NH regions also exhibit strong expression of I_f ,^[17] which is consistent with the pacemaker activity arising in these portions of the AVN. Nevertheless, activation of I_{Ca-L} and the deactivation of I_{Kr} also modulate pacemaker activity.

His-Purkinje System

Action potentials in the His-Purkinje system are noted for the fastest upstroke velocity in the heart— 500 – 600 $V \cdot s^{-1}$ —corresponding to the fastest conduction velocity.^[3-5] E_m is typically -90 mV, slightly more negative than in ventricle. APD is greater in the Purkinje system than elsewhere, especially at slow heart rates, and a distinct notch is observed between phases 1 and 2. Within the His-Purkinje system, the longest APD and ERP are in the terminal Purkinje fiber branches. The prolonged ERP in these myocytes is thought to reduce the risk of reentrant rhythms involving Purkinje fibers and ventricle. On the other hand, prolonged APD favors drug-induced early

afterdepolarizations, which propagate to the ventricle and may induce ventricular tachyarrhythmias such as torsade de pointes.^[13]

Fast conduction velocity in Purkinje fibers is due in part to a high density of I_{Na} . Both I_{Ca-L} and a substantial I_{Ca-T} are found, although the density of I_{Ca-L} is less than in ventricle.^[4,5] Several factors contribute to the long APD. The density of I_{K1} may be less than in ventricle, but this is controversial. A slowly inactivating component of I_{Na} also has been suggested. On the other hand, the density of I_{Kr} and I_{Ks} is similar to that in ventricle. Another difference is in I_{to} . In human heart, the recovery of I_{to} is much slower in Purkinje cells than in ventricle, and it is more sensitive to blockers such as 9-aminopyridine and tetraethyl ammonium, suggesting that different molecular species are responsible for I_{to} in different regions of the heart.^[4,5,11]

Ventricle

Regional variations in ventricular APD are responsible for the upright T-wave in the electrocardiogram, and they contribute to arrhythmogenesis. Epicardial action potentials have a much more prominent notch separating phases 1 and 2 and a shorter APD than those of endocardial myocytes. In addition, a population of midmyocardial cells (M cells) exhibit a pronounced prolongation of APD at slow heart rates, as found also in Purkinje cells.^[18] Left ventricular M cells have a shorter duration and more pronounced notch than those in right ventricle. M cells were first identified in isolated myocytes. In the presence of electrical coupling in intact tissue, the prolongation of APD in M cells at slow heart rates should be minimized by the influence of surrounding myocytes with shorter APD. Nevertheless, the preponderance of evidence argues that midmyocardial cells have a prolonged APD in vivo. The heart rate-dependent transmural gradient of APD and ERP is thought to be an important factor in reentrant arrhythmias, especially when APD is prolonged by slow heart rates or drugs.

CONCLUSION

Thus, the heart is anything but uniform in its bioelectric behavior. Heterogeneity of the action potential, conduction, and automaticity in the atria, ventricles, His-Purkinje system, and SA and AV nodes—and within each of these regions—can now be explained by differences in the expression of ion channels. Detailed knowledge of the diversity of cardiac bioelectricity is essential for understanding both normal electrophysiologic function and the consequences of disease processes.

INTRODUCTION

From the perspective of the operating physician, cardiac catheters represent technologic marvels and are a triumph of bioengineering. The design and ease of use of these devices have enabled physicians around the world to perform important diagnostic and therapeutic procedures to the benefit of countless numbers of patients.

HISTORICAL PERSPECTIVE

Physicians in the Greco–Roman and early Egyptian period had access to a variety of medical instruments that were designed to aid them in their treatment of the sick. Many instruments—including scalpels, hooks, forceps, drills, and catheters—were available to Hippocrates and are used today in a modified form of what was used in antiquity.^[1] As early as 3000 B.C., catheters were employed by physicians in order to cannulate obstructed urinary tracts to allow urine to pass freely from the body. The design of these early catheters was a simple, crude hollow tube made of steel or bronze. The S-curve catheter was specifically designed for men and the straighter catheter for women (Fig. 1).

In the early 1700s, Hale performed the first examination of the heart of a horse. He used an archaic catheter contraption made of brass pipes, a glass tube, and the trachea of a goose (Fig. 2).^[2] In 1844, Claude Bernard, using the horse as a model, inserted a mercury thermometer into the carotid artery and advanced it through the aortic valve and into the left ventricle to measure blood temperature. Over the next 40 years, his work with catheters and the measurement of intracardiac pressure in various animals became the

standard method for the study of cardiovascular hemodynamics.^[3]

The extension of these techniques to humans is credited to Werner Forssmann, a German surgical resident.^[4] In 1929 he experimented with a human cadaver and found that it was relatively easy to guide a urological catheter from an arm vein into the right atrium.^[4] The purpose of his investigation was to find a safer approach for intracardiac drug delivery. He took this approach one step further and passed a catheter through one of his own dissected left antecubital veins. He guided the catheter with the aid of fluoroscopy until it entered his right atrium. He confirmed the position of the catheter by a chest roentgenogram.^[4]

Forssmann made multiple attempts at self-catheterization during his training and was heavily criticized by his colleagues because of the perceived danger of his experimentation, as well as his unorthodox approach to scientific investigation. However, he was the first to document the feasibility of right heart catheterization in humans using radiographic techniques. Because of the constant harsh criticism, his interest in cardiology waned and he pursued a career in urology.

Despite the negative response to Forssmann's innovation in Germany, Andre Cournand in New York began utilizing cardiac catheters as a diagnostic tool in the early 1940s. He used these catheters to investigate cardiac function in normal and diseased patients.^[5,6] In 1956, Forssmann and Cournand shared the Nobel Prize in Physiology and Medicine for their foresight and contribution to the advancement of cardiac catheterization.

Over the ensuing years, catheter use for the diagnosis of heart disease advanced rapidly. The diagnosis of congenital and acquired (rheumatic) heart diseases, once so elusive to physicians, was facilitated greatly by this new catheter technology.^[7–10]

Fig. 1 Photograph of first known catheters to be used to access the urinary bladder in humans. (From website: www.Indiana.edu/~anccmed/instr1/html.)

Cardiac catheters were used in an indirect fashion to visualize the coronary arteries by flooding the aortic root with contrast dye, which then flowed into the coronary arteries. In the late 1950s, Mason Sones, a pediatric cardiologist at The Cleveland Clinic, conducted an imaging procedure in which dye was injected into the aortic root of a patient. During the procedure, the catheter accidentally entered the patient's right coronary artery and before it could be removed, a small amount of dye was released.^[11,12] The coronary artery tolerated the dye load and remained intact, and—most significantly—the patient suffered no adverse complications.^[12] Sones further modified the catheter and developed new designs that could enter the coronary arteries selectively. Combining selective coronary catheterization with high-quality imaging techniques, coronary angiography became a significant milestone in the diagnosis of coronary disease. Judkins and Adams further modified the technique of cardiac catheterization, resulting in a better understanding of the pathophysiologic mechanism of heart disease.^[13]

Catheter development continued to improve in the ensuing years but a full discussion of these improvements is beyond the scope of this article. However, a brief chronology of several advancements warrants mentioning. They include:

1. In 1964, Dotter introduced transluminal angioplasty to open blocked peripheral arteries with increasing catheter diameters.^[14]
2. The development of the balloon flotation catheter by Swan and Ganz in 1970.^[15]

3. In 1977, Grüntzig expanded on Dotter's techniques and introduced percutaneous transluminal coronary angioplasty (PTCA) to open blocked coronary arteries.^[16,17]
4. Catheter-based therapy combining PTCA and stenting of the coronary arteries provided significant improvement in the treatment of acute coronary thrombosis.^[18,19]

DIAGNOSTIC CARDIAC CATHETERIZATION IN ADULTS

The development of cardiac catheters and the many advances in imaging techniques have made coronary angiography a major tool in the diagnosis and treatment of coronary artery disease. Many noninvasive techniques such as magnetic-resonance imaging, fast computed tomography, and intravascular ultrasound have aided in the diagnosis of coronary artery disease. However, selective coronary angiography remains the gold standard.^[20,21]

There are numerous indications for the use of catheter-based coronary angiography, and as catheter technology improves, the indications may broaden. However, the most common indication for cardiac catheterization is the evaluation of coronary atherosclerosis.

There are several techniques used to access and view the coronary arteries using coronary catheters. In most patients, coronary angiography can be performed by brachial cut-down or by the more common

Fig. 2 Artist drawing depicting the first known attempt to measure intravascular pressures in a live horse. (From website: www.PTCA.org/history_timeline.html. Grossman; published by Lippincott, Williams, and Wilkins, Baltimore, 2000; p. 71; Fig. 4.1, panel A.)

percutaneous approach from the femoral, brachial, or radial artery.

FEMORAL ARTERY APPROACH

Femoral, brachial, and radial arterial entry gives access to the aorta and the left side of the heart. The femoral artery approach is most often used during coronary artery angiography.^[22] Trauma can occur to the vessel during access and may result in vascular compromise during or following the cardiac catheterization procedure. Assessment of the peripheral pulses is mandatory prior to accessing the arterial circulation. It is most important to assess the femoral artery and its

distal branches, including the dorsalis pedis (top of the foot below the ankle) and the posterior tibial (inside and behind the ankle) prior to cardiac catheterization. Once adequate pulses are determined, assessment of any changes can easily be made postprocedurally.

The femoral artery is a tube approximately 1 cm in diameter that crosses the inguinal ligament, which extends from the iliac crest to the pubis. The actual arterial entry is 1–2 cm below the inguinal ligament (Fig. 3).

Local anesthesia with 1% lidocaine is delivered to the superficial and deep tissue planes. Adequate anesthesia is provided to cover the complete depth of the skin-to-artery path to decrease the level of discomfort for the patient.

Single, anterior percutaneous arterial wall entry technique with a hollow tip-beveled needle is preferred to the original Seldinger double-wall puncture technique. The latter was associated with increased hemorrhagic complications.

The needle is introduced through the skin and advanced toward the artery at a 30–45° angle (Fig. 4). Once the artery is punctured, a flexible J-tipped guidewire is introduced through the hollow needle and advanced slowly and gently into the artery. Fluoroscopy is used frequently throughout the procedure to check for guidewire placement.

The guidewire is advanced to the appropriate position in the ascending aorta and the puncture needle is removed. Many laboratories utilize a catheter sheath inserted over the guidewire for increased comfort for the patient and limitation of the number of catheter exchanges through the artery. Various femoral catheters are then inserted with a J-tipped guidewire for left and right coronary artery evaluation.

If there is significant peripheral vascular disease and the femoral artery cannot be used to access the aorta and the left side of the heart, then the brachial and/or radial artery can be used. Care again must be taken to

Fig. 4 Schematic depicting the various steps in obtaining vascular access using the Modified Seldinger technique. See text for details. (From *Diagnostic and Therapeutic Cardiac Catheterization*, 2nd ed.; edited by C. J. Pepine, J. A. Hill, and C. R. Lambert; published by Williams and Wilkins, Baltimore, 1994; p. 91; Fig. 8.1.)

properly assess for adequate pulses prior to the procedure.

CORONARY CATHETER TECHNOLOGY

Of all the cardiac catheters, the development and manufacture of coronary catheters presents the most unique bioengineering challenge. Early angiographers were severely limited with primitive, nonradiopaque polyethylene catheters that were hand-fabricated and had to be filled with contrast agent to be visible under rudimentary fluoroscopes that provided poor imaging quality.^[23]

Charles Dotter, M.D., an interventional radiologist, made significant contributions to the field of cardiac catheterization and catheter design.^[24-26] Dotter was very innovative, and initially designed and invented his own interventional catheters. He used unconventional materials such as guitar strings, Volkswagen automobile speedometer cables, and vinyl insulation stripped from pieces of intercom cable. Dotter refined his inventions and finally developed catheters and guidewires made from Teflon. Since then, advances in catheter technology have contributed to improved diagnosis and treatment of atherosclerotic heart disease.

Key to the successful engineering of intravascular and intracardiac catheters was the explosive development of a class of materials known as plastics. Plastics include numerous organic, synthetic, or processed materials that revolutionized the manufacturing industry. A plastic is made up principally of a binder together with plasticizers, fillers, pigments, and other additives. The binder gives a plastic its main characteristics and often its name. Binders consist of very long-chainlike molecules called polymers. Plasticizers are added to a binder to alter the material properties of the compound such as flexibility and toughness. Fillers are added to further manipulate properties such as hardness and resistance to shock. Pigments are used to impart optical characteristics such as radiopacity.

There are two basic types of plastic useful to cardiac catheter manufacturing: thermosetting plastics, which cannot be resoftened after initially being subjected to

heat and pressure; and thermoplastics, which can be repeatedly softened and remolded by heat and pressure. When heat and pressure are initially applied to a thermosetting binder, the molecular chains become cross-linked, thus preventing any slippage if heat and pressure are reapplied. When heat and pressure are applied to a thermoplastic binder, the chainlike polymers slide past each other, giving the material plasticity, or the ability to be molded to a predetermined shape, and later capable of being deformed to some degree while retaining much of its previous shape.

Diagnostic cardiology catheters have evolved over the past few decades to include such modifications as smaller outer diameters, larger inner diameters, soft atraumatic tips, enhanced torque control, and a variety of shape designs. All this has been done in an attempt to make catheterizations easier for both physician and patient.

The construction of these multilayered plastic tubes involves the union of several elements, which determine the performance of the product (Fig. 5):

- The hub connects the catheter to syringe or power ejector.
- The strain relief acts as a reinforcement near the hub to prevent kinking of the catheter's main tubular section.
- The main tubular section is commonly referred as the body of the catheter.
- The proximal tip function is to support the shape transition between both braided and nonbraided segments.
- The distal tip of the catheter is designed to be soft and atraumatic in order to prevent vascular damage.

The market offers several catheter brands that basically share the same manufacturing steps:

Compounding

In the compounding process, plastic pellets are blended into a compound. Thermoplastic materials such as polyurethane or nylon are heated and blended with lubricants and radiopaque materials into a molten mix

Fig. 5 Schematic representation of the elements of a diagnostic cardiac catheter. (Courtesy of Cordis, Corporation, Miami, FL, a Johnson & Johnson company.)

that has the consistency of bread dough. The material is mixed further on rollers that spread the material to a consistent thickness. It is pulled off the rollers, cut into strips, and allowed to cool. The strips are diced into pellets that will be used in the extrusion process.

Extrusion

Extrusion refers to forcing, pressing, or pushing a material through a tool or devices for imparting a desired shape. The pelletized lot of compound is taken to the extrusion floor. The extrusion process heats the thermoplastic material and forces it into a tubular shape. This is accomplished in one of two ways, either by air extrusion or mandrel extrusion.

In the air extrusion process, the molten thermoplastic material is blown into its tubular shape by a volume of air, then passed through distilled water and allowed to cool.

In the mandrel extrusion process, the hot thermoplastic material is spread in a layer over a mandrel wire to form its tubular shape. This becomes the base coat layer of the catheter. It is passed through a column of water to cool. Sophisticated computers precisely control the thickness of the base coat.

Braiding

Stainless steel braiding makes up the middle of the catheter wall. A large spool of extruded, hollow tubular thermoplastic is placed into the braiding machine, which weaves a knitted pattern of braid onto the base coat using a certain number of strands of very fine stainless steel wire.

Following the braiding process, the large spool of braided base coat is taken back to the extrusion floor, where another layer of plastic is extruded over the braiding. This is the topcoat of the catheter.

Catheter Assembly

At the end of the topcoat extrusion line, the catheter bodies are cut into their approximate final length. The mandrel wire is removed. Each end of the catheter body is prepared for assembly by grinding and in some cases flaring the end.

At one end, a nonbraided tip segment is fused to the catheter body. At the other end of the catheter body, a strain relief is fused on, and then a polycarbonate hub is bonded to the catheter. Finally, the catheter is cut to its final length, fully inspected, and tested using hydrostatic pressure test.

Shape Forming

This is a key step with exacting standards. For instance, the success of the Judkins line of catheters in minimizing the time for coronary artery catheterization is due in large part to the recognition that the ostia of the left and right coronary arteries lie in relatively set planes with respect to the catheters' long axis. The catheters are taken to a station to form the tip into its specified shape. Forming rods preshaped in the intended curve are inserted into the catheter tip segments. The tip segment is heated for a specified time and then immediately cooled. The forming rods are removed and the catheter tips retain their desired shapes because they have been heat-set. This is the key characteristic of the thermoplastic materials used in the manufacture of coronary catheters.

The functional specifications of coronary catheters are influenced by the materials used in the manufacturing process and by engineering specifications such as catheter length, diameter size, wall thickness, and maximal injection pressure and flow rates.^[27] Important and key aspects of the physician-device and patient-device interface include the following:

- Torque control.
- Kink resistance.
- Flexibility.
- Pushability, related to friction.
- Stability during injection.
- Radiopacity.
- Shape retention.
- Thrombogenicity.

Relative to these key parameters, the ideal coronary catheter should be soft enough to avoid vascular trauma. This is particularly true for the tip of the catheter that ultimately engages the ostium of the coronary artery. However, the catheter must also be firm enough to maintain its preformed shape, especially as it warms from room temperature to body temperature. In addition, these catheters must also be advanced, retracted, and maneuvered by the application of rotational torque. During difficult cases in which there is extensive tortuosity of the aorta or iliofemoral arteries, extensive catheter manipulation may be required. The composition of the catheter shaft must allow for external forces that are applied to the distal end of the catheter outside the body to be transmitted reliably to the tip of the catheter in the ascending aorta.

Superimposed on these important parameters is the issue of catheter and lumen diameter size. Ideally, a coronary catheter would be the smallest size possible to minimize trauma to the arterial entry site (femoral, brachial, or radial). However, the need to maneuver

the catheter limits the extent of miniaturization that is possible. In addition, there are limits as to how small the catheter lumen can be. There are two major classes of coronary catheters that have two distinct purposes. Angiographic catheters are designed to inject contrast material into the coronary artery at a rate and volume that is sufficient to create a diagnostic quality angiogram. Achieving this goal is more difficult when using catheters with smaller lumen diameters are used. Angioplasty guiding catheters must not only allow for injection of contrast material, but also have lumens of sufficient size to allow the passage of the various devices used in contemporary interventional cardiology procedures.

Thus, there are important tradeoffs between the desire for the smallest possible coronary catheter and the ability of that catheter to accomplish its intended purpose. For instance, manufacturing a smaller catheter while keeping the lumen diameter constant requires that the shaft of the catheter be composed of thinner material. This increases the susceptibility of this catheter to kinking during catheter manipulation, particularly rotational torsion.

Historically, catheters have been manufactured from various biomaterials. Synthetic polymers have made a significant impact on catheter development, virtually replacing older biomaterials in cardiovascular procedures. This transition began with the shift from metal catheters to those made of polyethylene. Nylon became available in the 1930s, polyurethane was introduced in 1937 as a surface coating, silicones were introduced during World War II, and other biocompatible polymers were developed in the 1950s. A summary of the relevant polymers used in coronary catheter construction follows.

Teflon

This biomaterial has a low frictional coefficient and high memory, which allow for excellent gliding performance with decreased resistance. Because it has good memory, it cannot be shaped at temperatures below 100°C.

Nylon

This is the common name of a thermoplastic linear polyamide resin that has outstanding properties. This polymer has excellent chemical resistance, good stress crack resistance, low moisture absorption (0.9%), low coefficient of friction and high-pressure resistance with dimensional stability. Based on these properties, it is possible to design smaller catheters with a reduced inner diameter (ID) without compromising performance (the largest ID could be 0.057" and the smallest

0.042"). Nylon catheter construction is highly responsive to torque transmission. In addition, nylon catheters can be designed to provide a uniform ID from the hub of the catheter to its tip. This results in excellent flow dynamics and optimal angiographic results.

Polyurethane

This biomaterial holds an important role in cardiac applications, and the benefits of this material lie in its physical properties. This polymer has been described to bridge the gap between rubber and plastic and also has a load-bearing capacity comparable to cast steel. Outstanding properties of polyurethane include exceptionally smooth surfaces, resistance to colonization by fungal organisms, and excellent hydrolytic stability. Braided polyurethane catheters are built for maximum pushability and precise torque control. Nonbraided proximal segments and distal tips are designed for flexibility and shape retention.

Polyethylene

This thermoplastic biomaterial exhibits moderate-to-high tensile strength with moderate elongation. Polyethylene has high memory and can easily be reshaped during the manufacturing process.

Silicone

This is an unusual polymer in that it is partly organic and partly inorganic. Silicones are based on polymers in which the main polymer chain consists of alternating silicon and oxygen atoms. They are derived from sand and methyl chloride. The notable properties of this polymer are a high degree of lubricity, excellent water resistance, chemical inertness, retention of most physical properties at elevated temperatures, and compatibility with the human body. Silicone is often prepared with barium sulfate—a substance required to make it radioopaque—but this addition can also make it less elastic and flexible and more fragile.

PVC

Polyvinylchloride is a thermoplastic material; during its compounding into commercial resin, ingredients are added, such as stabilizers to prevent heat degradation, plasticizers to impart flexibility, lubricants as processing aids, fillers for cost-reduction purposes, and impact modifiers to improve toughness. The hubs of most catheters are composed of PVC and the production process is done by injection-molding. This polymer

Fig. 6 Photograph illustrating the differing thrombogenic potential between a coated and a noncoated catheter. (From website: www.surmodic.com.)

exhibits high friction and has the potential to grow hard over time.

A very important property for medical devices that come into contact with blood after insertion in a human body is thrombogenicity. Thrombogenicity is the ability of the device to induce formation of blood clots. For blood to clot, it is believed that thrombin must be generated in the blood. Several potent anticoagulants can prevent the formation of thrombin. The most widely used anticoagulant is heparin. When heparin is incorporated onto the surface of a medical device, the ability of the surface to induce formation of clots decreases, or in other words, the surface becomes antithrombogenic (Fig. 6). However, many heparinized surfaces tend to have poor stability *in vivo* and the antithrombogenicity of a heparinized surface tends to decrease as the surface heparin loses its potency to retard clot formation. New heparin compositions and coatings are needed to improve the antithrombogenic stability of heparinized surfaces. Examples of these coatings used in the diagnostic catheters industry are the MDX4-4159 fluid 50% medical-grade dispersion, trichloroethene, carnauba wax, and other mixtures of non-heparin synthetic hemocompatible materials such as hydrophilic coatings.

Heparin is a pharmaceutical that has been used clinically for decades as an intravenous anticoagulant to treat inherent clotting disorders and to prevent blood clot formation during surgery and interventional procedures. Heparin molecules are polysaccharides with a unique chemical structure that gives them specific biological activity. When heparin is immobilized onto the surface of a medical device material, it improves the performance of the material when it comes in contact with blood in several ways:

1. Provides local catalytic activity to inhibit several enzymes critical to the formation of fibrin (which holds thrombi together).

2. Reduces the absorption of blood proteins, many of which lead to undesirable reactions on the device surface.
3. Reduces the adhesion and activation of platelets, which are the primary component of thrombus.

Nevertheless, heparin compounds and methods to prepare them present many bioengineering challenges such as: 1) heparin's poor adhesion to surfaces, which requires special surface and thermal treatments that may result in degradation of surface properties; and 2) they must be applied in thick coating layers using toxic chemical compounds.

The MDX4-4159 fluid 50% medical-grade dispersion material provides an alternative solution that circumvents many of the problems related to preparation of heparin compounds. The MDX coating is a dispersion containing 50% active silicone ingredients in mixed aliphatic and isopropanol solvents. The significant features of this dispersion are:

1. It has excellent lubricity, providing a smooth surface to the catheters.
2. It has high adhesion to some plastics such as polyurethane used to build diagnostic catheters.
3. It offers an easy application from dilute solvent solutions.
4. It cures at room temperature upon exposure to atmospheric moisture.

The coating of the catheter surface may be applied by dipping or wiping the catheter body with the MDX4-4159 fluid (Fig. 7). Spray application can be used but is not recommended because of the high risk of inhalation toxicity. The coating thickness can be varied to fit individual needs. The coating should be thin enough to be invisible to the unaided eye. At 25°C (77°F) and 55% relative humidity, the coating should cure enough in 24 hours to allow handling and use of the coated catheters.

Trichloroethene (TCE) is a colorless liquid at room temperature with a somewhat sweet odor similar to ether or chloroform. It is used primarily as a solvent to remove grease from metal surfaces. In the diagnostic catheter industry, TCE is used to create a repellent or nonstick catheter surface. This prevents the build-up of cells and proteins that causes blood clot formation during the catheterization procedure. Carnauba wax can be added to TCE to create a solution that provides additional lubricity to the catheter surface. The manufacturing process to apply this solution involves dipping and wiping the surface of the catheter, and is similar to the process used with the MDX4-4159 coating (Fig. 7).

Because friction is a very important factor related to catheter performance, modern hydrophilic coatings

Fig. 7 Photograph illustrating the process of wiping the catheter surface following dipping in MDX4-4159 fluid. (Courtesy of Cordis de Mexico S.A. de C.V., Chihuahua, Mexico.)

(wet lubricity) have been applied to the external portion of the catheter in order to smoothen the otherwise rough surface. In many cases, these hydrophilic coatings were found to be antithrombogenic, causing many to employ them as an alternative to heparinization. Hydrophilic coatings can also limit bacterial colonization and reduce protein and platelet adhesion.

In comparison to known heparin compounds and the challenges of making and using them, hydrophilic solutions provide one or more of the following advantages:

- Spontaneous wetting and improved flow.
- Reduced procedure time.
- Reduced insertion forces.
- Increased patient comfort.
- Enhanced ability to maneuver through tortuous vascular anatomy.
- Reduced tissue irritation and damage.

The manufacturing process to coat the catheters with hydrophilic solutions is versatile and simple. The reagents are dissolved in water or a water/alcohol mixture, applied to a cleaned catheter shaft, and finally activated by an ultraviolet light lamp. The entire activation stage takes only seconds to minutes of exposure to ultraviolet light to accomplish the chemical bonding reaction at the catheter surface. This is a distinct advantage over other coating processes that require lengthy curing times. This technology uses no harsh chemicals and produces no hazardous by-products, and there is no need for surface-expanding pretreatment that can often affect the catheter's physical properties or performance. In addition, no expensive equipment is required to comply with environmental regulations.

Finally, this kind of technology adapts well to either batch processing or incorporation into continuous-flow production lines allowing high volume and lean manufacturing systems. Inspections can be done online for early feedback, and as a result, fewer catheters are rejected for failing to meet specifications. In general, this process maintains consistent performance with predictable outcomes, eliminating batch-to-batch variability.

COMMONLY USED CARDIAC CATHETERS

As stated earlier, initial attempts to perform coronary angiography used nonselective injections of contrast medium into the aorta to simultaneously opacify both the left and right coronaries. The development of new catheter technology has made nonselective coronary angiography obsolete except in cases where coronary anatomy is distorted or anomalous or the origins of saphenous vein bypass grafts must be visualized to guide subsequent selective cannulation. Today, cardiac catheterization involves selectively cannulating the coronary vasculature and the chambers of the heart. Several catheters are available that are preshaped and vary in design and luminal diameter. This is due to the anatomical differences in the right and left coronary origins as well as variations and pathology in the ascending aorta and arch. There are left and right catheters for engaging the corresponding coronary arteries respectively. The outer diameter of a catheter is determined in French units (1 French unit = 0.33 mm).^[28] The catheters are available in a variety of sizes ranging from 3.5 F to 8 F.

Smaller-diameter catheters allow for smaller arterial punctures, greater patient comfort, and earlier patient ambulation. On the other hand, catheters with a larger lumen offer better opacification of coronary vessels, thus improving the image resolution. They give the operator greater maneuverability and stability during the procedure and minimize dislodgement during contrast injection. The selection of the proper catheter size necessitates a balance between these properties, consideration for the size of the target vessels, and physician preferences based on individual experience and comfort level.

The Judkins-type catheters are the preferred catheters for coronary arteriography via the femoral approach in most cases. Other catheters commonly used in this route include the Amplatz-type catheters and the Multipurpose catheters. Preshaped bypass graft catheters are available for the saphenous venous grafts and the internal mammary grafts. Each of these various catheters has a unique method for engaging and disengaging the coronary ostia. Pigtail catheters are used for instrumentation of the left ventricle as well as

for any angiographic study that requires injection of larger volumes of contrast material.

JUDKINS CORONARY CATHETERS AND JUDKINS TECHNIQUE

The left and right Judkins catheters are preshaped to selectively engage the left and right coronary ostia. These catheters have tapered end holes for contrast injection. Both catheter types have a primary and a secondary curve to negotiate the aortic root and facilitate engagement of the left and right coronary, respectively. The secondary bend represents the major difference between the left and right Judkins catheters. In the case of the left, the bend approaches 180°, whereas it is about 30° with the right.^[29] Both catheters are available in various sizes ranging from 3.5 to 8 cm. Larger catheters can be custom ordered. In the left Judkins catheter, these sizes represent the distance between the primary and secondary curves (Figs. 8 and 9).

Because the right Judkins catheter has a less prominent primary curve, it is sized by the length of its secondary curve (Fig. 10). A 4.0-cm catheter will fit most adults. However, in patients with dilated or enlarged aortic roots, a larger-sized catheter may be required. The total length of a catheter from tip to hub is 100 cm. Custom-designed catheters of longer length are required in very tall patients or patients with extreme tortuosity of the aorta.

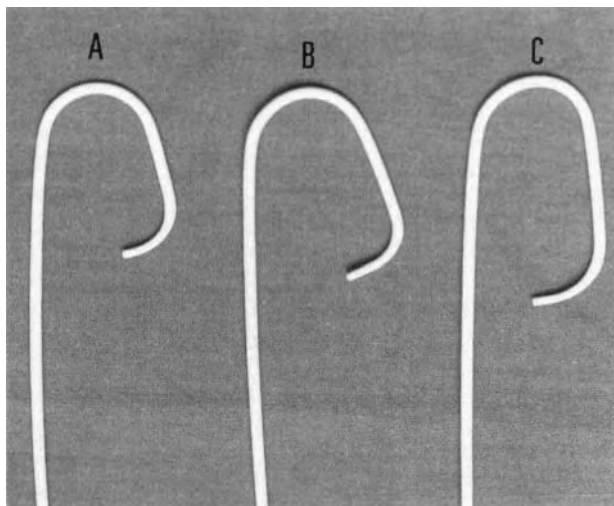

Fig. 8 Photograph of Judkins left coronary catheters. A:JL3.5; B:JL4; C:JL5. These numbers designate the length in centimeters between the primary and secondary curves. (From *Diagnostic and Therapeutic Cardiac Catheterization*, 2nd ed.; edited by C. J. Pepine, J. A. Hill, and C. R. Lambert; published by Williams and Wilkins, Baltimore, 1994; p. 136; Fig. 9.32.)

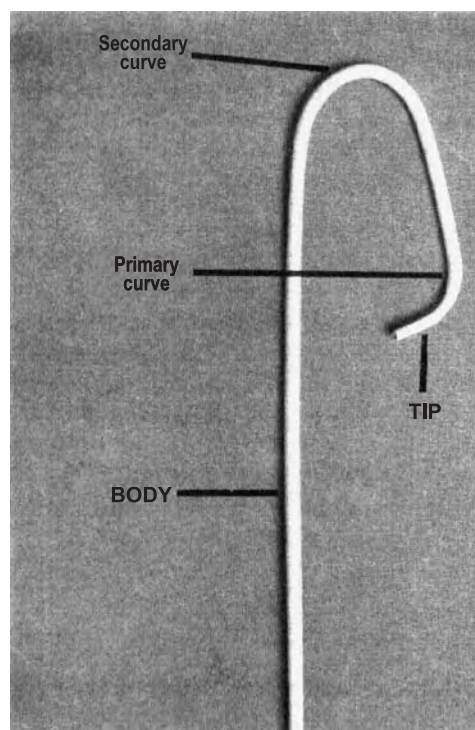

Fig. 9 Photograph of a JL4 coronary catheter demonstrating the different sections of the catheter. (From *Diagnostic and Therapeutic Cardiac Catheterization*, 2nd ed.; edited by C. J. Pepine, J. A. Hill, and C. R. Lambert; published by Williams and Wilkins, Baltimore 1994; p. 126; Fig. 9.18.)

The left Judkins catheter is easily directed into the left coronary artery with very little manipulation. The catheter tip is slowly advanced under fluoroscopic guidance as it follows the ascending aorta border. The unique double-curve design allows the catheter tip to fall into the opening of the left coronary artery, often with an abrupt forward motion. Sometimes, a minimal amount of clockwise rotation improves alignment of the tip with the left main trunk (Fig. 11).

The technique for cannulation of the right coronary artery is different than that of the left and requires slightly more catheter manipulation.^[28,30] With the fluoroscopy unit placed in the left anterior oblique position, the catheter is advanced into the ascending aorta with the tip directed caudally toward the feet. The catheter is advanced into the right coronary cusp of the aortic valve. The catheter is then pulled back about 2–3 cm above the valve and rotated 45–90° clockwise simultaneously. This combined maneuver transmits the torque to the catheter tip and the right coronary ostium is slowly engaged (Fig. 12). Another technique is to engage the right coronary artery from above its opening. The catheter is advanced 2–4 cm above the aortic valve. While the catheter is rotated

Fig. 10 Photograph of Judkins right coronary catheters. A:JR4; B:JR5; C:JR6. These letters designate the length of the secondary curve in centimeters. (From *Diagnostic and Therapeutic Cardiac Catheterization*, 2nd ed.; edited by C. J. Pepine, J. A. Hill, and C. R. Lambert; published by Williams and Wilkins, Baltimore, 1994; p. 136; Fig. 9.33.)

45–90°, it is advanced downward approximately 1–2 cm and the right coronary can be slowly engaged.

All catheters used during cardiac catheterization are attached to fluid-filled manometer systems for the measurement of arterial pressures. Close monitoring of the arterial pressure waveform during selective engagement of the left and right coronary artery is crucial because the first indication of important atherosclerotic disease involving the origin of these vessels could

Fig. 11 Diagram illustrating the selective cannulation of the left coronary artery using the Judkins left catheter. (From *Cardiac Catheterization and Angiography*, 2nd ed.; edited by W. Grossman; published by Lea and Febiger, Philadelphia, 1980; p. 162; Fig. 13-9.)

Fig. 12 Illustration of selective cannulation of the right coronary artery using the Judkins right catheter. (From *Cardiac Catheterization and Angiography*, 2nd ed.; edited by W. Grossman; published by Lea and Febiger, Philadelphia, 1980; p. 163; Figs. 13–10.)

be changes in the pressure waveforms as the catheter enters the vessel.

AMPLATZ CORONARY CATHETERS

Occasionally the Judkins catheters are unsuitable for engaging the coronary ostia. This is due to variations in aortic root configurations, aberrations in the left and right coronary artery origins that can displace them superoposteriorly, or anomalous origins of the coronary arteries. In these select instances, an operator may preferably change to Amplatz-type catheters that allow more rotational maneuvering and controlled probing of the ascending aorta than do Judkins catheters.

The distal end of Amplatz catheters has a preshaped half-circular curve with a tapered tip angled perpendicular to this curve. The left Amplatz catheter is available in various sizes ranging from AL0.75 to AL4 based on progressively larger curve diameters (Fig. 13).^[31]

The right Amplatz catheter has a similar—although smaller—distal end, and is available in two sizes, AR1 and AR2. As with the left Amplatz catheters, these numbers refer to progressively larger diameters of the half-circular curves. An AL1 or 2 and AR1 will fit most adults.

The left Amplatz catheter has a unique method of engaging and disengaging the left coronary artery. The catheter is advanced around the arch with its tip directed toward the left coronary ostium and pointing downward. The tip usually comes to rest below the ostium in the sinus of Valsalva. Further advancement causes the catheter tip to ride up the aortic wall and engage the left coronary ostium. At this point, slight retraction causes deeper engagement of the left main coronary artery (Fig. 14). To disengage the catheter, the operator has to paradoxically advance the catheter farther instead of withdrawing it. This backs the tip upward and out of the left main ostium. When

Fig. 13 Photograph of different sized Amplatz left coronary catheters. A:AL1; B:AL2; C:AL3. The letters refer to progressively larger diameters of the half circular curve. (From *Diagnostic and Therapeutic Cardiac Catheterization*, 2nd ed.; edited by C. J. Pepine, J. A. Hill, and C. R. Lambert; published by Williams and Wilkins, Baltimore, 1994; p. 137; Fig. 9.34.)

positioned properly, withdrawal (i.e., pulling) of the left Amplatz catheter during attempts to disengage the left main can actually cause the catheter to advance deeper into the vessel. The left Amplatz catheter is particularly useful in situations where the left anterior descending artery and the left circumflex artery have separate ostia, and subselective engagement of each is required to acquire diagnostic quality angiograms. This catheter can also provide greater stability and support for the passage of various interventional tools during the treatment of complex coronary stenoses. The left Amplatz catheter is more technically challenging to use and has higher incidence of coronary artery dissections compared to the Judkins catheter.

The right Amplatz catheter is engaged similarly to the right Judkins catheter by rotating clockwise 45° to 90° and simultaneously withdrawing it 1 to 2 cm (Fig. 15). In order to disengage, it may be pulled, advanced, or rotated.

Fig. 14 Illustration demonstrating the catheter maneuvers necessary to engage the left coronary with a left Amplatz catheter. (From *Grossman's Cardiac Catheterization, Angiography, and Intervention*, 6th ed.; edited by D. S. Baim and W. Grossman; published by Lippincott, Williams, and Wilkins, Baltimore, 2000; p. 219; Fig. 11.5.)

BYPASS GRAFT CATHETERIZATION

During prior coronary artery bypass surgery, reversed saphenous veins and the left and right internal mammary arteries may have been used as bypass conduits in a patient. It is helpful to know their presence and location during subsequent cardiac catheterizations. Vein bypass grafts are anastomosed to the anterior wall of the ascending aorta. The right coronary artery bypass graft is usually slightly anterosuperior to the right coronary artery origin. Left anterior descending artery and diagonal grafts are anastomosed farther to the left and higher, whereas the obtuse marginal grafts

Fig. 15 Graphic demonstrating engagement of the right coronary artery with a right Amplatz catheter. (From "The Guiding Catheter Shape Selector"; A Cordis Corporation (Miami, FL) Educational Resource.)

Fig. 16 Illustration showing the distal shape of the right coronary bypass catheter. (From “The Guiding Catheter Shape Selector”; A Cordis Corporation (Miami, FL) Educational Resource.)

are the highest and farthest left.^[28] Occasionally, an aortic root injection is necessary to locate the origin or to document occlusion of the aortic anastomosis of a vein graft. The left internal mammary artery originates anteriorly from the caudal wall of the subclavian artery distal to the vertebral artery origin. The right internal mammary artery originates from a similar location in the right brachiocephalic trunk.

The right Judkins catheter is versatile and is the catheter of choice for initial attempts at catheterization of the saphenous vein grafts. It can also be used to cannulate internal mammary bypass grafts, but, optimal engagement of the mammary artery is frequently not possible due to the shape of this catheter. For angiography of saphenous vein grafts with the right Judkins catheter, counterclockwise rotation usually works best to initially engage grafts anastomosed to either the right or the left coronary. After initial engagement, further gentle torque in either the clockwise or counterclockwise direction is needed to obtain a fully coaxial position of the catheter with the graft.

For internal mammary artery angiography, the right Judkins catheter must first be manipulated into either the subclavian artery on the left or the innominate artery on the right. Typically, the catheter is initially placed beyond the origin of the mammary artery and then slowly withdrawn. Once the catheter reaches the level of the thyrocervical trunk, slight counterclockwise rotation will often turn the catheter tip inferiorly into the origin of the internal mammary artery.

The Amplatz catheters are also suited for saphenous vein graft angiography due to the rotational maneuverability that allows controlled probing of the ascending aorta as described earlier.

In cases where cannulation of coronary vein bypass grafts is more challenging, the right and left coronary bypass catheters may have to be used. Similarly, use of an internal mammary graft catheter is often necessary in patients with a very vertical origin of the mammary artery.

The right and left bypass catheters are shaped similar to the right Judkins catheter with minor modifications to facilitate engagement of the vein graft ostia. The right coronary bypass catheter has a wider, more open primary curve that points the catheter tip inferiorly and facilitates the cannulation of the vertically oriented coronary artery vein graft (Figs. 16 and 17). As with the right Judkins catheter, counterclockwise rotation of the right coronary bypass catheter is required to engage the graft. Multipurpose catheters can also frequently be used successfully in situations where the right coronary graft is vertically oriented.

The left coronary bypass catheter has a smaller and sharper secondary curve when compared to the right Judkins coronary catheter. This facilitates the cannulation of the left coronary vein grafts that originate with a horizontal and upward takeoff from the aorta (Figs. 18 and 19). When a left coronary bypass catheter must be used to cannulate bypass grafts to the anterior descending or circumflex arteries, clockwise rotation of

Fig. 18 Illustration showing the distal shape of the left coronary bypass catheter. (From “The Guiding Catheter Shape Selector”; A Cordis Corporation (Miami, FL) Educational Resource.)

the catheter is usually required for successful engagement.

The internal mammary artery graft catheters have a hook-shaped tip that makes the engagement of the mammary arteries comparatively easier. This shape allows the catheter to be manipulated into a more vertical position with caudal orientation than a standard right Judkins catheter can be (Fig. 20).

PIGTAIL CATHETERS

For left ventriculography, a specialized pigtail catheter developed by Judkins is used. It has a preshaped tapered tip that makes a circle 1 cm in diameter with five to 12 side holes located on the straight portion of the catheter just proximal to the curve. Side holes in this section of the catheter help to create a cloud of contrast medium and improve stability during injection. Several methods exist to cross the aortic valve and enter the left ventricle. Most frequently, the pigtail catheter is advanced onto the aortic valve forming a gentle loop (Fig. 21). The catheter is then slowly withdrawn and frequently, as the loop uncoils, the catheter will prolapse across the valve and into the ventricle. When the aortic root is dilated, this maneuver is facilitated by using a guidewire to stiffen the pigtail catheter. In cases of aortic valve disease such as aortic stenosis, the pigtail catheter alone will not cross the stenotic valve. In these cases, the valve must be crossed with a guidewire (Fig. 21) and then the pigtail catheter is tracked over the guidewire and into the left ventricle. When using a guidewire to cross the aortic valve, great care must be taken to avoid inadvertent trauma to the left main coronary artery.

Upon entry into the left ventricle, the catheter is usually manipulated to find a position that does not cause frequent premature ventricular contractions. For most patients, a straight pigtail catheter sits most

Fig. 21 Graphic representation of the techniques used to cross the aortic valve with a pigtail catheter. This can be done either with (bottom panel) or without (top panel) a guidewire. See text for details. (From *Grossman's Cardiac Catheterization, Angiography, and Intervention*, 6th ed.; edited by D. S. Baim and W. Grossman; published by Lippincott, Williams, and Wilkins, Baltimore, 2000; p. 86; Fig. 4.11.)

quietly in the left ventricle. However, for horizontally oriented hearts, a 145° angled pigtail catheter may be preferable. The multiple side holes provide simultaneous exit routes for contrast media, thereby reducing the magnitude of catheter recoil and stabilizing the catheter. This design also eliminates endocardial staining that can be seen with side-hole catheters and further reduces the incidence of ectopy.

RIGHT HEART CATHETERIZATION

Right heart catheterization is often performed simultaneously at the time of coronary angiography. Right heart catheterization allows for hemodynamic measurements in the right atrium, right ventricle, and the pulmonary arteries. Blood oxygen saturations from these locations can also be assessed. The pulmonary capillary wedge pressure is an indirect measurement of left ventricular filling pressure. Measurements can also be utilized to obtain cardiac output to calculate valve orifice areas. In addition to the femoral vein approach, the internal jugular and subclavian veins can also be used for right heart catheterization, especially in an intensive care unit setting.

The balloon-tipped flotation catheter, originally designed by Drs. H. J. C. Swan and W. Ganz, is the most commonly used catheter for right heart pressure measurements.^[15] The balloon tip is inflated with room air or with carbon dioxide if entry into the arterial circulation is a possibility or concern. It allows the catheter to float through the right side of the heart with ease and safety in the majority of cases. The proximal end usually has four ports. Two of these open at the

level of the right atrium and pulmonary artery and are used for hemodynamic measurements, instillation of fluids, and aspiration. The third port inflates the balloon at the catheter tip, and the fourth port is used for cardiac output measurements using the thermodilution technique.

CONCLUSIONS

We have attempted to provide the reader with a general overview of techniques and equipment most commonly used during the procedure of cardiac catheterization in adult patients. Our discussion here is not comprehensive, particularly regarding the many other catheters that are available for special situations. The interested reader is referred to one of several excellent textbooks devoted entirely to the field of cardiac catheterization and vascular intervention.^[28-31]

INTRODUCTION

Echocardiography is used routinely for the assessment of regional myocardial function, with stress echocardiography used to identify ischemia in patients with coronary artery disease (CAD). However, clinical diagnosis based on visually assessed wall motion scoring from echocardiography images is semi-quantitative, operator dependent, and heavily weighted by operator experience. Tissue Doppler imaging (TDI), a newer technique used to assess myocardial muscle velocity, provides quantitative evaluation of systolic and diastolic motion velocities and intervals and derived parameters, such as the strain and strain-rate. As these methods rely on narrow-band Doppler phase-shift analysis, they inherit the disadvantages associated with Doppler, such as poor axial resolution, aliasing, and angle dependence of velocity estimates. Estimation of tissue displacements using cross-correlation, as in elastography, has been repeatedly shown to overcome many of the limitations associated with Doppler phase-shift methods.

In this entry we illustrate the production of two-dimensional strain images for evaluating cardiac function. Loops of in-phase/quadrature (IQ) data from a clinical scanner (GE Vingmed Vivid 5) were recorded during echocardiography examinations. Data were transferred to a computer for off-line processing. The IQ data were converted to radiofrequency (RF) echo signals, and elastograms depicting myocardial strain were obtained from successive RF echo signal frames. Full-field and scan-converted cardiac strain images were obtained along all the standard echocardiographic views. Cardiac strain image loops for normal subjects were compared with those obtained from two patients with CAD. Initial observations suggest differences in temporal and

spatial strain distribution between normal and diseased ventricles.

Cardiac elastography may provide quantitative and translation-independent measures of myocardial strain during the cardiac cycle, thereby providing a two-dimensional method for characterizing regional myocardial function.

BACKGROUND

Coronary artery disease is the leading cause of morbidity and mortality in the United States. Despite advances in prevention and treatment of this disorder, there remains a large patient population who are difficult to diagnose noninvasively, yet require percutaneous or surgical revascularization.^[1] Myocardial ischemia is generally associated with impaired regional myocardial function. Current clinical assessment uses analysis of myocardial wall motion abnormalities using echocardiography, nuclear imaging, or magnetic resonance imaging (MRI).^[1–4]

Echocardiography has been routinely used for the assessment of regional myocardial function as it provides real-time information, is portable, and is readily available. During systole short-axis echo, images of the left ventricle (LV) show wall thickening in the radial direction and shortening in the circumferential direction, while in the long-axis view shortening is observed as the base moves toward the apex. Thickening and shortening of the wall muscle are very useful indicators of myocardial performance.^[5] This provides strong evidence that the measurement of the regional strain will provide direct information on the regional myocardial function. In conventional echocardiography, global LV function is estimated by the shortening or ejection fraction, while regional LV

function is evaluated using segmental endocardial excursion or wall thickening. Although endocardial excursion is the most commonly used parameter, it does not reliably differentiate actively contracting from passively drawn segments (scar tissue). Wall thickening also may be difficult to evaluate, as the epicardium is often not clearly seen.^[6]

Use of myocardial strain for cardiac diagnosis was first described by Mirsky and Parmley.^[7] Regional strain has been measured invasively in experimental animal models using optical markers, sonomicrometry, and radio-opaque markers.^[8–10] Invasive measurements have shown that strain is inhomogeneous even in healthy animals, and that experimental ischemia induces increasing regional inhomogeneity.^[8,10,11] Changes in myocardial stiffness with ischemic changes and infarction have also been reported in the literature.^[12]

Noninvasive measurement of myocardial strain in human subjects was initially performed using MRI.^[13] Magnetic resonance tagging and phase-contrast MRI were used to obtain noninvasive and accurate measurements of myocardial motion.^[13,14] Estimation of the strain information required the acquisition of long-axis images during MR tagging, or velocity encoding in the slice direction for phase-contrast MRI.^[3,4] The main limitations of strain measurement using MRI are the low sampling rates and long examination times and fundamental limitations of the tag spacing of around 5–7 mm.

Tissue Doppler imaging, also called tissue velocity imaging, estimates local tissue velocities and tracks heart wall motion using Doppler techniques.^[15,16] One way of displaying TDI information is by color-coding and superimposing TDI estimates on a B-scan image, similar to color-flow imaging. The original method used pulsed Doppler and indeed that is now used on most routine exams at the lateral or septal base. However, the examination time required to survey 16 segments for TDI, one segment at a time, is not practical. Tissue Doppler imaging has been tried and found to be impractical or unworkable for the analysis of wall motion; however, it is used extensively for diastolic and systolic global function assessment. Tissue Doppler imaging also does not differentiate between active contraction and simple rotation or translation of the heart wall, nor does it differentiate passively following tissue from active contraction. Fleming et al. used the spatial gradient of the TDI velocity to measure relative changes in wall thickness, or strain-rate, to overcome this problem.^[17] However, as velocities decrease toward the apex, the signal-to-noise ratio decreases, limiting the usefulness in the apical part of the ventricle. Strain-rate plots using cross-correlation also have been reported, but only on M-mode data.^[18]

Recent studies evaluating myocardial and sub-endocardial function using strain-rate imaging compared to an invasive global evaluation of LV function conclude that despite the angle dependence of strain-rate imaging it is superior to MRI with respect to spatial and temporal resolution.^[19,20] The high spatial resolution with strain-rate imaging enabled the evaluation of segmental myocardial layers, differentiating subendocardium, midmyocardium, and epicardium.^[19] Hashimoto et al. obtained a significant difference in strain-rate values between the three layers identified above in the baseline condition and under hemodynamic alterations.^[19] The authors mention that the results of their study agree with recent tissue tagging studies in normal subjects showing that endocardial deformation is greatest in the longitudinal direction and verifying the endoepicardial gradient in normal LVs.^[21]

Strain-rate imaging enables the clinical evaluation of the LV layers that were previously possible only using invasive techniques, such as sonomicrometry.^[20] Noninvasive discrimination of subendocardium and midwall, however, is highly desirable as this analysis yields clinically significant findings.^[22] However, tethering effects of adjacent myocardium and translational heart motion can cause misinterpretation of regional wall motion with strain-rate imaging.^[20]

We are developing full-field cardiac elastography and evaluating its role in displaying myocardial strain and for detecting ischemia and infarction. In cardiac elastography, strain is imaged during the contraction and relaxation of the heart muscle. This differs from conventional elastography or stiffness-imaging techniques, which measure strain from externally applied compressions.^[23–25] However, virtually all the knowledge derived from the practice of external compression elastography can be applied for cardiac elastography. Recent improvements in the performance of cardiac ultrasound systems provide an opportunity for the application of elastography for estimations of myocardial strain.^[26–28] Fast acquisition of RF data frames is required of the ultrasound system to significantly minimize motion artifacts accompanying cardiac translation.

It has been estimated that 50% or more of all echocardiography studies performed are directed toward assessment of LV function. Our work addresses an important issue related to interpretation of these studies. Although scoring of wall motion is useful, particularly in skilled hands, clinical personnel seek more objective assessments of LV function than those provided in conventional echocardiography studies. The proposed cardiac elastography modality could be a powerful tool to extend the capabilities of echocardiography enabling differentiation between actively and passively moving muscle tissues.

MATERIALS AND METHOD

Method

A GE Vingmed Vivid FiVe ultrasound system (GE-Vingmed, Horten, Norway) was used to obtain two-dimensional gray scale and raw echo data frames for cardiac elastography. Data acquisition was performed in the University of Wisconsin–Madison Hospital echocardiography laboratory. A 2.5 MHz phased array transducer was used to collect images from the standard apical and parasternal long-axis views. Loops of IQ data collected over one heart cycle were transferred via a magneto-optical disk to a personal computer for off-line processing.

The IQ data were first converted back to RF echo signals sampled at 20 MHz using Echomat, a custom software program implemented in Matlab (Mathworks, Inc., Natick, Massachusetts, U.S.A.), and provided by GE-Vingmed. Cardiac elastograms were then generated by comparing corresponding beam-line data from consecutive RF frames using cross-correlation to detect tissue displacements.^[23] The localized myocardial strain was estimated from the axial gradient of the cardiac muscle displacement. A window length of 3 mm with a 75% overlap between data segments was used to generate the cardiac elastograms. The frame rate of 50 frames/sec for the GE-Vingmed system FiVe enabled tracking of small compressions of the heart muscle and limited motion artifacts. Batch programs developed using Matlab software were used to generate both “directional” and “absolute” cardiac elastograms. Directional elastograms are obtained by incorporating both the sign and the magnitude of the estimated strain in the elastogram, while the absolute elastograms depict only the strain magnitude.

Data were acquired on patients and normal healthy male volunteers. The patient results depicted in this paper show results from one patient diagnosed with CAD, and the other with dilated cardiomyopathy. Cardiac elastograms for both patients and normal subjects were evaluated by two clinical observers using qualitative visual analysis (QVA) of the strain images.

RESULTS

Full-field and scan-converted cardiac elastograms obtained in all standard echocardiographic views are presented in this paper. The cardiac elastograms shown present a one-to-one correspondence with the gray-scale images, allowing for easy comparison of structures of interest. Cardiac elastograms in the parasternal long-axis view; short-axis view; and two-, three-, and four-chamber apical views are shown.

Fig. 1 presents a gray-scale image and cardiac elastograms in the parasternal long-axis view at end-systole (ES). The ultrasound gray-scale image is illustrated in Fig. 1(A); a vector or directional strain elastogram, i.e., an elastogram that incorporates both positive (red) and negative (blue) strain information, as shown in Fig. 1(B); and an absolute strain elastogram, as shown in Fig. 1(C). Tissue strains in the anterioseptal (AS) wall, the posterior medial papillary muscle (PM), and the posterior wall (PW) are depicted in Fig. 1. Near ES, the PM is actively contracting, which is clearly observed in Fig. 1(B) as a red region, with muscles surrounding the PM undergoing relaxation (blue regions). The brightest spot is at the PM, which also yields the highest percent strain (see color bar at the right-hand side). Figs. 1(D) and 1(E) present one-dimensional axial strain profiles along the fifth beam line (along the PM) used to form the cardiac elastogram. Note the variation in this axial-strain profile for both absolute strain (D) and positive and negative strains (E). Peak strains are measured at the level of the PM, where the 4 cm depth corresponds to the AS, the 5–8 cm depth the PM, and the 10–12 cm depth the PW.

We use a frame rate of 50 frames/sec and capture strain information over 20 msec snapshots of the cardiac cycle. As we provide a snapshot of the cardiac deformation over 20 msec in each cardiac elastogram, it is extremely unlikely that the images would contain many artifacts. If artifacts were present, we would observe large noise errors (abrupt strain jumps in the elastogram similar to salt-and-pepper type noise artifacts) in the elastograms.^[23,25] Such artifacts clearly are not seen in the images presented, and were not seen during the image sequences processed.

Elastograms for the same patient at ED are illustrated in Fig. 2. From the elastogram in Fig. 2(B) the PM is now undergoing relaxation, as shown by the blue regions at the level of the PM at ED. One can also observe an increase in the volume at ED, along with the relaxation of the AS and PW. The peak strain occurred in both patients at ES at the PM (see Figs. 1 and 2).

Qualitative visual analysis (QVA) by the two clinical observers concluded that peak strain in normals occurred at the PM and the PW in ES and was more evenly distributed in ED. The patients, however, exhibited peak strain at the PM in ES. One of the primary differences observed from ES to ED is that the strains near ED are smaller than at the ES. Typically, peak strains at ED are much lower than at ES. This is consistent with the fact that during systole the heart is actively contracting, while during diastole the heart chamber is in the passive-refilling phase. This pattern is reflected on the values of the color bar that shows the range of strains depicted on the elastogram.

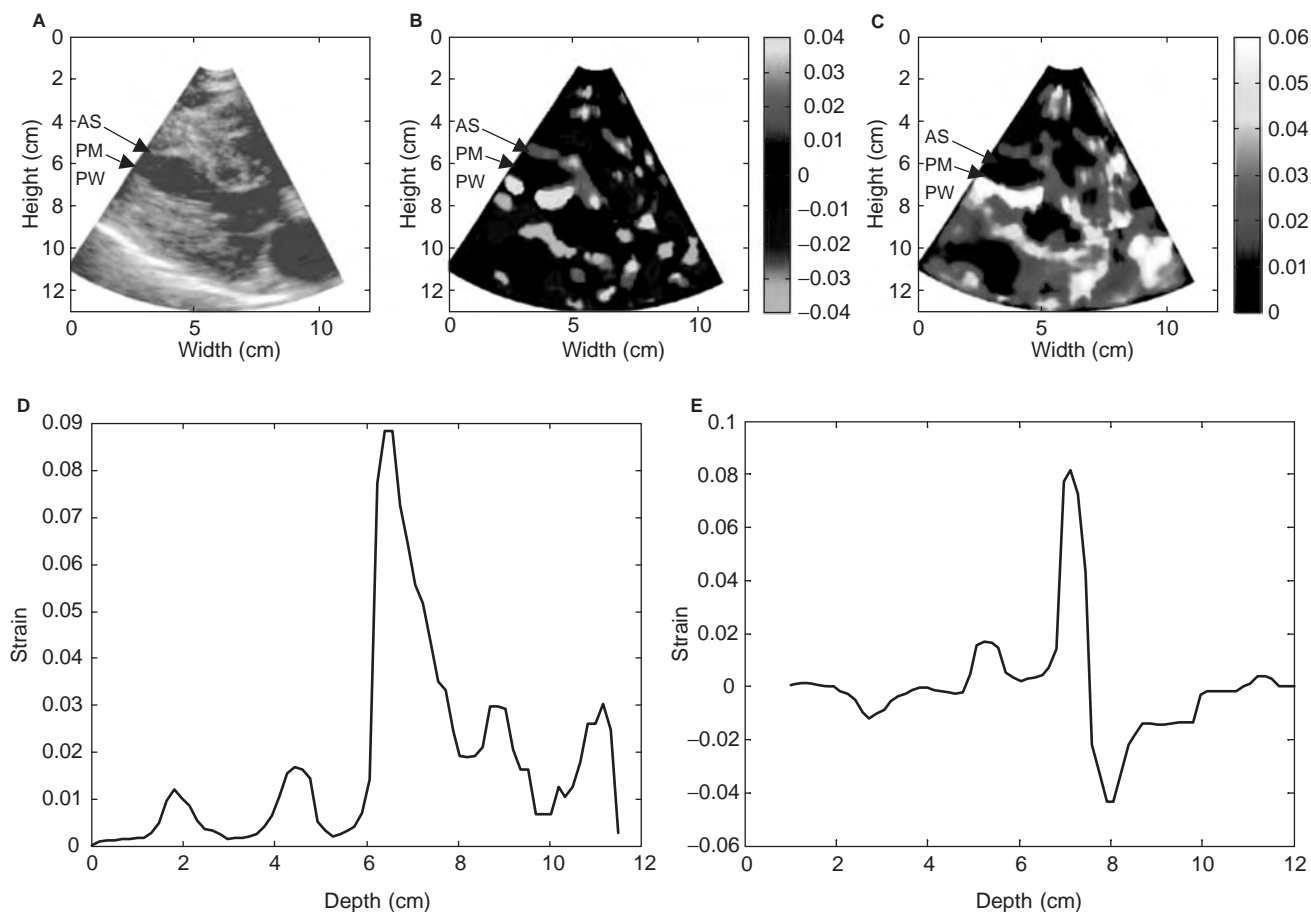

Fig. 1 Parasternal long-axis view, depicting (A) two-dimensional B-mode echocardiogram at end systole along with two-dimensional cardiac (B) vector or directional strain (incorporating both positive and negative strain information) and (C) absolute strain elastograms. The brightest spot is at the papillary muscle (PM), which also yields the highest percent strain (see colorbar at the right hand side). The spatial distribution of the strain is demonstrated by plotting the 5th A-line along the papillary muscle in (D) for absolute strain and (E) for both positive and negative strains. Peak strains measured at the level of the papillary muscle, where the 4 cm depth corresponds to the anterior septum, the 5-8 cm depth the papillary muscle, and the 10-12 cm depth to the posterior wall.

Fig. 2 (A) A two-dimensional gray-scale echocardiogram at ED is shown along with the respective elastograms. (B) Comparison of elastograms obtained from a parasternal long-axis view that show the absolute values of the strain. (C) Both positive and negative strains at ED.

Spatial and temporal interrogation along individual beam acquisition lines allowed quantitative assessment of anatomical and dynamic strain throughout the cardiac cycle. In the parasternal long-axis view of tissue strain in the AS wall, the posterior medial PM and the PW were measured at the ES and the ED. The peak strain occurred in the patients at ES at the PM (see Figs. 1 and 2). QVA by the two clinical observers revealed that peak strain in normals occurred at the PM and PW in ES and was more evenly distributed in ED. The patients, however, exhibited peak strain at the PM in ES, while it was more uniformly distributed in the normal volunteers.

As the heart is actively contracting near ES, and the local strains observed in the myocardium are significantly larger than at other times during the cardiac cycle, we examined the ability of cardiac elastography to depict myocardial strains near ES for all the standard echocardiographic imaging views. Examples are shown in Fig. 3. Short-axis echo images and elastograms of the patient with CAD are shown at ES (Fig. 3i). At ES, the chamber is at its smallest volume, which is clearly seen in the gray-scale echo images and in the cardiac elastograms. Elastograms also exhibit compressive strains in the walls of the ventricle at this time in the cardiac cycle.

Imaging along apical views provides the most challenging test for cardiac elastography, as motion of the heart from apex to base also occurs along with contraction and relaxation of heart muscle. However, this situation did not preclude the production of cardiac elastograms. Evidently, the 50 Hz frame rate resulted in only a small incremental motion between successive frames, while still providing adequate frame-to-frame heart muscle contraction. The motion seen in successive frames is roughly the total movement of the heart from apex to base divided by the number of frames over which this motion occurs. In our studies, this incremental motion was not large enough to decorrelate RF signals between successive frames, which would necessitate more robust and time-consuming algorithms for strain imaging. Fig. 3(ii), presents a two-chamber apical view of the heart in one of the patients with CAD. Maximal strain is seen in the anterior basal and midsegments.

In a similar manner, cardiac elastograms obtained using a three-chamber apical view of a normal subject are illustrated in Fig. 3(iii). Maximal strain is seen in the AS basal and midsegment. Figs. 3(iv) and 3(v) present the four-chamber apical view of the heart for the patient diagnosed with dilated cardiomyopathy and for a normal subject, respectively. Inhomogeneous strain distributions are noted in the cardiomyopathy patient and the patient with CAD, while the strain was more homogeneously distributed in the normal subject.

DISCUSSION

Cardiac elastography may provide improvements over observer-dependent judgments of myocardial contraction and relaxation estimated from conventional echocardiography for assessment of myocardial function. This new modality may also provide quantitative indices of regional myocardial function. We have presented cardiac elastograms obtained in the standard echocardiographic imaging views in this paper. Two-dimensional cardiac elastograms obtained using acquisition frame rates of 50 frames/sec appear to provide qualitative and quantitative strain imaging without translation artifacts.^[26,27] This two-dimensional strain imaging technique could be incorporated into future clinical scanners. However, much work needs to be performed to develop and evaluate this imaging modality.

Using an image acquisition rate of 50 frames/sec, we obtain unsaturated measured strains between frames. In addition to obtaining absolute estimates of strain, cardiac elastography can provide the direction of strain, i.e., contraction (positive values of the strain) and relaxation (negative values of the strain) of the heart muscle. The cardiac elastogram mode that provides the most diagnostic information has yet to be determined. Possible display choices, for example, include absolute strains, directional elastograms that display positive and negative strains, either positive or negative strains, or other modalities. The cardiologist may prefer one of these modes to evaluate diastolic function but may prefer another to evaluate systolic function. Accurate registration between the echocardiograms and the elastograms (similar to the display for color flow or TDI) may also facilitate the interpretation of these results.

Cardiac elastography addresses many of the limitations of tissue Doppler-based strain-rate imaging that have been described above.^[26,27] First, cardiac elastography could be performed to provide a two-dimensional strain information. Strains in the axial and lateral direction, along with Poisson's ratio have been estimated in elastography without using an incompressibility assumption.^[29] Radiofrequency echo signal data acquired along multiple angular insonification directions of the ultrasound beam have also been utilized to obtain axial and lateral strain tensors.^[30] Cardiac elastography provides strain information with excellent spatial resolution, dependent on signal processing parameters, i.e., the window length and overlap, along with the same temporal resolution provided by strain-rate imaging. As the strain information in elastography is obtained from successive frames of RF data, motion artifacts due to the translation and rotation of the heart may be minimized if high frame rates are available.

Fig. 3 (A) Two-dimensional gray-scale echocardiograms, (B) two-dimensional vector cardiac elastograms, and (C) two-dimensional absolute cardiac elastograms obtained near ES. (i) Short-axis view for a patient with CAD, (ii) two-chamber apical view for this patient, (iii) three-chamber apical view for a normal subject, (iv) four-chamber apical view for a patient with cardiomyopathy, and (v) four-chamber apical view for a normal subject.

These are currently implemented on the state-of-the-art scanners.

Cardiac elastography may be able to clearly characterize areas of hypokinesia and akinesia. Likely, it will also be used in infarction diagnosis, for displaying the infarcted areas, in addition to the ability of detecting residual contractility in infarcted areas. New physiologic information on systolic and diastolic events should be accessible. This may lead to the use of cardiac elastography in the assessment of conduction disturbances and regional systolic and diastolic function. In addition, models of stress-strain or force velocity relationships in the heart may be used to estimate regional wall stresses by combining regional strain with pressure values measured in the ventricle.

The raw capabilities to acquire full-field strain images are beginning to emerge on modern ultrasound scanners, such as the Vivid 7, with availability of digital echo data for both real-time and off-line processing. The algorithms and techniques developed in this project still must be assessed for both accuracy and diagnostic capability to determine the capabilities of this new form of echo data processing. Nevertheless, the analysis methods can be made available to other researchers who have access to RF echo data, either from the VingMed systems or from the other echocardiography apparatus supporting RF signals. We anticipate that future work will be directed toward real-time, on-line solutions to successful algorithms developed in this research. Cardiac elastography may provide quantitative information on myocardial strain and may lead to development of operator-independent indices for characterization of cardiac dysfunction and regional myocardial function.

CONCLUSIONS

Full-field cardiac elastograms can be obtained in the standard echocardiographic imaging views. Cardiac elastography may provide quantitative and translation-independent measures of myocardial strain during the cardiac cycle, thereby providing a two-dimensional method for characterizing regional myocardial function. Further work is required to evaluate the role of cardiac elastography in the detection of ischemia and infarction. Cardiac elastography may also provide valuable, noninvasive information of resting global and regional dysfunction and of induced ischemic regional dysfunction. The potential of cardiac elastography to successfully and noninvasively characterize ischemic myocardial tissue is also supported by results reported in the literature that demonstrate changes in myocardial stiffness with ischemia.^[12]

Cardiac Output, Basic Measurement Principles

Leslie A. Geddes

Professor Emeritus, School of Electrical and Computer Engineering, Purdue University, West Lafayette, Indiana, U.S.A.

CARDIAC OUTPUT

Introduction

The heart is a two-sided stroke pump in a double circulatory system. The right heart pumps blood through the lungs; the left heart pumps blood through the rest of the body. The output of the right heart is equal to the output of the left heart. In fact, the output of the right heart, after flowing through the lungs, is the input to the left heart. Similarly, the output of the left heart, after flowing through the arteries to the capillaries and collecting veins, is the input to the right heart. Fig. 1 illustrates these points. Cardiac output is, therefore, the output of either the right or left heart. Cardiac output (CO) is equal to the volume of blood ejected per beat, which is called stroke volume (SV), multiplied by heart rate (HR). Thus,

$$CO = SV \times HR.$$

It is easy to measure heart rate, but there are very few methods for measuring stroke volume. It is for this reason that recourse is taken to methods that measure the average cardiac output, which is usually expressed in liters per minute. To compare cardiac output in large and small subjects and among different species, two methods of normalization are used. One method expresses cardiac output per unit of body weight; the other divides it by the body-surface area.

Thus, the units are mL/min/kg of body weight and L/min/m² of body surface area. The latter unit is more frequently used and is given the special name “cardiac index.” Table 1 presents typical basal values for both quantities for a variety of species. Note the similarity of cardiac index values.

It is of some interest to note that the cardiac output for a typical 70-kg adult male subject at rest is about 5 L/min. If the heart rate is 72 beats/min, the stroke volume is $5000/72 = 69.4$ mL. Such a subject would have a body surface area of about 1.85 m²; therefore, the cardiac index is $5/1.85 = 2.7$ L/min/m². The cardiac output per kilogram of body weight is $5000/70 = 71.4$ mL/min/kg. In such a subject, if cardiac output dropped to 3 L/min, consciousness would be impaired.

Muscular exercise increases cardiac output dramatically. Table 2 presents typical values. Highly

trained long-distance runners, when in condition, can increase their cardiac output from a resting value of 5–25, or 30 L/min with maximal exercise. It is interesting to note that trained athletes have a resting heart rate that is much lower than untrained subjects; the heart rate of a trained athlete is 40–50 beats/min at rest. The resting cardiac output is about the same as in other subjects of similar size; therefore, the stroke volume of an athlete is much larger than that of an untrained subject. In general, there are two major cardiovascular differences in athletes: (1) the resting heart rate is low and (2) following exercise, the heart rate returns to a resting level very rapidly. In fact, the ability of the heart to increase its output and to return quickly to a resting value after exercise are cardiovascular parameters that identify physical fitness.

The cardiac output is shared by the various organs and tissues. A typical resting distribution is shown in Table 3 and Fig. 1B. It is interesting to note that the heart takes about one-twentieth of its output (via the coronary arteries) for its own operation. The brain requires about one-seventh of the cardiac output. These two important areas have a high priority for circulation, and there is little control over their flow rates. However, the amount of blood going to the other vascular beds is under considerable control, depending on the circumstances. Kidney, hepatic portal, muscle, and skin blood flows can and do vary considerably depending on circumstances. Fig. 1B illustrates these controls.

Table 3 shows the extraction of oxygen from the blood for the various circulatory regions. Note that the heart extracts the highest proportion of oxygen in comparison to other organs. It is noteworthy that venous blood contains a wide range of oxygen saturations. It is for this reason that the most representative sample of venous blood is found on the pulmonary artery.

BLOOD VOLUME

Before discussing the methods for measuring cardiac output, it is of value to identify the amount of blood in the body. Table 4 presents typical values for blood volume for different species in mL/kg of body weight. In humans, the blood volume is typically about 7% of

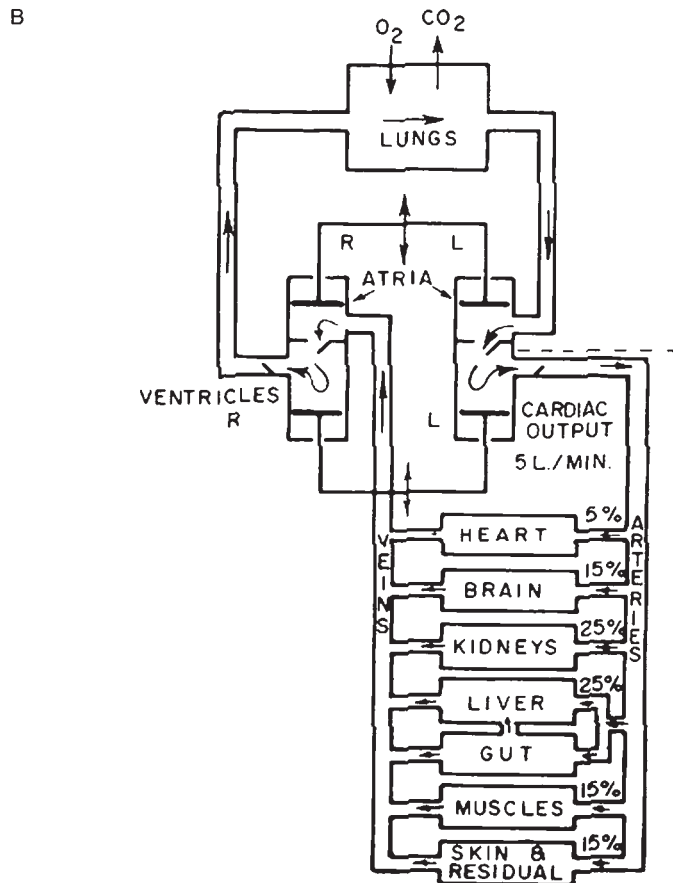

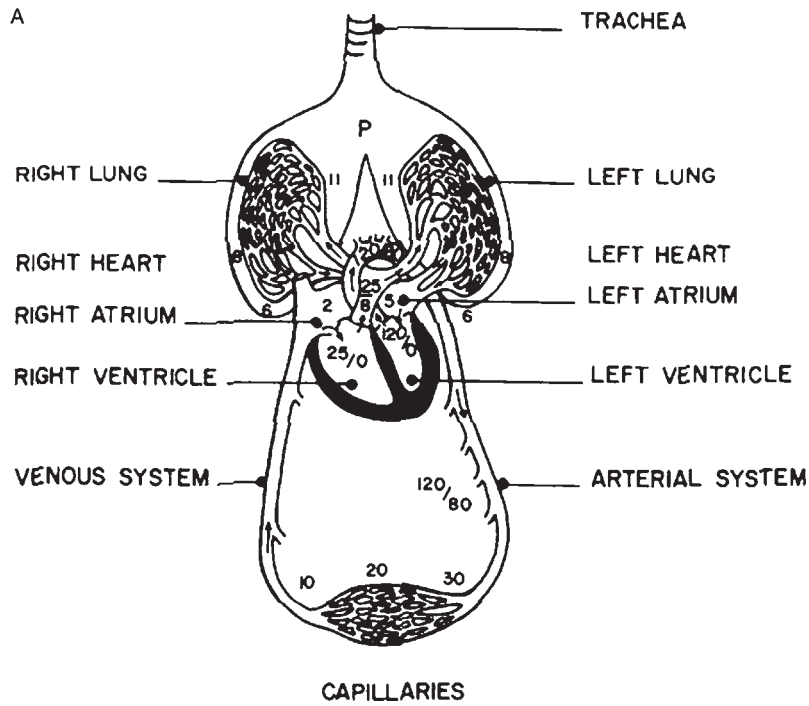

Fig. 1 (A) The circulatory system.
(B) Mechanical analog of the circulatory system.

Table 1 Cardiovascular data

Species	Weight (kg)	Area (m ²)	State	Cardiac output	Cardiac index (L/min/m ²)	CO (mL/min/kg)
Human (5 yr)		0.82	Basal	2.28	2.78	122

the body weight. Often the blood volume is stated as 70 mL/kg of body weight.

The blood volume of a subject is remarkably constant; however, its distribution is of some interest. For example, 60% is found in the veins and 13% is in the arteries. The lungs accommodate 12%, the heart 8%, and, surprisingly enough, only about 7% is in the capillaries, where all of the metabolic exchange takes place. It should be clear that a very small change in the size of the venous reservoir would allow accommodation of a large volume of blood. Venous pooling of blood is a serious problem in cardiovascular shock. The spleen is a reservoir for red cells that can be delivered to the circulation following blood loss. Parenthetically, when blood is donated by human volunteers, about 500 mL are withdrawn. Such a

donation amounts to about 10% of the blood volume and is relatively unnoticed by the average donor. The volume of blood in a subject is measured with the dilution technique, which is used to measure the volume of any irregularly shaped or inaccessible container. A measured amount (m) of detectable substance (indicator) is introduced to the fluid-filled container and, after complete mixing, a sample is withdrawn. The concentration (c) of the indicator in the sample is then measured; therefore, the volume of the container $V = m/c$.

In applying the dilution principle to measure blood volume, the indicator must have special properties. For example, there must be a minimum loss of indicator through the kidneys or by trapping in an organ. For this reason, two types of indicator are used: one combines with the plasma proteins and the other becomes incorporated in the red cells. Thus what is measured is either plasma volume or red-cell volume. Blood volume is calculated by measuring the fraction of cells (by centrifugation) and scaling the result. The fraction of cells is called the packed-cell volume (PCV) and is often expressed as a percentage. Because there are so many more red cells, than platelets or leukocytes, the percent red-cell volume (or hematocrit) is often used as a descriptor of the cell fraction in blood.

Evan's blue, a dye that attaches to plasma albumin, and radioiodine labeled albumin are the most frequently used indicators. The concentration of Evan's blue is measured with a spectrophotometer (at 640 nm) and the concentration of radioiodine-labeled albumin is measured with a radioactivity detector. The technique employed consists of drawing a blood sample and centrifuging it to separate the plasma from the cells. This procedure produces a plasma sample (blank) without the indicator and allows calculation of the packed-cell volume (cell fraction).

The indicator is injected intravenously and time is allowed for mixing of the indicator. At 10, 20, and

30 min, venous blood samples are withdrawn, centrifuged, and the concentration of indicator is measured in the plasma sample. With Evan's blue, the concentration is proportional to the optical density [log e (1/transmission)]. Similarly, the count-per minute rate is proportional to the concentration of the radioiodine albumin. These concentrations are plotted on a graph, which shows the slight loss of indicator. Fig. 2 illustrates a typical concentration-time curve which is extrapolated to zero time to identify the concentration of the indicator corresponding to zero loss.

This zero-time concentration is divided into the amount of indicator injected to obtain plasma volume. As a practical matter, it is more convenient to plot the optical density or counts/minute versus time and extrapolate to obtain the zero-time value. This Fig. 2 can then be converted to concentration by adding a known amount of indicator to the plasma bank and measuring it. The blood volume is the plasma volume divided by (1-PCV), where PCV is the packed-cell fraction.

DILUTION METHODS FOR CARDIAC OUTPUT

Although there are numerous methods of measuring cardiac output, the two that are frequently used are the Fick and the indicator-dilution methods. Both employ the dilution principle and will now be described. An indirect method which employs recording of the electrical impedance changes that appear between thoracic electrodes is also used in some clinics; this method will also be described.

Fick Method

Venous blood flowing through the lungs from the right heart to the left heart picks up oxygen and releases carbon dioxide (Fig. 3A). In 1870 Fick^[3] stated that if the amount of oxygen taken up (or the amount of carbon dioxide liberated) per minute is known and the oxygen (or carbon dioxide) concentration in the blood entering and leaving the lungs is known, it is possible to calculate blood flow through the lungs (cardiac output). A convenient way of understanding Fick's proposal is shown in Fig. 3B.

Fig. 2 Calculation of blood volume by determination of the zero-time concentration of an injected indicator.

Fig. 3 (A) The pulmonary circuit. (B) Principle employed in the Fick method using the conveyor-belt analog.

Consider delivery of oxygen to the blood to be equivalent to a conveyor belt in which venous blood from the right heart comes along in 100 mL beakers, which pass a dispensing reservoir that delivers oxygen. Thus the (arterial) beakers that have passed the oxygen dispenser contain more oxygen. Assume that the concentration of oxygen in the venous blood is 15 mL/100 mL blood (i.e., 15 %) and that the concentration of oxygen in the arterial beakers is 20 mL/100 mL blood. In this steady-state-conveyor-belt system it was found that 250 mL of oxygen disappeared from the dispensing reservoir each minute. Each 100 mL beaker of blood took up $20 - 15 = 5$ mL of oxygen; therefore, $250/5 = 50$ beakers must have passed each minute. Cardiac output must therefore be $50 \text{ beakers} \times 100 \text{ mL/beaker} = 5000 \text{ mL/min}$. These facts are usually expressed by the following familiar expression:

Cardiac Output

$$= \frac{\text{oxygen uptake/min}}{\text{arterial} - \text{venous oxygen concentration}}$$

Using the numbers given in the conveyor-belt analog:

$$\begin{aligned} \text{CO} &= \frac{250 \text{ (mL/min)}}{(20/100) - (15/100)} = \frac{250 \times 100}{5} \\ &= 5000 \text{ mL/min} \end{aligned}$$

The oxygen uptake is measured using a spirometer equipped with a carbon dioxide absorber. A typical record of oxygen uptake is shown in Fig. 4. Note that the oxygen uptake, which is the slope of the recording, must be corrected to body temperature and saturated

with water vapor by using the correction factor shown in Table 5.

$V_s = FV_c$ where V_s is the standardized condition and V_c is the collected condition.

$$V_s = \frac{(1 + (37/273)) (P_B - P_{H_2O})}{(1 + (t^\circ C/273)) (P_B - 47)} V_c = FV_c$$

The concentration of oxygen in the arterial and venous blood is less easily measured. Two instruments, the Van Slyke manometric apparatus or the LexO₂con analyzer, are used. The former is a gasometric instrument in which the oxygen content is measured by removal of the oxygen from the blood sample. The LexO₂con is an electrochemical instrument that counts the oxygen molecules and indicates the O₂ content in the sample of blood introduced. The indication represents volume percent at 0°C and 760 mm Hg dry air. Therefore, this Fig. 4 must be corrected to body temperature and ambient pressure, saturated.

The Fick method is reliable but requires steady-state conditions. It can be applied using carbon dioxide and, with slightly more difficulty, foreign gases. The highest accuracy is obtained when the mixed venous sample is obtained from the pulmonary artery; right ventricular blood is next best. The arterial sample can be obtained from any convenient artery.

Indicator-Dilution Method

Stewart^[5] showed that if a known concentration of indicator is introduced into a flowing stream and the temporal concentration of the indicator is measured at

$$CI = \frac{8.552}{1.98} = 4.32 \text{ L/min/m}^2$$

Fig. 4 Measurement of oxygen uptake with a spirogram, and sample calculation of cardiac output using the Fick method.

a downstream point, it is possible to calculate the volume flow. To illustrate the salient points of the indicator-dilution method, consider a fluid flowing at a constant rate in a tube of cross-sectional area a , as shown in Fig. 5. Assume that m grams of a soluble and detectable indicator are rapidly introduced to form a uniform cylinder of indicator in the fluid. If a concentration detector is placed slightly downstream and its output is recorded, an idealized rectangular concentration-time curve of amplitude C will be recorded as the cylinder passes. The practical use of this idealized concentration-time curve will now be illustrated.

In a tube containing a flowing fluid, flow is equal to the velocity of flow (v) multiplied by the cross-sectional area (a); flow $\phi = va$. Velocity is distance divided by time, and in the model the cylinder of indicator moves L units of distance in t s, the value for t being identified on the concentration-time curve; therefore, $v = L/t$. Substituting L/t for velocity, $\phi = La/t$. However, La is the volume of the cylinder (V) and, therefore, $\phi = Vt$. It is not possible to measure the volume of the cylinder, but it is possible to measure concentration (C), which is equal to m/V . Substituting this quantity gives:

$$\phi = \frac{m}{Ct} = \frac{\text{mass of indicator injected}}{\text{concentration} \times \text{time}}$$

The expression just derived illustrates that in the idealized case, if m grams of indicator are injected and

the calibrated downstream concentration-time curve is recorded, it is possible to calculate flow. In a practical situation, the cylinder of indicator would be spread out into a teardrop shape owing to the velocity profile in the tube. Therefore, the concentration-time curve will rise rapidly and fall slowly as shown in Fig. 5B. However, a rectangular concentration-time curve can be obtained from this typical dilution curve by measuring the area under it and dividing by the base. Performing this operation provides a mean concentration C for the time t . Thus,

$$\phi = \frac{m}{Ct}$$

There is an extremely important subtlety about this flow expression. Note that it is only necessary to know the amount (m) of indicator injected and the downstream concentration-time curve. The concentration-time curve can be recorded from any downstream branch. The important requirement is that the indicator is injected so that it mixes with all of the flow.

In the measurement of cardiac output the indicator is injected into the right atrium, right ventricle, or pulmonary artery and the dilution curve is obtained by withdrawing arterial blood (from any large artery) into the detector at a constant rate. With the thermal-dilution method, injection is into the right atrium and detection is in the pulmonary artery.

Fig. 5 Genesis of the dilution curve.

Before describing practical application of the indicator-dilution method, several important facts should be recognized, the most important of which is that cardiac output must remain constant for the duration of measurement. The characteristics of the indicator are also very important. Obviously, it must be detectable and not be a stimulant or depressant to the circulatory system. It must be retained for a period long

enough to permit inscription of a dilution curve. Indicators that are lost from the circulation between the injection and measuring sites provide a falsely high value for cardiac output because C is too small and is in the denominator of the flow expression. Indicators that are rapidly cleared from the circulation allow repeated determinations without indicator buildup. Indicators that are retained in the circulation can build up to excessively high concentrations if repeated determinations are made. If the indicators are colored dyes, there is the possibility of altering skin color until the indicator is cleared.

A wide variety of indicators are used to measure cardiac output; Table 6 presents a typical list, along with the type of detector employed for each. However, in clinical medicine, the dye and thermal-dilution methods are perhaps the most popular.

The method of obtaining a dilution curve from which cardiac output can be calculated is shown in Fig. 6. The site of injection for the indicator is the right atrium, ventricle, or pulmonary artery.

In the illustration, a catheter connected to the indicator-filled syringe has been advanced down the right jugular vein. In the human the basilic vein in the arm is used as the entry point.

To inscribe the dilution curve, an arterial catheter is connected to the detector for the indicator, which is in turn connected to a motor-driven withdrawal syringe as shown in Fig. 6. The catheter is introduced into a major artery, such as the femoral, and advanced into the aorta. The indicator is then injected rapidly and blood is drawn through the detector, the output of which is recorded to obtain the dilution curve as shown. Note that the dilution curve does not return to zero indicator concentration because of recirculation of the indicator. To process the dilution curve, this recirculation must be removed and the dilution curve for a single pass must be synthesized. The method of performing this correction will now be described.

Table 6 Indicators

Material	Detector	Retention data
Evans blue (T1824)	Photoelectric, 640 μ m	50% loss in 5 days ^a
Cardiogreen	Photoelectric, 800 μ m	50% loss in 10 min ^b

^cTaylor^[9]

^dIt is estimated that there is less than 15% loss of diffusible indicators during the first pass.

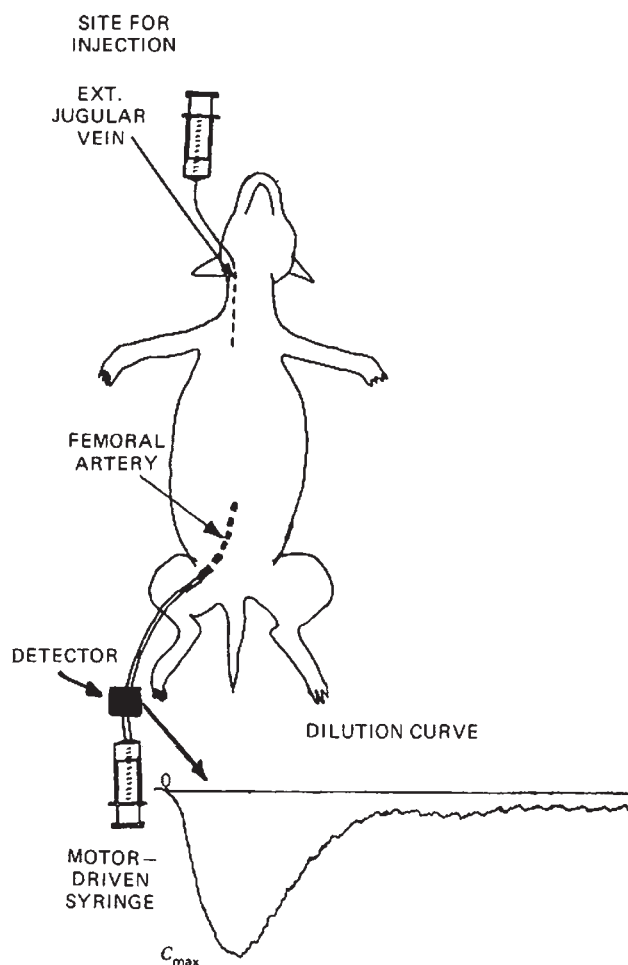

Fig. 6 The indicator-dilution technique.

Because the descending limb of the dilution curve is exponential, semilogarithmic plotting of this part of the curve provides a means of identifying the end of the first pass, which, for practical purposes, is taken as the time for the dilution curve to fall to 1% of its maximum concentration. Semilogarithmic plotting is usually performed first on the uncalibrated dilution curve so that a true single-pass curve can be synthesized and measured for area to determine the mean height for the time of one pass. Fig. 7A illustrates a typical dilution curve showing: recirculation on the downslope; Fig. 7B presents a plot of the downslope of this curve. Note that the part of the curve reflecting recirculation departs from the linear portion of the downslope. Extrapolation of the linear portion allows identification of the time for the practical end of the dilution curve, which is taken as 1% of the maximum height (C_{\max}) of the dilution curve, that is, the time corresponding to $C_{\max}/100$. The dilution curve can be completed by plotting the heights for times earlier than the extrapolated end time as shown by the dashed line in Fig. 7A. Then the area under the corrected dilution curve is measured and divided by its length; this gives a

mean height which is converted to a mean concentration (C) after calibration of the detector in terms of amplitude on the record.

Calibration of the detector is accomplished easily by obtaining a blood sample and adding a known amount of indicator to it. Then this mixed sample is drawn through the detector and the deflection is recorded. In this example, the indicator calibration amplitude corresponds to 0.43 g/L of indicator in blood. The mean concentration (area of the dilution curve divided by its base) corresponds to a mean concentration of 0.173 g/L of indicator in blood. Since the corrected dilution curve is 18.5 s in duration, the cardiac output per minute is as follows:

$$CO = \frac{60 \times 0.15}{0.173 \times 18.5} = 2.81 \text{ L/min}$$

As stated previously, this value for cardiac output would be expressed as cardiac index, that is, cardiac output per square meter of body surface area. In this case the body weight of the dog was 12 kg. The body surface area was 0.59 m² (area = 11.2 $W^{0.667}$, where W is body weight in grams and the area is in square centimeters). Therefore, the cardiac index is 4.76 L/min/m²; obviously, the animal was not in a basal state.

Thermal-Dilution Method

The thermal-dilution method in which the indicator is a cold liquid is a variant of the indicator-dilution method. A thermal detector is used to record the downstream decrease in temperature which, when recorded, constitutes the thermal-dilution curve. The usual site for injection is the right atrium, and the detecting site is the pulmonary artery. A special balloon-tipped catheter,^[10] with a thermistor at the tip, is used to detect the temperature change. The same catheter has a side port which permits injection of the cold solution into the right atrium. Another lumen is used for pressure monitoring. Fig. 8 illustrates the principle, and a typical thermal-dilution curve is shown in Fig. 9.

The advantages of the thermal-dilution method are many and, in part, relate to the way it is used. Any suitable cold biocompatible solution can be used as the indicator; isotonic dextrose (5%) at 0°C is the most popular. Because the detecting site is in the pulmonary artery and the indicator is injected into the right atrium, recirculation minimally obscures the downslope of the dilution curve. Therefore, a simple integrator can be used to determine the area under the dilution curve. Since the dilution curve is inscribed with a detector calibrated in degrees centigrade, it is not necessary to prepare calibrating solutions. Moreover, there is no indicator buildup, and dilution curves can be

Fig. 7 (A) Calculation of cardiac output from the corrected dilution curve. (B) Semilog plot of the downslope of the dilution curve shown in Fig. 7A. Note that the portion of the downslope of the dilution curve that is exponential is linear on the semilog plot. Extrapolation of the line joining the points forming the straight line allows the acquisition of values for the dilution curve during recirculation. In practice, extrapolation is carried out to find a time corresponding to 1% of the maximum height of the dilution curve. In this example the end of the dilution curve was found to occur at 18.5 s and the amplitudes between 12 s (where recirculation became apparent) and 18.5 s (the end of the curve) were used to complete the dilution curve shown in Fig. 7A.)

obtained as often as every few minutes. Diminishing these considerable advantages only slightly is the need to apply a correction factor to account for the heat transfer through the catheter and loss to the vessel walls during injection of the indicator. There is also the need to obtain the temperature of the pulmonary artery blood prior to injection of the thermoinicator. Fig. 9 illustrates small variations in temperature prior to appearance of the dilution curve; averaging takes care of this.

The fact that a cold solution can be used as an indicator was reported by Fegler^[11] who validated the method in a model and then in dogs in which thermocouples were placed in the right ventricle and aorta. The indicator was 3–5 mL of Ringer's solution at 18°C, which was injected into the inferior vena cava.

The model and the dog studies provided conclusive evidence for the accuracy of the method and the expression he developed for cardiac output. Additional corroborative data in dogs were provided by Goodyer et al.^[12] who used the dye and Fick methods as references. Two important improvements were reported in this study: (1) a thermistor was employed as the detector and (2) a correction factor was applied to correct for heat transfer through the catheter. The method was then used in man by Ganz et al.^[13] with 5% dextrose in water at 0°C as the indicator. To reduce the need for correcting for heat loss in the catheter, a thermistor at the injection site was used to measure the temperature of the indicator as it entered the right atrium. The cardiac output values were compared with those obtained using cardiogreen dye; excellent agreement was

Fig. 8 Method of injecting the thermal indicator into the heart.

obtained. Finally, the technique was made practical enough for bedside use by Forrester et al.^[14] who developed a balloon-tipped catheter that incorporated a thermistor at the tip. A second lumen in the catheter allowed recording pressure from the catheter tip. A third lumen communicated with an injection port 30 cm proximal from the tip of the catheter in the pulmonary artery. The catheter was introduced into an arm vein, advanced into the right atrium, where the balloon was inflated. The blood flow guided the tip into the right ventricle, and its presence there was confirmed by recording the pressure. Then the catheter

was advanced into the pulmonary artery, its presence there being confirmed by the pressure recording. At this time the balloon was deflated and thermodilution curves were obtained by injection of the cold dextrose solution into the atrium via the third lumen which was in communication with the side port.

Verification Studies. After applying the correction factor for heat transfer through the #7F multilumen catheter, Forrester et al. obtained cardiac outputs on 40 critically ill patients. They validated the method with in vitro pump studies, and the average difference in flow amounted to about 3%. A later evaluation of the

Fig. 9 The thermal indicator-dilution curve.

Fig. 10 Eighty-three simultaneous measurements of cardiac output using thermodilution (CO_{TD}) and indocyanine green (CO_{IG}) showing close agreement [$r = 0.994 \pm 2.79$ (SEM)]. Source: With permission from Elsevier (see Ref. [15]).

thermodilution method in man was presented by Weissel et al.^[15] who reported excellent agreement with values obtained with cardiogreen when a thermal correction factor was applied; Fig. 10 presents the data.

Calculation of Cardiac Output. The expression for calculating cardiac output with the thermal-dilution method contains several terms not found in other indicator-dilution formulas because of the physical properties of the indicator and blood. The indicator is a cold solution, which subtracts calories from the blood that it contacts; thus, the indicator is negative calories. Heat-exchange calculations depend on the mass of material, its specific heat, and the temperature difference through which the material is raised or lowered. In fact, the product of these three quantities is the number of calories exchanged. For this reason the thermodilution equation must include specific heat terms. In addition, with the thermal-dilution method, a known volume (not mass) of cold liquid is injected. Volume can be converted to mass by multiplying by specific gravity. Therefore, since the thermodilution method is based on heat exchange measured in calories, the flow equation must contain terms for the specific heat and the specific gravity of the indicator and blood.

The expression usually employed when a #7F thermistor-tipped catheter is employed and 5% dextrose is injected into the right atrium is as follows:

$$CO = \left(\frac{V(T_B - T_i)60}{A} \right) \left(\frac{S_i C_i}{S_b C_b} \right) F$$

where V = Volume of indicator injected in mL, T_B = Temperature (average) of pulmonary artery blood in degrees centigrade before injection of the indicator, T_i = Temperature of the indicator ($^{\circ}C$), 60 = Multiplier required to convert mL/s into mL/min, A = Area under the dilution curve in (s) ($^{\circ}C$), S = Specific gravity of indicator (i) and blood (b), C = Specific heat of indicator (i) and blood (b). The ratio $S_i C_i / S_b C_b = 1.08$ for 5% dextrose and blood of 40% packed-cell volume, F = Empiric factor employed to correct for heat transfer through the injection catheter wall. For a #7F catheter, $F = 0.825$ (Weissel et al.^[15]).

Entering these factors into the expression gives:

$$CO = \frac{V(T_B - T_i)53.46}{A}$$

where CO = cardiac output in mL/min, $53.46 = 60 \times 1.08 \times 0.825$.

To illustrate how a thermodilution curve is processed, cardiac output will be calculated using the dilution curve shown in Fig. 9:

$V = 5$ mL of 5% dextrose in water $T_B = 37^{\circ}C$ $T_i = 0^{\circ}C$
 $A = 1.59^{\circ}C$ s

$$CO = \frac{5(37 - 0)53.46}{1.59} = 6220 \text{ mL/min}$$

Despite the potential source of error due to heat loss through the injection catheter from which the empiric

factor F is derived, the thermal dilution method is remarkably reliable. Correlation values for cardiac output with cardiogreen dye in patients were reported by Weissel et al.^[15]; these data are shown in Fig. 10. The high degree of agreement using the empiric factor ($F=0.825$) is impressive. Perhaps the most attractive feature of the thermal-dilution method is the minimal recirculation, which makes it easy to process the dilution curve by hand or a simple computer. In low-output situations, conventional dilution curves are obscured by recirculation and the endpoint is not easily determined. The lack of recirculation artifact with the thermal-dilution method makes it attractive in low-output situations. However, in very-low-output situations, there may be significant indicator heat loss to vessel walls, which will result in an overestimate of cardiac output.

Diffusible Indicators. In many instances, diffusible indicators, which leave the vascular bed via the capillaries, are used to measure cardiac output. Saline and dextrose 5% in water (D5W) are examples, and whether cardiac output is overestimated depends on the way the indicator is used. The determining factor is the presence or absence of a capillary bed between the point of indicator injection and measurement. If there is an intervening capillary bed, the indicator loss therein will result in an overestimate of cardiac output. However, if there is none, and good mixing is achieved, cardiac output will not be overestimated.

The foregoing explains why D5W, a diffusible indicator, can be used without error because injection is in the right atrium and measurement occurs in the pulmonary artery. Grubbs et al.^[16] has used saline, another diffusible indicator, to measure cardiac output without error by injecting it into the right atrium and detecting it in the pulmonary artery. Likewise, we (Geddes et al.^[17]) measured left-sided output without error by injecting the saline in the left ventricle and measuring the dilution curve in the descending aorta.

If a diffusible indicator is injected into the venous system and the dilution curve recorded on the arterial side, an overestimate of 15% is typical. Chinard et al.^[18] predicted this situation, which was quantified by Grubbs et al.^[16] using saline.

IMPEDANCE CARDIOGRAPHY

The impedance cardiograph is an instrument that employs four circumferential thoracic electrodes to measure the pulsatile changes in resistance (impedance) offered to the flow of high-frequency alternating current to obtain a signal related to stroke volume. The pulsatile change in impedance is usually displayed on a graphic record, which can be processed to provide a value for stroke volume. At present, impedance

cardiography is one of the very few noninvasive methods that provides a measure of stroke volume, which when multiplied by heart rate is cardiac output.

Principle

Fig. 11 illustrates the principle employed in impedance cardiography. Low-intensity (e.g., a few milliamperes), high-frequency (e.g., 100 kHz) sinusoidal alternating current from a constant-current generator (I_k) is applied to metal-ribbon electrodes placed around the neck and abdomen (1,4). With this arrangement, the same current flows through the subject irrespective of the subject size and electrode impedance.

The flow of current through the thoracic tissues produces a potential difference detected by the two inner electrodes (2, 3), which are also metal ribbons placed around the thorax so that the heart is between them. Any variation in conducting properties of the thoracic contents will alter the potential difference between electrodes 2 and 3. Inspiration increases, and ejection of the stroke volume from the right and left ventricles decreases, the impedance between the potential-measuring electrodes. The respiratory induced change is much larger than the cardiac-induced change. Therefore, to obtain a clear cardiac signal from electrodes 2 and 3, the subject must be breathing slowly or hold his breath for a few heart beats.

Although band electrodes were used in early experimental studies, present systems for clinical measurements use standard ECG spot electrodes.

Fig. 12 illustrates the relative magnitude of the respiratory and cardiac impedance changes and illustrates typical cardiac impedance signals obtained during breath-holding.

High-frequency alternating current is used for impedance cardiography for reasons of safety. The

Fig. 11 The tetrapolar method of recording the thoracic impedance cardiogram (Z_0 and ΔZ).

Fig. 12 Respiratory and cardiac impedance changes.

change in thoracic impedance provides a high-frequency signal of varying amplitude appearing between electrodes 2 and 3. The varying alternating voltage is amplified and demodulated to provide an analog signal that can be recorded graphically; Fig. 13 is an example.

Calculation of Stroke Volume

Various methods have been used to process the impedance cardiogram to obtain a value for stroke volume. The two that are presently used will be described. It is important to recognize that the peak-to-peak value for ΔZ illustrated in Fig. 13 is not the quantity used to calculate stroke volume, although it is related. The cardiac-induced impedance change reflects a change in impedance that is the difference between the inflow of blood to the thoracic vessels (from the heart) and the outflow of blood from the thoracic vessels to all other regions of the body. Therefore, to estimate the true volume change that would occur in the absence of thoracic outflow, the maximum rate of impedance

Fig. 13 The impedance cardiogram pulse and its relation to the R and T waves of the ECG, along with a sample calculation of stroke volume.

change during the early ejection period is determined and used to obtain the impedance change that would have occurred with no outflow from the thoracic vessels. The rationale underlying this technique is that outflow from the thoracic vessels is minimum at the beginning of cardiac ejection. Fig. 13 illustrates the cardiac impedance pulse and the graphical extrapolation technique used to obtain the corrected value ($\Delta Z'$) for entry in the equation developed by Kubicek et al.^[19]:

$$SV = \rho \left(\frac{PL^2}{Z_0^2} \right) (\Delta Z')$$

In this expression ρ is the resistivity of blood in ohm-cm at body temperature, L is the distance between the voltage-measuring electrodes (2, 3) in cm, and Z_0 is the basal impedance of the thorax in ohms, which is the baseline on which the pulsatile impedance rides, and $\Delta Z'$ is the extrapolated impedance change in ohms, as shown in Fig. 13.

Because extrapolation of the rising phase of the cardiac-induced impedance change is open to subjective error, it is often more convenient to include an electrical differentiation circuit in the impedance cardiograph. Thus, two output signals are provided: one is the cardiac-induced impedance change (ΔZ) and the other is the time derivative or differential (dZ/dt) as shown in Fig. 14. By knowing the maximum rate of change of impedance ($(dZ/dt)_{\max}$) and the period over which it occurs, namely, the ejection period (T), the following expression can be used to calculate

Fig. 14 The impedance cardiogram and its time derivative (dZ/dt), along with a sample calculation of stroke volume.

Table 7 Resistivity (ρ) of blood at 37°C

Species	Resistivity (ohm-cm)	Correlation coefficient
Dog	$55.5e^{0.024H}$	0.98
Human	$51.6e^{0.024H}$	0.97
Baboon	$57.5e^{0.019H}$	0.99
Cow	$59.9e^{0.016H}$	0.97
Goat	$58.3e^{0.015H}$	0.99
Cat	$53.9e^{0.023H}$	0.99
Monkey	$53.7e^{0.019H}$	0.99
Sheep	$56.9e^{0.019H}$	0.97
Camel	$56.4e^{0.016H}$	0.98
Average for nine species	$55.2e^{0.02H}$	0.96

Data obtained for packed-cell volumes (H) ranging from 0 to 50%.

stroke volume:

$$SV = \rho \left(\frac{L^2}{Z_0^2} \right) (T) \left(\frac{dZ}{dt} \right)_{\max}$$

Calibration signals in the impedance cardiograph allow quantification of the record to obtain Z_0 and $(dZ/dt)_{\max}$. Fig. 14 illustrates a typical record. The value for the resistivity (ρ) of blood depends on the percent packed-cell volume (H). For humans, the resistivity in ohm-cm was given by Geddes and Baker (20) as:

$$P = 51.6 e^{0.024H}$$

Often it is undesirable to draw a blood sample to measure the packed-cell volume (H) or resistivity (ρ). In such a case it is often assumed that a normal packed-cell volume of 40% exists. Therefore, the resistivity at 37°C is 130 ohm-cm. Table 7 presents values for a variety of species.

Verification Studies

Of particular importance is the relationship between cardiac output measured by impedance cardiography and by conventional techniques such as the indicator-dilution and Fick methods. Table 8 presents a summary of the validation studies to 1974. In some of these studies, the correct value for blood resistivity was used; in others an assumed value or a room-temperature value was entered into the equation. Nonetheless, it would appear that, in general, impedance cardiography provides a value for cardiac output that agrees with the true value (as obtained by an accepted method) or overestimates cardiac output by as much as

about 25%. A comparative study by Denniston et al.^[21] is shown in Fig. 15.

A large number of studies have shown that impedance cardiography tracks changes in cardiac output with good accuracy; this point was made by Denniston et al.^[21] in a study of normal subjects exercising on a bicycle ergometer. Fig. 16 illustrates the ability of the impedance cardiogram to track cardiac output as determined by the indicator-dilution method using indocyanine-green dye.

Mohapatra et al.^[22] pointed out the important fact that the degree of overestimation of cardiac output by the impedance method is dependent on the packed-cell volume. From a study on infants and adults they developed a correction factor (F), which when multiplied by the impedance cardiac output gives true cardiac output. Thus the Kubicek stroke volume expression becomes

$$SV = \frac{\rho L^2 T F}{Z_0^2} \left(\frac{dZ}{dt} \right)_{\max}$$

The value for F is shown in Fig. 17 and the mathematical expression for it is

$$F = 2.524 - 1.121 \log_{10} H$$

in which H is the packed-cell volume in percent. Note that for a packed-cell volume of 40%, the value for F is 0.83.

A practical consideration worthy of note is the value of L , the separation between the two (inner) potential-measuring electrodes (2, 3). Usually this dimension measured along the sternum is different than the magnitude when measured along midaxillary lines and on the back. In this situation it is of value to determine the mean value for L by making multiple measurements (chest, back, and along midaxillary lines). This technique was advocated by Denniston et al.^[20] Because stroke volume is usually overestimated, some advocate using the minimum value for L .

In conclusion, although cardiac-output values obtained by impedance cardiography usually overestimate true cardiac output, the technique is of considerable value in a variety of situations when invasive measurements cannot be made. It must be emphasized that the comparison studies made in humans were based on techniques (e.g., Fick and indicator-dilution) that averaged cardiac output over a minute or more, whereas the impedance method provided a value for stroke volume that was multiplied by average heart rate to obtain cardiac output. The fact that it is sometimes necessary for the subject to stop breathing for a few heart beats irritates some investigators. However, its ability to provide a value for stroke volume on a beat-by-beat basis is a highly attractive feature. Many newer instruments incorporate processing circuitry so that graphic recording is not needed and cardiac output is indicated on a digital display.

Contraindication

Impedance cardiography should not be applied to patients with implanted pacemakers. Using impedance cardiography to monitor a patient with an implanted pacemaker during surgery, Aldrete et al.^[23] reported that the patient's heart rate increased to 120/min. Drug therapy failed to reduce it and the ECG showed

Fig. 16 The relationship between dye-cardiac output and impedance cardiac output (corrected) in subjects exercising on a bicycle ergometer. Source: Redrawn by permission from American Physiological Society (see Ref. [21]).

Fig. 17 The correction factor (F) reported by Mohapatra et al.^[22] for correcting impedance cardiac output values.

pacemaker spikes at 120/min. When the impedance cardiograph was disconnected, the heart rate returned to 72/min. The event occurred a second time.

Worthy of note is the fact that the 2.5 mA, 70-kHz current applied for impedance cardiography gained access to the pacemaker via the pacing electrodes, which are virtually in line with the 70-kHz current path. The pacemaker was of the programmable type and had been operating properly for 11 months prior to the event. It is clear that the 70 kHz current caused the pacemaker rate to increase from 72 to 120 beats/min. Neither the instruction manual for the pacemaker, nor that for the impedance cardiograph identified this hazard.

INTRODUCTION

The first asynchronous single-chamber permanent pacemaker was implanted during the late 1950s.^[1] During the past 50 years, permanent pacemakers have developed after many years of cooperation among physicians and biomedical engineers and fierce competition among device companies into an important and commonly used technology for treating slow heart rates. While the initial pacing systems were the size of a breadbox and used an electrical outlet as a power source, current devices weigh approximately 25 grams, are completely self-contained, and provide complex programmable options that mimic physiologic activity of the heart. In the year 2000, over 225,000 pacemakers were implanted in the United States and more than 600,000 worldwide.^[2] This article will review the anatomy and physiology of the cardiac conduction system, the components of a pacing system, pacemaker function, and the clinical indications for permanent pacing.

PHYSIOLOGY OF THE CARDIAC CONDUCTION SYSTEM

Cellular Activation

Cardiac cells (myocytes) undergo a series of characteristic changes in surface voltage when exposed to electrical stimulation.^[3] Atrial and ventricular myocytes are surrounded by a cell membrane that, among other things, provides an electrical insulation between the intracellular ionic concentrations (mostly K^+) and extracellular ones (mostly Na^+ and Ca^{2+}). The cell membrane consists of bilayer structures composed of molecules with a polar (charged) side and a nonpolar fatty side. Because ions are not very soluble in hydrophobic environments like the cell membrane, they cannot normally cross the membrane, thus maintaining a concentration gradient and a net membrane potential of about -85 mV. Cells can synthesize linear polymers of amino acids (membrane proteins) that can interact with the membrane. Some of these can span all the way through the membrane,

thereby forming aqueous pores (ion channels) that connect the intra- and extracellular and allowing the flow of ions. If an electrical stimulus is provided to resting cells, ion channels for Na^+ and Ca^{2+} open and the cell becomes quickly depolarized ($0-10$ mV) due to the inward flow of Na^+ and Ca^{2+} ions. Cellular depolarization initiates the release of intracellular stores of Ca^{2+} ions, which in turn leads to contraction of the myocyte. An outward flow of K^+ returns the cell to the polarized rest state. The whole excitable cycle for a human cardiac cell usually lasts for a few hundred milliseconds.

Specialized myocytes in the sinoatrial (SA) node and atrioventricular (AV) node (see below) have a special additional property of spontaneous depolarization. Gradual relative accumulation of cations on the inside of these cells leads to continuous regular depolarization of the cells. Depolarization of these “pacemaker” cells causes depolarization of atrial and ventricular cells and leads to repetitive electrical activation of the heart.^[4]

Cardiac Conduction System

The normal electrical impulse of the heart is initiated at the SA node, which was originally identified by Keith and Flack in 1907. The SA node is located high in the right atrium at the junction between the superior vena cava and the atrium; this structure serves as the natural “pacemaker” for the heart. The SA node is richly innervated by nerve fibers from the autonomic nervous system, which regulate the heart rate under a variety of physiologic conditions (Fig. 1).

When relaxed, the right atrium receives blood that has circulated through the body after delivering oxygen and nutrients, while the left fills with newly oxygenated blood returning from the lungs. After an electrical impulse leaves the SA node, it spreads throughout the atria, causing contraction that pushes the blood through valves into the relaxed ventricles. The electrical wavefronts from both atria converge at the atrioventricular (AV) node, a small subendocardial structure located within the interatrial septum. The AV node, like the SA node, is connected to the autonomic nervous

system, so that if SA node disease results in loss of pacemaker activity, the AV node can serve as a “backup” pacemaker, although at a slower heart rate than that of the SA node. The AV node produces a small delay in the electrical activation that allows the ventricles to be filled with the blood coming from the atria. After this delay, the activation is quickly spread to the ventricles through a specialized conduction system (Bundle of His, the right bundle, the left bundle, and the Purkinje fibers). This architecture allows rapid simultaneous activation and contraction of both the right ventricle, which pumps blood to the lungs to be oxygenated, and the left ventricle, which pumps oxygenated blood to the body; ventricular activation is usually complete within 100 ms.

The electrical impulse just described can be altered or disrupted in many different ways. In this article, our primary concern is slow heart rates, also known as bradycardia. When the heart rate is too slow, tissues throughout the body may not receive sufficient oxygen and other nutrients. Bradycardia can be due to two physiologic causes: 1) decreased automaticity of normal pacemaker tissue (usually the SA node) or 2) blocked conduction of the electrical impulse (usually at the level of the AV node or Bundle of His).

Electrocardiogram

The electrocardiogram (ECG) represents the sum of all the cardiac electrical activity measured from the surface (Fig. 1). The instantaneous wave of depolarization can be followed throughout the myocardium by looking at the ECG. The electrical signals generated by the SA node are not large enough to be measured by the ECG. However, as the atria are activated, an electrical signal of 1–3 mV can be recorded on the ECG. This first deflection is called the P wave. The relatively small mass of the AV node, the His bundle, and the right and left bundles are also not of sufficient amplitude to be recorded on the ECG, but ventricular activation results in a QRS complex. The QRS complex is relatively large (7–12 mV), because of the larger number of ventricular myocytes. A final wave called the T wave is due to ventricular repolarization. The duration of ventricular contraction can be estimated from the QT interval, which is measured from the beginning of the QRS complex to the end of the T wave. If the SA node fails to fire normally, a P wave will not be seen (since the atria are not depolarized) and a pause is observed (Fig. 2). If AV node conduction is completely blocked, P waves will be seen (since the atria are depolarized by the SA node), but QRS complexes will not be seen after the P waves. Instead, QRS complexes will occur at a slower rate due to ventricular depolarization from “pacemaker” cells distal to the site of block.

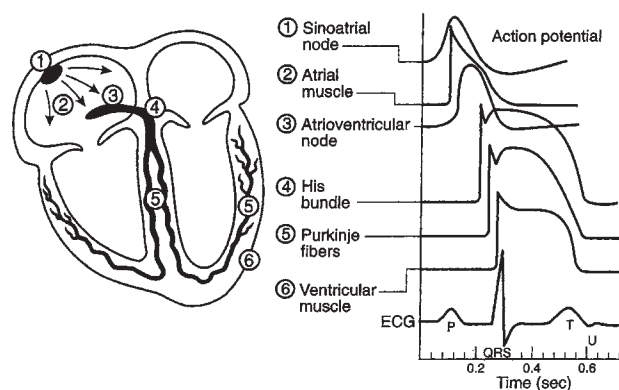

Fig. 1 Conducting system of the action potentials of various tissue types and their correlation with the surface electrocardiogram. The cardiac impulse starts in the SA node and spreads throughout the atria, and the P wave is inscribed. The AV node and His bundle form the normal axis of atrioventricular conduction. The QRS complex is inscribed as the ventricles are depolarized. The T wave is due to ventricular repolarization. The duration of ventricular contraction or systole correlates with the QT interval (the interval from the beginning of the QRS complex to the end of the T wave). Diastole, or ventricular filling, occurs from the T wave to the beginning of the next QRS complex.

CARDIAC PACEMAKERS

Present-day permanent pacemakers are composed of two main components: the pulse generator that contains the battery, specialized circuitry, and the connector or header block; and one or two leads that transmit the electrical impulse from the pulse generator to atrial or ventricular tissue (Fig. 2).

Pacemakers function by repetitively delivering electrical impulses to atrial and ventricular tissue. This small amount of energy (1–2 mA) is sufficient to depolarize tissues and initiate the wave of depolarization and contraction. The stimulation or pacing threshold is defined as the minimal amount of energy or stimulus to consistently depolarize the heart muscle.^[5] The pacing threshold is measured in terms of both amplitude in volts (pulse strength) and the duration of time in milliseconds for which it is applied to the cardiac tissue. There is a predictable hyperbolic relationship between strength duration and pulse amplitude, resulting in the strength-duration curve. At short pulse durations, a small change in the pulse duration is associated with a significant change in the pulse amplitude required to achieve depolarization.

In addition to providing electrical stimulation to the myocardium, pacemakers can also monitor intrinsic cardiac activity. Sensing is the ability of the pacemaker to detect or sense native cardiac depolarization. Intrinsic cardiac signals (known as electrograms) are produced by the wave of electrical current through the myocardium and can be recorded by the pacemaker

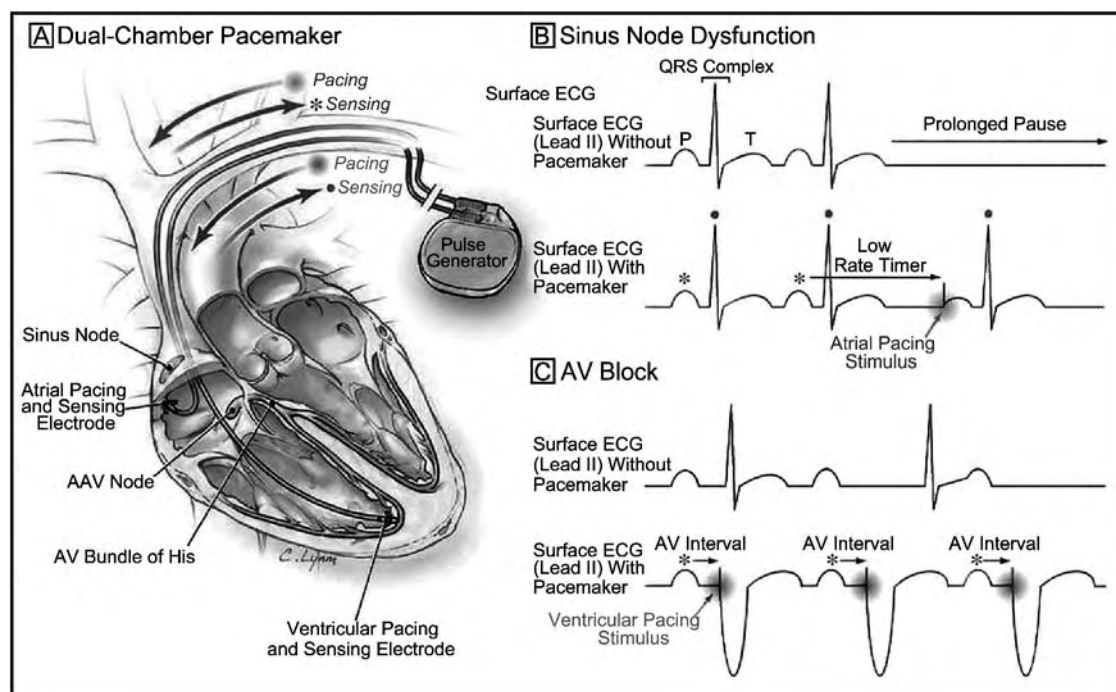

Fig. 2 Dual chamber pacing. A) Schematic of a dual-chamber pacemaker. Leads are usually placed in the right atrium and right ventricle. The leads are connected to a pulse generator usually located in the shoulder area. The leads are used to transmit current from the pulse generator (pacing) and also to transmit intrinsic electrical activity from the cardiac tissue (sensing). B) In sinus node dysfunction, loss of atrial activity leads to a prolonged pause. When a pacemaker is implanted, atrial activity (pink asterisk) and ventricular activity (blue circle) are sensed. If the low rate timer expires without sensed atrial activity, an atrial pacing stimulus is provided to maintain the heart rate. C) In complete AV block, there is no relation between atrial and ventricular activity. With dual-chamber pacing, atrial activity is sensed and the AV interval is initiated. When the interval expires, a ventricular pacing stimulus is provided. In patients with sinus node dysfunction, sensed ventricular activity due to normal AV conduction inhibits the pacemaker. Using this set of timers (low-rate and AV interval), dual-chamber pacemakers maintain AV synchrony regardless of the cause of bradycardia. (Used with permission from Ref. [2].)

electrodes and transmitted back to the pulse generator via the pacing leads. Reliable sensing depends mostly on the amplitude of the electrograms; pacemakers function optimally if the atrial electrogram is greater than 2 mV and the ventricular electrogram is greater than 7 mV. Ventricular electrograms are considerably larger than atrial electrograms due to increased ventricular mass.

Pacing Leads

Cardiac pacing leads are the weakest link in permanent pacing; most pacing failures are due to some malfunction of a lead component.^[6] These components include the electrode, the conductor, the insulation, and the connector or header pin. In order to function reliably, pacing leads must be able to survive in the harsh endocardial environment *in vivo*. Ideally the leads must be constructed of durable materials, which provide stability, flexibility, adequate conductive and resistive properties, and most importantly endocardial contact

within the heart. Not surprisingly, the “perfect” lead has yet to be developed and is a work in progress.

Most current lead designs utilize a tip electrode and a ring electrode 1–2 cm proximal to the tip. In almost all cases, the tip electrode is used as the cathode and the ring electrode as the anode. Optimal pacing and sensing characteristics favor pacing electrodes with a small radius and large surface area. By decreasing the lead radius, current flow can be minimized by providing increased electrode resistance and greater current density, which results in extended battery life and reduced pacing thresholds.

The composition of electrodes has changed in both shape and material composition over the years; to increase the electrode surface area, manufacturers have used pores, filament mesh, and various coatings with microspheres. The composition of the electrode is essential to its long-term performance; unfortunately, relatively few materials have proven satisfactory for pacing electrodes. Electrode degradation and corrosion can happen over time, and the “ideal” electrode must be biologically inert, resist degradation, and produce little

in the way of tissue inflammation and fibrosis at the electrode–endocardial interface. A number of metals, such as copper, zinc, mercury, nickel, lead, and silver, cause toxic reactions with the myocardium.^[7] Current materials in use are platinum–iridium, Elgiloy (a composite alloy of nickel, chromium, cobalt, manganese, molybdenum, and iron), and carbon. Typically after lead implantation, pacing thresholds increase due to the intense inflammatory response at the electrode–endocardial interface. Complex electrode designs that gradually release steroids have been developed that markedly attenuate the inflammatory response and are associated with reduced pacing thresholds.

Leads can be fixed to the endocardium via several methods. In passive fixation leads, small tines or fins positioned immediately behind the electrode are used to secure the lead within the trabeculae of the right atrium and/or ventricle. Active fixation leads use various types of barbs or screws that are imbedded within the myocardium to provide lead stability. Unlike passive fixation leads, actively fixed leads invade the endocardium and can cause transient elevation of the pacing thresholds at implantation. Both types of lead fixation, when implanted properly, have a very low incidence of dislodgment. Passive fixation leads can be placed in a relatively limited number of areas that have well-defined trabeculae (right atrial appendage and right ventricular apex), whereas active fixation leads can be placed anywhere within the right atrium or right ventricle.

The pacing lead conductor is commonly made of a multifilament design to facilitate tensile strength and reduce resistance to metal fatigue. Conductor materials are made of relatively noncorrosive alloys such as MP35N, which is a composite of nickel, chromium, cobalt, and molybdenum.^[7] The lead conductor is made of wire that conducts current from the pulse generator to the pacing electrode and sensed cardiac signals from the electrode(s) to the sensing amplifier of the pulse generator. The current generation of leads most commonly uses a coaxial design, with an inner coil extending to the distal electrode and the outer coil terminating at the proximal electrode. A layer of inner insulation separates the conductor coils.

Silicone and polyurethane are the two materials that have predominated lead insulation, each having its advantages and disadvantages.^[6] Silicone rubber has a performance record of more than 30 years; it is easily fabricated, molded, and repairable. Silicone's disadvantages are that it tears and cuts easily, is thrombogenic, has a higher friction coefficient in the blood, and is subject to cold failure. In contrast, polyurethane insulation exhibits very high tear and tensile strengths, high cut resistance, low friction in blood, high abrasion resistance, less thrombogenicity, and superior compressive properties. However, the disadvantages of

polyurethanes include relative stiffness, lack of repairability, sensitivity to manufacturing processes, their potential for environmental stress cracking (ESC), and metal ion oxidation (MIO). The two most common causes of polyurethane lead insulation failures are ESC and MIO, particularly in leads manufactured with Pellethane 80A and 55D. In ESC, if cracking propagates through the full thickness of the insulator to the conductor, lead failure can occur. In MIO, oxidative degradation of the polyurethane insulation occurs because of a reaction between the polymer and oxygen released by hydrogen peroxide produced from inflammatory cells at the electrode–endocardial interface.

The lead connector unites the lead to the pulse generator; contemporary leads are standardized to conform to international guidelines, which mandate that leads have a 3.2 mm in-line diameter. This mandate was established because some leads and connector (header) blocks were incompatible, requiring the development of multiple adaptors. Some patients who have functioning leads of the older variety (5.0 or 6.0 mm diameter designs) still require lead adaptors when the pulse generator is replaced. The development of an international lead connector standard has enabled physicians to combine various lead designs with different pulse generators.

Pulse Generator

The cardiac pulse generator is a machine having a power source and circuitry that produces the output stimuli. Energy stored within the device's battery travels through the connecting pathway to pace the myocardium, and energy then flows back to the pacemaker to complete the circuit. Specifically, all pulse generators include a power source, an output circuit, a sensing circuit, a timing circuit, and a header block with connector(s) to attach lead(s) to the pulse generator. Today, most pacemakers also include some type of rate-adaptive sensor, the ability to communicate with a programmer (telemetry), and the ability to record and store clinically relevant electrograms. Recent advances in pacemaker technology have exponentially increased the complexity of modern-day devices, while at the same time device size continues to decrease and the longevity continues to increase.

Over the last three decades pacemakers have utilized a number of battery technologies.^[8] There have been many different power sources ranging from nuclear, which generated toxic and radioactive elements; photoelectric cells; rechargeable nickel–cadmium cells that had to be charged on a weekly basis; and biogalvanic sources. Lithium iodine is currently the only power source being used in pulse generators today. Lithium is an anodal element and provides the supply of electrons;

iodine is the cathodal element and accepts electrons. The cathodal and anodal elements are separated by electrolyte, which serves as a conductor of ionic movement but as a resistive barrier to the transfer of electrons (lithium iodide). The pacing leads and the endocardium complete the circuit. In contrast to first-generation power sources, such as mercury-zinc cells, a lithium iodine cell has a more predictable and gradual decrease in battery voltage as it approaches depletion.

At the beginning of life for a lithium iodine battery, the cell generates approximately 2.8 V, which decreases to 2.4 V when approximately 90% of the useable battery life has been attained. The voltage exponentially degrades to 1.8 V when the battery reaches end of life (EOL). At the EOL, most devices lose programmability, frequently reverting to a fixed high output mode to maintain pacing and ensure patient safety. Lithium iodine cells have a relatively low but measurable self-discharge rate. Thus, even when a pulse generator is sitting in packaging on a shelf, not connected to a lead, its battery capacity is slowly being depleted. This has prompted manufacturers to provide device-specific shelf-life dates. Manufacturers also designate a device-specific voltage that triggers the elective replacement indicator (ERI), which alerts the physician that replacement of the pulse generator will be required within several months.

Two things determine the pacemaker longevity: battery capacity and device drain, which is mostly determined by usage. More specifically, longevity of any battery is determined by a number of factors, including chemical composition of the battery, size of the battery, external load factors, amount of internal discharge, and voltage decay characteristics of the cell. The external load factors that influence device longevity are pulse duration and amplitude, stimulation frequency, pacing lead impedance, and the amount of current required to operate the device and store diagnostic information. As a general rule, pacemaker longevity is primarily determined by how much actual pacing is required. Pacemaker longevity will be extended if a patient has intrinsic cardiac activity that is sensed by the pacemaker and inhibits delivery of pacemaker stimuli.

For pacing, the current drain is a function of output voltage, pulse width, pacing rate, and lead impedance. The pacing pulse is generated by charging of the output capacitor, which is then discharged to the cathode tip of the pacing lead. Since the voltage of a lithium iodine cell is 2.8 V, specialized circuitry is used to allow the physician to vary the voltage delivered to the endocardium. By programming the pacemaker to provide the minimal voltage required to reliably pace the heart, the physician can safely extend pacemaker longevity. Pulse generators are constant voltage, implying a constant voltage pulse throughout the pulse duration.

Actually, there is some decay of voltage from the leading and trailing edges of the stimulus impulse; the magnitude of the drop depends on the pacing impedance and pulse duration. The lower the impedance, the greater the current flow from the fixed quantity of charge on the capacitor and the greater the voltage drop throughout the pulse duration.

The intracardiac electrogram is amplified and filtered via the sensing circuitry of the pacemaker. The input impedance must be larger than the sensing impedance to avoid attenuation of the intracardiac electrograms. The signal is filtered and compared with a reference voltage, known as the sensitivity setting. Signals with an amplitude of this reference voltage or greater are sensed as true cardiac events and are then sent to the timing circuitry within the pulse generator (Fig. 3). Signals with amplitude below the reference amplitude do not reset the timing circuitry of the pacemaker. Sensing circuits also incorporate noise reversion circuitry that causes the pacemaker to revert to a noise reversion mode, such as asynchronous pacing whenever the rate of signal received by the sensing circuitry exceeds the noise reversion rate. This feature is key to preventing the inhibition of pacing when the device is exposed to environmental electromagnetic interference.

The timing circuitry of the permanent pacemaker uses a crystal oscillator that regulates the pacing functions with great accuracy. The output from the oscillator and signals from the sensing circuit are sent to a timing and logic control board that operates the internal clocks, which in turn regulates several different timing cycles of the pulse generator. The logic functions of present-day devices are controlled by microprocessors that form a specialized integrated circuit. The microprocessor serves as the central process unit of the device and utilizes two kinds of memory, RAM (random access memory) and ROM (read-only memory). The trend in pacemaker technology has been to use increasing amounts of RAM, which provides greater ease in storing data. Static RAM is gaining popularity among device engineers because critical data is not lost when the power is turned off.

CARDIAC PACEMAKER FUNCTION (PACING MODES)

In order to understand how permanent pacemakers function, it is essential to comprehend the coding system that has been developed by the NASPE/BPEG alliance (North American Society of Pacing and Electrophysiology/British Pacing Electrophysiology Group). For pacemakers, the NASPE/BPEG code consists of a four-position system using a letter in each position to describe a specific function of the pacing system. The four

Fig. 3 Single-chamber pacing in a patient with sinus node dysfunction: differences between VVI and AAI pacing modes. *Top:* In the VVI pacing mode, intrinsic ventricular activation is sensed (S) by the pacemaker (first QRS complex), which inhibits the pacemaker and resets the low rate timer. The pacemaker is set at a base rate of 60 bpm so that after 1000 ms, when the low rate timer expires (E), and since the pacemaker did not sense any cardiac electrical activity, a pacing stimulus is delivered that leads to ventricular activation (second QRS complex) and the low rate timer is again reset. The low rate timer again expires without sensed cardiac activity and another pacing stimulus is delivered (third QRS complex) and the low rate timer is reset. Before the low rate timer expires, intrinsic cardiac activity occurs and is sensed by the pacing system that inhibits the pacemaker output and resets the low rate timer again. This continuous resetting of the low rate timer after paced or sensed events prevents the heart rate from dropping below a programmable level. *Bottom:* In the AAI pacing mode, cardiac activity in the atrium is sensed and the response to a sensed signal (S) is inhibition of pacing output. Since the lead is in the right atrium, when the low rate timer expires (E), atrial pacing occurs. The AAI pacing mode is effective for treating bradycardia due to sinus node dysfunction. However, if the patient develops atrioventricular conduction block either spontaneously or as a result of necessary medications, significant bradycardia may occur. (Used with permission from Phillips, R., Kusumoto, F.M., Goldschlager, N. Pacing in the elderly. *Am. J. Ger. Card.* 2002, in press.)

letters together describe the pacing mode of a specific pacemaker. The first position designates the chamber(s) paced. The letters utilized are **V**, **A**, **D**, and **O** to designate **V**entricle, **A**trium, **D**ual chamber, or **O**ff. The first generation of pacemakers could only pace; they had no ability to respond to or “sense” a patient’s intrinsic cardiac rhythm. Shortly after the introduction of the asynchronous pacemaker, it was discovered that the pacemaker could induce life-threatening tachyarrhythmias. Tachyarrhythmias occurred when a pacing stimulus was delivered during a vulnerable period of the cardiac cycle, usually at the end of ventricular repolarization (R on T phenomenon). The ability to sense intrinsic cardiac activity was an important advance in pacemaker function. The second letter of the NASPE/BPEG code denotes what chamber(s), if any, are being monitored for intrinsic cardiac activity (**V**, **A**, **D**, or **O**).

The third letter corresponds to the response of a pacemaker to a sensed event. The letters used in this position are **I**, **T**, **D**, and **O** to designate **I**nhibited,

Triggered (or **T**racking), **D**ual response, or **O**ff (no response). In the inhibited response, if the pacemaker senses an event, it will inhibit the pacemaker and reset the device to start a timing cycle called the lower rate timer. Delivery of a stimulus (pacing) occurs only if the lower rate timer expires without any sensed activity. For example, a pacemaker programmed to the VVI pacing mode would pace and sense the ventricle, and if a sensed QRS occurred before the pacemaker stimulus was due, it would withhold the stimulus (be inhibited) and reset for another cycle (Fig. 3). An AAI pacemaker is identical in all ways to a VVI pacemaker except for the fact that the pacing lead is in the right atrium rather than the right ventricle.

The triggered mode is often a source of confusion since it is not normally used in the current generation of pacemakers. Instead of inhibiting the output when the pacemaker senses an intrinsic event, a pacing stimulus is delivered when the sensed event occurs. In a VVT programmed device, the pacemaker will pace at the

lower rate timer unless a sensed QRS occurs. If a QRS is detected before the lower rate timer expires, the device will immediately deliver (or trigger) a pacing stimulus and reset the lower rate timer. On the surface electrocardiogram, pacing stimuli will be observed within the native QRS complexes.

Most pacemakers implanted today use the DDD pacing mode. While the DDD pacing mode is more complex since it requires the interaction between the atrial and ventricular signals and two separate leads, it provides the most physiologic responses in a variety of conditions. In the DDD pacing mode, if an atrial event is sensed, the atrial output is inhibited and a timer called the atrioventricular interval (AVI) is started in the ventricular channel. If the AVI expires without a sensed ventricular event, the pacemaker will assume AV conduction is blocked and deliver a ventricular pacing stimulus. If a spontaneous ventricular event occurs before the AVI expires, the pacemaker will assume intrinsic AV conduction is present and will not deliver a ventricular pacing stimulus. The lower rate timer is most commonly "atrially based" and will deliver an atrial stimulus if the lower rate timer expires without a sensed event. The DDD pacing mode provides physiologic depolarization of the atria and ventricles regardless of whether bradycardia is due to SA node dysfunction or AV block (Fig. 4).

The three most commonly used pacing modes are AAI, VVI, and DDD (Table 1, Figs. 2, 3, and 4). The AAI pacing mode, which uses a single lead placed in the

right atrium, prevents bradycardia in patients with sinus node dysfunction and maintains AV synchrony. However, if the patient develops AV conduction block, bradycardia is not prevented. The VVI pacing mode, which uses a single lead placed in the right ventricle, prevents bradycardia in both abnormal automaticity and AV block, but AV synchrony is not maintained. The DDD pacing mode, which usually requires implantation of two separate leads in the right atrium and right ventricle, prevents bradycardia and maintains AV synchrony in both sinus node dysfunction and AV block.

The fourth position in the NASPE/BPEG code designates the presence of certain programmable features of the device. The designations are presumed to be hierarchical, so if a device has a more advanced function, it is presumed to have all lower functions as well. The letter codes for the fourth position are **O**, **P**, **M**, **C**, and **R**, for **nO**-programmable features, **P**rogrammable for three or fewer parameters, **M**ulti-programmable (more than three parameters), **C**ommunicating with telemetry, and **R**ate adaptive (sensor driven). Since the current generation of pacemakers are all multiprogrammable and allow telemetry, the fourth letter is usually reserved to denote the presence of a rate modulation sensor.

Thirty years ago, a series of studies demonstrated that approximately 50% of patients that required permanent pacemakers for bradycardia at rest also had blunted heart rate responses to exercise.^[5,9] Manufacturers have developed a variety of sensors that

Fig. 4 Timing cycles and function of the DDD pacing mode. The first P wave is sensed by the pacing system, which inhibits the delivery of an atrial stimulus and begins the initiation of the AV interval (AVI). The AVI is designed to mimic the PR interval and allow efficient atrial filling of the ventricles. No intrinsic ventricular activity occurs so that when the AVI expires a ventricular stimulus is delivered (first QRS complex). The ventricular stimulus initiates the low rate escape interval. When the low rate timer expires (E), an atrial output stimulus is delivered since no sensed atrial activity has occurred during this interval. After the atrial stimulus the AVI begins, and when the AVI expires a ventricular stimulus is delivered (second QRS complex) and the low rate timer is reset. Before the low rate timer expires, atrial activity is sensed (P in the atrial sensing channel), which inhibits the delivery of an atrial stimulus and begins the AVI. However, before the AVI expires, intrinsic atrioventricular conduction occurs, which results in a spontaneous QRS (R in the ventricular sensing channel) that is sensed by the pacing system and causes inhibition of the ventricular output and again resets the low rate timer. The low rate timer expires again and an atrial output stimulus is delivered. Intrinsic atrioventricular conduction results in a spontaneous QRS (fourth QRS complex), which causes inhibition of the ventricular output and again resets the low rate timer. respond to physical, electrical, or chemical stimuli that estimate metabolic need and vary the pacing rate depending on input from the sensor. In the United States, motion is the most commonly used sensor. In general, motion correlates with activity; motion is sensed by a piezoelectric crystal or by an integrated circuit silicon accelerometer located within the pulse generator. In a person with a pacemaker programmed to the VVIR pacing mode that uses a motion sensor, the pacing rate will be set to a lower rate at rest (60 beats per minute is commonly programmed), but with activity the pacemaker will gradually increase the pacing rate. The amount of activity required to increase the pacing rate and the rate of increase in the pacing rate can be separately programmed by the physician so that rate-adaptive pacing systems can be adjusted for use in both sedentary and active patients.

CLINICAL INDICATIONS FOR PERMANENT PACING

A detailed discussion regarding the clinical indications for permanent pacing is beyond the scope of this article. The decision to implant a permanent pacemaker requires interaction between the physician and patient. In an effort to standardize the indications for permanent pacing, the American College of Cardiology (ACC) and the American Heart Association (AHA) formed a joint task force to review the clinical data and recommend indications for permanent pacemaker implantation based on the clinical evidence.^[10]

Traditionally, pacemakers have been used for the treatment of bradycardia due to sinus node dysfunction and atrioventricular block. Other potential indications for permanent pacemaker implantation include autonomic nervous system disorders, cardiomyopathy, and the prevention of atrial fibrillation.

Sinus Node Dysfunction

Sinus node dysfunction (sick sinus syndrome and tachycardia-bradycardia syndrome) includes a broad spectrum of cardiac arrhythmias. Electrocardiographic manifestations of sinus node dysfunction include sinus bradycardia, sinus arrest, sinoatrial block, and paroxysmal supraventricular tachycardias alternating with bradycardia or even asystole. Sinus bradycardia can be a normal physiologic finding in the trained athlete, who commonly has awake resting heart rates in the 40-beats-per-minute range. These athletes may also have sleeping heart rates in the 30s with sinus pauses as long as 2.8 seconds.^[11] As emphasized in the following sections, the presence of symptoms, rather than a specific heart rate or duration of a pause, is the most important factor for deciding whether a permanent pacemaker should be implanted. Sinus node dysfunction disorders account for more than half of permanent pacemaker implants.^[12] Prior to pacemaker implantation it is important to correlate symptoms with the rhythm disturbance via a 24-hour ambulatory ECG monitor or a patient-activated event recorder; however, the correlation of symptoms with rhythm disturbance often proves difficult given the intermittent nature of these episodes. It should also be emphasized that a precise correlation of the symptoms of cerebral hypoperfusion with bradycardia may not be discovered. Decreased perfusion pressure to the brain itself may cause confusion which may allow the event to be unrecognized by the patient, and the sedentary lifestyle of the patient may lead to under-recognition of sinus node dysfunction by patients, family, and physicians.^[13] Currently, patients with documented symptomatic bradycardia as a result of sinus node dysfunction should receive a permanent pacemaker. In addition, patients in whom sinus node dysfunction is thought to be the cause of symptoms should be considered for permanent pacemaker implantation, even in the absence of direct correlation between symptoms and rhythm disturbances.

Atrioventricular Block

Atrioventricular (AV) block is electrocardiographically classified as first-, second-, and third-degree or complete heart block; anatomically, AV block is classified as supra-, intra-, or infra-His. In first-degree block, there is a 1:1 relationship between atrial and ventricular contraction, but the time between these events is abnormally long. Electrocardiographically, in first-degree AV block, the PR interval (measured from the beginning of the P wave to the beginning of the QRS complex) is greater than 220 ms. First-degree AV block is generally not considered an indication for pacing. However, some patients with severely prolonged PR interval (usually >300 ms) may require permanent pacing, as the result of nonphysiologic timing of atrial and ventricular filling and contraction; pacing may alleviate symptoms by restoring normal physiologic timing. In second-degree AV block, some but not all P waves are conducted to the ventricles. Second-degree AV block is subclassified as Type I when the PR interval prior to a dropped QRS complex is longer than the PR interval after the dropped QRS complex and Type II when the PR intervals before and after the dropped QRS complex are the same. The distinction is important, since Type I second-degree AV block is associated with supra-Hisian block and Type II second-degree AV block is associated with intra- or infra-His block. Intra-Hisian and infra-Hisian block are associated with a poorer prognosis due to the unreliability of subsidiary pacemakers below the His bundle. In practical terms, all symptomatic patients with second-degree AV block and asymptomatic patients with Type II second-degree AV block should receive permanent pacemakers. In third-degree AV block, no P waves are conducted to the ventricles. In general, all patients with third-degree AV block receive permanent pacemakers.

Other Indications for Pacing

Autonomic nervous system disorders are the causative mechanism in 10% to 40% of patients that experience transient loss of consciousness and postural tone (syncope). In these conditions, triggering of the autonomic nervous system results in a transient decrease in blood pressure due to bradycardia and peripheral vasodilation. The two most common examples of neurally mediated syncope are carotid sinus hypersensitivity syndrome and vasovagal syncope. The pathophysiology of vasovagal syncope is not completely understood but appears in part to be initiated by activation of myocardial mechanoreceptors, which leads to inhibition of efferent sympathetic tone and increased efferent parasympathetic tone, resulting in peripheral vasodilation and inappropriate bradycardia.

Pacing does not treat the peripheral vasodilation but may attenuate symptoms by preventing bradycardia. Several recent multicenter studies have suggested that pacemaker implantation may be beneficial in selected patients with severe symptoms.^[14,15] In older patients, carotid sinus hypersensitivity may be associated with syncope and unexplained falls. In carotid sinus hypersensitivity, stimulation of the carotid artery leads to bradycardia (pauses of more than three seconds) and hypotension (>50 mm Hg drop in systolic pressure). A recent multicenter study found that pacing therapy was associated with a fourfold decrease in recurrent falls in patients with carotid sinus hypersensitivity.^[16]

Pacing therapy may be useful for patients with advanced heart failure due to cardiomyopathy. Some patients with cardiomyopathy have dysynchronous left ventricular activation where the lateral wall of the left ventricle is activated very late relative to the inter-ventricular septum. Since left ventricular contraction is occurring sequentially rather than simultaneously, the efficiency of ventricular contraction is significantly reduced. In these patients, the duration of the QRS complex is often >150 ms, which reflects the slow rate of ventricular depolarization. Specially designed leads that are placed in the left ventricular venous system are used to restore a more normal left ventricular activation pattern. Pacemakers utilizing these leads have been associated with improved hemodynamics and quality-of-life in patients with severe congestive heart failure.^[17,18] As more information becomes available, the authors believe that pacing will become more commonly used for this condition.

Finally, pacing may have an adjunctive role for the treatment of atrial fibrillation. Preliminary data from the Dual Site Atrial Pacing for Prevention of Atrial Fibrillation (DAPPAF) trial suggests that atrial pacing reduces the frequency of atrial fibrillation episodes.^[19] However, additional studies will be required before pacing can be widely recommended in this situation.

CONCLUSION

It is clear that permanent pacemakers are truly an extraordinary technology, perhaps among the most important medical innovations of the twentieth century. As the number of elderly Americans with SA node and conduction system disease increases, it is inevitable that the number of permanent pacemaker implants will continue to rise. In addition, the indications for pacing will continue to expand beyond the treatment of bradycardia. Device and lead technologies will no doubt continue to advance, becoming even more reliable and durable. The evolution of the pacemaker provides an important example of the interplay

between medicine and engineering to develop an important tool for the treatment of cardiovascular diseases.

INTRODUCTION

The field of cardiac tissue engineering is advancing at a rapid pace. Cardiac function is intimately linked to the three-dimensional organization of the heart. Cell-based therapies designed to reconstruct dysfunctional or damaged domains of the heart must successfully recapitulate the structure and function of the intact tissue. To fabricate a three-dimensional prosthesis that exhibits the structural and functional properties of intact cardiac tissue presents many challenges. In this article we provide an overview of the research in this field with emphasis on collagen scaffold-based engineering of a cardiac patch.

OVERVIEW

Normal Heart

The normal adult heart weighs about 300 grams and is an incredibly efficient and durable pump lasting up to 120 years. On average, the heart pumps roughly 6000 liters of blood per day. This blood supply ensures that all of the tissues and vital organs are sufficiently perfused, oxygenated, and supported nutritionally and that CO₂ and other waste products are effectively eliminated.^[1] To tissue-engineer a replacement heart, or even replacement components, is therefore a formidable challenge.

Heart Disease

Cardiac dysfunction currently accounts for 750,000 deaths annually in the United States, which is nearly twice the rate of all cancer deaths combined. The annual cost of ischemic heart disease is approximately \$100 billion dollars. Malfunction of the cardiac system has profound negative physiological consequences. Cardiac dysfunction can be broken down into five main categories: 1) Pump failure, which most

frequently consists of damaged muscle that contracts too weakly or inadequately, causing ineffective emptying of the chambers. Less frequently the muscle may develop the inability to relax fully resulting in the ineffective filling of the chambers. 2) Obstruction of flow is usually caused by the formation of a lesion that interferes with the proper functioning of one or more of the valves. These obstructions cause an excessive pressure drop reducing the available pressure to perfuse the tissues. They can also impair valve closure leading to regurgitation within a chamber. 3) Regurgitation of flow is typically a partial failure of one or more of the valves in the heart causing flow reflux and increased workload on the emptying chamber. 4) Conduction system malfunctions cause incomplete or asynchronous contraction of the cardiac myocytes, usually detected as an atrial or a ventricular fibrillation. 5) Breach of the circulatory system is a more acute condition than the others and is usually an externally inflicted wound or aneurysm of the aorta or ventricle. The patient loses sufficient blood volume to allow the heart to maintain blood pressure and the victim can eventually exsanguinate.^[1]

Any one of the above conditions is sufficient to transport the patient along the path toward congestive heart failure, regardless of the cause; the only long-term treatment for this end-stage condition is transplantation. However, this treatment option is available only on a limited basis and there are presently long lists of patients waiting for available hearts. The material available for the transplantation and correction of cardiac abnormalities in children is even more limited. In a variety of conditions, it is theoretically possible to correct the damaged myocardium by surgically excising the dysfunctional area and reconstructing that domain of the heart by implanting healthy cardiac tissue. In order to successfully carry out this type of treatment, two major hurdles must be overcome. The first is to identify a source of donor tissue that will not be rejected. The tremendous advances in stem-cell technology indicate that it will be feasible in the near

future to have a source of autologous cells for transplantation. The second hurdle is the focus of this chapter, the development of the technology necessary to grow in vitro a segment of myocardium composed of cardiac myocytes, extracellular matrix constituents, and interstitial cells that closely mimic the intact tissue.

BACKGROUND ON CARDIAC TISSUE ENGINEERING

In recent years there has been significant engineering and scientific effort expended in an attempt to shift the treatment paradigm from one of replacement and substitution via cardiac transplantation to one of regeneration via either in-vivo or in-vitro tissue engineering.^[2] Much of the effort has been focused on regeneration of the non-functional segments of the damaged myocardial wall, repair of damaged valves, and/or ventricular assist devices for both the right and left ventricles.

The two main areas of regenerative cardiac research are: 1) injection of cells in an effort to repopulate damaged areas of muscle, and 2) in-vitro tissue engineering of cardiac valves and patches of cardiac muscle, and engineered ventricular assist devices to restore the pressure differential necessary for normal cardiac function. The development of the biomaterials, fabrication techniques, and tissue/cell delivery systems and technology to engineer mechanical devices must proceed in parallel with stem-cell technology in order to realize a tissue-engineered treatment for heart disease.

Injection of Cells

A variety of cell sources to repair injured myocardium have been used including skeletal myoblasts,^[3,4] fetal and neonatal cardiomyocytes,^[5,6] and stem cells.^[7] The basic premise is that live cells can be deposited by injection into and around a developing cardiac scar. The cells will then engraft into the existing tissue and be guided by the microenvironment and the extracellular matrix to adopt the appropriate architectural arrangement. Signaling mechanisms provided by the microenvironment will then stimulate the cells to develop into functioning myocytes that will proceed to integrate and connect electrically to the surrounding functional tissue. Injection studies have demonstrated healthy and functioning transplanted cells within heterotopic areas as well as the areas of myocardial infarction. Additionally, some studies have noted minor improvements in regional systolic performance, compliance, peri-infarct perfusion, and global ventricular function.^[8-10] On the cellular level, grafted cardiomyocytes have the capacity to form gap-junctions with host myocardium.^[11] These results indicate that this is a promising area that needs further investigation.

Tissue Engineering of Constructs

The most popular in-vitro tissue-engineering approach is to fabricate a scaffold consisting of a biocompatible material in the desired geometry. The scaffold is then seeded with the desired cell types and the composite is allowed to form the requisite cellular phenotype, function, signaling, and intercellular connections necessary for function as an intact tissue. Much of the early work in tissue engineering used two-dimensional culture techniques. These techniques, while providing significant and useful information, failed to produce viable engineered constructs that could be used clinically in heart repair. The major drawback of these constructs was that they were too thin and lacked sufficient mechanical integrity to be clinically significant. These two-dimensional systems did demonstrate the significance of the extracellular matrix (ECM) composition and geometry to the fabrication of in-vitro tissues. The aligned collagen system of Simpson et al. shows the importance of collagen and that the collagen must be arranged in a parallel, fibrillar form to elicit the elongated rod-shaped phenotype typical of in-vivo cardiomyocytes.^[12] McDermitt et al. further demonstrated the importance of the ECM in micro printing laminin streaks on tissue culture plastic. This work showed that cardiomyocytes cultured on micro-patterned laminin streaks of appropriate line width and spacing can achieve an elongated rod-shaped phenotype and intercalated disks.^[13] These aligned cultures exhibit polarized electrical properties, a characteristic necessary for normal excitation and the generation of organized contractions.

The current thinking in tissue engineering of cardiac systems is that repair of areas affected by ischemic heart disease can be accomplished by the fabrication and implantation of either a muscle patch or, for more advanced forms of heart failure, a tubular ventricular-assist device. Both of these approaches require a three-dimensional tissue scaffold. The scaffold could provide temporary biomechanical support for the cells in a more clinically appropriate geometry and result in more mature cultures with respect to cellular differentiation and electrical properties.^[14]

The primary difficulties encountered with the early three-dimensional scaffolds were inefficient methods for cell seeding, poor cell distribution, poor cell-cell and cell-scaffold interactions, and standard culture conditions in dishes and flasks that were not able to support the cultures. Thus, they failed to elicit biologically appropriate phenotypes and tissue function or failed to survive. Several investigators overcame these problems with cell seeding in ground-breaking studies by attempting to culture cells in the microgravity environment of space.^[15] These studies showed that in an environment with reduced gravitational force, cell-cell

and cell-scaffold interactions permitted much higher density cultures with more in-vivo-like cellular phenotypes.^[15-18]

Bioreactors

The National Aeronautical and Space Administration (NASA) has developed a randomized gravity-vector rotating-wall bioreactor that can be used to transport sensitive biological experiments into space. This reactor randomizes the acceleration force generated by the launch of the space shuttle and minimizes its impact on these experiments. These NASA bioreactors are also being used in ground-based studies to minimize the influence of gravity on cell culture by mimicking the microgravity conditions found on the space shuttle in orbit.^[18] When combining a three-dimensional scaffold with cardiac myocytes in the bioreactor, a cardiac construct with a high cellular density and mature, elongated cells that contract spontaneously and synchronously develops.^[19] Further advantages to these systems have been an improved rate of cellular seeding efficiency, most likely due to an improvement in aerobic metabolism, and reduced cellular stress within the dynamic environment due to high bulk flow conditions with minimal shear stress.^[15] In addition, in-vitro cultures grown within a dynamic environment more closely resemble native tissue with respect to protein characteristics and ultrastructural features.^[16,17] Overall, the utilization of bioreactors has become a powerful research tool that improves the cultivation of cardiac myocytes.

Approach to Tissue-Engineering a Cardiac Patch

One approach to achieving a successful cardiac implant is to pattern the development of the cultured extracellular and cellular components after the intact heart. The logic justifying this approach is that structure and function are intimately associated; therefore, if we are able to recreate the structure, the necessary function should follow. So what can we learn from intact tissue? The intact heart is composed of a series of overlapping cellular layers.^[3,18] Within any given cell layer the rod-like myocytes of the myocardium are arrayed in parallel with one another along a common axis. This parallel alignment is essential for the efficient distribution of electrical signals throughout the myocardium and the ability of the heart to eject blood effectively into the vascular tree. As the individual layers of parallel myocytes develop within the heart during embryogenesis and begin to contract, the increased force must be contained and directed to the ventricular chambers.^[19] To direct these mechanical forces, a three-dimensional, stress-tolerant, connective tissue network forms early in

development.^[4] The coordinate elaboration of the ECM during the development of the multilayered myocardium indicates that the ECM plays a role in directing the formation of the complex fiber patterns of the heart by providing positional information to the differentiating myocytes. The lesson to be learned is that if the tissue engineering process develops a patterned ECM, the cellular components will develop the same pattern. Thus, the composition and arrangement of this connective tissue network is essential.

The cardiac ECM is composed primarily of interstitial collagens. The fibrils of this collagen network surround the myocytes and tether adjacent cell layers together (Fig. 1). It is now evident that the changes in the ECM that occur in development and disease represent a dynamic adaptation to physiological change. Any perturbation that alters the normal arrangement of the myocytes within the myocardium, as the result of either a congenital defect or a pathological condition, alters the efficiency of electrical conduction and the ability of the heart to generate contractile force. To correct these defects, it is necessary to replace the tissue with an engineered construct that mimics the electrical and mechanical properties of the normal tissue. As a consequence of the functional characteristics and architecture of the intact heart, any cell-based procedure that is used to repair a segment of damaged myocardium must consist of myocytes that exhibit the functional and structural properties of the surrounding myocardium.

In addition to its structural role in the heart, the ECM also functions as a repository for signal molecules such as growth factors, cytokines, and extracellular proteases. The complex interplay of these biochemical factors and the mechanical events associated with cardiac function direct the formation of the heart and biochemically

Fig. 1 A schematic drawing representing the physical communication that exists between the intercellular and extracellular environments in a cardiac myocyte. The connection can be traced from the myofibrils, across the cytoskeleton-integrin complex, and out into the ECM. This connection is essential for the formation and maintenance of normal cardiac myocyte phenotype.

link the myocytes to the other organ systems, enabling the heart to adapt to a variety of physiological conditions.^[6-8] Signals that originate in the ECM play an important role in development as well as in the adaptation to physiological signals throughout life.^[9]

Structural and Functional Arrangement of the ECM in the Heart

The ECM of the heart consists of a complex mixture of collagens, proteoglycans, noncollagenous glycoproteins, and growth factors that are produced and secreted into the extracellular environment by the fibroblasts. However, the principal structural component of the ECM is collagen. The collagen-based network of the heart appears to direct the expression of the rod-like cell shape by cardiac myocytes and the formation of the three-dimensional structure of the heart. The chemical identity and arrangement of this network is subject to change during development and in response to different physiological conditions.^[20] During neonatal development the collagen-based matrix is rapidly elaborated and develops into a stress-tolerant network that assists in distributing the mechanical forces associated with cardiac function.^[21] The collagen network of the heart has been demonstrated to control the elastic properties of the ventricular wall.^[12,22-24] In the adult, several factors, including nutritional factors, mechanical stimulation and biochemical feedback, have been shown to regulate the expression and accumulation of collagen.^[25]

Regulation of Myocyte Phenotype by the ECM

Most in-vitro culture methods for isolated cardiac myocytes have shown that it is necessary to use purified components of the ECM to get isolated cells to attach and adapt to the culture environment.^[26] While it is known that these ECM components are essential to promote the attachment and survival of myocytes in vitro, it has only recently been documented that the arrangement of a particular ECM component can dictate the shape that a cardiac myocyte will express in vitro (discussed in preceding text).^[2]

Interaction of Collagen and Myocytes; Integrins

In primary cell culture the specific interaction of collagen with receptors of the integrin family controls many aspects of the processes that regulate the shape that a cardiac myocyte expresses under a given set of culture conditions. Many of these phenotypic signals appear to be communicated across the plasma membrane by members of the integrin family of ECM receptors. The

functional integrin receptor consists of an α and a β chain that are non-covalently linked to one another. Different α and β chains interact with one another to form receptors that bind to components of the ECM. Within the intracellular space, the cytoplasmic tail of the integrin complex interacts with components of the cytoskeleton, the elaborate internal scaffolding that stabilizes myofibrillar structure and cell shape. In the heart during neonatal life, the α -1, β -1 integrin is the predominate isoform. However, α_2 , α_3 , α_5 , α_7 , and β_1 isomers have been identified and are present at varying concentrations under different physiological conditions and states of development.^[27]

In myocytes, collagen associates with the cell surface in two distinct ways: 1) perpendicular at a site near the Z band (Fig. 1), and 2) lateral associations parallel to the surface of the myocyte. Members of the integrin family mediate the first type of attachment to the surface. These specialized receptors transduce biochemical and mechanical signals from the ECM to the internal milieu of the cell.^[28] The integrins are coordinately synthesized with ECM components,^[29] associated with regulation of the cardiac myocyte phenotype,^[12] and intimately associated with the delivery of contractile force.^[30,31] Collagen is also associated and linked to the surface of the cardiac fibroblast through specific interactions mediated by the integrins; both high- and low-affinity interconnections between the interstitial cells of the heart and collagen have been identified.^[32] These different binding affinities appear to enable the fibroblasts to migrate on collagen (low-affinity) as well as to contract and place mechanical tension across the collagen network (high-affinity).^[33]

Mechanical Forces and Myocyte Biology

Mechanical signals play an important role in directing myocytes to assume the distinctive cytoarchitectural features of the differentiated myocyte as well as the overall structural arrangement of intact muscle.^[12] Mechanical forces associated with cardiac function during various stages of development have been shown to regulate the expression^[34] and degradation^[30,35] of a variety of contractile and regulatory proteins. Mechanical stimulation is of particular importance in the cardiovascular system in a variety of developmental and disease conditions. During development and in the adult, the cells and tissues are continually subjected to physical forces. A primary developmental force in the heart is mechanical stimulation resulting from contractile force as well as an increase in pressure and volume.^[36] The role of mechanical stimulation in cell function has been difficult to investigate due to methodological problems preventing a logical and systematic approach to the isolation of the mechanical

stimulation. To study the role of mechanical stimulation in a controlled environment, several types of *in vitro* mechanical cell stimulators have been developed. A variety of biological responses such as cell size, regulation, expression,^[34] synthesis, and degradation^[35] of a variety of contractile and regulatory proteins are measured and shown to be influenced by the application of mechanical tension. It will be essential to pre-adapt cardiac tissue constructs to mechanical stresses prior to transplantation.

Characteristics of a Biomaterial as a Tissue-Engineering Substrate

Based on the structure, function, and endogenous composition of the ECM of cardiac muscle, the logical choice for a scaffold material to construct a tissue-engineered construct would be collagen. This would be true for the majority of tissues in the body. So why have many tissue engineers chosen to avoid collagen? The answer is that they have not been able to obtain the correct physical properties for the collagen when used in other systems, such as artificial blood vessels, and thus the artificial vessels have failed when transplanted. So, what are the necessary properties for a scaffold for artificial muscle? From a biological standpoint, the material must be noncytotoxic and biodegradable, the byproducts of biodegradation must be nontoxic, and the scaffold must promote or at least support the maintenance and synthesis of new tissue. Collagen meets these requirements as the endogenous ECM and when used in culture. From a mechanical standpoint, the scaffold must have an appropriate modulus, possess flexural rigidity, have a surface energy that is not too hydrophobic or too hydrophilic, and thus provide a mean pore size and pore volume fraction to support the cells and fluid necessary to form a tissue.

In nature, collagen, as the dominant ECM component of cardiac muscle, possesses all of these features. The challenge is to recreate them *in vitro*. The scaffold must have a biodegradation rate that is fast enough to allow for the normal homeostatic remodeling of the tissue, but not so high as to have a tissue engineered construct fail before it integrates into the surrounding tissue. In other systems such as blood vessels, this is where conventional preparations using collagen gels and permutations of this type of material have fallen short. One can crosslink collagen with aldehydes to the point that they will last for years, but this collagen will not support cell growth or tissue remodeling. The key is to develop alternative processing and/or crosslinking methods to achieve the desired properties. There are also other practical/clinical properties necessary for an ideal scaffold. It must be able to “hold a stitch” so that

it can be sutured into the surgical site. It must not undergo contracture or scarring and should not promote a chronic inflammatory response. These combined characteristics are a tall order for any scaffold and most tissue engineers have turned to synthetic materials to achieve many but not all of the necessary characteristics. We propose that it is worth the effort to alter the “manufacturing” of collagen substrates since in nature it is the ideal scaffold.

DATA IN SUPPORT OF USING THE ROTATING-WALL BIOREACTOR

The data presented below were obtained from experiments conducted in the microgravity of space in collaboration with NASA. The goal of the experiments was to determine if rounded cardiac myocytes added as a suspension would: 1) interact with a template monolayer of cells on a collagen substrate to form a multilayered culture and, 2) if the rounded cells added to the aligned cells on the collagen substrate would attach to the template of aligned cells and adopt an aligned cell shape even though they were not in direct contact with the collagen-coated substrate. If both conditions were met, the experiments would provide important information showing that a pre-existing template of cells could communicate the phenotypic information stored in an underlying collagen gel to a second population of myocytes not in direct contact with the collagen fibrils. These conditions are essential if a multilayered culture of cardiac myocytes that has a phenotype similar to that of an *in vivo* myocardial wall is to be developed for subsequent implantation into a damaged heart.

To this end, we used a modification of the aligned collagen gel system^[12] to engineer a three-dimensional prosthesis of cardiac muscle cells. In the aligned collagen gel system, cells are plated onto a thin, polarized matrix of type I collagen fibrils prepared on a solid substrate. This matrix is produced by applying a solution of ice-cold, neutral type I collagen to a specially treated silicone rubber film or other suitable surface, using a sterile nylon brush, at a concentration of 0.62 $\mu\text{g}/\text{mm}^2$. The substrate is then tipped and the collagen solution is allowed to drain across the surface. Once this application process is completed, the collagen is allowed to polymerize at 37°C for 1 hour. This procedure results in a thin layer of collagen fibrils that are arrayed in parallel with one another along the direction that the solution of collagen was originally drained (Fig. 2A and B).

Under conventional culture conditions, fetal,^[37] neonatal cardiac myocytes,^[12] and neonatal cardiac fibroblasts^[38] will attach to these collagen gels and express an elongated *in vivo*-like, cell shape. The

rod-like myocytes of cultures plated onto aligned collagen are distributed in parallel with one another (Fig. 2C) and as a population; the cells exist as a monolayer in a tissue-like pattern of organization. The aligned phenotype of muscle cells cultured on this substrate is very different from the pattern of organization that is observed when these cells are cultured on native plastic, nonaligned collagen, or laminin (Fig. 2D). The geometry and biochemical nature of this interaction appear to be critical in promoting the expression of the aligned phenotype. Disrupting the aligned structure of the collagen or altering its chemical composition suppresses the expression of the aligned phenotype.^[12] Blocking the function of either the α_1 or β_1 integrin (the predominate integrin isoforms expressed by these cells) with antibodies directed against the extracellular domains of these molecules inhibits cell adhesion and disrupts the expression of the aligned phenotype. Similar results were obtained when we used antisense oligonucleotides (ODNs) to inhibit the accumulation of the α_1 subunit of the integrin complex.^[39] Blocking the accumulation of vinculin, a cytoskeletal protein of the cardiac costamere and Z-disk with antisense ODNs also suppresses the expression of the aligned

phenotype.^[37] Cells treated with antisense ODNs against vinculin did not align and were unable to assemble normal myofibrils.

The aligned phenotype in these cultures resembles the organization of muscle cells within a single cellular layer of intact heart. Data from our experiments indicate that the phenotypic information that directs the expression of this pattern of organization is stored in the chemical identity and tertiary structure of the ECM. This information is translated into signals that control the muscle cell shape. Unfortunately, the monolayer nature of these cultures makes them unsuitable as a tissue-engineered construct capable of surviving transplantation. In order to be useful for this type of clinical application, the cultures must more closely mimic the three-dimensional structure and mechanical integrity of intact tissue. This requires the prosthesis to be composed of multiple layers of muscle cells arrayed along a common axis. Our attempts to induce the formation of a multi-layered culture under conventional conditions have been unsuccessful. However, large multicellular aggregates can be induced to form in the microgravity of space and in devices designed to provide high nutrient delivery in a buoyant, low-shear environment on the ground^[40,41] mimicking the high buoyancy and low-shear conditions of space. While these aggregates can be quite large, they are not distributed in a clearly defined, three-dimensional pattern of organization, a hallmark of intact cardiac tissue. For this reason, they are also unsuitable for use in reconstructive surgery.

On four separate space shuttle flights, we have successfully used a confluent monolayer of aligned myocytes as a template for the fabrication of a multilayered aligned culture. In these experiments, we first established a confluent layer of aligned cardiac myocytes on a solid substrate for several days on the ground, and then placed them on the shuttle in one chamber of a two-chambered device designed to mix different cell populations in the microgravity of space. In the second chamber we placed a suspension culture of freshly isolated myocytes. When the shuttle reached orbit the suspension of rounded myocytes in chamber two was mixed with the template layer of aligned myocytes in chamber one. The cultures were fixed and preserved for microscopic examination 24–96 hrs after mixing.

To distinguish the two populations of cells, prior to mixing them we labeled the suspended cell population in the second chamber with the membrane-intercalating agent, DiI, prior to loading them into the chamber. Myocytes in the template layer were preloaded with DiO. Both dyes are incorporated into the membranes of cells and when excited at the appropriate wavelengths of light, DiI fluoresces green and DiO fluoresces red. By the use of confocal microscopy, this allowed us to identify unambiguously the origin of each cell

Fig. 2 A) Phase contrast micrograph of an aligned collagen gel painted onto a culture dish. B) SEM micrograph of a similar gel showing the aligned grooves in the polymerized collagen and the fibrils. C) SEM micrograph of myocytes plated onto aligned collagen fibrils. They express an elongated rod-like phenotype similar to that seen in vivo. D) Neonatal cardiac myocytes plated onto a thin gel of nonaligned collagen fibrils. These myocytes express a stellate cell shape. Magnification, A ~ 100 ×, B ~ 2500 ×, C ~ 2100 ×, D ~ 1800 ×.

C

population at the conclusion of the experiment (Fig. 3). In mixing experiments conducted at microgravity aboard the space shuttle, the rounded cells added in suspension attached uniformly over the surface of the template layer (Fig. 3A) and spread out in parallel with the long axis of the underlying cells to form multilayered cultures of aligned myocytes. Unlike the cultures of myocytes combined aboard the space shuttle in orbit, myocytes mixed in ground-based control experiments and exposed to normal gravity became unevenly distributed and formed aggregates on top of the template culture (Fig. 3B). The cells of these aggregates did not spread on the template layer even after 72 hours of

culture and the myocytes of these aggregates failed to assemble myofibrils (Fig. 3B, inset).

The results of these experiments suggest that phenotypic information in the aligned collagen is communicated by the template layer of myocytes, which are in direct contact with the collagen, to the overlaying myocytes, which are not in direct contact with the collagen. To characterize how this information might be conveyed by the template layer, we used anti-N cadherin antibodies to block cell–cell communication after mixing. As before, we prepared a template layer of aligned DiO-labeled cardiac myocytes in a culture vessel. In a second culture vessel, freshly isolated DiI-labeled cardiac myocytes were mixed in suspension with anti-N cadherin antibodies. The two culture vessels were then loaded onto the space shuttle; upon reaching orbit the two cell populations were mixed as described previously. After 48 and 96 hours, replicate cultures were fixed in 2% paraformaldehyde. Cells treated with irrelevant antibodies served as controls. Microscopic analysis indicated that cells mixed in ground-based experiments in the presence or absence of anti-N cadherin antibodies failed to form multilayered cultures (Fig. 3C). As before, cells added in suspension in ground-based experiments formed a series of aggregates on the surface of the template layer and failed to spread in parallel with the underlying myocytes. There were no obvious differences in the appearance of these two treatment groups. Control cultures mixed in the microgravity of space formed multilayered sheets of myocytes that were arrayed along a common axis and in parallel with the underlying collagen fibrils, as previously reported (Fig. 3E). In contrast, cell cultures mixed in microgravity and in the presence of anti-N cadherin antibodies failed to form multilayers (Fig. 3D). Myocyte organization in these cultures resembled those prepared under conventional ground-based conditions. Rounded cells added under these conditions formed a discontinuous layer of cell aggregates consisting of rounded myocytes on the surface of the template layer. These data indicate that cell–cell interactions mediated by the N cadherin molecule play a role in transducing the phenotypic information necessary to induce the formation of multilayered constructs.

To mimic the low-shear force environment of microgravity we have used the Synthecon Rotary Cell Culture System (RCCS). The RCCS provides a unique environment with low-shear force, simulated microgravity, and high mass transfer, all taking place in a conventional tissue culture incubator. Similar to the flight studies, a template layer of aligned myocytes on solid substrate (silicone rubber in this case, tissue culture plastic on the shuttle) were placed in the bioreactor and cultured for 3 days. Figure 4 shows the multilayer mixed culture of myocytes and fibroblasts

Fig. 3 A) Myocyte cultures 96 hours after mixing in microgravity. Myofibrils have been stained with rhodamine phalloidin and are depicted in the red channel. The distribution of Dye I is illustrated in the green channel (identifies cells originally added in suspension to the template layer of myocytes). Rounded cells appear uniformly distributed over the template layer when mixed in microgravity. This micrograph illustrates the uniform distribution of cells added in suspension to a template layer of aligned myocytes. B) Ground-based control experiments where cells in suspension were added to a template culture consisting of a dense monolayer of aligned myocytes (red). Cells added in suspension formed aggregates on the surface of the template culture and did not spread out (green). C) Cultures prepared under conventional conditions (ground-based, normal gravity) in the presence or absence (not shown) of N-cadherin antibodies fail to form multilayers. D) Blocking cell–cell communication by the addition of N-cadherin antibodies disrupts the formation of multilayered cultures of aligned myocytes. E) Control cells mixed in microgravity (flight) form multilayered cultures of aligned myocytes. Magnification, A 130 \times , B 200 \times , C,D,E 125 \times .

grown in the bioreactor from an aligned monolayer and additional cells added in suspension.

These experiments demonstrate the feasibility of developing multilayered cultures of myocytes. In actual use, cardiac implants would be prepared in a conventional tissue culture facility in a rotating-wall bioreactor. These devices are designed to promote cell-to-cell contacts while providing high nutrient delivery in a buoyant, low-shear environment as previously described. In order to add stability and biocompatibility to the cardiac muscle constructs for transplantation, we have chosen to use sheets of extruded collagen as the initial base substrate upon which the multilayered construct of aligned myocytes is assembled. Fig. 5A is a scanning electron micrograph of representative sheets of collagen used in the bioreactor to support the aligned cardiac cells. These sheets have considerable material integrity and an aligned orientation of fibrils that facilitates the alignment of the myocytes. We have taken these collagen substrates and coated them with our thin, aligned collagen gel templates using a soft nylon brush as described above and plated neonatal rat cardiac myocytes in a culture dish and maintained for 3–5 days *in vitro*. These substrates were then placed into the RCCS bioreactor and seeded with freshly isolated myocytes (7 million cells). The substrates were allowed to free-float or were attached to the outer wall of the RCCS. The excess cells in the reactor form aggregates, as previously described by others.^[40] We have added more cells to the construct either in the RCCS or in a culture dish. These cells add to the construct and align yielding a thicker more robust construct. To date, after adding cells to the

Fig. 4 A) SEM of template layer in cultures mixed in ground-based experiments. In regions that lack the large multicellular aggregates the template layer consists of a single layer of cells. The monolayer nature of the template layer is evident. The elongated cells of the template layer rest on a matrix of collagen fibrils. B) Scanning electron micrograph of the cultures prepared in microgravity. Myocytes exhibit an elongated rod-like shape and are distributed in multiple layers. The image depicts a cell resting on a bed of myocytes. Multiple layers of cells are visible; the underlying collagen fibrils are completely covered by myocytes. C) Scanning electron micrograph of the cultures prepared in the RCCS. The myocytes exhibit an elongated rod-like shape and are distributed in multiple layers.

construct two times, we have achieved spontaneously beating constructs as large as $18 \times 95 \times 1$ mm (Fig. 5B–D). Although cells add to the construct if it is floating, the rotation needs to be higher than when attached to the outer wall. We have experienced problems with the constructs dislodging from the wall and we are working on ways to attach the substrates more effectively. Maintaining the cultures on the outer wall and running the reactor at relatively slow rates (15 rpm) yields the best results. However, if the construct dislodges and then floats in the space between the walls, then the rotation rate necessary to allow cells to interact with the construct is much higher (30 rpm). The best results to date (Fig. 5) have been obtained with the construct on the outer wall and at a rotation rate of 15 rpm and adding cells in a culture dish for the second seeding. The whole construct appears to be contracting in unison indicating that the seeded cells are electrically connected. The construct in Fig. 5 is the largest we have made to date, but the RCCS comes with larger chambers that could accommodate larger pieces of substrate. These data suggest that bioreactors may provide the environment necessary to fabricate large-scale constructs of clinically relevant mass.

Fig. 5 A) Scanning electron micrograph of an extruded type I collagen substrate. The collagen fibrils are shown with their characteristic wavy structure. This is an example of the type of substrate used in the RCCS bioreactor. The cardiac construct seen in B–D was produced using this type of collagen substrate. B, C, and D are three still frames from a real-time video of a cardiac construct spontaneously contracting in a culture dish. The three frames are at 0, 12, and 32 seconds into the video, respectively. The construct is four weeks old and is constructed using the collagen substrate described above in A and seeded with neonatal rat cardiac myocytes in a RCCS bioreactor. The construct is about $18 \times 95 \times 1$ mm and rotates in the culture dish as it contracts. The video can be seen at: www.nyu.edu/dental/research/faculty/terracio.html. A magnification $\sim 500 \times$.

C

CONCLUSIONS

Cardiac function is intimately linked to the three-dimensional organization of the heart. Cell-based therapies designed to reconstruct dysfunctional or damaged domains of the heart, regardless of the source of the donor material, must successfully recapitulate the structure and function of the intact tissue. To fabricate a three-dimensional prosthesis that exhibits the structural and functional properties of intact cardiac tissue presents many challenges, some of which have been addressed in this article. In addition to those discussed, the tissue engineer will also be challenged with pre-adapting the construct to the mechanical environment of the heart and designing each construct to the individual patient. The field of cardiac tissue engineering is advancing at a rapid pace and these are exciting times. It is conceivable that in the near future the pathology associated with a severe myocardial infarct may be alleviated by an implanted tissue-engineered heart patch derived from the patient's own stem cells or donor myocytes grown on an artificial scaffold such as collagen.

Cartilage Regeneration

Department of Bioengineering, Rice University, Houston, Texas, U.S.A.

INTRODUCTION

Joint pain is one of the leading causes of disability for an aging population. Joint pain is normally associated with the degeneration of hyaline cartilage, a form of cartilage that lines the articulating surfaces of joints. Cartilage degeneration normally occurs because of injury or primary osteoarthritis.

Cartilage is considered a simple tissue due to its avascular, aneural, alymphatic, and nearly acellular nature; however, clinical and experimental attempts to regenerate functional hyaline cartilage with mechanobiological properties matching those of native tissue have proved to be extremely challenging. Implantation of other tissues and devices has proved inadequate to match hyaline cartilage's ability to absorb and redistribute physiological loads. Tissue engineering has recently emerged as an exciting and possible solution for providing functional restoration of hyaline cartilage. The strategy of tissue engineering aims for the regeneration of cartilage through the utilization of cells, scaffolds, chemical factors, and mechanical forces. Current research following various tissue engineering paradigms has had a variety of success levels. This article will provide an overview of articular cartilage structure-function characteristics, and will focus on current research and results for the regeneration of this vital and complex tissue.

ARTICULAR CARTILAGE ANATOMY AND PHYSIOLOGY

Articular cartilage is a specialized form of hyaline cartilage that is found in diarthrodial joints. A variety of other cartilages exist in the body, including fibrocartilage and elastic cartilage. Tissue engineering has mainly focused on regeneration of articular cartilage, which at present could stand to solve the largest number of orthopedic problems including the treatment of osteoarthritis. It is estimated that osteoarthritis alone affects 20.7 million Americans. Furthermore, osteoarthritis and other musculoskeletal disorders cost the U.S. economy nearly \$65 billion dollars per year in direct expenses and lost wages and

productivity.^[1] A full understanding of the tissue's anatomy and physiology must occur to foster the accomplishment of articular cartilage regeneration.

Articular cartilage is essential for normal diarthrodial joint function.^[2] Existing as the contact surface of joints, articular cartilage functions to transfer and effectively lessen loads from one subchondral bone to another. Articular cartilage and synovial fluid combine to form a wear-resistant and friction-reduced surface that is only a few millimeters thick. This solid-fluid nature of cartilage creates a mechanoprotective environment that is favorable for the tissue's exceptional durability.^[3]

Unlike most tissues, cartilage is avascular, aneural, and alymphatic and contains a sparse number of cells (chondrocytes) that are encased in an extracellular matrix (ECM). In articular cartilage chondrocytes constitute approximately 10% of the total volume.^[4] Articular cartilage is often considered a fiber-reinforced gel containing a fluid phase of primarily water that makes up 75–80% of the wet weight of cartilage.^[4] The remaining solid phase contains approximately 50% collagen, 30–35% proteoglycans and 15–20% glycoproteins by dry weight of tissue.^[5] These assembled macromolecules are responsible for the matrix architecture and give articular cartilage its inherent structure and properties.

Collagens constitute the major portion of the dry weight of cartilage. Type II collagen is the most abundant, accounting for 80–85% of the collagens and is a specific marker of chondrocyte differentiation.^[3,6] Type II collagen is largely responsible for the tensile strength of cartilage. Small amounts of collagen types V, VI, IX, X, and XI are also found in hyaline cartilage. The associated collagens, types IX and XI account for 3–10% of total collagen and are important for the organization and structure of fibrils.^[3]

Proteoglycans are a specific class of glycoproteins consisting of glycosaminoglycan (GAG) chains covalently attached to a central core protein. Aggrecan is the predominant proteoglycan found in articular cartilage. Aggrecan interacts with hyaluronan, an unbranched polysaccharide with a molecular weight in the millions, to form large multi-molecular aggregates that are entrapped within the collagen network.^[3,6]

Mature articular cartilage is an anisotropic material that is often classified into four distinct zones in succeeding vertical sections. Starting from the articular surface, cartilage is separated into the superficial, middle (transitional), deep (radial) and calcified zones. These zones vary greatly in structure and composition (Fig. 1).^[7]

The superficial zone composes 10–20% of the full thickness of cartilage.^[7] This zone is characterized by densely packed collagen II fibrils that are oriented parallel to the surface and chondrocytes that appear to be flattened. A high tensile strength and stiffness is imparted to this zone from the combination of tangentially oriented collagen fibrils and a high water content.^[8] The middle zone serves as a transition from the tangential orientation of the superficial zone to the radial orientation of the deep zone and contains randomly oriented collagen and more rounded cells.^[7] The deep or radial zone is often the thickest zone in adult articular cartilage. This zone has the lowest water and total collagen content, but collagen fibrils are the largest in diameter. Deep zone chondrocytes are surrounded by a pericellular matrix and are arranged in columns perpendicular to the joint surface. From the radial zone, sheets of collagen fibrils extend into the calcified zone to strengthen the bond of cartilage to bone. The calcified zone is noticeably separated from the deep zone by a plane called the tidemark and contains fewer metabolically active chondrocytes that are encased in calcified matrix.^[3,8]

The chondrocyte is the sole metabolic unit responsible for the production and maintenance of cartilage. Chondrocytes originate from mesenchymal stem cells (MSCs), which have been shown to be able to differentiate *in vitro* into a number of phenotypes.^[9] Mature chondrocytes are long-lived cells that show no detectable cell division in healthy adult cartilage. Chondrocytes exist in a low-oxygen-tension environment and preferentially maintain anaerobic glycolysis.^[4,6] Since cartilage is avascular, chondrocytes must obtain oxygen and nutrients from synovial fluid. Transport is facilitated during joint movement when compressive forces change the synovial fluid composition in cartilage.

Healthy cartilage exists in a constant state of matrix remodeling. Collagens are turned over slowly, while proteoglycans have a half-life of a couple of weeks.^[10] Chondrocytes regulate the process of matrix remodeling through the production of catabolic and anabolic growth factors and cytokines. In articular cartilage, anabolic pathways generate ECM components such as collagen II and proteoglycans. These molecules are often used as positive indicators of articular cartilage production. Catabolic pathways lead to degenerative disorders such as osteoarthritis. Production of collagen type I, interleukin-6, and nitric oxide are often indicators of osteoarthritic cartilage.^[11]

THE BIOMECHANICAL ENVIRONMENT

The interaction between the collagen matrix and large multimolecular aggregates gives articular cartilage its important physical properties. Aggrecan trapped within the network is highly sulfated and creates a fixed negative charge. This charge imbalance attracts cations into the matrix creating a high osmotic swelling pressure due to the Donnan effect. Resistance in the collagen network acts to balance the swelling property of cartilage. This swelling property allows articular cartilage to dissipate transient loads through changes in osmotic and hydrostatic pressure when fluid is transferred from loaded to unloaded areas.^[3,6]

When cartilage is placed under compressive loads, fluid flows through the porous matrix, as modeled by the biphasic theory.^[12] The application of the biphasic model yields three intrinsic properties from a creep indentation test: the compressive aggregate modulus, which indicates ability to respond to compressive loads; Poisson's ratio, which provides a measure of apparent compressibility; and permeability which quantifies the resistance to flow in the porous solid.^[2,12] The mechanical properties of articular cartilage depend on biochemical composition and anatomical location. Human articular cartilage has demonstrated a compressive aggregate modulus ranging from 0.530 MPa to

Fig. 1 Articular cartilage structure. Schematic representation of adult articular cartilage organization of matrix and cells into zones.

1.816 MPa, a Poisson's ratio ranging from 0.00 to 0.098, and a permeability ranging from $0.710 \times 10^{15} \text{ m}^4/\text{Ns}$ to $2.173 \times 10^{15} \text{ m}^4/\text{Ns}$.^[13,14] In diarthrodial joints, articular cartilage is exposed to a wide range of static and dynamic loads. During vigorous activities, stress amplitudes can rise to 10–20 MPa and cartilage compression can be up to 45%.^[15]

ARTICULAR CARTILAGE REPAIR

It is well known that articular cartilage has a limited capacity for self-repair. Numerous experimental and clinical procedures have attempted to induce or enhance the healing of focal cartilage lesions created by injury or disease. Generally, articular cartilage lesions do not heal and result in symptoms such as joint pain, locking, and disability.^[16]

The repair response to nonpenetrating cartilage defects is often minimal since no access is gained to the vascular supply. As a result, the healing response is not initiated and there is no source of progenitor cells to fill the site. Chondrocytes in the adjacent matrix are responsible for any repair that occurs. Often these cells will divide but have trouble migrating into the defect site due to entrapment in the cartilage matrix. As a result, an open defect is left in the cartilage surface, which can worsen with time and use.^[10]

Spontaneous cartilage healing is associated with defects that penetrate the bone and bone marrow spaces to gain access to the vascular supply. This allows the healing response to initiate the formation of a fibrin clot over the defect. Eventually the site will fill with a tissue that resembles hyaline cartilage in appearance. However, the cartilage is often primarily composed of fibrocartilage, which is mechanically inferior to healthy articular cartilage. This tissue is unable to function properly and degrades in a relatively short period of time.

A variety of clinical procedures for the treatment of cartilage defects have been developed including lavage and arthroscopy, shaving, debridement, Pridie drilling, microfracture, and tissue grafting.^[16] Most of these treatments have seen short-term success in the restoration of joint function and in the reduction of pain, but nothing has produced long-term, functional hyaline cartilage tissue. Of these procedures, autologous tissue grafting techniques have had the most success. Autografts can be obtained from low-weight-bearing areas in the knee and transplanted to cartilage defects. These cartilage grafts show short-term survival, however, and donor site morbidity is of concern. Similar results have been observed with autologous periosteal flaps that are sutured over penetrating defects created by drilling techniques. Excitement has been generated over a new technique named autologous chondrocyte cell

transplantation, which is employed frequently in clinical practice. This technique involves the injection of cultured chondrocytes underneath a periosteal flap that is sutured over a nonpenetrating cartilage lesion. Chondrocytes are harvested from a donor site in an earlier procedure. In the initial clinical studies, good to excellent results were seen in most patients. Upon two-year examination the repair cartilage resembled hyaline cartilage in gross morphological appearance. Longer-term evaluation is still needed to determine the function and durability of the new tissue. Autologous chondrocyte cell transplantation should not be considered a panacea since encouraging results have been observed only for the healing of focal chondral defects, not for the treatment of osteoarthritic joints.^[17]

CARTILAGE REGENERATION: APPLIED TISSUE ENGINEERING

The ultimate goal for the treatment of cartilage injuries is articular cartilage regeneration, where the neocartilage is completely indistinguishable from host cartilage. This differs from repair cartilage, where the result is a functional tissue that resembles hyaline cartilage in appearance but differs in biochemical composition, morphology, and biomechanical properties.^[2,18]

Historically the assessment of repair cartilage has been based on gross morphology and histology. More recently, the importance of determining the tissue's functional abilities has become evident. Biochemical and biomechanical properties can serve as indirect measures of neocartilage's functional ability. Quantitative measurement of collagen and glycosaminoglycan content serve as adequate means for biochemical evaluation of neocartilage. Common measurements for both use radioactive isotope incorporation techniques. Measurement of biomechanical properties is the most important evaluation of an engineered tissue's ability to function as native cartilage. An indentation test is one of the most common means of obtaining the mechanical properties of a neotissue *in vitro*.^[2] More recently techniques have been developed for *in vivo* mechanical assessment of cartilage. An arthroscopic indentation probe named Actaeon^[19] is an example that currently enjoys clinical use.

The functional restoration of damaged and diseased articular cartilage has proved to be extremely challenging. Current clinical procedures meant to repair cartilage defects often have unpredictable results. As a consequence, tissue engineering of articular cartilage has evolved as an important and possible solution to the enigma of cartilage regeneration. Cartilage tissue engineering aims to create regenerated articular cartilage through the manipulation of four main variables:

Fig. 2 Tissue-engineered cartilage. Illustration of application of the tissue engineering methodology to cartilage regeneration.

scaffold materials and structure, cell type, chemical factors (peptides and cytokines/growth factors), and mechanical forces (Fig. 2).^[7] The complex interactions of these variables make the engineering task difficult, but great strides have been made in recent years.

SCAFFOLD SELECTION

Current methods for regeneration of cartilage have concentrated on the use of biodegradable polymer scaffolds of natural and synthetic origin. The choice of material is an important consideration when designing a scaffold for *in vitro* or *in vivo* use. Scaffolds selected for cartilage regeneration *in vivo* should have several important properties. First, the scaffold should be biodegradable and bioresorbable, with degradation kinetics matching the rate of new tissue formation. The material should be nontoxic and should be non-stimulatory to inflammatory cells. Degradation products of the material should follow the same criteria. The scaffold should contain a porous network, to allow for tissue growth and diffusive transport of nutrients. Finally, the surface should facilitate cell attachment, proliferation, and differentiation of seeded cells.^[20] The *in vitro* requirements of a scaffold often are not as strict concerning biocompatibility, but are important since in the end *in vitro* studies should lead to *in vivo* work.

The mechanical requirements of an ideal scaffold often depend on whether application will be *in vitro* or *in vivo*. For both instances, the scaffold must provide the proper support structure to protect and facilitate the growth of seeded cells. For *in vivo* use, the scaffold should have good fixation to the defect site. Mechanical properties of the *in vivo* scaffold should be similar to that of native hyaline cartilage and should be able to

function under the native loading environment. A scaffold that is seeded and cultured *in vitro* does not require the same mechanical rigidity to a similar *in vivo* construct. *In vitro* constructs can be cultured for implantation for a sufficient amount of time for a mechanically acceptable tissue to form.^[20,21]

Because new materials are constantly being discovered, the mechanical and chemical characterization of biomaterials is an important field of study for cartilage scaffold materials. Many biomaterials have seen application to other cell types; in this article only the materials that have seen positive results for chondrocytes and cartilage regeneration will be discussed. For a more extensive review of scaffold materials and design see Refs. [16] and [20].

Natural Polymers

Naturally derived materials often provide superior strength and exhibit high molecular and macroscopic organization. Contrary to the popular belief that natural materials are nonimmunogenic, many natural polymers are antigenic and produce a chronic inflammatory response. Due to natural derivation, the possibility of disease transmission is also of concern. Another common problem with natural polymers is processing them to consistent grade and properties.^[22]

One of the most extensively studied natural polymers for articular cartilage engineering is collagen, specifically type I collagen. Collagens are found in many connective tissues throughout the body. Scaffolds made of collagen can be degraded and remodeled by chondrocytes to allow for tissue growth. It has been demonstrated that proliferation of chondrocytes is encouraged in collagen I gels, but chondrocytes are only able to maintain their phenotype for a few weeks before dedifferentiation into a more fibroblastic

phenotype.^[2] Success has been seen using collagen I scaffolds in conjunction with cross-linked proteoglycans.^[23] Unlike in collagen I gels, chondrocytes cultured in collagen type II scaffolds do not show signs of dedifferentiation,^[24] but unfortunately collagen II scaffolds are hard to fabricate.^[20]

Agarose is a natural derivative of seaweed that is used to fabricate gels. Cartilage constructs can be made from agarose so that chondrocytes are fully encapsulated within. Agarose gels provide a three-dimensional environment that helps maintain the chondrocytic phenotype. These constructs have been used as a vehicle for mechanical stimulation of chondrocytes and have shown positive results for matrix production. However, tissue formation may be hindered in the gel since agarose degrades very slowly both *in vitro* and *in vivo*. Unlike synthetic polymers, the degradation rates of agarose gels cannot be tailored to match that of proliferating cartilage tissue.^[20]

SYNTHETIC POLYMERS

Most successful attempts to achieve engineered cartilage constructs have utilized synthetic materials. With synthetic polymers physical and chemical properties can be modified. As a result, mechanical strength and degradation rates can be tailored to specific applications. Unlike natural polymers, there is no fear of pathogen transmission and synthetic polymers can be mass-produced with relatively reproducible properties and characteristics.

The most widely used synthetics in engineered cartilage constructs are the poly(α -hydroxy esters): poly(glycolic acid) (PGA), poly(L-lactic acid) (L-PLA) and their copolymer poly(D,L-lactic glycolic acid) (PLGA). These materials are all FDA approved for certain human implantations. In addition, these alpha polyesters degrade by hydrolysis into bioresorbable by-products.

PGA has seen wide use in medicine for some time as a suture material. *In vivo*, PGA shows a degradation time of 2–4 weeks. PGA is often extruded into small polymer strands that are molded into a nonwoven felt for use as a scaffold. Porous PGA scaffolds can also be fabricated using salt leaching techniques. Molded felt PGA scaffolds provide seeded chondrocytes with a very porous matrix (~90%) for attachment and proliferation. Unseeded PGA meshes are mechanically inferior to native tissue and require tissue formation for mechanical strength. Freed and associates have used PGA scaffolds extensively for cartilage regeneration research.^[25] Their studies have shown good production of matrix compared to controls, as characterized by measurements of total collagen and GAGs. During

tissue formation the PGA scaffolds also demonstrate suitable degradation characteristics.^[25]

Lactic acid exists in two stereo-isoforms, which give rise to four distinct types of PLA: poly(D-lactide), poly(L-lactide), poly(D,L-lactide) and poly(meso-lactide).^[26] Generally, only the semi crystalline L-PLA and the amorphous D,L-PLA are used in cartilage scaffolds. L-PLA usually shows degradation rates ranging from a few months to many years. Similar to PGA, L-PLA is often extruded into small fibers and molded into a nonwoven mesh for cartilage scaffolds. Porous L-PLA scaffolds have also been utilized for bone regeneration scaffolds.

PLGA is a copolymer of lactic acid and glycolic acid. The material properties of PLGA can be varied by the ratios of the two monomers used during polymerization. Ratios higher in monomeric lactic acid show longer degradation times. For example, PLGA that has a 75/25 ratio of D,L-PLA/PGA has a degradation time of 4–5 months, while the 50/50 ratio shows a degradation time of 1–2 months.^[27] Similar to L-PLA and PGA, the copolymer can be fabricated into felt, or as a porous, solid scaffold for use in cartilage regeneration. Athanasiou and associates have experimented extensively with 50/50 ratios of D,L-PLA/PGA showing biocompatibility and ability to carry mechanical loads *in vivo*.^[28,29]

CELLS FOR CARTILAGE REGENERATION

Cell types for engineered cartilage constructs have come from both fully differentiated chondrocytes and progenitor cells. Chondrocytes are easily obtained from freshly excised articular cartilage. Tissue is harvested from specimen joints and then enzymatically digested with collagenase to isolate chondrocytes from their extracellular matrix. Often these primary chondrocytes must be expanded in two-dimensional culture to reach the cell densities needed for seeding three-dimensional scaffolds. Interestingly, chondrocytes that propagate in monolayer do synthesize cartilage matrix. However, the tissue that forms is fibrous in nature and has poor organization. For cell expansion, often several passages are needed to reach the required cell densities. A passage is defined as enzymatic (e.g., via trypsin) release of chondrocytes from monolayer followed by subsequent reseeding at lower cell number. Two to four passages can be performed without dedifferentiation to a fibroblastic phenotype.^[18]

Mesenchymal stem cells (MSCs) are highly proliferative, multipotent cells that have shown increased use in bone and cartilage engineering. MSCs can be isolated from bone marrow and expanded in culture without loss of osteochondrogenic potential.^[9] Differentiation can proceed *in vitro* or *in vivo* and can be further

guided by the addition of growth and differentiation factors.

The importance of initial cell seeding density of constructs is important for tissue formation. Few systematic studies have been implemented to decipher optimal initial cell densities to induce cartilage formation. It has been previously observed that scaffolds seeded with densities of less than 10 million cells per mL will result in little or no cartilage tissue formation.^[18]

CHEMICAL FACTORS

Chemical modifications to tissue-engineered scaffolds have many benefits for tissue formation. Depending on the modification, such additions can aid attachment, proliferation, differentiation, and matrix production of seeded cells. Surface modifications such as protein coating and peptide attachment have been used to control cell attachment to scaffold surfaces. Growth factors and cytokines are often included to guide the differentiation, proliferation, and matrix production of cells in scaffolds.

Surface Modification

Integrin-receptor reactions mediate the attachment, spreading, and transmembrane signaling of chondrocytes on substrates. Chondrocytes express a variety of integrin subunits including α_2 , α_5 , α_6 , α_{10} , α_v , and β_1 .^[30] These integrins form heterodimers that bond to a variety of extracellular molecules. The choice of chemical modification to the surface of a scaffold requires consideration of the integrin and ligand involved.

Protein adsorption is a common method of enhancing surface attachment to a scaffold. The choice of protein coating used can greatly affect scaffold biocompatibility and can induce an immune response upon implantation. Protein adsorption is easily accomplished by choosing a hydrophobic scaffold material. ECM proteins such as collagen or fibronectin are often used as scaffold coatings. Collagen I and fibronectin have been shown previously to enhance chondrocyte attachment to surfaces.^[20]

Peptides are short amino acid sequences that are derived from larger adhesion proteins. Sequences from the active binding regions of proteins can be isolated so that only a few amino acids are required for receptor-mediated attachment instead of the entire protein. Often, peptide sequences are securely tied to scaffold surfaces using covalent bonds. A linker chain can be added to avoid steric hindrance and to provide enough clearance from the surface to allow receptor-ligand binding.^[20] The density of peptides on the scaffold surface is an important consideration because high

concentrations of peptides can decrease cell motility and therefore hinder spreading and proliferation of chondrocytes. The Arginine-Glycine-Aspartic acid (RGD) sequence is the most common peptide sequence used for cell attachment because chondrocytes have multiple integrin dimers that recognize and bind to the RGD sequence. Longer peptides that contain RGD sequences are also utilized to facilitate attachment to certain materials. Examples include sequences such as **GRGD**, **GRGDSP**, and **CGNGEPRGDTYRAY**.^[20]

Growth Factors and Cytokines

The addition of growth factors to scaffolds or areas of cartilage degeneration offer a means of enhancing cell differentiation and proliferation. Proteins such as transforming growth factor beta (TGF- β), insulinlike growth factor (IGF), platelet-derived growth factor (PDGF), hepatocyte growth factor (HGF), basic fibroblastic growth factor (bFGF), bone morphogenetic proteins (BMPs) and interleukin-4 (IL-4) alone and in combination have been experimentally shown to affect chondrocytes. The majority of growth factor–cartilage scaffold studies have been conducted in vitro where factors can be delivered and distributed through media. For in vivo application, special consideration must be made to incorporate growth factors into the scaffolds to achieve even distribution throughout the construct. Often growth factors do not have the same effects in vivo as seen in vitro due to their soluble nature as well as unforeseen interactions with the body.

Transforming growth factor- β 1 (TGF- β 1) and insulinlike growth factor-I (IGF-I) are two of the most widely researched regulatory factors for cartilage regeneration. Various studies using TGF- β 1 have found conflicting results, showing the inhibition of chondrocyte proliferation or the production of proteoglycans and collagen. IGF-I has been consistently shown to stimulate chondrocyte proliferation and synthesis of ECM molecules. A recent systematic study exposed non-woven PGA scaffolds cultured in spinner flasks to varying concentrations and combinations of IGF-I, TGF- β 1, IL-4, and PDGF.^[31] It was found that IGF-I substantially increased construct wet weights and total amounts of collagen and glycosaminoglycans (GAGs), but did not significantly change wet weight fractions of either compared to controls. TGF- β 1 was found to increase total collagen and the wet weight fraction of collagen while decreasing the amount of GAGs. The combination of IL-4 and TGF- β 1 increased construct wet weight as compared to TGF- β 1 or IGF-I alone while inhibiting GAG depletion. These results confirm previous findings that demonstrated IL-4's ability to inhibit proteoglycan degradation in cartilage.^[31]

IN VITRO CULTURE—MECHANICAL ENVIRONMENT

Chondrocytes in loaded articular joints experience a multitude of forces, including hydrostatic, compressive, tensile, and shear forces (Fig. 3). The application of these forces has been shown to be important for maintenance of the chondrocyte phenotype and for the production of cartilaginous tissue. Through the process of mechanotransduction, cells regulate transcriptional activities based on mechanical signals received at their surface. Mechanical signals can induce cytoskeletal remodeling and can stimulate anabolic or catabolic pathways in cartilage. Focal adhesions allow chondrocytes to “sense” their mechanical environment; they also provide anchorage to ECM molecules. Integrins and other constituents (e.g., cytoskeletal related proteins) allow focal adhesions to transmit mechanical forces across the cell membrane to coordinate cytoskeletal and transcriptional changes.^[32]

The biochemical and mechanical characterization of individual chondrocytes is vital for elucidation of the complex pathways influencing cartilage formation or destruction. The single-cell approach,^[33] a recently formulated methodology, offers a means of simplifying this characterization. Techniques such as cytoindentation, cytodetachment, and reverse transcriptase-polymerase chain reaction (RT-PCR) are tools to

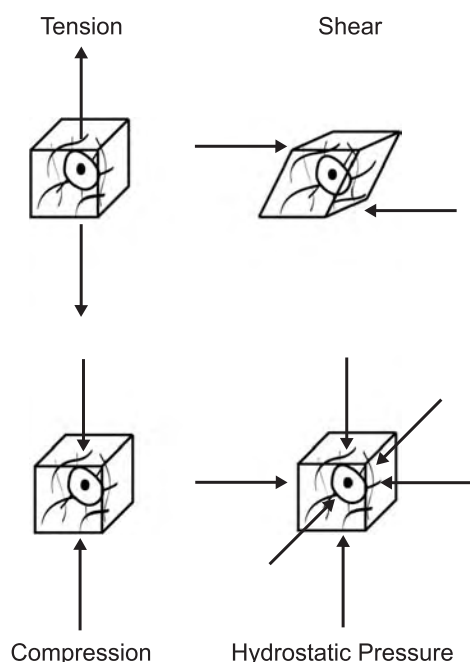

Fig. 3 Forces experienced by chondrocytes. Illustration of forces borne onto chondrocytes through matrix and fluid interactions in articular cartilage.

decipher the effects of forces on single chondrocytes. More information on cell mechanics of chondrocytes and the single-cell approach can be found elsewhere.^[33]

In vitro culturing conditions for cartilage should mimic the mechanical environment of native hyaline cartilage to induce proper tissue formation. In general, constructs exposed to extraneous forces show increased proliferation and production of matrix. Several methods have been employed to offer mechanical stimulation to chondrocytes in vitro. These methods can be grouped into three categories: those that use hydrostatic pressure, direct compression, or shear as the biomechanical stimulus. For a more complete review of mechanical culturing of cartilage see Ref. [11].

Hydrostatic Pressure

During joint articulation, synovial fluid inside the joint capsule generates hydrostatic pressure as a result of resistance to flow in the cartilage matrix. As a result chondrocytes experience hydrostatic pressure during periods of loading. During regular activity, the interstitial pressure within a normal diarthrotic joint cycles between 7 and 10 MPa.^[34] As part of an in vitro tissue-engineering approach, cultures are placed in chambers to expose cell-seeded constructs to hydrostatic pressure. Often the pressure is cycled at a prescribed frequency and at physiological loads to mimic the host environment of cartilage. Loads between 0.1 and 15 MPa and frequencies between 0.05 and 1 Hz have generated positive results in chondrocyte cultures compared to controls.^[11]

Direct Compression

Compressive forces are generated within the articular joint due to surface-to-surface contact. During joint loading, cartilage is compressed as forces are distributed throughout the matrix. Direct compression bioreactors have been utilized to expose cartilage constructs to compressive forces during culturing. A variety of designs exist, but all use a similar mechanism that involves the translation of a flat surface onto the top of a construct, under load or displacement control. Dynamic compression, unlike static compression, has proved to be effective for stimulating cartilage formation in constructs. Studies have produced positive results for cartilage regeneration, but were often limited by the machinery used. Experiments have examined frequencies ranging from 0.001 to 3 Hz, loads from 0.1 to 24 MPa, and strains from 0.2 to 25%.^[11]

Shear Forces: Bioreactors

The use of bioreactors is the most common way of culturing cartilage constructs in a shear environment. Beyond the mechanical environment, bioreactors provide mixing of media for more efficient nutrient transport and waste removal. Some of the bioreactors used for the *in vitro* culture of chondrocyte-seeded scaffolds include spinner flasks, perfusion bioreactors, and rotating-wall bioreactors.

Spinner flasks are the simplest type of bioreactor used for culturing cartilage constructs. Usually scaffolds are attached to needles that hang from a stopper. Media circulation is facilitated through gentle mixing by a magnetic stir bar. Cells are normally added to the media and are allowed to attach on their own to the scaffolds. Spinner flasks are often used as a means of seeding scaffolds with chondrocytes before transferring the constructs to more complex bioreactors.^[25]

Direct perfusion reactors offer a means of reducing shear gradients in a culture environment and eliminating mechanical mixing. Mass transfer is achieved by a simple design that forces media through fixed scaffolds. The bioreactor usually consists of a hollow vessel where media enters one end and exits out the other. Fresh media can be constantly supplied, but research has shown that recycling of media can encourage tissue growth by retaining the extracellular proteins (e.g., growth factors and cytokines) produced by growing chondrocytes.^[11] The cells in three-dimensional perfused cartilage scaffolds experience shear forces, which have been shown to up-regulate matrix production. Perfusion studies have demonstrated mixed results for culturing of cartilage constructs. Using direct perfusion, Pazzano and colleagues demonstrated an increase of 118% in DNA content, an increase of 184% in GAG content, and an increase of 155% in hydroxyproline incorporation (measure of collagen synthesis) compared to static culture.^[35] Alignment of chondrocytes to the direction of flow was also observed. Perfusion bioreactors are also able to align collagen fibers and thus offer a method of influencing cartilage matrix architecture.

The most promising overall results for culturing cell-seeded cartilage scaffolds have come from rotating-wall reactors. These reactors are a modification of the perfusion design that instead offers a low-shear environment. The rotating-wall reactor was originally developed by NASA to simulate the effects of microgravity on cell culture but has found application for the *in vitro* culture of cartilage constructs.^[11] The design consists of concentric cylinders with adequate space for media and scaffolds to be placed in between the walls. Normally the outer wall of the reactor rotates, thus providing shear force and facilitating fluid flow inside. Indirect perfusion systems are often added as a means

of replacing the media. Results from rotating-wall cultures have shown higher fractions of collagen and GAGs compared to mixed flasks and static culture. Freed and associates found that bovine chondrocyte-seeded PGA scaffolds cultured in rotating-wall reactors produced 68% as much GAGs and 33% as much collagen II per gram wet weight as compared to natural calf cartilage.^[25] The neotissue generated in the constructs produced morphologies that approached that of native articular tissue, which has not been seen in other bioreactors or culturing conditions.

CONCLUSION

Full regeneration of cartilage is the best solution to the problem of cartilage damage caused by disease and injury. Tissue engineering is poised to offer the best approach of achieving cartilage regeneration through the selection and manipulation of four main variables: cells, scaffold, chemical factors, and mechanical environment.

Successes of current research have demonstrated the feasibility of the tissue engineering paradigm for the achievement of cartilage regeneration. There is an important need for cartilage regeneration, which currently cannot be accomplished with clinical procedures in a consistently successful manner. This solution is still not attainable, because there is still much knowledge and experience to be gained before fully functional cartilage can be created.

Cell Culture Assays

P. J. Doherty

Department of Clinical Engineering, University of Liverpool, Liverpool, United Kingdom

INTRODUCTION

Biomaterials science has developed very rapidly in recent years and has now achieved a high level of sophistication in terms of research, manufacture, and testing. Every new biomaterial, whether selected for implantation or to be used externally in contact with the human body, undergoes an extensive array of testing using a diversity of techniques. Increasingly, in-vitro test methods are playing a significant role. Appropriate selection of testing methods can fundamentally assist in the research and development of biomaterials. Although animal-testing procedures (in-vivo testing) remain valuable and are still the most widely employed and dependable means of biological assessment before clinical trials, the quantity of animal testing has been restricted in recent years. This is partly because the huge increase in the use of artificial materials in the body has been accompanied not only by an increase in the required legislation, but also by an increase in public concerns about the use of such materials and about the appropriate use of animals.

In-vitro cell culture techniques have been proposed for many years as an alternative to animal testing. Although such a suggestion remains controversial, it is certainly true that the effective use and sophistication of the cell culture test has improved. The application of cell culture assays in the field of biomaterial evaluation has developed alongside the significant use of cell culture in drug toxicology studies, and the potential for replacing animal studies is ever closer. New techniques in cell biology and cellular genetics will continue to provide in-vitro assays that are more relevant to in-vivo and clinical situations. Nevertheless, it is also true that much of the cell culture testing carried out and reported today is not useful and may indeed be misleading.

The primary purpose of the ISO standard 10993 “Biological Evaluation of Medical Devices” is the protection of humans. Part five of the standard deals with ‘Tests for cytotoxicity—in vitro methods’ and presents guidelines for the evaluation of toxicity. Although toxicity testing is not the sole function of the cell culture test, it is the increase in toxicity tests for biomaterial evaluation that has led to the plethora of in-vitro cell culture testing employed in the biomaterials field today. These include testing regimes that attempt to

measure cytotoxicity, cytocompatibility, cell adhesion, genotoxicity, haemocompatibility, cell proliferation, and a host of other measurable cell parameters.

BACKGROUND

The use of cell culture testing for biomaterial evaluation has relatively recent origins, despite the fact that we have had the ability to culture living cells outside of the body for a much longer period of time. The development of cell culture for fundamental biological investigations can be divided into three phases.^[1] The first, up to 1838, was mainly concerned with the definition and hypothesis of cell origin and form. The second, from 1838 to the beginning of the 20th century, was relatively inactive; in-vitro techniques had been demonstrated but proved difficult to master. The work of Harrison in 1907,^[2] and Carrell in 1912^[3] confirmed these researchers as the initiators of the cell culture techniques that are employed today. Although tissue and cell culture methods developed from that time, problems of infection and contamination from bacteria and fungi meant that the potential benefits offered by these new techniques were limited to specialist workers.

The discovery of antibiotics, the introduction of the laminar airflow cabinet, and the development of synthetic culture media during the 1950s and 1960s has transformed the use of this valuable biological tool and has allowed researchers from a diversity of backgrounds to employ the techniques of cell culture successfully.

The terms tissue culture and cell culture are often used to describe the same processes. The original studies of Harrison and Carrell employed small biopsies of tissue or embryo from which discrete cells propagated. Most in-vitro testing today employs cloned cells and is properly named cell culture. In 1961, Hayflick and Moorhead^[4] carried out studies on the life span of cells in culture and stimulated subsequent interest in the development of continuous cell lines. These continuous or established cell lines became commercially available and led to biological test methods that introduced a degree of uniformity and standardization (Figs. 1 and 2).

The advantages of using cell culture tests in biomaterial evaluation are numerous. A significant saving of time and money is possible when compared with

Fig. 1 Optical photomicrograph showing normal murine L929 fibroblast cells, following methylene blue staining. The plasma membrane and nuclear membrane are clearly visible and the nuclear contents can be observed. Cell mitosis is also in evidence. This is an example of normal fibroblast cell line culture (original magnification $\times 200$).

the same material evaluation carried out *in vivo*. The numbers of animals required can be greatly reduced. A huge range of cell types can be employed *in vitro*. These include the use of human cells and other animal primary cell lines. The test environment can be carefully controlled and monitored. The exact composition of the test sample is known (or should be known) and can be altered at any stage in the procedure. The duration of

Fig. 2 Optical photomicrograph showing rounded murine L929 fibroblast cells, following methylene blue staining. Cell spreading has been inhibited following contact with a biomaterial substrate. This is an example of a reversible cellular effect (original magnification $\times 200$).

contact with cells is also easily controlled. The effect on the cells, induced by the test material, can be observed by microscope or quantified by cell counting or biochemical measurement of another cell parameter. A rapid result can be obtained if required. The potential for transfer of cell lines between laboratories allows for greater reliability in testing and the opportunity for standard testing.

It is easy to identify many differences between the *in-vitro* environment and the behavior of a cell *in situ*, and this provides the argument for the many skeptics who view cell culture as at best an inadequate alternative to animal testing and at worst an ambiguous and misused biological tool. However, many cell functions can be demonstrated and challenged in culture, and, as long as the limitations of the techniques are recognized, *in-vitro* testing will continue to prove a valuable resource in biomaterial evaluation. The methodology of culturing cell lines and deriving and culturing primary source cells is well established and many protocols are available.^[5]

A Confusion of Terms

The term biocompatibility is often associated with cell culture testing of biomaterials. In many cases simple *in-vitro* test methods have been employed with a potential biomaterial as the test sample. If a positive result is obtained, *i.e.*, the cells remain viable, the material is labeled biocompatible. If the cells die or are significantly adversely affected, the material is labeled nonbiocompatible. This is a serious misuse of the term biocompatibility and a misuse of the *in-vitro* test.

Biocompatibility is not the result of a single event or phenomenon. It refers to a collection of processes involving different but independent mechanisms of reaction between a material and its host tissue. Biocompatibility refers to the ability of a material to perform function. The ability to perform and to continue to perform this function depends not only on its interaction with tissue but also on the intrinsic mechanical and physical properties of the material. The definition of biocompatibility^[6] refers to appropriate host response. It does not stipulate that there should be no response. This may be a minimal response or indeed a more aggressive response. The definition refers to specific application. Biocompatibility should always be described with reference to the situation in which a material or device will be used. No material should be described as biocompatible without further qualification. Biocompatibility, therefore, is not an intrinsic property of any material. The majority of *in-vitro* tests employed in biomaterial evaluation measure cytotoxicity. However, lack of toxicity cannot be equated with biocompatibility. Cell culture assays are not biocompatibility assays.

BIOMATERIAL TESTING

Using cell culture to evaluate the effects of drugs was already a well-established procedure in the 1960s when such testing was first used to examine biomaterials. The studies of Rosenbluth^[7] and Guess^[8] detail the development of the agar overlay assay. A refined and standardized format of this test is presented by Autian^[9] as part of a structured program of biomaterial evaluation. The agar overlay test remains widely employed and reported today despite a number of significant limitations. These include the presence of the agar as a barrier between cell and test sample leading to a subsequent reduction in sensitivity. The test model itself provides an essentially nongrowing culture of cells that is incapable of revealing selective effects on the cell cycle. There is uncertainty in ascertaining an end point, although this is true of many of the cell culture tests in use today. No account is taken of lesser injury indiscernible by vital or nonvital staining. Nevertheless, it should be noted that the agar overlay test formed part of the earliest attempts to introduce a degree of uniformity and standardization to in-vitro biomaterial evaluation. This was true not only for the test procedure itself, but also in attempts to introduce an effective means of subsequent evaluation. The agar overlay test formed the foundation for the variety of in-vitro screening tests that are employed today in biomaterial evaluation and is one of the recommended test methods described in the relevant ISO standard.^[10]

Standards

The safety evaluation of medical devices is generally based on in-vivo testing and evaluates acute and chronic toxicity and inflammation, irritation and sensitivity, carcinogenicity and mutagenicity, allergic responses, haemocompatibility, and systemic toxicity. It is not possible to assess all of these factors using in-vitro assays; however, test models have now become established that permit the in-vitro evaluation of acute toxicity, genotoxicity,^[11] haemocompatibility,^[12] necrotic cell death, and apoptosis.^[13]

The introduction and development of in-vitro testing has raised many concerns with respect to reproducibility and proper regulatory control. The establishment of new in-vitro assays requires three steps: development, validation, and acceptance. Acceptance of in-vitro assays involves satisfying the regulatory bodies, the manufacturers, and the users. At present there are few, if any, properly validated in-vitro tests.^[14]

International standard ISO10993, part 5 was developed as the result of a harmonization of various existing standard procedures and the outcome reports of working groups. The standard acknowledges the

widespread use of in-vitro cytotoxicity testing and defines a scheme for testing that allows the user to identify the most appropriate test procedures. These tests specify the incubation of cultures of mammalian cells with the medical device or component part of the device (i.e., the direct test method) or with an extract derived from the device (i.e., the indirect test method). Tests using agar diffusion and filter overlay are also detailed here. Information is provided on appropriate test sample preparation for direct testing and the most appropriate means of producing extracts for indirect testing is presented in some detail. The standard provides details on a number of recommended established cell lines, although these are not exclusive. The standard further provides details on how cytotoxicity may be most appropriately determined. This evaluation is categorized as follows:

1. Assessment of cell damage by morphological means.
2. Measurement of cell damage.
3. Measurement of cell growth.
4. Measurement of specific aspects of cell metabolism.

This standard notes that evaluation may be by qualitative or quantitative means. It should also be noted that the standard does not present a single in-vitro method for cytotoxicity evaluation but allows the user to select an appropriate range of tests. Furthermore, at no point does the standard use the term biocompatibility in connection with this type of test. Another important aspect of the standard is the reference made to negative and positive control materials that should be employed in all test systems.

Replacement of animal testing should not be the objective of in-vitro assays, and an appropriate use of both in-vitro and in-vivo testing is the most sensible approach to biomaterial evaluation. Simple in-vitro assays can provide screening information and play a significant role in the early phase of investigation. Subsequent studies should employ more specific in-vitro models in parallel with animal studies. This level of testing should include the use of human cell lines.

Screening Tests and Cytotoxicity Testing

The test procedures identified in ISO 10993, part 5 are designed to evaluate cytotoxicity. The primary goal of such tests is to determine safety. As such, these can be considered screening tests for use in the development and research of novel materials and for the quality control of medical devices (both component parts and final products). Even at this simple level of testing relevant information can be garnered with respect to the final use of the test material. However, the user must be careful to appreciate the simplicity of such

testing. For example, it is prudent that any cytotoxicity evaluation should employ more than one cell line and where appropriate and possible make use of human primary cell lines. Even simple screening tests can benefit from some level of quantification where this can be sensibly applied. Although ISO 10993 does make reference to the use of subjective, semiquantitative grading systems based on microscopy observations, these will rarely produce any meaningful data and do not easily allow for the comparison of data between different laboratories or indeed different users. Qualitative, descriptive assessment of cell morphological changes by an appropriately trained individual remains a more meaningful technique. However, quantification using measurements of cell metabolic functions are readily employed and can provide accurate and reproducible data easily transferred between researchers. These include cell-counting procedures, both manual and automatic, assessment of DNA levels,^[15] or the determination of cell activity by the 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazoliumbromide (MTT) assay.^[16]

Specific Testing

Cytotoxins may have reversible or irreversible effects, which may be immediate or delayed. Toxic effects do not always result in cell death. A cytostatic cell response is often reversible and may be the result of deprivation of a nutrient or growth factor or the presence of a negative growth regulator.^[17] Establishing an appropriate end point for cytotoxicity studies is difficult as there is often no clear boundary between cytotoxic effects that will lead to cell death and other discernable but potentially irreversible effects. There is no single in-vitro test available that will supply all of the information required to assess a potential biomaterial.

The earliest in-vitro test was the Salmonella test for mutagenicity developed by Ames.^[18] This remains the established in-vitro procedure for evaluation of the potential mutagenicity of materials. In recent years a number of more sophisticated and hopefully more reliable test procedures have been introduced. Most cytotoxicity screening tests employ established cell lines. However, it is clearly possible to employ primary cell lines, in many cases cells derived from human source, as the basis for in-vitro tests. The introduction of primary cells and the development of methods of evaluation that provide information on aspects other than cytotoxicity may be considered a step beyond the simple screening tests detailed and recommended in ISO10993. Primary cell lines can provide cultures that are close to the biological nature of the tissue of origin. However, subculture of primary cells can be achieved for only a limited time period before the artificial culture conditions stimulate a

change in cell phenotype. Finite cell lines are generally restricted to fibroblasts and have, as the name suggests, a limited life span. The use of continuous culture i.e., a cell line that has the capacity for infinite survival, overcomes these deficiencies. Yet, continuous cultures are often derived from tumors and may not express the characteristics of the original tissue.

Although aspects of cytotoxicity remain relevant, it is appropriate to consider other cell parameters that in-vitro testing can challenge, e.g., cell adhesion, cell spreading and orientation, cell proliferation and metabolic stimuli, cell activation, and cell and tissue engineering.

Cell adhesion is an extremely important factor to assess when considering biomaterial performance. In the majority of cases cell-material adhesion is a positive and required property, and many studies on implant materials are designed to improve the degree of cellular adhesion. However, cell adhesion may be an undesirable property for a number of medical device applications. It may also be possible to design biomaterials such that they are selective in allowing cells to adhere, and in-vitro assays are ideal research tools for such studies.^[19]

Cell motility and spreading, which involves cell cytoskeletal reorganization, the establishment of focal contact points, and the response of cells to physical features on the biomaterial substrate are other areas of considerable interest to the biomaterial scientist^[20,21] with respect to cell guidance and tissue engineering applications.

A measurement of cell proliferation is widely used to determine the response of cells to biomaterial contact. Proliferation can be quantified by manual cell-counting techniques (haemocytometer) or electronic counting. Electronic methods are rapid and have lower inherent error compared to manual methods. Also, counting can be prone to misinterpretation as cell clumps and cell debris may be counted indiscriminately. Fluorescent or antibody labeling are now routinely used to determine cellular constituents and these methods allow for accurate quantification by flow cytometry.^[22]

The MTT test is now widely in use for biomaterial evaluation. It is a quantitative measure of the metabolic activity of cells that measures the activity of the mitochondrial enzyme succinate dehydrogenase. The test relies upon the reduction of the tetrazolium salt component of the MTT to formazan, an aqueous insoluble compound. Using an appropriate solvent, the quantity of formazan can be determined by spectrophotometry. It is important to note that the MTT assay cannot distinguish between cell loss and metabolic inhibition. Furthermore, stringent controls must be employed when examining short-term cultures.

Most viability assays rely on damage to the integrity of the cell membrane. This is readily examined by

measuring the ability of the cell to uptake or exclude dyes such as methylene blue or neutral red.

It should be noted that there are a large number of test models available. Users should take care that they select methods of testing that are most likely to provide the information desired. In-vitro testing must be employed in such a way as to provide a rigorous examination of the material under test.

Meaningful evaluation of the results obtained is undoubtedly the major challenge with any cell culture test system. Ideally the test should have an evaluation program that is easily and reliably repeatable. The difficulty lies in producing an accurate method of quantitatively evaluating the effect a material may have on the cells, such that the test produces a meaningful result. Cell culture testing should of course be only one stage in any biocompatibility evaluation and the results obtained from such testing should not be used alone to make a judgement about a material. However, there are a number of factors that can be taken into account in order to maximize the usefulness of these tests.

Measurements of pH are easy to make but may not provide a great deal of useful information. Cells are initially incubated in a buffered environment. In a static system a normal rise in cell population will inevitably lead to a fall in pH levels. Some test materials will cause a rapid and deleterious change in pH levels leading to cell death. However, in the static and highly sensitive test system this may not be a relevant measure of cytocompatibility.

Cultured cells are prone to genetic instability. This is clearly demonstrated as primary cell cultures undergo dedifferentiation in culture. Continuous cell lines may

Fig. 3 Scanning electron micrograph showing murine L929 fibroblast cells cultured within a three-dimensional polyether (urethane) biomaterial scaffold. The cells are demonstrating an altered morphology; however, viable cells proliferate within this structure for time periods in excess of 20 weeks (original magnification $\times 200$).

produce a cell population that is significantly different from the source tissue. Cell cultures also lack the cell–cell and cell–extra-cellular matrix interactions of tissue, which are required to define phenotype. However, the significant developments made in tissue engineering in recent years have seen the creation of three-dimensional cell constructs, usually with biomaterial scaffolds in which the cell–cell and extra cellular matrix contacts are developed and maintained (Fig. 3).^[23]

In recent years an examination of cell adhesion molecules (CAMs) and cytokines, regulators of immune and inflammatory responses, have routinely been used as markers of cell activation and potential cytocompatibility.^[24]

REQUIREMENTS OF THE IN-VITRO TEST

Three types of in-vitro assay are generally available. Short-term assays of viability, long-term assays measuring cell survival, and intermediate assays that measure cell proliferation or a cellular metabolic parameter as a measure of viability or toxicity.

The disadvantage of viability assays is that they often overestimate cell survival and are often subjective. Growth curves can be used to compare cytotoxic effects or growth inhibition. It should be noted that cell numbers at any specific point of time are dependent on many factors including the lag phase of the cell population, the initial cell inoculum, the effect any toxic insult has on an initial inoculum, and the doubling time of the cell line.

There are two basic approaches to in-vitro testing when employed in the evaluation of biomaterials. One is to determine the potential for a negative effect on the cells. This is the way most in-vitro testing is employed. This is particularly true of the identification of cytotoxic or mutagenic effects. However, it is increasingly true that biologically active medical devices are designed such that they have a positive and beneficial effect on cell growth or cell repair. In-vitro testing can readily be employed to monitor this.

If the in-vitro test is to be presented as a viable supplement as well as an alternative to animal experimentation, there are a number of requirements it must satisfy. The most obvious and widely quoted is a reduction in cost and time. However, there are other requirements that must be taken into consideration. Dividing and metabolizing cells must be in contact with the material or an appropriate extract of the material under test. This is not the case with the often-quoted agar overlay test. The test method must be easily and reliably repeated, and there should be a simple and rapid means of evaluation. Such testing can be readily carried out; however, tests should not be used to simply indicate pass or fail. Where possible an

accurate quantitative means of recording results should be employed.

LIMITATIONS OF THE IN-VITRO TEST

Throughout cytotoxicity testing procedures for bio-material evaluation, the major disadvantage in the use of cell cultures is the difficulty in interpreting the results obtained in a clinically significant manner. The objective is to provide meaningful results. Although test samples can be examined in contact with human primary cells, the response of such cells cannot be assumed to be the same as the response produced by cells that are part of the human body. Complex interactions and responses are absent during these tests. An often cited criticism of cell culture testing is that it is too sensitive. This is the result of the relatively static conditions that normally exist in the Petri dish. These conditions exclude the detoxification pathways provided in the body by the kidney and liver. When operating cell culture assays, a number of practical problems may be encountered that will affect the way the test procedure is evaluated. In many cases, cytotoxicity is encountered as a result of substances leaching from a bulk/solid material. Test samples may not be homogeneous in nature, and substances may leach at different rates from the same sample. It is usually necessary that a device is broken down into its constituent parts for cytotoxicity testing. These individual component parts should be examined individually and in combination. Occasionally, a nontoxic or inert material is produced through the combination of two or more toxic or volatile constituents. In such a case it must be established that, under the conditions in which the device will be used, there is no likelihood of the device breaking down into its constituent parts. To satisfy this requirement the device should be examined under a variety of extreme conditions. Normally, however, materials can readily be examined as components of a final product.

When examining a number of test materials it is important to ensure that, as far as possible, the test conditions are the same for all materials. It is not difficult to ensure that there is no significant difference in the number of cells added to each test well or dish; however, the manner in which cells are added can have a significance that is often overlooked. Cells may be added to the tissue culture dish before the addition of the test material. A suspension of cells may be introduced to the dish and test materials at the same time. Cells may be added exclusively to the surface of the test material. The consequences of each technique should be considered when evaluating cellular response.

One of the most significant disadvantages of the agar overlay test method is the presence of agar in the

test environment. However, many direct contact test methods employ some form of adhesive or anchoring material. The presence of a third party in the test system will have a considerable significance on the response of cells. This can be true even with the use of commercially available tissue culture polystyrene dishes.

Contamination by bacteria and fungi is the most commonly encountered hazard in the cell culture laboratory. Despite the use of laminar flow cabinets that provide a sterile working air flow and the presence of antibiotics in the culture medium, proper aseptic technique is essential. It is appropriate that cell laboratory workers be appropriately trained and follow strict operating procedures. The media used for the cultivation of mammalian cells in culture provide perfect growth conditions for the majority of bacteria and fungi. Most of these organisms will grow more rapidly than the animal cells, whose environment they have invaded, and will eventually create conditions toxic to the cells. Contamination in a laboratory can rapidly spread and wipe out entire stocks of cells. The most obvious means of avoiding contamination is to ensure that there are no unwanted organisms present at any stage of the procedure. This is achieved by good aseptic technique and by following proper sterilization procedures.

Test materials from devices, which are normally supplied nonsterile but are sterilized before use, should be sterilized by the method recommended by the manufacturer and subsequently handled aseptically throughout any extraction or direct contact testing. The effects of sterilization methods on the material or device must be considered. Any material introduced into a cell culture environment should be sterile, via heat treatment (steam/dry), gamma irradiation, or gaseous ethylene oxide.

Safety

The fact that primary cell cultures are capable of propagating viral contaminants means they should always be considered potentially infectious.^[25] It is important that researchers involved in the culture of cells in vitro, particularly primary cell cultures, be able to adequately assess the risks involved and take the steps required to provide appropriate protection. A guide to the relevant risk assessment is provided by Jones.^[26]

CONCLUSION

In-vitro testing is now widespread and becoming ever more complex and sophisticated. Developments in cell biology and genetics and the significant deployment of

cell culture testing in toxicology studies are advancing such test methods ever closer to the day when they may effectively replace animal testing. At present, however, this is not the case, and it is not likely that *in vitro* will replace *in vivo* in medical device evaluation in the foreseeable future. Indeed, it is apposite that in the majority of cases *in vitro* will not replace but supplement animal testing.

The simplest form of *in-vitro* models in biomaterial evaluation is the commonly used screening tests that, by an assortment of means, measure cytotoxicity. More specific test methods are available. These may make use of human cell lines, primary cell lines, and testing regimes that challenge the medical device or biomaterial in an environment that simulates much more closely the intended clinical application. Great care must be taken in the evaluation of all *in-vitro* test methods, and the significant limitations must be considered during any means of evaluation. *In-vitro* testing should be only one stage in a program of biomaterial evaluation. Cytotoxicity tests do not assess biocompatibility and should not be used to do so.

Cell-Material Interaction

Aditya Chaubey

Karen J.L. Burg

Department of Bioengineering, Clemson University, Clemson, South Carolina, U.S.A.

INTRODUCTION

The fate of any biomedical device depends on its initial contact with the surrounding tissue, because proteins start adsorbing on its surface within seconds. The intrinsic property of the material, including its chemistry, governs the quantity and orientation of the protein that is adsorbed on its surface, which, in turn, regulates the performance of the device. Hence, to successfully create a clinically viable cell-based device, the initial interaction between the material and the cells must be understood. Although much progress has been made toward better understanding this process, there are still many issues to resolve before whole organs can be developed.

Biomaterials have evolved from inert materials solely providing mechanical support and function to materials that actively elicit a response from the surrounding tissue. As such, polymeric biomaterials are key components in cell-based devices, providing support and direction for proliferating cells. Both the bulk and the surface properties differently affect the nature of a polymer; hence, surface modification is used to modulate the surface properties to control the proliferation and differentiation of cells.

BIOMATERIALS: A BASIC INTRODUCTION

Organ transplantation is currently a standard clinical treatment for patients suffering from permanent organ failure. The practice of transplanting organs has existed for many decades and, with the considerable improvement in surgical techniques and immunosuppressive drugs, has become a viable clinical option. However, the biggest problem associated with organ transplantation is that the demand for organ replacement far exceeds the available supply; the difference will only increase with time. Tissue engineering in the past decade has emerged as a key technology in the potential regeneration of whole organs.

One form of tissue engineering involves harvesting healthy cells from a patient's body, culturing those cells in vitro, seeding them on an absorbable scaffold, and then implanting the cellular construct into the patient's body. The scaffold directs the cells to form tissue, while slowly absorbing. A more formal

definition of tissue engineering is “application of the principles and methods of engineering and the life sciences towards the fundamental understanding of structure–function relationships in normal and pathological mammalian tissues and the development of biological substitutes to restore, maintain or improve tissue function.”^[1] The most crucial aspect for the success of a tissue-engineered device is the interaction between the cells and the scaffold material onto which the cells are seeded. In these unique devices, biomaterials serve to provide three-dimensional, structural environments for the cells. Tissue engineering scaffolds should encourage proliferation and differentiation of the particular cell type and should be designed with the local implantation site in mind.

Biomaterials were traditionally defined as materials that could be implanted in the body to perform a specific function and interact in a defined, positive manner, ideally causing minimal tissue reaction. The earliest hip implants, for example, were made with smooth surfaces from chemically nonreactive materials like titanium or stainless steel. These materials fulfilled their desired function and were termed “inert” due to the low level of associated foreign body response.^[2,3] The lack of normal tissue in growth, due to implant smooth surface textures, resulted in high rates of component loosening and bone absorption, highlighting the need for improved implant fixation.^[4,5] These early failures led to the use of implants with microporous surfaces, which offered better stabilization at the bone–implant interface by allowing bone ingrowth. The observation that a material could actively encourage the surrounding tissue to act in a specific and desired way led to a change in the direction of the biomaterials industry and also a new definition of “biomaterial.” Hence, a biomaterial can be defined as any synthetic or natural material that is implanted in the body and elicits a specific reaction from the body at either a local or a systemic level. This revised definition marked an increased effort to understand the interaction between an implant material and surrounding tissue.

BIOMATERIALS CLASSIFICATION

The majority of biomaterials can broadly be separated into three classes: metals, ceramics, and polymers.

Polymers can be subdivided into synthetics or naturally derived plastics, which can be further subclassified as absorbable/degradable or nonabsorbable. Common metals used as implants include titanium, stainless steel, and other alloys. Metals are most commonly used for load-bearing applications, although they are also sometimes used in other devices requiring high mechanical integrity, like stents. Issues of note with metal implants include wear, corrosion in the body environment, and the release of metal ions in the body. Bioactive ceramics like calcium phosphate ceramics and bioactive glasses avoid these problems. The surface of a hip implant, for example, may be coated with bioactive glass to form a thin layer of calcium phosphate. This layer of calcium phosphate stimulates the adjacent bone cells to form new bone,^[6] and thus, in accordance with the contemporary understanding of biomaterials, plays an active role in inducing a favorable reaction from the body. The third class of biomaterials is polymers; polymers are increasingly finding more use in a wide variety of applications, including scaffolds in tissue engineering applications. Some of the most common synthetic polymers used are polyurethanes (used to form pacemaker leads), poly(2-hydroxyethyl methacrylate) (pHEMA; used to form contact lenses), poly(L-lactide) (PLL), polyglycolide (PG), and poly(lactide-coglycolide) (PLG; used to manufacture sutures and drug delivery vehicles). PLL, PG, and PLG are absorbable, which makes them very attractive for tissue engineering applications. PLL, PG, and PLG are among the best characterized absorbable polymers and are used extensively in a variety of clinical applications. Because many variables govern the interaction between a cell type and a biomaterial, a complete characterization of the bulk and surface properties of a biomaterial is absolutely necessary for a thorough understanding of the interaction between the two.

EFFECT OF MATERIAL PROPERTIES ON CELLS

The interaction between a material and the surrounding tissue depends on a number of material properties, such as the material wettability, surface chemistry, rigidity, and topography. This interaction can be visualized in terms of cell functions like attachment, locomotion, proliferation, and differentiation. Wettability of a surface can be measured as a function of contact angle and is an indicator of surface energy of the material. Materials with a high surface energy (for example, ceramics and metal oxides) have high affinity for serum proteins, the presence of which in turn increases cell attachment.^[7] In the absence of serum proteins, cell attachment is enhanced on positively charged surfaces. Materials having an

intermediate wettability are most often best suited for cell attachment. The rigidity of a material surface also exerts an influence on the attachment of cells. Generally speaking, so called “anchorage-dependent” cells require a solid substratum for growth and maintenance of function. Many anchorage-dependent cells do not proliferate and, instead, retain a rounded shape on materials with very low modulus, such as hydrogels. The texture of an implant material is also an important parameter in determining its success and is designed according to the intended application of the implant. A rough surface increases the overall surface area of the implant surface and hence provides more potential for cell attachment; however, the effect of texture is dependent on the cell type. For example, it has been demonstrated that whereas fibroblasts prefer smooth surfaces for attachment, macrophages prefer relatively rougher surfaces, a phenomenon termed rugophilia.^[8] The roughness of an implant surface can also alter the affinity of cell types to hydrophobic and hydrophilic surfaces. The geometrical configuration of an implant influences its biocompatibility by determining the level of development and orientation of the capsule formed as a result of the normal foreign body response. An implant with sharp corners, for example, induces higher inflammatory activity around the corners, with the eventual preferential formation of a thick, dense capsule at these regions.^[2,3,9] Excellent review articles in the literature overview various surface properties and their effect on the cellular response. Properties/responses reviewed include surface energy,^[10] surface charge, and cell spreading.^[11]

Three-dimensional scaffolds are meant to provide support to the cells or tissues by providing an appropriate three-dimensional architecture. Additionally, these scaffolds can be tailored to provide proper cell adhesion and proliferation, which in turn will promote better signaling pathways, consequently leading to better incorporation of the cell-material construct in the body. Surface modification has emerged as an important tool to modulate surface properties and render materials more attractive to any particular application. For example, it has been demonstrated that when tissue-culture polystyrene (TCPS) is coated with pHEMA, cell spreading decreases with increasing amounts of pHEMA^[12]; however, when pHEMA is treated with sulfuric acid, cell spreading is greatly enhanced. Cell adhesion and spreading are similarly increased when TCPS is treated with glow discharge or radiofrequency plasma deposition. It is believed that surface modification primarily increases the adsorption of serum proteins and thereby leads to an increased cell attachment, rather than directly affecting the cell attachment to the surface. PL and PG, for example, can be easily processed into complex 3-D shapes, are well characterized, are approved by the U.S. Food and

Drug Administration for specific *in vivo* applications, and are particularly well suited to tissue engineering applications because they are biodegradable. Despite all these advantages, their surface properties, which are not ideal for cell adhesion and proliferation, make them unsuitable for many applications. These absorbable polyesters lack functional groups on the polymer chain; the presence of methyl groups in PLL makes it highly hydrophobic in nature. Because cell growth and proliferation are better suited to hydrophilic surfaces, PLL in unmodified state is not ideal for cell attachment. However, cell affinity to PLL surfaces may be increased by surface modification. Some routinely used methods for this purpose are plasma treatment^[13], entrapment of a functional group within the polymer chain^[14], and partial hydrolysis by acid and base^[15] treatments. Surface modification can also be accomplished by incorporating extracellular matrix (ECM) molecules on the surface of the implant material; these molecules enhance cell attachment because cells recognize them through their adhesion ligands and thus are more likely to adhere to an ECM-coated surface. Liu and coworkers, for example^[16], reported that surface modification of poly(α -hydroxy acids) (PHAs) could be accomplished by immobilizing gelatin on the PHA surface, thus facilitating increased cell attachment and proliferation and augmenting the deposition of collagen fibers and other cell secretions. Although modifying a 2-D surface (e.g., a thin polymer film) is relatively straightforward, the same is not true for a 3-D scaffold, because other parameters such as bulk porosity and surface features increase the scaffold complexity; modification treatments are limited by the rate of diffusion.

NATURAL BIOMATERIALS

Synthetic biomaterials that are biodegradable in nature are well suited to tissue engineering applications. Synthetics are, for example, easily processed into 3-D shapes, reproducibly manufactured on a large scale, and have controlled mechanical and degradation properties. Also, because these materials absorb with time, they do not lead to lingering, long-term deleterious effects. However, a critical shortcoming of many synthetic biomaterials is their lack of cell-recognition sites. The success of any tissue engineered device is based on the attachment of cells to the substrate; in general, cell adhesion involves the cell surface receptor recognition of small molecules called ligands that are located in the extracellular space. The presence of specific ligands on a biomaterial surface, commonly true of naturally derived biomaterials, greatly enhances and facilitates the process of cell adhesion to any surface. Natural biomaterials include polysaccharides,

polypeptides, amino acids, and their combinations. Some specific examples of natural biomaterials are collagen, fibronectin, fibrin, chitosan, and gelatin. The advantages offered by naturally derived biomaterials can often include increased cellular affinity and similarity of structure to the surrounding tissue. However, these biomaterials also have disadvantages, such as increased susceptibility to infection, antigenicity, limited production scale-up potential, and unpredictable degradation properties over an extended period of time. The process of designing a 3-D scaffold from natural materials is also challenging because of the difficulty associated with controlling design parameters like architecture and controlled porosity.

Collagen is one of the most commonly used natural materials as a scaffold. It is composed of three chains wound into a triple helix, is the most abundant protein in the body, and is responsible for structural integrity. More than 20 different kinds of collagen types are found in the body, affording different properties. Type I collagen is the most common among all the types of collagen and is the chief component of tendons, cartilage, and bones. Collagen is mainly synthesized by cells responsible for laying down the ECM, such as fibroblasts, myofibroblasts, osteoblasts, and chondrocytes. Because collagen has high mechanical strength, encourages cell attachment, offers good resistance to degradation, and has low antigenicity, it can be used in a wide variety of applications. The mechanical stability and the rate of degradation of collagen can be enhanced by chemical crosslinking and, hence, many different agents such as glutaraldehyde, tannic acid, and 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide (EDC) have been used to crosslink collagen. An example of a tissue engineered product containing collagen is Apligraf[®] (manufactured by Organogenesis and marketed in the United States by Novartis), a bioengineered skin composed of a bovine collagen scaffold containing human fibroblasts and overlaid with a differentiated epithelium. However, this product is allogenic in nature (i.e., the cells do not belong to the patient on whom the product is intended to be used) and, hence, although the cells provide growth factors that enhance wound healing, complete integration of these cells in the patient's body likely does not occur. DuraGen[™] is another clinical product that uses collagen; this product is an absorbable collagen matrix graft that is used in spinal and cranial dural repair. DuraGen has had limited success in many patients requiring dural repair following anterior and posterior spinal surgery.^[17] Arginine-glycine-aspartic acid (RGD) peptides form a sequence of amino acids, found routinely in the ECM, that promote cell adhesion. Modification of collagen scaffolds by incorporation of RGD peptides leads to a significant increase in the attachment of cells on the

scaffold without any significant increase in the proliferation of cells.^[18,19]

Fibronectin is a common glycoprotein that is involved in many cellular processes including tissue repair, blood clotting, and cell migration/adhesion. Fibronectin sometimes serves as a general cell adhesion molecule by binding cellular integrins to collagen or proteoglycan substrates. Fibronectin matrix formation is initiated by fibronectin binding to cell-surface receptors, followed by assembly and reorganization of the cell-surface-associated fibronectin into fibrils. Three-dimensional fibrin gel scaffolds have demonstrated promise for vascular engineering applications.^[20] Furthermore, when the initial cell-biomaterial interaction of silicone is modified by covalently immobilizing fibronectin on its surface,^[21] silicone samples appear to have higher cell affinity. The selection of a particular natural material as a material to modulate cell attachment or proliferation depends on the specific application or the cell type under consideration. Hyaluronic acid (HA) is a naturally occurring biopolymer that has desirable properties and potential as scaffolding for tissue engineering. HA is a major component of connective tissue and of the synovial fluid, and it functions to cushion and lubricate various joints, such as the knee joint. A promising use of HA is in alleviating the pain caused by osteoarthritis. Supplements of hyaluronic acid help restore the health of the joint by increasing the thickness of the synovial fluid. This fluid lubricates the joint, which can allow a greater range of motion with less pain. Hyaluronan binding proteins on cell surfaces are HA receptors and mediate the effects of HA on the cell (especially cell adhesion and migration). Researchers have demonstrated that hyaluronic acid induces chondrogenesis of mesenchymal stem cells.^[22] The structure of HA can be chemically modified to generate a wide range of physical properties to better aid in the differentiation of chondrocytes. Natural biomaterials, because of the intrinsic nature that promotes their interaction with different cell types, hold considerable promise in the field of tissue engineering.

SYNTHETIC MATERIALS WITH RGD PEPTIDES

Synthetic materials may be surface modified by covalently binding proteins or peptides that are involved in various adhesion and proliferation signal pathways. The result affords the predictability of a synthetic biomaterial as well as the superior interaction that natural materials offer with the cells or the surrounding tissue. The most common material covalently attached to a synthetic biomaterial surface and used to enhance cell adhesion to a biomaterial is the RGD peptide sequence. Integrins are membrane proteins

found in the cellular plasma membrane that serve to bind to ligands found in the extracellular space. Integrins link the intracellular cytoskeleton of cells with the extracellular matrix by recognizing and interacting with ligands, such as RGD peptides. Thus, ligands such as RGD may cause the relay of information into the cell that triggers processes associated with cell attachment, growth, division, survival, differentiation, and apoptosis. RGD peptides found on biomaterials interact with the cell integrin receptor sites, which can, in turn, initiate cell signaling processes and influence the cellular adhesion rate of the cells on a material.^[23]

Ceramics are extremely biocompatible and also display osteoconductive properties; hence, a large number of calcium phosphate biomaterials have been proposed for use as bone filler materials. However, in addition to inadequate bulk load-bearing properties, these materials also lack any significant osteoinductive properties. The covalent attachment of defined densities of RGD peptides onto the surface of hydroxyapatite can increase the attachment and differentiation of osteoblasts,^[24] specifically causing increased DNA content, alkaline phosphatase activity, matrix protein expression, and mineralized nodule formation. Other research demonstrated that incorporation of RGD peptide on polymer surfaces for small-diameter vascular graft applications allows enhanced cell adhesion and spreading.^[25]

MICROTOPOGRAPHY AND ITS INFLUENCE ON CELL BEHAVIOR

Tissues and the cells that comprise the tissues in the body are arranged in precise spatial patterns, where the type of patterning observed depends on the tissue type and function. Microscopic evaluation of the structure of bone, for example, reveals a definite and characteristic pattern of arrangement. The ground substance of bone is arranged in concentrated layers (lamellae) around the small canals that run parallel to the long axis (shaft) of the bone. These canals, called haversian canals, are interconnected with one another via Volkmann's canals and contain a blood vessel, a nerve, and a lymph vessel. Each haversian canal is surrounded by concentric layers of bone matrix (called lamellae) and concentric rings of bone-forming cells (osteoblasts). This compact and highly defined structure maximizes the load-bearing ability of the bone. The configuration demonstrates the complex and definitive architecture of tissue in the body and the role of the structure in achieving its functionality. Chemical and physical cues are provided to the proliferating cells to arrange themselves in the requisite patterns. Logic suggests that for a tissue engineered device to be

successful in vivo it must not only provide the biochemical environment of the native tissue, but also provide a spatial arrangement that facilitates normal tissue function. Over the years many efforts have been made by researchers to study the interaction of cells with materials of a defined surface microtopography.^[16] Cells respond to surface features and react to them, leading to what is termed “contact guidance.” Efforts include study of the behavior of nerve cells cultured on spiderwebs and coverslips, as well as the evaluation of cell orientation on randomly scratched (grooved) mica substrates. These types of studies contributed to our basic understanding of cell interaction with microtopography. However, the studies fail to address, among other things, the structural dimensions of the tissues and precise repeatability over 3-D areas, comparable to that in vivo.

Advances in microfabrication technology opened new avenues for fabrication of substrates that have dimensional and chemical features similar to that found in tissues. Use of microfabrication technology enables the control of cell–surface interactions at the micro- or nanometer scale. Many reports in the literature suggest that surfaces with microgrooves affect the orientation and migration of cells.^[9,27] However, the mechanism and even the exact role of the microgrooves is poorly understood because it is difficult to compare reported studies as a result of methodology differences. For example, cell alignment is significantly affected by differences in groove depth, but differences in groove width are not very critical in influencing cell alignment.^[28] Several reports in the literature claim that microtexture is not correlated to cell proliferation; alternately, many reports claim exactly the opposite.^[29] Clearly, there is much work to be done in this area in order to provide viable tissue-engineered devices, because they are dependent on the adhesion and differentiation mechanisms/behaviors of cells on scaffolds. Surfaces with rough microtopography, for example, enhance osteoblast differentiation by encouraging osteoblasts to secrete factors that enhance osteogenesis, while decreasing osteoclast formation and activity.^[30] Researchers have demonstrated that, in many instances, implant surface topography effects can override implant chemistry, and by modulating the surface topography, one can radically alter the implant/tissue interface and overall biocompatibility.^[9] Similarly, micropatterning of natural materials has been investigated to enhance cell–surface interactions and the tissue–implant interface by spatially directing the growth of cells. Cellular differentiation and proliferation are affected by the interaction among hormones, growth factors, surface chemistry, and surface microtopography.^[31] To control cell-material interactions, a huge array of factors must be considered, including the form of the

material, the bulk and surface chemistry, the surface texture, the surface charge, and the biochemical and mechanical attributes of the implant site. Understanding of cell-material interaction has increased markedly over the past years, but there remain many important questions to answer and issues to address in order to realize the full potential of biomedical device design.

CONCLUSIONS

Biomaterials have evolved from providing simple mechanical support to providing support while purposefully influencing a desired response from the surrounding tissue. At the heart of this advance is the increase in our understanding of the cell-material interaction at both the micro and the macro level. As interest in developing cell-based devices grows, so will the necessity for extensive and well-controlled, repeatable studies of cell-material interactions.

Centrifugal Blood Pumps

Gerald E. Miller

The Artificial Heart Laboratory, Virginia Commonwealth University, Richmond, Virginia, U.S.A.

INTRODUCTION

The use of centrifugal blood pumps for cardiovascular support and heart assist have resulted from the marriage of a very successful class of standard fluid pumps with an urgent need to stem one of the largest causes of death in the United States—cardiovascular and heart pathologies. Centrifugal pumps have long been used as water pumps, oil pumps, air fans, and a host of other industrial, automotive, space, and home applications. They are one class of rotary pumps, the others being axial pumps and mixed-flow pumps. The use of such a pumping technology to address a growing need for cardiac support is a natural extension of these devices, and has resulted in the development of dozens of such pumps for use to propel blood. Over the last two decades, the use of rotary blood pumps has steadily grown to the point that they are now employed clinically as often as the more historically known positive displacement pumps, such as the older Jarvik pumps, and the latest pumps such as the HeartMate pump, the LionHeart pump, the Abiomed pump, and so on.

Centrifugal pumps offer advantages over other pumping modalities in that they can produce large pressure increases and large flow rates at relatively low rotation speeds. As the history of centrifugal pumps for nonmedical applications is long, the developments and advances in such a technology have been significant. Many centrifugal pumps have been used for specialized fluids, including those that are highly volatile (such as rocket fuel) as well as those that have suspensions of particles (such as motor oil). Development of centrifugal pumps for such applications has resulted in versions that are designed for sensitive fluids and can thus produce stable flow regimes. The use of such pumps to propel blood is thus a natural extension, as this is another sensitive fluid that has deformable particles and that requires stable flow. It is thus not surprising that many centrifugal pumps are now employed for cardiovascular support and are in various stages of clinical and bench-top trials.

CENTRIFUGAL PUMPS—GENERAL INFORMATION

Centrifugal pumps are one class of rotary pumps or rotodynamic pumps that are sometimes called

turbomachinery. Fluid motion is directed within a housing by means of blades, vanes, or impellers (propellers that are within a housing). The housing has no valves and thus is not closed, contrary to positive displacement pumps (such as piston pumps and diaphragm pumps used to propel blood), all of which have valves and closed volumes. The use of a housing for a centrifugal pump is to collect fluid along or from the rotating elements and direct it towards the outlet. Fluid normally enters the pump housing within the “eye” of the pump near the center (above) the rotor and leaves at the periphery. A centrifugal pump increases the pressure of the fluid from a small value at the inlet to a larger value at the outlet. This is much the same way that air flows within a tornado or hurricane. The center or eye of the tornado has little flow and is a source of low pressure. However, at the periphery, due to the spinning action of the tornado, the flow rate is high, as is the pressure.

For centrifugal pumps, flow and pressure increases are affected by several factors including size of the rotating element (blades, rotor, impeller), number of rotating elements, their configuration (slanted, straight, curved), size and shape of the housing, and rotation rate of the rotating elements. A typical centrifugal pump with housing and rotating element is shown in Fig. 1. Standard measures of performance and design analysis include the specific speed N_s , which relates the pressure head (pressure rise) and volume flow rate when operating at optimal efficiency. $N_s = N \times Q^{1/2} / H^{3/4}$, where N = rotation rate of the impeller, Q = volume flow rate, and H = pressure head (rise).^[1] The net positive suction head (NPSH), which evaluates the pump inlet pressure with respect to vapor (dissolved gas) pressure and is a measure of the tendency toward cavitation (bubbling of gases) in the fluid; and pump energy can be obtained from Bernoulli's equation. $N \times T = \{(P_{out} - P_{in}) / \rho\} + \{(V_{out}^2 - V_{in}^2) / 2\} + g (Z_{out} - Z_{in})$, where T = torque, ρ = fluid density, V = fluid velocity, g = coefficient of gravity, and Z = elevation/height.^[1]

Centrifugal pumps, unlike their positive displacement counterparts, are not affected by inlet pressure. In effect, they draw their own inlet vacuum and thus are not affected by preload, the venous pressure that supplies blood for heart assist devices. This is contrary to the natural heart and to all positive displacement

Fig. 1 Typical design of a centrifugal blood pump with flow entering above the rotor and exiting peripherally. The rotor can be magnetically rotated or shafted. The central inlet flow above the rotor is at a low pressure and the exit flow is at a higher pressure. The resulting pressure rise is called the pressure head.

blood pumps (such as the HeartMate and other diaphragm/piston type blood pumps), all of which are affected by inlet pressure and flow conditions. If venous return to the natural heart is reduced, cardiac output is reduced. Centrifugal pumps are not so affected. This is a great advantage over traditional blood pumping systems.

However, the outlet flow rate of centrifugal pumps is affected by the outlet load pressure that the fluid faces upon leaving the pump. If the outlet (load) pressure is high, then the pump must produce flow against a greater load. Because centrifugal pumps are designed to produce a pressure rise as opposed to a guaranteed outlet flow, then a large afterload to the device will adversely affect the outlet flow rate. It is possible in such pumps to produce a “dead head” effect—the pump spins, but no flow occurs. This is due to the pressure at the outlet (tubing/vessel) being larger than the pressure at the outlet port of the pump. The solution for such situations is to increase the rotation rate of the centrifugal pump, which supplies more energy to the fluid, increases the outlet pressure, and results in increased outlet flow of the pump. This adverse effect of increased afterload on outlet flow of centrifugal pumps represents a disadvantage over positive displacement pumps that produce an outlet flow regardless of afterload pressure, thus, their name—positive displacement, meaning they displace a certain volume of blood (stroke volume) regardless of the load against which they pump. The cardiovascular analogy is that aortic hypertension adversely affects centrifugal pumps while not affecting positive displacement pumps. However, decreased venous return does not affect centrifugal blood pumps but it does adversely affect positive displacement pumps. A description of the effects of afterload on the performance of centrifugal pumps at various rotation rates is shown in Fig. 2.

Centrifugal pumps offer other advantages over the more classical positive displacement blood pumps. They do not require valves and thus avoid calcification, pannus formation, and thrombus formation that have often plagued positive displacement blood pumps.^[2–4] They usually require less energy to operate, as there is not a large piston or diaphragm to push against. They can operate in either steady or pulsatile mode and are quite responsive to changing drive conditions in that the rotation rate can be adjusted “on the fly” if there are feedback mechanisms to be employed. As there is no fixed and constrained volume, there is no need for a compliance chamber, as has been required for many positive displacement pumps.^[1,5] Thus, the use of centrifugal pumps to propel blood and serve as cardiac assist offers significant promise. It is no wonder that numerous versions are in various stages of clinical trials for cardiac assist and replacement.

CENTRIFUGAL BLOOD PUMPS

Centrifugal pumps have been investigated to propel blood for several decades, producing versions that have different rotating elements and different housing configurations. Rotating elements, known as rotors, consisting of bladed impellers, stacked cones, parallel discs, and ridge-type rotors, have all been employed in various designs of centrifugal blood pumps. Housings that have straight inlets centered above the rotor, or canted inlets with the opening above the rotor, or offset inlets have all been employed. The only constant among all versions of such pumps has been that the fluid enters above the rotor in a region of low pressure and radial flow, and exits at the periphery in a region of high pressure and radial flow. Centrifugal pumps thus convert axial flow into radial flow through the

Fig. 2 Typical centrifugal blood pump relationship between pressure head and flow rate as a function of pump rpm. Pressure head drops as a function of outlet flow rate for a constant rotation rate.

Fig. 3 Baylor-Nikkiso centrifugal blood pump with purging chamber below the rotor to reduce thrombosis as a result of blood stagnation. (From Ref. [6].)

rotating element at the base of the housing. The inlet and outlet ports of the pump are typically perpendicular to each other. Most centrifugal pumps have conical housings that conform to the tornadolike fluid flow fields that are generated by the impeller/rotor assembly. This housing naturally increases in diameter from the inlet (at the top center of the device) toward the periphery where the radial fluid flow collects to exit the pump. A typical centrifugal blood pump and housing (using a centrally placed rotor/impeller) are 50–75 mm in diameter and 30–40 mm high, weigh 200–300 g, and use a brushless DC motor.

Many centrifugal pumps have employed a shaft through the housing (with a shaft seal), which connects the rotor to the drive motor. Other versions have employed some form of magnetic suspension of the rotor, which might achieve stability by means of pivot bearings that ride within a cavity at the base of the housing. Still other pumps produce complete magnetic suspension including both levitation and radial stabilization of the rotor within the housing. Many of the developed centrifugal blood pumps have resulted from

collaboration between companies and universities/medical centers, including several collaborations between Japanese firms and U.S. medical centers.

One such example is the Baylor-Nikkiso centrifugal pump which has been under investigation for many years and represents a collaboration between the Japanese firm Nikkiso and the Baylor College of Medicine in Houston.^[6–10] This pump has a shaft and shaft seal as well as magnetic coupling. Together, these provide radial and axial stability as well as a mechanism to spin the impeller. One unique aspect of this design is the use of a fluid purging system to avoid stagnation near the shaft seal by providing a washout flow rate via a purging fluid. This pump is shown with the purging system in Figs. 3 and 4, indicating the effects of purging and nonpurging versions on the development of thrombus formation. The pressure/flow relationship for this pump is presented in Fig. 5 and is typical of centrifugal blood pumps. At higher rotation rates of the impeller, the flow rates increase, as do the outlet pressures at the periphery/outlet of the pump, in part to counterbalance any tendency for a flow decrease as a result of increased afterload.

The Baylor College of Medicine has also collaborated on the Baylor Gyro series of pumps, which utilize magnetic coupling to spin the rotor, but also utilize a pivot bearing to allow the rotor some degree of radial and axial stability. This is a collaboration with Kyocera Corporation. The spinning rotor rides above a bearing with a conical projection from the rotor that sits above the bearing, acting like a gyroscope. This pump is shown in Fig. 6. One interesting aspect of the Baylor Gyro series of pumps is that various inlet configurations have been tested, including canted inlets and offset inlets in an attempt to optimize flow patterns within the housing.^[11–19] An eccentric inlet port design is presented in Fig. 7 and the pressure/flow relationship of this pump can be seen in Fig. 8. Again, the family of pressure/flow relationships for various rotor speeds indicates higher rotation rates resulting in

Fig. 4 Baylor-Nikkiso centrifugal blood pump: the effect of purging (A) vs. nonpurging (B) of the spacing below the rotor. More thrombosis occurs in the nonpurged system, indicating areas of blood stagnation. (From Ref. [6].)

Fig. 5 Baylor-Nikkiso centrifugal blood pump performance curves depicting pressure head as a function of outlet flow rate for varying pump rpm. Pressure head drops as a function of flow rate for a constant rpm, typical of centrifugal pumping systems. (From Ref. [7].)

Fig. 6 Baylor Gyro centrifugal blood pump with a pivot bearing and magnetically driven rotor. Hydrodynamic forces lift the rotor within the housing with the pivot bearing serving as a guide. (From Ref. [13].)

higher outlet pressures and flow rates in order to counterbalance any tendency for a flow decrease as a result of increased afterload.

Another mechanism to propel blood by means of a centrifugal design utilizes spinning disks within a spiral volute housing. This work was initiated at Texas A&M University in collaboration with the Texas Heart Institute and was later continued at Virginia Commonwealth University. This system employs multiple, donut-shaped, rotating disks with fluid entering axially into the spacing at the center of the disks. The fluid is then propelled via shearing and centrifugal forces within the spacing between the disks to provide radial flow.^[20-25] The spiral

Fig. 7 Baylor Gyro pump with diagonal input. Output is at the periphery as is common with other centrifugal pump designs. (From Ref. [13].)

Fig. 8 Baylor Gyro centrifugal blood pump performance curves indicating pressure head as a function of outlet flow rate for varying rpm. There is a slight decrease in pressure head for higher flow rates, which is typical of centrifugal pumping systems. (From Ref. [13].)

housing collects the radially spun fluid and redirects the fluid toward the outlet at the periphery to reproduce axial flow, albeit at right angles to the inlet flow. This pump is based upon the Tesla Turbine, a multiple-disk pump that has previously been investigated for use to propel liquid rocket fuel for over five decades.^[26–29] The multiple-disk pump is shown in Fig. 9 and its pressure/flow relationship is presented in Fig. 10. Unlike other centrifugal

Fig. 9 Multiple-disk pump with parallel rotating disks and a spiral volute housing. (From Ref. [21].)

Fig. 10 Multiple-disk blood pump performance chart depicting flow rate as a function of afterload, the load against which the pump must produce flow. (From Ref. [24].)

blood pumps, the housing of the multiple-disk pump is circular, not conical, as it surrounds the circular-shaped disk assembly.

One of the more clinically successful pumps in terms of overall usage is the BioMedicus BP-80 pump and its successors.^[30–32] This pump utilizes magnetic forces to not only suspend, but also rotate the rotor. The rotor consists of a series of stacked cones with small blade-like projections on the cones to assist in propelling the fluid. As with most centrifugal pumps that utilize rotating elements located at the base of the housing, the flow field within the housing resembles a vortex with the fluid entering above the rotor and spinning outward from the center of the housing toward the periphery, where it builds momentum, pressure, and velocity. In fact, the BioMedicus pump is advertised to produce a “constrained forced vortex.” One advantage of this design is that the rotor has a magnetic disk at its base, which is married to another magnetic disk in the drive unit that exists outside the housing. This allows the entire pump head to be twisted off the drive unit and replaced with a clean pump head, should the old head be affected by thrombosis. This pump is depicted in Fig. 11 and, like most impeller-type pumps, has a conical housing.

The Cleveland Clinic has developed the CorAide centrifugal blood pump, which has been bench-tested on a mock circulatory system^[33] and tested in calves.^[34,35] The pump is designed to be permanently implantable and consists of a rotating assembly that is

Fig. 11 BioMedicus BP 80 pump with rotating cones and a full-bottom magnetic disk connected to a driving magnet. (From Ref. [30].)

completely suspended and noncontacting (shaftless). This pump operates in steady flow mode and has produced low hemolysis, plasma-free hemoglobin, and thrombosis levels that require less anticoagulant therapy. This pump is shown in Fig. 12.

Fig. 12 Cleveland Clinic CorAide centrifugal blood pump. (From Ref. [33].)

Fig. 13 HeartMate III centrifugal blood pump. (From Ref. [3].)

The HeartMate III centrifugal blood pump^[2-4] has been used as a left ventricular assist device and was developed by ThoratecCardiosystems, the same company that designed the positive displacement, pusher plate Heartmate pump.^[5] This pump operates with a magnetically suspended, levitated, and rotated rotor and has produced physiological pressures and flow rates in experimental studies in calves. The pump design is presented in Fig. 13 and its performance (pressure vs. flow vs. rpm) can be seen in Fig. 14.

The aforementioned pumps are but a sampling of numerous designs from Japan, China, Austria, France, Korea, Singapore, Australia, and the United States, among others. The majority of devices under development have originated from either Japan or the United States and often involve the collaboration of both countries. Many centrifugal pumps under development have similar designs with a centrally placed impeller/rotor, a conical housing, and pressure/flow characteristics that indicate decreasing flow at higher load pressures and a series of performance curves with higher flow rates at higher rotation rates of the impeller assembly. All of these devices have been tested on the bench (in vitro) using flow visualization techniques to evaluate the flow field and predict any regions of flow irregularities, as well as pressure/flow measurements to evaluate pump performance. Hemolysis testing has been accomplished both in vitro and in vivo to determine the efficacy of these pumps as viable blood pumping devices. Thrombosis has also been evaluated in these pumps by examining the excised pumps after a significant period of pumping to visually determine any regions where flow stagnation has resulted in thrombus formation.

Fig. 14 HeartMate III centrifugal pump performance curves depicting pressure head vs. flow rate for varying pump rpm. Pressure head decreases at higher flow rates typical of centrifugal pumps. (From Ref. [4].)

EVALUATION OF CENTRIFUGAL BLOOD PUMPS

In vitro evaluation of centrifugal blood pumps employs a mock circulatory system that produces a physiologic load on the device, which is similar to that which may be experienced in the body during clinical or animal trials. A typical mock circulatory system consists of a fluid capacitor, fluid resistor, and venous reservoir as shown in Fig. 15. The capacitor is a fluid chamber with an elastic back-resistance element that consists of either a leaf spring or a pressurized air chamber, separated from the fluid chamber by an elastic diaphragm. By varying the leaf spring position or the back pressure of the air chamber, one can vary the compliance of the capacitance element and thus simulate a variety of physiological and/or pathological conditions. The capacitance chamber moves up and down either rapidly or slowly depending on the back-resistance setting. During steady flow, the compliance chamber is inactive, as there are no flow pulsations to cause any movement of the fluid chamber. The fluid resistor element is merely tubing placed between two flat plates with wing nuts (or a drive motor) controlling the compression of the tubing between the two plates. The tubing cross-sectional area is thus manipulated, which produces a controllable fluid resistance by creating a larger or smaller pressure drop resulting from the area reduction increment. The inlet pressure to the pump is affected by the height of fluid in the venous reservoir.

Although centrifugal pumps are not affected by preload conditions (inlet/venous pressure), the use of a venous reservoir is designed to mimic the reduction in fluid perturbation aspects of the human venous system. A blood analogue, typically a glycerin/water mixture (40/60%), is employed in the mock circulatory system

to avoid the need to use real blood (and the resulting thrombosis that may occur) and to allow various fluid visualization techniques to be employed. The blood analogue produces a viscosity (3.5–4 centipoise) and density (1.05 g/cc) similar to those of whole blood, and is a commonly employed technique for in vitro testing.

Flow visualization techniques are often employed to evaluate the flow field within the pumping chamber of centrifugal blood pumps as well as within the inlet and/or outlet cannula of such pumps. Particle image velocimetry (PIV) is a commonly used technique to evaluate the flow fields, and consists of lasers that illuminate neutrally buoyant particles embedded within the blood analogue, a digitizing camera to monitor the tracks produced by the illuminated particles, and controlling software to analyze the flow field data. A typical particle image velocimetry system is shown in Fig. 16. The system produces snapshots of velocity vectors (movement of numerous particles along pathlines) such as that depicted in Fig. 17. By examining the particle tracings, one can determine regions where stagnation occurs (which may lead to thrombosis,) or regions where large shear rates occur (which may lead to hemolysis). By placing various portions of the housing or cannula within the camera viewpoint, one can zoom in on regions of particular interest. Numerous snapshots can be summed and averaged to produce trend graphs, such as that shown in Fig. 18. Other flow visualization systems employ laser Doppler anemometer (LDA) techniques whereby the laser energy illuminates particles or the fluid itself, and the scattering or reflection is monitored as an indication of fluid velocity—hence the Doppler aspect to this system. The output of such a system produces snapshots or trend graphs similar to that generated by the PIV

Fig. 15 Typical mock circulatory system for in vitro testing of artificial hearts and ventricular assist devices. The system mimics the circulatory load that an artificial heart must face.

Fig. 16 Particle image velocimetry (PIV) system for visualizing the velocity patterns in and around ventricular-assist devices and artificial hearts. The lasers illuminate fluorescent particles imaged by a charged coupled device (CCD) camera. (From Ref. [25].)

system, albeit by different means. A typical LDA system is shown in Fig. 19.

Hemolysis testing, both *in vitro* and *in vivo*, is commonly utilized to evaluate the efficacy of centrifugal blood pumps to serve as long-term cardiac assist devices. The pumps operate for an extended period using whole blood, with the blood sampled periodically for plasma-free hemoglobin, an indication of excessive lysis of red cells. For those studies conducted *in vivo*, there are other tests that are conducted to evaluate the performance of the pump in a physiological setting including platelet levels and activation, renal function, and cardiac perfusion. Often, these pumps are compared to each other and to the roller pump (the commonly used pump for cardiopulmonary bypass) in terms of hemolysis. A typical hemolysis curve for centrifugal pumps is shown in Fig. 20 and indicates a slow rise in plasma-free hemoglobin toward a plateau. Despite the nature of the vortexlike flow field within the typical conical housing of a centrifugal blood pump, the level of hemolysis generated by such pumps is minimal. This is likely due to the short duration that red cells are in contact with the neighboring zone of the

Fig. 17 Vector mapping of the velocity field from a PIV flow visualization system. This is a snapshot image of the neutrally buoyant particles in the flow field. The vectors (arrows) depict the direction of each particle and the arrow length indicates the velocity magnitude. (From Ref. [25].)

rotor/impeller. Although the rotation speeds of most centrifugal blood pumps range from 1200–4000 rpm, each red cell is in contact or near the impeller for only an extremely brief time period. Although the vortex generated by many centrifugal blood pumps can produce somewhat unpredictable velocity patterns within the housing, this does not appear to significantly affect blood pumped by such a device.

ISSUES RELATED TO CLINICAL DEVELOPMENT OF CENTRIFUGAL BLOOD PUMPS

The use of centrifugal blood pumps in a clinical setting has resulted in limited success. There are three major uses of artificial heart technology: an assist pump for temporary assistance of a recovering heart following open heart surgery, a bridge-to-transplant pump that is implanted for longer periods as a long-term assist until a donor heart is obtained for a transplant, and as a total heart replacement for a severely failing heart. As an assist pump, both centrifugal pumps and other blood pumping modalities have been quite successful, because their use is temporary (a few days) and the patient is typically hospitalized in a cardiac intensive care unit. The total heart replacement has been a difficult hurdle for any pumping system to produce, as the long-term issues of hemolysis, thrombosis, power availability, feedback and control, and other patient health issues have been difficult to successfully address. It is the middle ground, the bridge-to-transplant, where many blood pumping systems have been employed as a staging system to provide adequate cardiac support to the patient until a donor heart is available. Because this use may result in long-term application of the blood pump and usually requires implantation, the issues related to the total heart replacement are similar to those for the bridge-to-transplant versions.

Fig. 18 Contour mapping of the flow field from a PIV flow visualization system, representing the average of 100 snapshot vector plots. The color scheme is shown at right with velocity values. The red colors represent higher velocities and blue colors represent lower velocities. (From Ref. [25].)

Thrombosis is still a significant issue in the long-term use of centrifugal blood pumps—in fact, with virtually all types of blood pumps. Once the thrombus is released due to vibrations or shear and becomes an embolus, then the chances for stroke and other vascular complications arise. As the generation of a thrombus is associated with stagnation zones within the blood velocity field, it is imperative to avoid stagnant zones within both the rotor and housing and the inlet and outlet cannula of the device. Feedback and control of the device is another area of considerable concern and interest. The development of a reliable long-lasting series of sensors to monitor blood pressure, flow rate, plasma-free hemoglobin, blood oxygen levels, and other associated physiological measures is of paramount importance in order to determine whether the device is functioning properly or to predict potentially dangerous situations before there are irreversible adverse effects on the patient.

Power consumption and the ability to renew and recharge battery sources transcutaneously is an issue that must be successfully addressed for centrifugal blood pumps as well as other pumping modalities. Thus, it is common to bench-test centrifugal blood pumps in order to monitor voltage and current needs in the pump as well as pump efficiency. It is in this arena where centrifugal pumps may have an advantage over other blood pumping modalities, as the long and

successful history of nonmedical applications of such pumps has resulted in devices that are highly efficient, utilize small motors, require small driving voltages, and draw small currents. In addition, these pumps do not need to push a large volume of fluid in contact with a piston or diaphragm, do not need to build pressure within a closed housing (with valves) such as occurs in isovolumetric contraction in the natural heart, and operate at rotation rates that are smaller than axial flow blood pumps. Nonetheless, the long-term viability of these or any blood pumps is dependent on the ability to continually power the pump *in vivo/in situ* and to continually recharge the power system in a reliable manner.

CONCLUSION

Centrifugal blood pumps have been widely utilized in numerous clinical settings, and various versions have been examined by numerous research groups worldwide. The development of centrifugal blood pumps represents an important marriage between industry, academia, and medical centers. It is perhaps the field that produces the greatest such collaboration. It also represents a strong collaboration among research

teams from many nations where the pumps are designed and bench-tested in one location and then evaluated clinically elsewhere. The International Society for Rotary Blood Pumps and its host journal *Artificial Organs* are ample evidence of such widespread collaboration. A multinational group dealing with rotary blood pumps meets annually to present their latest findings and demonstrate the latest pump designs.

The successful long-term use of centrifugal pumps in nonmedical settings has given rise to a number of advances that have been in evidence in the blood pumping versions developed over the last three decades. The advantage of centrifugal pumps is the large pressure gradient and the potential flow rates that can be generated and thus produce more than adequate support for cardiac assist or replacement over a wide range of physiological and pathological conditions. The very rapid response time between altered pump controls and the resulting changes in pressure and flow are another large advantage over other cardiovascular pump designs. The future is indeed promising for the further development and clinical testing of centrifugal blood pumps. However, as with any long-term implantable device to be used in the human body, there are issues to overcome before the term “artificial heart” becomes a reality.

Ceramics

Robert H. Doremus

Department of Material Science and Engineering, Rensselaer Polytechnic Institute, Troy, New York, U.S.A.

INTRODUCTION

Ceramic materials have been used in human activities for many millennia. In recent years they have found application as replacement or repair materials in the human body, starting with the use of porcelain in restorative dentistry.^[1] Compared with other materials used in the body, such as polymers and metals, ceramics can have excellent biocompatibility, but suffer from lack of impact resistance in applications where high stress is applied to the implant, such as in hip replacements. Nevertheless, ceramics are used in prosthetic and biomedical applications where impact resistance is not so important, as listed in Table 1. Materials used in the body must be compatible with physiological materials and functions. In Table 2 some desirable properties of materials in the body are listed.

Processing of crystalline ceramics and glass ceramics is briefly described in the next section. Then, there is a section on fracture and fatigue of ceramics. Mechanical stability is often essential in the use of ceramics as implant materials. Ceramics have been used as implants without a thorough understanding of their mechanical properties, and the result has often been failure of the material and its rejection as an implant material. The following section is devoted to a discussion of hydroxylapatite (HA) as an implant material. It is an attractive material for implants, because it is completely biocompatible and bonds strongly to bones. Bones and teeth are composed of HA with some carbonate, so the bone cells recognize synthetic HA as a compatible material. Other ceramic materials with potential as implants are described in the section on other ceramics.

Composite materials can enhance the properties of the matrix or embedded material, and have attractive potential as implants. To take advantage of the chemical compatibility of ceramics with body fluids, and the impact resistance of metals, ceramics are coated onto metal substrates; these combined materials are described in a section on composites and one on coatings. Many natural materials are combinations of crystalline ceramic particles in a polymeric matrix. An example is the shell of a clam, which contains calcium carbonate particles in a protein matrix, and is very strong and durable. Synthetic materials are made that try to copy some of these structures. This approach is discussed in

the biomimetics section. Some of the present review is taken directly from Ref. [2]. There are also other reviews in Refs. [3–5].

PROCESSING OF CERAMICS

Crystalline ceramics are usually made in three steps: forming of a powder to the desired shape, partial drying, and firing at high temperatures to produce dense material.^[6,7] The firing step can include a hold at intermediate temperature to burn out organic binders. In slip casting the powder in a slurry is poured into a mold that absorbs excess water; the resulting ware can be fired directly without further drying.

In traditional ceramics such as porcelain, powdered raw materials such as clay (hydrated aluminosilicates), feldspar (alkali aluminosilicates), and silica sand are used directly as mined. For specialty uses, such as in electronics and most bioceramics, properties are strongly influenced by impurities and particle size of the starting materials, which must therefore be carefully controlled. Precipitation from solution and pyrolysis of organic precursors, including polymers or gels, are methods of producing pure powders.

Powders are usually pressed damp in metal dies or dry in lubricated dies at high enough pressure to form material strong enough to hold together until it is sintered. An organic binder such as polyvinyl alcohol helps to bind the powder together. Drying at about 100°C is a critical step in preparing damp-formed pieces for firing. Too much or too little water in pressed powder can lead to blowing apart the ware on heating, or to crumbling, respectively. Binder is removed by heating to a higher temperature in air to oxidize the organic binder to carbon dioxide and water.

When a piece is fired, the powder particles join together to form a solid, porous mass; as firing continues, most of the pores are removed, forming a compact, dense, polycrystalline solid. Sintering together of the particles can occur entirely in the solid state or from a mixture of solid particle and liquid. A liquid phase aids sintering; a small amount of liquid coats grain boundaries in the dense solid, and a larger amount can provide a glassy matrix for solid particles, as in porcelain, and is called vitrification.

Table 1 Current and proposed applications of bioceramics

Dental restorations: crown, caps, dentures, fillings
Tooth root replacements
Rebuilding the alveolar ridge
Whole-tooth replacements
Reconstructive middle ear surgery
Fracture healing
Spine surgery
Rebuilding of facial and cranial bones
Filling mastoid defects
Filling bony defects, for example, in tibial plateau fractures
Female sterilization

Materials that are difficult to sinter to dense bodies can sometimes be sintered by a combination of heat and pressure called hot pressing. The main problem in hot pressing is to find materials for dies that will withstand pressure of 30 MPa or higher above 1000°C. Graphite is widely used, but it is quite expensive and has a short life as a die, so hot pressing is used only for pieces of high value. Hot pressing is also slow because of the time required to heat and cool the dies for processing each piece.

FRACTURE AND FATIGUE OF CERAMICS

The mechanical failure of brittle materials such as ceramics results from propagation of cracks from flaws in the material, either on its surface or in the bulk volume. When a tensile stress, S , is applied to a thin, deep flaw of depth c with a flaw tip radius of p , the stress S_t at the crack tip is:^[8]

$$S_t = 2(c/p)^{1/2}S \quad (1)$$

Since the tip radius is usually several orders of magnitude smaller than the crack depth, the applied stress is greatly multiplied at the crack tip. Thus, brittle materials fail at applied tensile stresses much lower

Table 2 Desirable properties of implants

No toxicity
Mechanically stable: do not fracture or deform excessively
No foreign body reaction
No stimulation of undesirable growths or chemical reactions in body fluids and tissues
No decomposition
No resorption, or at a desired rate

than the theoretical stress required to break the chemical bonds in the solid material.

The strengths of ceramics are usually measured in bend (flexure) tests of rod or bar samples, with three or four contact points on the specimen. Fibers are usually tested in tension. A convenient method for measuring strengths of ceramics is the diametral test.^[9,10] In this test a right circular cylinder, a few millimeters in diameter and in thickness, is compressed along the diameter of the cylinder between flat plates. Pads of ductile material (e.g., copper) are inserted between the sample and the plates to prevent crushing of the sample at the diameter ends. A tensile stress is developed normal to the loading diameter along both surfaces of the sample and also across a plane through the sample from one surface to another. Thus, both surface and volume flaws can contribute to sample failure. Samples for the diametral test can be cut from a long cylindrical sample, and are therefore easy to make in large quantities.

Vardar and Finnie^[9] tested rock samples and showed that the failure strengths from the diametral test were a factor of about 1.2 smaller than failure strengths from bend tests. Thus, strengths from diametral tests should be multiplied by 1.2 to compare them with bend strengths.

When the failure strengths of a number of identical brittle samples are measured under the same conditions of sample preparation and loading, the strengths vary over a wide range, for example, by a factor of 2. This distribution of strengths can be expressed statistically. A distribution function often used for strengths is the Weibull function.^[11]

$$F = 1 - \exp[-S/S_0]^m \quad (2)$$

in which F is the fraction of samples that breaks below stress S , and m and S_0 are constants. The Weibull modulus, m , is a measure of the spread and the skewness of the distribution. It is desirable to have a method of measuring the bonding between bone and an implant. A widely used way for semiquantitatively measuring the bone-implant bonding is the pushout test. In this test a cylindrical sample is implanted, for example, into the cortex of a femur of an animal, and after the bone plus the implant is recovered the force needed to push the implant out of the bone is measured.

A more quantitative test for measuring the strength of bone-implant adhesion has been described by Nakamura, Yamamuro, Higushi, Kukubi, Ito.^[12] A plate ($2 \times 10 \times 15 \text{ mm}^3$) was implanted into a hole in a rabbit tibia such that the plate extended right through the tibia from the medial to the lateral cortex. After sacrifice of the animal, at the end of the experiment, the bone was cut so that two semicircular bone segments were each bonded to the plate on either side. Each bone segment was held by a hook connected to an Instron test

machine. In this way the bonding strength of the bone to the implant could be measured directly. A segment of bone without an implant was tested in the same way for comparison.

When oxides are held under a tensile stress in aqueous solutions or water vapor, they become weaker. This fatigue can be tested in several ways.^[13] In a static fatigue test the samples are held under constant load until they fail. In metals, fatigue tests are usually conducted with a variable (cyclical) applied stress, because this mode leads to more rapid failures than a static load. However, in ceramics the integrated load time function gives the same fatigue times as a cyclical stress, so there is no special deterioration of the strength for cyclical loading.

To make predictions of the time to failure for a brittle material, one must choose a suitable stress–failure time function. The function most often used is a power law:

$$\log t/\tau = n \log(S/S_N) \quad (3)$$

where t is the time to failure, S is the applied stress, and τ , n , and S_N are constants. S_N is the failure strength under conditions where there is no fatigue. The parameter n is a measure of the fatigue susceptibility of the material. A large (>50) value of n means a material has little fatigue sensitivity (large times to failure); a low (>10) value of n means the material is highly sensitive to fatigue (short time to failure). Tau (τ) is a scaling parameter for the time of failure.

In silicate glasses a function that fits the distribution of $\log t/\tau$ values better than Eq. (3) is:^[13]

$$\log(t/\tau) = g(S_N/S) \quad (4)$$

in which g is a constant. This function can be extrapolated to long fatigue times more reliably than Eq. (3); neither Eq. (3) nor Eq. (4) shows a fatigue limit, which is an applied stress below which no failure occurs.

A brittle material such as a ceramic or glass deforms elastically until it fractures; thus, if the applied stress is plotted as a function of the relative deformation or strain, a straight line results. A ductile material such as aluminum deforms linearly at very low stresses, but at higher stresses plastic deformation results and the stress–strain curve becomes nonlinear; more and more stress is required to increase the strain. Toughness can be defined as the ability of a material to absorb energy during plastic deformation, and an indication of toughness can be obtained from the area under the stress–strain curve for a static test, which represents the work required to fracture the material.

A quantity called the critical stress intensity factor K_c can be measured for a solid material. If there is a crack

or notch of depth c in a material which is subjected to a tensile stress (mode I loading), K_c is defined by

$$K_c = S(\pi c)^{1/2} \quad (5)$$

in which S is the stress required to cause the crack or notch to propagate to failure. K_c is sometimes considered as a material or intrinsic property of a material, but many experiments show that K_c depends on extraneous factors such as sample microstructure and treatment history. Thus, K_c is not an intrinsic property of a material. The critical stress factor, K_c , is sometimes called the toughness of a brittle material, a term which is highly misleading because brittle materials are not “tough” (have good impact resistance). The term toughness should be limited to descriptions of ductile materials, as described in the preceding paragraph.

HYDROXYLAPATITE

The mineral phases in mammalian bones and teeth are HA, $\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$, containing some additional carbonate. Growing bone attaches directly to HA implants by chemical bonding; there is no foreign body reaction, fibrous layers, or other chemical changes at the bone–HA interface.^[14–16] Thus, HA is an ideal implant material from a chemical and bone-bonding perspective. HA, of course is brittle, so it is not suitable for application which requires impact resistance, such as hip socket replacements.

Dense HA containing no pores or second phases was made by pressureless sintering of fine, precipitated crystals of HA in a damp cake at 1100°C for 1 hr.^[17] To make samples without pores or second phases the stoichiometry must be exactly that of HA, that is (Ca:P ratio of 5:3). Without pores or second phases the dense HA is translucent to transparent; the pores and second phases scatter light to make HA samples opaque.

Translucent HA with no pores or second phases has high strength (up to 200 MPa in diametral tests) and excellent fatigue resistance.^[10,17] HA samples of lower density, containing pores and second phases, have lower strength and fatigue resistance. A detailed examination of some previous results on inferior quality samples of HA shows that their reduced strength and fatigue resistance results because of pores, second phases, and impurities in these materials.^[2] When high-purity HA is properly made so it has no pores or second phases, it has strength and fatigue properties that permit many biomedical implant applications.

Coatings of HA on metals and composites of HA with other ceramics are being explored to overcome the lack of impact resistance of HA and are discussed in the composites and coatings section. One can conclude that HA is the most attractive ceramic material for implants,

especially because of its excellent bonding to bones and teeth.

OTHER CERAMIC MATERIALS AS IMPLANTS

Dense, pore-free β -tri-calcium phosphate $\text{Ca}_3(\text{PO}_4)_2$ can be made by sintering precipitated fine crystals in much the same way as HA was made.^[18] The resulting material is strong, and bone bonds well to it without any foreign body reactions. A possible advantage of tri-calcium phosphate over HA as an implant material is that it is slowly reabsorbed by body fluids, because it is more soluble in aqueous solutions than apatite. There is more background information on calcium phosphates in Ref. [19].

Jade (base composition $\text{Na}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 4\text{SiO}_2$) was found implanted in teeth of Mayan women, of the period 600–800 A.D., perhaps for ornamental and restorative purposes.^[20] Natural jade is a quite hard, durable crystalline mineral of ceramic.

Porcelain has been used for restorative dentistry since the late 18th century. (See Ref. [1] for a review of materials in dentistry.) Porcelain inlays and crowns were made by Charles H. Land in the late 19th century by fusing the porcelain on to platinum foil in the form of a model of the tooth. Porcelain can be made with optical properties that match teeth with additions of either silica or alumina particles; such particles also increase the strength of the porcelain. Porcelain crowns can also be made strong by fusing the porcelain to a metal coping; however, the metal changes the appearance of the crown. Porcelain restorations can also be cast in a mold.

Porcelains contain various mixtures of clay (e.g., kaolin, $\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2 \cdot 2\text{H}_2\text{O}$), feldspar ($\text{K}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 6\text{SiO}_2$), and quartz sand. A typical hard porcelain for whiteware contains 50% clay, 25% feldspar, and 25% sand. Dental porcelains have more feldspar and little or no sand. A typical composition is 95% feldspar, 5% clay. The result is a highly glassy material that is translucent and melts at a lower temperature because of the high feldspar content. During firing of porcelain the feldspar melts first to provide a molten matrix that speeds consolidation of the powders and gives a glassy matrix on cooling. The clay dehydrates and transforms to fine, elongated crystals of mullite, $3\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$, that provide additional strength to the resulting material. Any quartz or alumina particles partially dissolve, and the residual crystals increase strength but reduce translucency.

Material properties of porcelains are not sensitive to small changes in composition, forming methods and firing temperatures. As the firing temperature or amount of liquid (feldspar) increases, more silica and alumina dissolve in the feldspar melt, increasing the

viscosity and lowering the reactivity of the molten feldspar. Porcelains, therefore, have a glassy matrix, and chemical properties that resemble those of a potassium aluminosilicate glass; they are strong, chemically durable, and can be fired at relatively low temperatures and short times. These properties have made porcelains a satisfactory restorative material in dentistry, with the particular advantage of optical matching teeth, but the disadvantage of brittleness.

Aluminum oxide is very hard (9 on the Mohr scale), stable to high temperatures, and chemically durable. Polycrystalline sintered alumina is very strong compared to most ceramics, although it is brittle. Its strength, abrasion resistance, and chemical inertness have made it attractive for dental and bone implants.

Porous calcium aluminate was made by sintering fine alumina powder with coarse calcium carbonate at 1450°C for 24 hr.^[21] Pore sizes from 20 to 100 μm resulted by using different sizes of the calcium carbonate particles; the pore size was about the same as the particle size. The carbonate decomposed to calcium oxide, which then reacted with alumina to form two calcium aluminate phases, $\text{CaO} \cdot \text{Al}_2\text{O}_3$ and $3\text{CaO} \cdot 5\text{Al}_2\text{O}_3$. With a starting composition of about 27% CaO and 73% Al_2O_3 (by weight), the amounts of the two phases were about those expected at equilibrium (20% $\text{CaO} \cdot \text{Al}_2\text{O}_3$, 80% $\text{CaO} \cdot 5\text{Al}_2\text{O}_3$). Porous $\text{CaO} \cdot \text{TiO}_2$ and $\text{CaO} \cdot \text{ZrO}_2$ were also made by reaction of calcium carbonate with TiO_2 or ZrO_2 . One reason for porous implants is to provide a place for bone to grow into, to hold the implant mechanically. However, porosity weakens the solid implant, and the spaces in the pores not filled by bone invite bacterial infiltration and infection.

Glassy carbon is produced by pyrolysing cross-linked organic polymers such as cellulose, phenylformaldehyde, and polyfurfuryl alcohol under carefully controlled conditions.^[22] The microstructure consists of random crystallites about 5 nm in size, in contrast to the ordered layer structure of graphite. The density of glassy carbon (1.4–1.5 gm/cm^3) is lower than that of graphite, but glassy carbon has low porosity and permeability. The mechanical properties are similar to those of silicate glasses; the strength and modulus are higher than those of graphite. Glassy carbon is chemically inert compared to graphite, probably because of its low porosity. Glassy carbon is quite expensive to manufacture.

There was a flurry of interest in glassy carbon implants in dentistry in the mid-1970s.^[5] Bone does not bond to glassy carbon, so the implants and tooth replacements were made in various shapes, such as blades, with holes for bone to grow into to anchor the implant. Some of these implants were initially successful, but fractured or loosened after a few months to 1 or 2 yr after implantation. The fatigue resistance of glassy carbon should be high.

Pyrolytic carbon coatings have been used in a variety of implant applications, such as heart valves and artificial arteries.^[5] Artificial joints and parts of heart valves have been made of solid carbon. Pyrolytic carbon has good fatigue resistance.

COMPOSITES

Combinations of ceramics with either other ceramics or other materials can lead to improved properties and thus to more applications. Most work has been done on composites with HA because of its excellent biocompatibility, so this review is devoted to composites with HA, either as a matrix or as a filler.

Reinforcing materials have been incorporated into HA to improve its mechanical properties. Metal and ceramic wires have been hot-pressed in an HA matrix at 1000°C and 1 kbar for 15 min;^[23] in such processes, it is necessary to match the coefficients of thermal expansion (CTE) closely to make dense and crack-free composites. The most successful alloys for wires were Hastalloy (51% Ni, 22% Cr, 9% Mo, 18% Fe) of 8 μm diameter and FeCrally (79% Fe, 16% Cr, and 5% Al) of 20 μm diameter; the oxide reaction layers on the wire surfaces gave good bonding to HA. FeCrally composites containing 20% and 30% wire volume were stronger than HA.

Alumina is hard and strong, so Al₂O₃ powder has been sintered with HA at temperatures of 1100–1400°C to form dense composites.^[24–29] One problem with such constructs was that the alumina catalyzed the decomposition of HA by the formation of calcium aluminates (CaAl₂O₄, CaAl₄O₇), for example, in the reaction

The water formed in this reaction can lead to porosity in the sintered composite and thus weaken it.

Addition of 5 wt% calcium fluoride to the sintering mixture reduces the porosity of the alumina–HA composites and increases their strengths.^[24–29] Partial substitution of hydroxyl groups in apatite by fluoride at temperatures of about 800°C reduces decomposition of apatite by Eq. (6) and leads to lower porosity in the apatite because less water is produced. In this case, the pertinent reaction is

In the alumina–HA composites the CaO reacts with Al₂O₃ to form CaAl₂O₄:

Strengths of alumina–HA composites above the 200 Mpa strength of pure apatite were reported for these composites with low porosity.^[24,27,28] The fracture toughness of alumina–HA composites were also reported to be higher than the value of 1 Mpa√m for pure, dense HA.^[24,26,27]

Because of its high mechanical strength and chemical inertness in the human body, zirconia (ZrO₂) is also an attractive additive for zirconia–HA composites. These composites can be produced in two different ways. In the first, apatite and zirconia powders are mixed, cold-pressed into a desired shape, and sintered at temperatures from 1100°C to 1300°C.^[24,30–33] In the second method, the apatite and zirconia are precipitated from aqueous solution by mixing solutions of Ca(NO₃)₂, (NH₄)₃PO₄, and ZrOCl₂^[24,34,35] to form mixtures of HA and ZrO₂ crystals, which are then sintered.

Zirconia also increases the tendency for decomposition of the HA, as does alumina. In this case, a possible reaction is:^[24,32,33]

Again, the formation of water increases the porosity of the sintered composite and reduces its strength. Addition of 5 wt% CaF₂ to the mixture substitutes fluorine for OH at about 800°C by the reaction of Eq. (7) and reduces the formation of water and the resultant porosity.^[24,33] Diametral tensile strengths of greater than 300 MPa are possible for HA–zirconia composites containing 40 wt% ZrO₂.^[24] Higher fracture toughness was also reported for HA–zirconia composites as compared to pure HA.^[24,33,35]

Mixtures of HA granules in a variety of matrices have also been used in various implant applications. HA in plaster of Paris (calcium sulfate or gypsum, CaSO₄·2H₂O) has given good results in alveolar ridge augmentation and in the treatment of periodontal defects.^[4] This mixture can be shaped to fit a variety of defects and sterilized without changing its form or properties. After implantation, the plaster of Paris is gradually replaced by fibro-vascular tissue, and the HA particles remain firmly in place. A more complex mixture containing hydroxylapatite, corticocancellous cranial bone, Bacitracan powder, and thrombin was implanted into a variety of bony defects.^[4] The autogenous bone was presumed to stimulate subsequent bone growth; however, the osteocytes originally in this bone did not survive the transplantation surgical procedure, so new cells must grow to provide new bone growth.

COATINGS

To take advantage of the excellent biocompatibility and bonding of HA to bone, the HA can be coated on

a metallic substrate to make a composite material with good impact resistance.^[36,37] The HA coating also prevents the metal from reacting with body fluids, and migration of metal reaction products into neighboring tissues.

The most commonly used alloys for implants are based on titanium, cobalt–chromium, and stainless steel (iron, nickel, and chromium). They have good resistance to body fluids and reasonable strength, but they all induce fibrous encapsulation and some degree of foreign body reactions.

Many different methods of coating HA onto metals have been used including plasma spraying,^[36–39] sputtering,^[40,41] polymer-assisted^[42] dipping,^[43] sol–gel processing,^[44] electrophoretic deposition,^[45] and hot isostatic pressing.^[46] However, none of these methods has led to a satisfactory coating because such coatings contained cracks, pores, second phases, and residual stresses that reduced their durability and led to partial or complete disintegration of the coating in body fluids.^[2,47]

In plasma spraying, the most used coating method, a fine (<50 μm) ceramic powder is blown through a plasma torch flame onto a metallic substrate. The plasma is very hot, but if conditions of flow are regulated, the powder can have a temperature much lower than the plasma. In ambient air, HA begins to decompose above about 1200°C; this reaction can be suppressed by adding water to the powder stream. Some plasma-sprayed deposits of HA show evidence of melting before deposition, which means that the HA powder reached a temperature above its melting temperature of about 1500°C.

In a detailed study of bonding of HA to titanium in several different kinds of experiments, it was shown that the HA bonds strongly and chemically to titanium^[48] to form perovskite, CaTiO₃, at the HA–titanium interface by the following reaction:

The TiO₂ is formed on the titanium surface either by oxidating in air or by residual oxygen or water. Since the HA and titanium react and bond strongly, it was concluded that cracks and weakness at the HA–titanium interfaces result from stresses generated by the mismatch between the CTE of these materials.^[48] In a study of bonding of HA composites to different alloys,^[24] it was found that when the CTE of the HA composite and the alloy were close (within about ±5%), the HA and alloy bonded tightly without cracks at the HA–alloy interface. For example, composites consisting of 25–40 wt% Al₂O₃, HA, and 5 wt% CaF₂ had CTE close to that of an alloy of titanium containing 6% Al and 4% V; the HA composite formed thick coatings on this alloy with good interfacial bonding.

Thus, the key to making successful coatings of HA on metals and alloys is to match their CTE closely.

BIOMIMETICS

Many biological structures have remarkable mechanical properties, in addition to the chemical properties required in physiology. Examples are bone, many sea-shells, and sponge spicule. Some of these structures have high strength and remarkable impact resistance. They are made up of combinations of an organic matrix and inorganic crystals. For example, bone consists of fine plate-like HA crystals (with dimensions of about 20 nm) bonded in a matrix of the fibrous protein collagen. Abalone has aragonite (CaCO₃) platelets in an organic film that grows to become nacre (mother of pearl).

The unusual properties of these structures have led to the idea of making similar structures synthetically. Since this process copies nature, it has been given the name biomimetics. There is a review of many aspects of biomimetics in the new journal *Nature Materials* with 97 references.^[49] For the present discussion, I will select a few examples from this review; the reader is referred to the review article for more details and references.

The goal of biomimetics research is to construct structures of various interesting inorganic materials in a protein matrix. The protein bonds to the inorganic solids; the main difficulty is to assemble these micro-composites into larger-scale structures that mimic natural structures (such as bone and nacre) that have a complex hierarchy of architectures from the initial scale (a few tens of nanometers) to macroscopic structures (millimeters). The first step in this process is to find proteins and polypeptides that bind to the nanoinorganic crystals and then to assemble them into macrostructures.

Proteins are large complex organic “molecules” vital to life. They come in a wide variety of sizes, shapes, and chemical constituents. Examples are the fibrous collagen that forms the bone matrix, and globular albumin in blood. Proteins are made up of amino acids, which are molecules containing carboxyl (COOH) and amine (NH₂) groups. Amino acids form chains of molecules called peptides or polypeptides, which are then folded and bonded into the complex structures of proteins. Proteins bond to solid surfaces (and other molecules) as determined by the specific organization of the carboxylate and amine groups in them; proteins also have recognition mechanisms related to their size and shape. Thus, the challenge of biomimetics is to find or synthesize polypeptides and proteins that bond as specifically as possible to inorganic materials.

Some particular inorganic materials that are being studied in biomimetic architectures are fine gold

particles,^[50] “quantum dots” (small particles) of GaInAs,^[51] and carbon nanotubes.^[52] Bonding of proteins to a variety of other inorganic solids^[49] such as silicates, ZnO, CaCO₃, Fe₂O₃, and ZnS is also possible.

Some other biomimetic applications involve proteins that copy unusual behavior in living systems. One possibility is proteins that serve as actuators in micro- and nanodevices.^[53] Another application is a contractile protein from broad bean as a driver for a micro-motor.^[54] Much more work is required to copy the architectures and functions of proteins and protein-inorganic combinations in nature.

PROSPECTS

Ceramics are being developed for a variety of implant applications, with HA, especially in composites with other ceramics and as coatings on metals, being the most promising. Architectures that copy natural combinations of proteins and inorganic materials (biomimetics) also are highly attractive for applications.

Ceramics in Dentistry

Nicolas M. Jedyakiewicz

School of Dentistry, The University of Liverpool, Liverpool, U.K.

INTRODUCTION

Teeth are complex organs of the human body and consist of several component tissues, both hard and soft (Fig. 1). If lost, a tooth cannot be regenerated. If damaged, a tooth cannot be repaired by the body. The tooth is subject to many damaging influences. Dental caries (tooth decay) damages teeth by bacterial attack, demineralising and softening the enamel and the underlying dentine. Acidic fluids such as canned drinks and salad dressings cause chemical dissolution and demineralization of the tooth surface. Trauma may chip, crack, or fracture teeth. Those who are fortunate enough to retain their teeth into later life discover the problems brought about by a lifelong developing payload of wear, fatigue, and dietary corrosion within the substance of teeth. The body has a limited capacity for remineralization, where early decay or chemical dissolution has damaged a tooth surface; but if the integrity of the tooth is further threatened, then the best that the tooth can do is to form a calcific mass within the dental pulp. This creates a physical barrier against the intrusion of bacteria and oral fluids, but in no way replaces damaged or missing tooth tissue.

Such a limited response to damage means that few people in the developed world are able to avoid encounters with restorative dentistry. Restorative dentistry concerns itself with repairing damaged teeth and their supporting structures. Patients are increasingly demanding that such repairs should not only function in the manner of an undamaged tooth, but also look like an undamaged tooth. Aesthetics are today of paramount concern, and the only medical material that in any way provide a durable and satisfactory solution to the aesthetic repair of teeth is ceramic. This article examines the manner in which dental porcelains attempt to meet the challenges set by the need to achieve an appropriate visual appearance, whilst providing sufficient strength to accept the loads placed upon teeth during function.

THE STRUCTURE OF TEETH AND THE DERIVATION OF THE AESTHETIC FORM

Teeth have a complex structure with a layer of enamel firmly attached to a supporting framework of dentine.

Enamel forms a crystalline shell of hydroxyapatite. It has an anisotropic structure that is aligned to the direction of maximum loading. The dentine is a strongly anisotropic framework of fluid-filled microtubules that contain cellular components of the underlying dental pulp. The dentine has viscoelastic properties and functions with the overlying enamel in accepting the mechanical load of the bite. The union between the enamel and dentine is profoundly strong and enables the synergistic mechanical behavior of these two rather different materials. It is the creamy blue–white translucency of the enamel sitting upon the rather more opaque and yellow dentine that gives the distinctive appearance to the tooth. The main physical characteristics of a tooth, which contribute to its aesthetic form, are the color (in terms of hue, chroma, and saturation), translucency, and surface reflectance. Opalescence, fluorescence, and metamerism also challenge the dental ceramist in matching the appearance of a tooth. The complexity of such a color can be seen in the handmade ceramic crown, shown in Fig. 2. Analyzing and matching the aesthetic characteristics of a patient's tooth is one of the most challenging elements of restorative dentistry. Furthermore, this description must be communicated to a technician in a remote laboratory where ceramic restorations are made. The conventional approach is to use a series of color-matching tabs that are held adjacent to the tooth surface, and an evaluation and match is made by the dentist. This is fraught with problems such as the color balance of the illuminating light and even the incidence of minor color blindness in the operator. Recently, several automated color analysis devices have been produced, the most sophisticated using hand-held spectrophotometers to analyze the color.^[1]

One problem in matching the optical characteristics of the existing teeth is that the natural appearance is not constant throughout life. Surface biofilms attach differentially to teeth and restorations and may absorb stain, although these may be removed by professional cleaning. A greater problem is that the color and translucency of teeth alter as age progresses, and a ceramic restoration that matches the tooth of a teenager precisely, will not be an effective match when the patient reaches middle age. Cosmetic bleaching of teeth can complicate matters, because unnatural levels of whiteness can be achieved. The bleaching process must

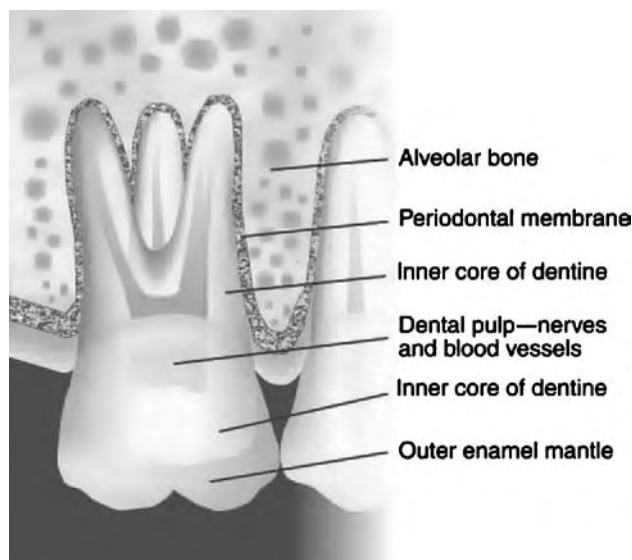

Fig. 1 Diagrammatic representation of the structure of a human tooth.

be refreshed regularly to maintain the brightness. Whilst a gradual color change in the dentition as a whole is not so noticeable, the presence of a fixed reference color in the form of a ceramic restoration can be very distracting.

Overall, the replacement of enamel and dentine with prosthetic materials is extremely challenging. Repair is equally difficult. Any repair needs to have sufficient physical properties to resist repetitive biting forces, and must be fully sealed to the remaining tooth tissue to avoid microleakage at the interface. Furthermore, such a repair may need to function and the seal may need to the tooth remain intact for several decades.

REQUIREMENTS OF CERAMICS IN DENTISTRY

The Oral Environment

The human mouth provides one of the most inhospitable environments for structural materials. It is warm, wet, and both chemically and biologically active. It is capable of generating quite massive force concentrations, and the variance in such characteristics between individuals is enormous. The challenges in restoring damaged tooth tissues are therefore considerable in terms of the mechanical behavior of structural repair materials. The challenges are compounded by the need for the repairs to blend visually into the existing tooth structures. A range of materials are used commonly in repairing teeth and replacing missing teeth, and these include cast metals, dental amalgam, glass polyalkenoate cements, and resin composites. Metals offer the greatest strength and durability. The most successful aesthetically is dental

Fig. 2 A completed ceramic crown showing the complexity of color and translucency that is needed to match adjacent teeth.

porcelain, but the mechanical properties are often barely adequate. The challenge to dental science is to endow dental porcelains with sufficient attributes of strength, corrosion resistance, fatigue resistance, and other such factors to enable them to restore damaged teeth for the remaining lifetime of the patient.

Teeth

Physical properties

Teeth, and in consequence dental restorations, are subjected to considerable but varying and repetitive loads. Loading occurs not only during normal biting and chewing, but also in aberrant processes such as the form of nocturnal grinding known as “bruxism.” A small adult may apply as little as 80 N load upon maximal bite. A large and muscular individual may raise 1000 N. Typical values for normal chewing are in the order of 50–250 N, rising to 550–880 N during parafunction.^[2] Therefore, the clinician has to analyze each situation very carefully to make an appropriate choice of dental restoration.

Generally speaking, even when selected correctly, dental ceramics are only marginally able to withstand the loading that may be expected to be applied to them during function and parafunction. The greatest challenge with dental ceramics is to achieve an adequate level of strength in any given clinical situation. The required physical properties and testing methods for dental ceramics are specified in ISO standard 6872.^[3]

Biological properties

Artificial repair materials, when used in the human body, must be biocompatible—that is, they must

invoke an appropriate response from the host organism. This may range from no response at all, to repair and regeneration. When teeth are repaired, there are three main concerns regarding biocompatibility. The first concern is the development of an appropriate biofilm on the surface of the restoration. All surfaces of normal teeth are coated with a biofilm, and it is via the biofilm that remineralization of teeth can occur. It is also the cause of demineralization, when local areas where microorganisms are attached are able to metabolically alter the local pH and commence the processes of dental caries or tooth decay. It is important that any artificial surface does not attract colonization with bacteria that may be pathogenic to the adjacent host tissues. This is essential in cases where a dental restoration comes into contact with the soft tissues of the gums and the periodontal ligament. The periodontal ligament is the attachment of the gum and bone to the tooth. It is a unique structure in that it is the only point in the entire body where the envelope of epithelium that protects us from the outside world is broken. The ligament is complex in form, and the attachment to the tooth surface is mediated via hemidesmosomes. This attachment is the structure that becomes damaged in periodontal disease, and this process may be exacerbated directly by irritant materials or indirectly by the change in profile of the bacterial flora brought about by the nature of the surface of the restoration.

Secondly, there must be some form of seal or adhesive fusion between the restoration and the adjacent tooth tissue. This is essential to prevent the ingress of bacteria and their metabolic products past the restoration and into deep dentine, where irritation of and damage to the underlying dental pulp may occur.

Thirdly, the material itself must not in any way be toxic or leach out any toxic or mutagenic components into the dentine of the tooth or into the mouth.

Ceramics are generally excellent in all these respects. They are usually relatively inert. When polished or glazed correctly, they do not facilitate the development of an inappropriate biofilm, and they do not sustain an overgrowth of pathogenic bacteria. They can be firmly attached to the tooth with dental adhesives and mostly do not leach out any toxic components.

LIMITATIONS OF CERAMICS IN DENTAL APPLICATIONS

Applications of Ceramics in Dentistry

When teeth are damaged, three main types of restoration are used to effect a repair: block replacement (fillings and inlays), shell coverage (crowns), and

Fig. 3 Repair of teeth (from left): block form (fillings and inlays), laminate form (dental veneers), and shell form (crowns).

surface lamination (dental veneers) (Fig. 3). In the case of block replacement, there is a large volume of material that is usually supported on several surfaces by the containing tooth. The significant thickness of the restoration helps in resisting loads, and adequate strength is relatively easily achieved. Shell form coverage represents the typical dental crown. The tooth is reduced to a generally conical form upon which a crown can be cemented. Traditionally, the cement layer is merely a lute or watertight seal composed of an inorganic cement. In such a configuration, the ceramic crown needs great strength to resist biting loads.

Surface lamination is a more recent innovation. An all-ceramic restoration—either a full crown veneer or a part veneer—is fabricated. The fitting surface of the ceramic restoration is then etched with hydrofluoric acid to create microscopic convolutions into which a resin may be run (Fig. 4). Similarly, the tooth surface is prepared by etching with phosphoric acid. This creates a surface on the enamel, similar to that of the etched ceramic. The surface of the dentine behaves rather differently, but the demineralizing effect of the acid etching leaves a surface that can be diffused with polymer resins to gain an adhesive bond. In this manner, the ceramic restoration can be firmly attached to the underlying tooth substance, and this compound form achieves a very high working strength. Clearly, such a process requires a disciplined and careful clinical stage, and contamination at any point in the attachment procedure may compromise the mechanical strength of the restoration enormously. From an aesthetic viewpoint, however, a superlative result can be achieved, and the advantages have been demonstrated in clinical practice.^[4,5]

DENTAL CERAMICS

Feldspathic Porcelain

The original form of dental porcelain is feldspathic porcelain. This type of porcelain presents as a powder, which is mixed with water to form a slurry, and this is

Fig. 4 Ceramic surface. (A) After machining to form and (B) after etching with hydrofluoric acid. Field of view: $60 \times 60 \mu\text{m}$.

stacked up onto a die form by hand and then sintered in a furnace. The die is cast in dental stone from a dental impression, and it is covered with a foil of platinum upon which the restoration is built up (Fig. 5). The foil is removable from the die and is used to carry the stacked porcelain powder to the furnace where it is sintered, maintaining the form of the fitting surface of the crown. The process of sintering causes the porcelain mass to shrink considerably, and this shrinkage must be accommodated by overbuilding before firing. Sintering leaves a dense but microscopically rough and porous outer surface to the restoration, and this must be filled

Fig. 5 Stacking feldspathic dental porcelain powder upon a die to form a dental crown.

in and sealed by the application of a glaze layer of a lower melting point ceramic.

Whilst the shape of the fitting surface is maintained by the foil matrix, shrinkage of the ceramic still occurs. This leads to small crack defects on the fitting surface of the restoration. These blemishes are known as Griffith's flaws, and they contribute greatly to a reduction in the overall strength of the restoration, because it is from these defects that cracks propagate when the crown is loaded (Fig. 6). The whole process of building up a ceramic crown is immensely labor intensive, and very high levels of skill are needed. Nevertheless, by building up crowns with various matching colors and translucencies of porcelain powder, a result that is indistinguishable from the natural teeth can be achieved. Glazed ceramics also provide a surface that is very resistant to the buildup of dental plaque and is very acceptable, biologically, to soft

Fig. 6 Crack defects occur on the fitting surfaces of ceramic crowns owing to shrinkage upon firing. The carrier resists deformation as the porcelain shrinks and therefore crack defects open up. These are known as Griffith's flaws, and their presence or absence determines the strength of the crown.

tissues that contact it. The greatest problem is that the strength of such a restoration is very low, limiting the application to situations where loading forces are minimal.

Porcelain Bonded to Metal

The problem of Griffith's flaws on the fitting surface of feldspathic porcelain crowns has been noted above. By bonding the porcelain to a metal carrier, the inner surface of the porcelain mantle is left under tension, and crack flaws do not form at the metal–ceramic interface (Fig. 7). The metal carrier then becomes part of the crown. This increases the strength of restoration by eliminating the initiation points of potentially propagating cracks. The strength of this combination enables porcelain to be used on load-bearing surfaces, but the downside is that the metal must be hidden under a layer of opaque ceramic before the translucent layers are added.

The challenge in achieving the combination of ceramic bonded to metal is that the metal must have a higher melting point than the ceramic, so that the ceramic powder can be fused over it. The second problem is that normally ceramics have a much lower coefficient of thermal expansion than metals. This would mean that as the metal carrier cooled and shrank, the overlying ceramic would fracture off.

In 1962, Weinstein formulated a porcelain powder that had a high coefficient of thermal expansion and low fusion temperature.^[6] A gold alloy with a relatively low thermal expansion and a high fusion temperature was achieved by alloying gold with platinum and palladium. Finally, by adding a small amount of tin to the metal, a tin oxide layer can be created on the metal carrier that can fuse with the metal oxides of the applied porcelain. The glassy phase of the porcelain dissolves the oxide at the metal surface to form a bond with the metal. In this manner, porcelain could be coated and bonded onto a metal base giving an

enormous gain in strength. A second advantage is in the precision of fit, because this is now determined by metal casting rather than by the sintered porcelain powder.

A metal substructure allows an extension of the restoration where necessary. For example, a tooth may be replaced by a crown that is attached to one or more crowns on teeth adjacent to the gap in the form of a bridge. Fig. 8 shows metal–ceramic crowns that have been precision milled to enable the attachment of a removal denture to replace missing teeth.

In recent years, several lower cost alloys have been developed to substitute for the original precious metal system. These include palladium–silver alloys and nickel–chromium alloys.

Porcelain bonded to metal is of the highest strength, and this is the most ubiquitous method of using ceramics in dentistry.

High-Alumina Porcelain

To the clinical dentist there seems to be an inverse relationship between aesthetics and strength in dental ceramics. As the strength increases there is a significant loss of aesthetics. One of the earliest attempts to achieve greater strength in ceramic crowns was the use of high alumina feldspathic porcelain—typically 40% Al_2O_3 . The alumina increased the strength by blocking crack propagation, but this is at the expense of an almost complete loss of translucency. Therefore porcelain crowns with high-strength core structures were developed, whereby an aesthetic porcelain overlay was fired against a high-strength but opaque core (Fig. 7B). The downside of this technique is that the minimum thickness of the crown increases, requiring the dentist to cut back the tooth further. If insufficient space is provided to the technician, then a crown is returned to the dentist with a bright alumina core showing through the surface.

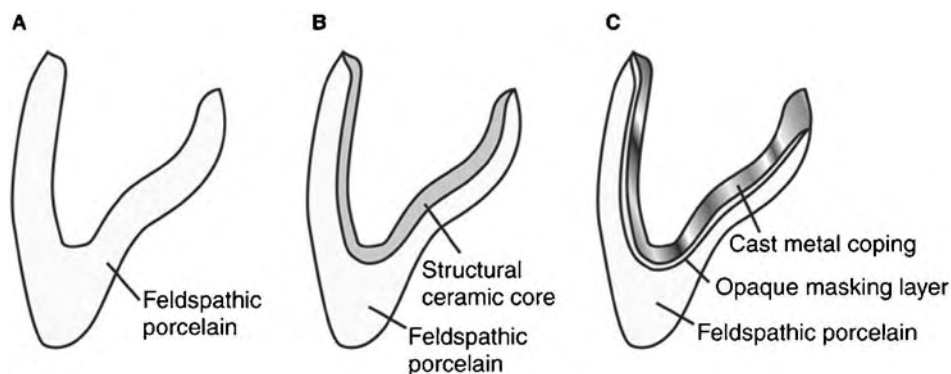

Fig. 7 Structural form of dental crowns. (A) A conventional porcelain jacket crown, (B) a porcelain crown reinforced with a structural ceramic core and (C) a porcelain-fused-to-metal crown.

Fig. 8 Three porcelain-bonded-to-metal crowns on a laboratory model. The metal substructure is left open on the hidden side and has been precision milled to enable a denture to be attached onto the crowns. The retention of these teeth increases the stability of the denture very considerably.

Glass-Infiltrated Cores

A further development of the high-strength ceramic core approach uses a sintered core of alumina or zirconia that is subsequently infused with molten lanthanum glass. The system is marketed as “In-Ceram” (Vita-Zahnfabrik, H. Rauter GmbH & Co, Bad Sackingen, Germany).

The ceramic core is formed by applying a slurry of alumina powder to a die in a process that is known as slip casting. This core is dried and then fired very slowly in a furnace, typically at over 1120°C for 10–12 hr. This temperature is insufficient to melt the alumina, but does permit solid-phase sintering to occur between adjacent particles. This results in a highly porous structure with little shrinkage compared with conventional dental porcelain. This porous shell form is placed in a dish and sprinkled with lanthanum glass powder. In a further firing at 1100°C for around 5–6 hr, the glass melts and infiltrates into the porous alumina core. At the end of the process, excess glass is attached to the surface of the core and is ground off with rotary diamond grinders. The resultant core is used as a base upon which conventional feldspathic porcelain powders are applied to develop the final structural and aesthetic form. Whilst the strength is increased significantly, the fitting surface of the restoration does not lend itself easily to adhesive cementation techniques because it resists etching.

Glass Ceramics

Glass ceramics were developed for dental applications by the Corning Glass company in the late 1980s,^[7] and were marketed under the brand name “Dicor” and

“Dicor MGC” (machineable glass ceramic). Glass ceramics offer some novel advantages for dental applications. Firstly, they are relatively, dimensionally constant when cast or hot pressed to shape. Secondly, they can be machined relatively easily, allowing them to be fabricated by computer-aided design–computer-aided manufacturing (CAD–CAM). The surface that results from machining can be polished successfully to give an excellent external surface to the restoration. The machined surface can also be etched to create a microscopically porous surface that is appropriate for adhesive attachment on the fitting surface.^[8] Glass ceramics are also very aesthetic, as they can be formulated to replicate both the color and the translucency of human enamel.

Glass ceramics have several possible formulations. Typically, the microstructure consists of a highly interlocked array of tetrasilicic fluormica crystals at approximately 70% by volume in a nonporous glass matrix.^[9] Oxide colorants are added. The glass is melted at temperatures in excess of 1400°C, and then cooled and annealed. At this stage the glass is clear and may be shaped by casting or rolling. The material becomes a glass ceramic at the next stage, where it is, in its final shaped form, reheated at between 650°C and 1150°C for several hours, a process of tempering that is sometimes referred to as “ceramming.” This produces a uniform dispersion of randomly oriented tetrasilicic mica crystals. The tempering process is critical in both time and temperature to ensure appropriate crystal growth. If the crystals are either too small or too large, then the physical properties of the final material will be compromised. The mica crystal plates are around 2 μm in size, and their formation causes the transparent material to become translucent and to develop the final color and aesthetic form, as well as the final strength.

If the glass ceramic is to be cast or pressure formed, it is supplied as clear glass ingots that require post-processing in a furnace. If the material is to be machined, it is supplied fully processed as a glass ceramic block, with the final optical characteristics fully established. Glass ceramic crowns are pressed or machined in the full, required shape, and additional ceramic material is not normally added. Therefore, the final aesthetic form may require the application of surface stains to achieve a fully characterized color match to the underlying tooth.

Leucite-Reinforced Ceramics

The glass ceramic “Empress” (Ivoclar-Vivadent, Schaan, Liechtenstein) is a glass ceramic with leucite crystal precipitation within the material.^[10] Like the Dicor material, it can be either machined or hot pressed.

Alumina-Reinforced Ceramics

High-purity alumina powder can be isostatically compacted into ingots that can then be machined into a substructure for dental ceramic restorations. Following machining, the shaped mass is sintered at temperatures in the range 1600–1800°C, a process that transforms it into a dense polycrystalline solid with substantial physical properties. Dimensional changes occur during the sintering process, and therefore the pattern shaping of the ingot is usually performed by a CAD–CAM system that allows an overbuild proportional to the final shrinkage. Conventional dental porcelains can then be built up over this core to form an aesthetic restoration. This principle underlies the Procera AllCeram system (Nobel Biocare AB, Gothenburg, Sweden), which uses a digitizer to scan a conventional model die. The data are then sent to a central processing factory, where the construction of the alumina coping occurs. The core is then returned to the participating dental laboratory for the completion of the process by the addition of aesthetic feldspathic porcelains.

The fitting surface of an alumina-cored crown cannot be etched to gain micromechanical attachment of adhesive luting cements. Therefore, many of the advantages of adhesive luting are unavailable in this method.

Zirconia-Reinforced Ceramics

Zirconia offers the highest strength material for the ceramic reconstruction of teeth. Although impressive by comparison with other forms of dental ceramics, when compared with metals, there is still a massive discrepancy. A zirconia-based restoration may have a flexural strength one order of magnitude greater than that of a feldspathic porcelain crown. Metals may achieve more than two orders of magnitude. Therefore cast metal restorations remain the most durable method of repairing in high-stress situations such as multiple unit bridgework.^[11] The vulnerable zone in bridgework is the connector, which is the component that attaches the replacement tooth to the crowns on the adjacent teeth. Ceramic connectors need to be substantial to resist flexural loading as biting occurs. Zirconia connectors over 7 mm in diameter have been shown to be unable to resist maximum biting loads.^[12]

Zirconia has a dense white color. This is unacceptable for the final appearance of a dental restoration, but it does give a suitable backdrop for the buildup of other aesthetic ceramics as a surface veneer. It is in this manner that zirconia is used, mainly to form a substructure around which aesthetic but lower strength veneer porcelains can be applied. Coloration of the

zirconia core is now becoming available, and this means that the balance between the thickness of the high-strength core and the overlying aesthetic porcelain can be altered in favor of strength.^[13]

The great strength of zirconia is attributed to its resistance to crack propagation by a mechanism of transformation toughening. Zirconia undergoes a volume change related to a tetragonal phase to monoclinic phase transformation. After initiation at the surface, a propagating crack causes a transformation of adjacent zirconia grains into a monoclinic phase. The monoclinic phase occupies a larger volume, and therefore compressive stresses are induced in the material at the crack front. More energy is required for the crack to propagate further, and therefore the progress of the crack may be halted.

Zirconia is a difficult material to fabricate. During machining, the same phase transformation that provides it with strength causes a dimensional change. Hence, it resists machining aggressively because of its high fracture toughness.

As a work around, many systems use a block of consolidated zirconia particles that is machined to an appropriate form. The machined block is then fired slowly in a furnace to sinter the zirconia into the high-strength structure. Sintering results in a considerable shrinkage of the material that may be in the range of 25%. This must be compensated for, by shaping the material into an appropriately oversize block, before firing. This cannot be done by a technician, and therefore CAD–CAM systems are used (Fig. 9). Like the alumina cores, zirconia cores cannot be etched to gain micromechanical attachment of luting cements to the fitting surface.

Fig. 9 Zirconia frameworks for porcelain crowns machined oversize by CAD–CAM (CERCON), prior to trimming and firing.

Ceramic Resin Composites

The commonest method of using ceramic materials to restore teeth is to insert a composite paste of powdered glass or ceramic bound in a polymerizable plastic resin. The resin enables adhesives to be used, to bind the restoration to the underlying tooth. The disadvantage of this system is that the resin systems that are used currently shrink upon setting, and this polymerization shrinkage must be accounted for in the placement process. Deterioration of the resin in the hostile environment of the mouth is a limiting factor in the life of such restorations. Nevertheless, it is such resin composite materials that provide the best interface between ceramic restorations such as crowns and veneers and the underlying tooth substrate.

Bulk Fillers

Methods of fabrication

Some aspects of fabrication methods for dental ceramics have been touched upon earlier, but their importance requires further examination.

Accuracy and fit

The dental ceramic restoration must be made to very high degrees of accuracy. It must fit precisely to the prepared tooth surface, with just enough space to permit an interposed adhesive film. It must have an occlusal (biting surface) shape that provides a precise series of contacts with the opposing teeth, and a shape that precludes interfering contacts when the jaw moves in a grinding or chewing pattern. The restoration must also fit between adjacent teeth with enough contact pressure to prevent the interposition of food debris, but without so much pressure that the restoration could not be fitted without the contacting teeth being forced aside.

Whilst certain adjustments can be made by the dentist at the time of fitting the restoration, notably to the occlusal surface and the points contacting adjacent teeth, such adjustments can damage the surface finish. Some ceramics can be quickly reglazed if a glazing furnace is to hand, but such a stage is time consuming and expensive in surgery time. An unglazed rough ceramic surface can cause significant wear of the opposing tooth surfaces and should be avoided.^[14] One advantage of machineable ceramics is that they are usually both internally dense and free of porosity, and are polishable to a high glaze. This can be achieved easily at the chair-side.

Many aspects of the subjects discussed herewith are involved with accuracy of fit and the dimensional

changes that occur within the fabrication processes. Therefore, this raises the question of how accurate a fit is needed. All laboratory made restorations need to be cemented into place, and the cement must occupy an evenly space layer between the crown and the tooth. When a crown is being fitted, it is filled with a low-viscosity cement and then pressed onto the prepared tooth. The cement has to flow, and the excess material has to be expressed out at the marginal gap. The limit of this flow and the resultant marginal fit will be a function of both the rheological behavior of the cement and fit of the crown. To allow for the thickness of the cement layer, the die upon which the crown is fabricated is often coated with several layers of a varnish to build up the potential cement space. The varnish is omitted from the margins of the die to allow tight closure of the crown.

Overall, a marginal fit of 50 μm is generally accepted as good. In actual practice, the marginal fit is frequently in excess of 100 μm .

To achieve such a precision of fit, the technician must be provided with an accurate high-resolution impression of the prepared teeth. Vinyl polysiloxane impression materials provide both accuracy and resolution to contemporary dental impressions. Such materials are also acceptably stable in transit, and enable an effective model to be cast in the dental laboratory in a high-strength dental stone. Such models are visible in Figs. 5 and 8.

Mapping the biting surfaces of dental restorations to the contacts and movements of the opposing jaw is more complicated. Various methods and devices are available to record this information. This is used to set up and adjust a model of the working jaws that is referred to as a dental articulator.

Sintering

Sintering is a process whereby a paste of particulate form is heated to the point where surface melting of the particles just begins to occur. This allows fusion of the surfaces of adjacent particles without full melting, and conglomeration into a single mass. Sintering allows a structure to retain its shape. One step further in melting and flow would occur, and the shape would be either compromised or lost altogether. The process is accompanied by a considerable degree of shrinkage, and this must be accommodated in the fabrication process. The methods of compensation for this shrinkage are effective, and sintering produces accurately fitting dental restorations.^[15] Contemporary furnaces raise and lower the temperature of the workpiece according to programmes that are specific for the particular porcelain product. A slow preheat outside the furnace drives off water from the porcelain, to prevent the generation of steam later in the firing cycle. The workpiece is introduced into the furnace,

and the binders are burnt off to allow intimate contact between the porcelain powder particles. The temperature is increased subsequently until sintering occurs. Exclusion of air by the establishment of a vacuum during the firing cycle is an important element of achieving the correct porcelain density during sintering. The cooling phase is equally important to prevent internal stresses and subsequent cracking.

Casting

Casting is the process whereby a molten mass is injected into a void within a mould in the manner of the lost wax process. The mass is allowed to cool, and then the mould is broken away to release the cast object. Again, dimensional changes occur for many materials that are processed in this way. The exceptions are the glass ceramics. These materials exhibit very little change in dimension upon casting.

Hot pressing

Hot pressing is where a glass-like mass of ceramic is heated until softening occurs. The softened mass is then squeezed under pressure into a mould. The advantage of this method is that the ceramic is not molten, and therefore dimensional changes during the forming process are reduced.

Copy milling

The celay machine is a sophisticated copy-milling machine that can be used to follow a pattern and copy the shape into a block of ceramic. The operation requires the preparation of a die and the manufacture of a pattern from the die. The pattern is then placed on one side of the machine, with a ceramic blank being inserted into a chuck on the other side. A diamond-grinding cutter follows the motion of a tracing stylus, which is moved by the operator over the pattern until contact is achieved. The process is repeated over the entire surface of the pattern until the shape has been fully translated over to the recipient ceramic block. A range of matching cutters and styli allow fine detail to be copied.

CAD-CAM

Computer-controlled machining of dental ceramics offers several advantages over manual systems. Firstly, it allows the use of materials that could not be fabricated by conventional methods. Secondly, it may reduce the need for skilled dental technicians for basic restorations.

The CAD-CAM systems consist of several key components. There must be a shape acquisition device to determine the shape of the substrate tissue against

Fig. 10 A Cerec CAD-CAM milling unit. Inset left: machining an onlay restoration. Inset right: detail of the movements possible with the milling cutters.

which the restoration is to be made. Secondly, there must be a computer system to generate the spatial form of the restoration. Thirdly, there must be some form of machining or milling device to fabricate the restoration.

One of the first CAD-CAM systems in dentistry was the laboratory-based Procera system (Nobel Biocare, Göteborg, Sweden). This uses a touch probe scanner to map the surface shape of model die. High-strength alumina or zirconia copings are machined, and then aesthetic dental porcelain is added and fired conventionally. High levels of success have been claimed for this system.^[16]

The most established CAD-CAM system in dentistry is the Cerec system (Cerec, Sirona, Bensheim, Germany).^[17] This started off as a chair-side system that could scan a prepared tooth surface and generate an all ceramic restoration to fit it, whilst the patient was in the chair for a single appointment. The device combined a shape acquisition unit, a milling unit, and a computer system into a small mobile trolley that was used in the dental operatory. In the latest version of the system, the shape acquisition unit and the milling machine have been separated. The machine is multi-functional and can be used either at the chair-side or in the dental laboratory.

A feature unique to the Cerec system is the hand-held three-dimensional scanner that is used to acquire the morphologic profile of the prepared tooth. A striped reference pattern is projected onto the tooth surface in infrared light through telecentric lens. The distortion in the stripes brought about by the surface contour is observed through the same lens by a digital camera. The recorded pattern is used to build up a shape model of the tooth surface. The whole scanning and recording process takes a fraction of a second, so the scanner can be held by the dentist without a rigid support.

The machining system comprises two electrically driven and water-cooled machining heads fitted with diamond cutters (Fig. 10). These cutters act simultaneously upon opposing the sides of a centrally mounted and rotating ceramic blank. A full range of the shapes required for dental restorations can be cut. Restorations produced by the system have been demonstrated in clinical trials to offer high levels of clinical performance.^[18]

The CAD-CAM also offers an alternative to slip casting in building up restorations using glass infiltration techniques (see above). Blocks of alumina, zirconia, or spinel are manufactured by hot pressing. These porous blocks machine quite freely into a core form. The cores are then infiltrated with an appropriate glass and processed conventionally, with the technician building up the shape, form, and color with overlays of feldspathic porcelain.

Ceramic Preforms

Ceramic inlays are normally constructed to be tight fitting to the surrounding tooth structure, and to be retained with a composite resin cement. One method of achieving this is to cut a cavity into the tooth using a truncated cone-shaped diamond burr and then to insert a size-matched truncated cone of silanated glass ceramic. The Cerana system (Cerana, Nordiska Dental AB, Helsingborg, Sweden) offers such a range of matched cutters and ceramic cones. Clearly, it will not always be possible for a precise truncated cone form to match the carious lesion in the tooth, and therefore any deviation of the cavity form from a circular shape can be accommodated by an infill of composite resin. Such composites are often used as restorative materials by themselves, and, therefore, the extensions of the cavity form that are filled with a composite do not compromise the restoration to any great degree.

Adhesion to Ceramics

Ceramic restorations gain significant strength from being firmly bonded to the underlying tooth. Whilst this

Fig. 11 Trauma in the form of being kicked by a horse has fractured off the entire enamel shell from the outer surface of this patient's first premolar tooth. A veneer of ceramic was machined by CAD-CAM and bonded on in a single visit.

is a desirable approach for all ceramic restorations, some types such as veneers are entirely dependent upon adhesive placement (Fig. 11). The conventional method of preparing a ceramic for adhesion is to etch it with hydrofluoric acid, typically at a 5% concentration. In the case of sintered ceramics, this opens up microscopic involutions into the surface and allows interpenetration of polymeric resins into the ceramic surface, giving a micromechanical bond (Fig. 4). This attachment is enhanced by the use of coupling agents—methacrylate functional organosilanes—that are applied to the etched surface. The silanes attach to the silica in the ceramic and link to the polymers in the cement system.^[19]

Some ceramics, such as zirconia, that are used for coping construction are highly resistant to hydrofluoric acid etching, and other forms of surface modification such as tribochemical silica coatings may be necessary.^[20] Bonding may be improved by grit blasting the fitting surface. While this does not create the micro-involutions of etching, it roughens the surface micro-profile very considerably, and therefore increases the surface area that is available for bonding.

CONCLUSIONS

Ceramics are used widely in dentistry in many different forms. No single system yet offers the desirable combination of high strength, excellent aesthetics, and simplicity of fabrication. Metals form an essential component of the dentist's reconstructive technology, and the gap between the strength of metallic restorations and the strength of ceramics remains significant. Whilst zirconia cores with porcelain veneer layers offer much promise, long-term clinical trials are not yet available. The CAD–CAM is a maturing technology that reduces many of the variables in fabrication; but on a global basis, the cost remains quite high, limiting its use to populations that enjoy a strong economic structure.

INTRODUCTION

Chitin is the second most abundant biopolymer on earth (after cellulose). Its annual production is estimated to be almost as high as the production of cellulose. The chemical structure of chitin is similar to that of cellulose, with the hydroxyl group at position C-2 replaced by an acetamide group. Chitosan is obtained by alkaline deacetylation of chitin, present in fungal cell walls and exoskeletons of arthropods such as insects, crabs, shrimps, lobsters, and other vertebrates.^[1] The length of the chitin molecule ranges from 5000 to 8000 N-acetyl-D-glucosamine residues in crabs and may be only 100 residues in the case of some yeasts. However, these values often decrease as a consequence of chitin degradation during its deproteinization in hot alkali solution. Chitosan is a nontoxic biocompatible polymer used unambiguously in all sectors of medicine and pharmacology.^[2] This article discusses biomedical applications of chitosan, with emphasis on developments in drug and gene delivery, and a brief discussion of tissue engineering and food technology.

USES OF CHITOSAN

Chitosan (Fig. 1) may be the only biomaterial used in every sector of the medical and pharmaceutical industries, as well as in other applications.^[3–10] One characteristic of chitosan—its low aqueous solubility at a physiological pH of 7.4—limits its use as an absorption enhancer in some pharmaceutical applications. To overcome this limitation, researchers have taken advantage of the reactive functional groups of chitosan at the C-2 (amino group), C-3 (primary hydroxyl), and C-6 (secondary hydroxyl) positions to make various chitosan derivatives.^[2,3,11] Chitosan was discovered to accelerate wound healing in 1970, leading to applications in wound-healing bandages.^[12] Chitosan has been investigated as an excipient in the pharmaceutical industry in direct tablet compression,^[13] as a tablet disintegrant,^[14] for production of controlled-release solid dosage forms,^[2,4,7,8,15] and

for the improvement of drug dissolution.^[16,17] Consumption of chitosan has been clinically approved and is being marketed around the world as a trapper of fat. Chitosan is usually a high-molecular weight polymer possessing positive charge. It has film-forming ability as well as gelation characteristics and therefore finds applications in the formulation of nonviral gene delivery systems.^[18,19]

DRUG DELIVERY

Literature suggests that chitosan has been extensively investigated for its potential in the development of controlled-release systems.^[20,21] Controlled drug delivery technology is based on the systematic release of a pharmaceutical agent to maintain a therapeutic level of the drug in the body for a sustained period of time (Fig. 2). This may be achieved by incorporating the therapeutic agent into a degradable polymer vehicle, releasing the agent continuously as the matrix erodes. This concept has been demonstrated using chitosan as an excipient in various forms (viz., in hydrogels, microspheres, nanoparticles, films, etc.) (Fig. 3).^[2,22–26] Numerous such systems have been reported in the literature.

Risbud and Bhonde^[27] studied the sustained release of antibiotics in polyacrylamide–chitosan hydrogels, in an attempt to explore the favorable properties of both polyacrylamide and chitosan. Hydrogels were prepared by cross-linking an acrylamide–chitosan mixture (8:2 v/v) with N,N' methylene bisacrylamide. The gels were further characterized by SEM and octane contact angle measurements. Swelling, cytotoxicity, and release studies of the hydrogels were performed. Amoxicillin was used as a model drug. The researchers found the hydrogels to be porous with a pore size of approximately $104 \pm 7.61 \mu\text{m}$, and observed matrix degradation after the drug was released from the hydrogels at pH 7.4.^[27] They observed no pH-dependent swelling; however, a swelling ratio of about 16 was found in all buffers studied at the end of 24 hours. About 56% of the drug was released after 24 hours and 77% was

Fig. 1 Structural difference between cellulose, chitin, and chitosan.

released after 75 hours, showing the sustained-release nature of the matrix.^[27]

Chenite and coworkers^[28–31] reported novel thermosensitive chitosan gels possessing a physiological pH that can be held liquid below room temperature for encapsulating living cells and therapeutic proteins; they form monolithic gels at body temperature. The first report discusses the transformation of pH-gelling cationic polysaccharide solutions into thermally sensitive pH-dependent gel-forming aqueous solutions, without

Fig. 2 Schematic representation of conventional versus controlled drug release formulations.

Fig. 3 (A) Chitosan drug delivery; (B) various chitosan formulations in drug delivery. (From Science Finder, April, 2003.)

any chemical modification or cross-link.^[28] The gel formation resulted from the addition of polysalts bearing a single anionic head, such as glycerol-, sorbitol-, fructose-, or glucose-phosphate salts (polyol- or sugar-phosphate).^[28] Chenite et al. found the chitosan/glycerol phosphate (C/GP) gels well suited to the delivery of sensitive biological materials such as proteins and living cells. Subcutaneous injections of gels formulated with a bone-inducing growth factor (BP) demonstrate that C/GP gels can deliver active BP, leading to de novo cartilage and bone formation in an ectopic site.^[28] Subcutaneous gel implants had beanlike shape and remained morphologically intact when excised at 3, 6, 12, 24, 48, and 72 hours and at 7 days.^[28] Studies were also performed by encapsulating various cell lines, in an attempt to demonstrate the cytocompatibility of C/GP gels. These studies found cell viability higher than 80% over extended periods of time when cultured in vitro.^[28] Subsequent studies analyzed the gels for the sustained delivery of drugs;^[29] for rheologic concerns,^[30] and for the effect of steam sterilization on thermo-gelling.^[31] Molinaro et al.^[32] evaluated the biocompatibility of the four chitosan/GP solutions in vivo. From these studies it was concluded that a higher degree of deacetylation of the chitin chain is desirable for superior biocompatibility.^[32] Ruel-Garièpy et al.^[33] reported on thermosensitive chitosan-based hydrogels containing liposomes for the delivery of hydrophilic molecules. The system thus developed is capable of releasing macromolecules over a period of several hours to few days in a controlled manner; however, with low-molecular weight lipophilic compounds, the release is completed within 24 hours.^[33] Chenite et al. have proposed a mathematical model to characterize the kinetics of release.^[30] Martin et al.^[34,35] investigated palmitoyl glycol chitosan hydrogels for the delivery of macromolecules.

Fig. 4 Chemical structure of deoxycholic acid-modified chitosan.

Lee et al.^[36] reported self-aggregates of deoxycholic acid-modified chitosan as a novel carrier of adriamycin, where deoxycholic acid was covalently conjugated to chitosan via EDC-mediated reaction to generate self-aggregated chitosan nanoparticles (Fig. 4). About 49.6 wt% of adriamycin (ADR) was physically entrapped inside the self-aggregates, and the characteristics of the self-aggregates were analyzed by dynamic light scattering, fluorescence spectroscopy, and atomic force microscopy (AFM). Drug release studies were performed in PBS solution pH 7.2.^[36]

Alonso and coworkers^[37,38] reported chitosan nanoparticles for controlled release of doxorubicin and cyclosporin A. The entrapment of a cationic hydrophilic molecule (doxorubicin) was achieved by masking the positive charge of doxorubicin by complexing it with the polyanion-dextran sulfate. This modification resulted in efficient encapsulation of doxorubicin in comparison to controls.^[37] They have also investigated the possibility of forming complexes between chitosan and doxorubicin prior to the formation of nanoparticles, which resulted in low complexation efficiency and indicated no dissociation of the complex upon formation of the nanoparticles.^[37] Cell culture studies showed that those containing dextran sulfate were able to maintain cytostatic activity relative to free doxorubicin-loaded nanoparticles, whereas doxorubicin complexed to chitosan before nanoparticle formation showed slightly decreased activity. The foregoing studies suggest that the drug-bound nanoparticles entered the cells before release occurred in the cells.^[37] Another study reports ocular drug delivery.^[38] The preparation technique (based on an ionic gelation process) is extremely mild and involves the mixture of two aqueous phases at room temperature. The formation of the nanoparticles resulted from the interaction between negative groups of the sodium tripolyphosphate (TPP) and the positively charged amino groups of chitosan.^[38] These nanoparticles had a mean size of 293 nm, a zeta potential of +37 mV,

and high cyclosporin-association efficiency and loading (73 and 9%, respectively). The in-vitro studies revealed a fast release during the first hour followed by a constant release over a period of 24 hours.^[38] In-vivo experiments in rabbits following topical instillation of cyclosporin-loaded nanoparticles led to therapeutic concentrations in external ocular tissues for 48 hours, while maintaining negligible or undetectable cyclosporin levels in inner ocular structures, blood, and plasma. The drug levels were found to be significantly higher than those achieved by cyclosporin suspension or in chitosan solution containing cyclosporin.^[38] Felt et al. also studied the delivery of antibiotics to the eye using chitosan.^[39] The influence of the molecular weight, degree of deacetylation, and concentration of 4 different samples of chitosan on pharmacokinetic parameters of antibiotics in tears was investigated over time. Felt et al. observed that the chitosan products of high molecular weight and low deacetylation degree significantly increased the antibiotic availability.^[39] Ko et al.^[40] investigated preparation and characterization of chitosan microparticles for controlled drug delivery following a procedure similar to the foregoing. Ionic cross-linking of chitosan with TPP led them to microparticles within the range 500–710 μm with encapsulation efficiencies higher than 90%. Other methods for preparation of chitosan particles through ionic gelation have been investigated as well for slow release of drugs.^[41] Gadolinium-loaded chitosan nanoparticles (Gd-nanoCPs) were prepared by the novel emulsion-droplet coalescence technique.^[42] In-vitro cellular accumulation of gadolinium incorporated into chitosan nanoparticles was studied in L929 fibroblast cells.

Banerjee et al.^[43] reported a procedure for preparation of chitosan nanoparticles cross-linked with glutaraldehyde and also studied the biodistribution of nanoparticles thus prepared in rabbits. They found that the nanoparticles measure 30 nm in length when 10% of the amine groups are cross-linked, and 110 nm in length when 100% are cross-linked. When intravenously injected in mice, these cross-linked particles appeared in blood for a considerable period of time. The administration of ^{99m}Techneium-tagged nanoparticles in rabbits also confirms the presence of the administered particles in blood, and distributed in the heart, liver, kidneys, bladder, and vertebral column. Banerjee et al. also found these particles distributed in the bone marrow, raising the possibility that these particles may be used for bone imaging and targeting.^[43]

Junginger and coworkers^[44,45] extensively investigated chitosan and its derivatives as intestinal absorption enhancers. They synthesized trimethyl chitosan chloride (TMC) at different degrees of quaternization and demonstrated its activity as absorption enhancer at neutral pH values similar to those found in the intestinal tract.^[46–49] This quaternized polymer

forms complexes with anionic macromolecules and gels or solutions with cationic or neutral compounds in aqueous environments and neutral pH values. Trimethyl chitosan chloride has been shown to considerably increase the permeation of neutral and cationic peptide analogues across Caco-2 intestinal epithelia. The mechanism by which TMC enhances intestinal permeability is similar to that of protonated chitosan. It reversibly interacts with components of the tight junctions, leading to widening of the paracellular routes. This chitosan derivative does not provoke damage of the cell membrane, and does not alter the viability of intestinal epithelial cells. Coadministration of TMC with peptide drugs was found to substantially increase the bioavailability of the peptide in both rats and juvenile pigs compared with administration without the polymer.^[46–49]

Vandenberg et al.^[50] carried out a series of experiments to evaluate the influence of a number of physicochemical factors on the diffusion of a model protein—bovine serum albumin (BSA)—from dried chitosan-coated alginate microcapsules. The factors tested include alginate and chitosan concentration, calcium chloride concentration in the gelation medium, loading rate, chitosan molecular mass, and pH of the gelation medium. Alginate and chitosan concentrations were found to have influence on BSA retention during microcapsule manufacture and acid incubation, whereas calcium chloride had influence during the gelation process. Bovine serum albumin retention during manufacture was not significantly altered by the protein-loading rate or pH of the encapsulation medium. However, protein retention during acid incubation decreased significantly with increasing protein-loading rate and encapsulation medium pH. Vandenberg et al. also investigated the influence of the post-manufacture washing step, and found that microcapsules washed with acetone significantly increased protein retention during acid incubation.^[50] Continuing along a similar line of research, Huang et al.^[51] investigated formulation factors in preparing betamethasone (BTM)-chitosan microspheres with a spray-drying method using gelatin-A and ethylene oxide-propylene oxide block copolymer as modifiers. They found that BTM-loaded microspheres demonstrated good drug stability, high entrapment efficiency, and a positive surface charge. They also observed that in-vitro drug release is dependent on gelatin content.^[51] Gentamicin-loaded microparticles were prepared using chitosan hydroglutamate (CH), hyaluronic acid (HA), and a combination of both polymers by a solvent evaporation technique.^[52] In-vivo evaluation of these newly developed particles for nasal delivery of gentamicin was carried out in rabbits. The bioavailability of the drug was found to increase significantly when administered as microparticles rather than free drug

administered as 1.1% solution of 2.1% dry powder.^[52] Mi et al.^[53] investigated cross-linked chitosan microspheres as injectable implants. The chitosan microspheres were prepared by spray-drying and were further cross-linked by glutaraldehyde and genipin, where glutaraldehyde cross-linked microspheres served as a control. When the in-vivo biocompatibility and degradability of these microsphere implants was tested, intramuscular injections into the skeletal muscle of a rat showed less inflammatory reaction in the case of genipin cross-linked than did its control glutaraldehyde cross-linked microspheres. Mi et al. also found the glutaraldehyde cross-linked microspheres degraded within 12 weeks, whereas the genipin microspheres stayed intact after 20 weeks, as observed by SEM experiments.^[53] The structural differences between glutaraldehyde cross-linked and genipin chitosan microspheres are shown in Fig. 5.

Physical mixtures of sodium diclofenac (SD)-chitosan salts have been investigated.^[54] Chitosan salts were obtained by dissolving chitosan in solutions containing aspartic, glutamic, hydrochloric, lactic, and citric acids. The salts were further collected as dry powders by simple spray-drying and were then mixed with SD. How different types of acid influence the release of SD from the physical mixture was studied during gastrointestinal transit. Glutamic and aspartic salts were found to provide the best release.^[54]

GENE THERAPY

Applications that use various lipids and polymers to deliver DNA have been the subject of intense examination for more than a decade. Polymers display striking advantages as gene delivery carriers. Furthermore, they can be specifically tailored for a proposed application by choosing appropriate molecular weights, by cell coupling, by tissue-specific targeting moiety, or by performing other modifications that confer specific physiological or physicochemical properties. In this respect, chitosan enjoys a unique place in the pharmaceutical arena due to its versatile properties. It is being investigated as a potential nonviral carrier for gene delivery (Fig. 6). Depending on its molecular weight and degree of deacetylation, chitosan is capable of forming small and stable complexes with plasmids. Subsequent paragraphs discuss recent reviews of chitosan research^[18,19] and chitosan's role in gene delivery.

MacLaughlin et al.^[55] studied chitosan and depolymerized chitosan oligomers as condensing carriers for in-vivo plasmid delivery. To form complexes with plasmid, each chitosan oligomer or polymer (2% w/v) was dissolved in acetic acid by sonication. The final concentration of the solution was brought to 0.4% w/v

Fig. 5 Structural differences between glutaraldehyde and genipin cross-linked chitosan microspheres.

Fig. 6 Chitosan in gene delivery and tissue engineering (From Science Finder, April, 2003.)

by adding water and the solution was sterile-filtered for removal of particles greater than 200 nm. This chitosan solution was then added to an aqueous suspension containing 25–400 mg of plasmid in a total volume of 1 ml by gentle pipetting to form nanocomplexes of a selected charge ratio.^[55] The solution was vortexed rapidly for 3–5 min and left for 30 min at room temperature to ensure complete complexation.^[55] The in-vitro transfection was tested in Cos-1 cells and the in-vivo expression was tested in the intestinal tissues. In vivo, higher levels of expression were measured with the plasmid/chitosan/GM225.1 formulation than with naked plasmid in the upper small intestine. The overall expression levels achieved using the DOTMA:DOPE-based formulation were lower than those achieved with plasmid/chitosan/GM225.1 complexes, and there were fewer tissue extracts showing positive chloramphenicol acetyltransferase (CAT) expression (Table 1). It is interesting to note that the in-vitro results were reversed. The parameters influencing particle size and stability include chitosan molecular weight, plasmid concentration, and charge ratio. Plasmid/chitosan complexes made of higher-molecular weight chitosan were more stable to salt and serum challenge. Complexes of a 1:2 (–/+) charge ratio were shown to be most stable. In vitro, the highest level of expression in the absence of serum was obtained using a 1:2 (–/+) complex made with 102 KDa chitosan, which was approximately 250 times less than the level of expression observed with Lipofectamine™, a positive control. Particle size was found to not influence expression, although inclusion of the pH-sensitive endosomolytic peptide GM227.3 in the formulation enhanced levels of expression with the 1:2:0.25 (–/+ /–) complex (200 µg/mL), with very low expression levels (100-fold less) compared to Lipofectamine™. Cui and Mumper^[56] used chitosan-based

nanoparticles for topical genetic immunization. They investigated two different formulations (viz., pDNA-condensed chitosan nanoparticles and pDNA coated on preformed cationic chitosan/carboxymethylcellulose (CMC) nanoparticles). From these studies it is evident that both chitosan and chitosan oligomer can complex CMC to form stable cationic nanoparticles and thereby attain pDNA coating. Topical application of the various chitosan-based formulations under investigation resulted in both detectable and quantifiable levels of luciferase expression in mouse skin after 24 hours.^[56]

Thorough investigation of chitosan as an efficient gene transfection agent in vitro and in vivo by Leong and coworkers^[57–61] resulted in a series of reports describing various modifications. They investigated important parameters for the preparation of nanoparticles and characterized the physicochemical properties of the system. Protection for encapsulated DNA by chitosan particles was confirmed.^[60] Leong et al. investigated the effects of coencapsulating a lysosomolytic agent—chloroquine—on transfection efficiency.^[60] They also proposed plausible schemes (shown in Fig. 7) for transferrin and KNOB protein conjugation in an attempt to improve the surface property and result in improved transfection efficiency.^[60] Furthermore, the chitosan–DNA particles were PEGylated (shown in Fig. 8) to improve their storage stability and yield a formulation that can be lyophilized without loss of transfection ability.^[60] Tissue distribution of the chitosan–DNA nanoparticles and PEGylated nanoparticles following intravenous administration was investigated.^[60] It was found that clearance of PEGylated nanoparticles was slower than clearance of unmodified particles at 15 mins. Higher depositions in the kidney and liver, however, did not produce any difference after 1 hour.^[60] It was observed that transfection efficiency was cell-type dependent and 3–4 times higher than the background level in HEK293 cells, and 2–10 times lower than achieved by Lipofectamine™.^[60] Mohapatra and coworkers^[61] used these chitosan nanoparticles^[60] to demonstrate their protection factor in acute respiratory syncytial virus infection in BALB/c mice following intranasal gene transfer. Illum et al.^[62] reviewed chitosan as a novel nasal delivery system for vaccines.

Hoggard et al.^[63] used chitosan nanoparticles of different molecular-weight chitosan (Table 2) for intratracheal administration in mice and compared the results with polyethyleneimine in vitro. After intratracheal administration, they observed both polyplexes distributed to the mid-airways, where transgene expression was observed in virtually every epithelial cell using a sensitive pLacZ reporter containing a translational enhancer element.^[63] Hoggard et al. observed a similar result, where PEI polyplexes induced more

rapid onset of gene expression than did chitosan.^[63] Corsi et al.^[60] evaluated the potential of chitosan–DNA nanoparticles for gene transfer on human mesenchymal stem cells (MSCs), human osteosarcoma cells (MG63), and human embryonic kidney cells (HEK293). HEK293 cells were found to be the most transfected cells, compared to MSCs and MG63.^[64]

In their studies, Sato and coworkers^[65] optimized transfection conditions for chitosan-mediated gene delivery. The transfection studies were carried out using a tumor cell line (Human-lung Carcinoma A549

cells, HeLa cells, and B16 melanoma cells 1×10^5 cells/well), and indicated that the transfection efficiency of chitosan complexes is dependent on the pH of culture medium, the stoichiometry of pGL3:chitosan, and serum and molecular mass of chitosan.^[65] Transfection efficiency at pH 6.9 was higher than that at pH 7.6. The optimum charge ratio of the pGL3:chitosan was 1:5. Chitosan polymer of 15 and 52 kDa largely promoted luciferase activities. Transfection efficiency mediated by chitosan of >100 kDa was less than that by chitosan of 15 and 52 kDa.^[65]

Fig. 7 (A) Conjugation of transferrin through periodate oxidation; (B) conjugation of transferrin through a reversible disulfide linkage.

Kim et al.^[66] reported self-aggregates of deoxycholic acid-modified chitosan as DNA carriers. In order to control the size of self-aggregates, chitosan was depolymerized with various amounts of sodium nitrite, and hydrophobically modified with deoxycholic acid to form self-aggregates in aqueous media, shown in Fig. 4. They observed that the size of the self-aggregates varied in the range of 130–300 nm in diameter, where the chitosan molecular mass has influence on the sizes.

Thanou et al.^[67] reported quaternized chitosan oligomers as novel gene delivery vectors in epithelial cell lines. They synthesized trimethylated chitosan (TMO) using oligomeric chitosan (<20 monomer units). They observed spontaneous complex formation of TMOs with RSV- α 3 luciferase plasmid DNA ranging in size from 200 to 500 nm.^[67] They found that, when tested in Cos-1, the transfection efficiencies of

chitoplexes are lower than those of DOTAP (N-(1-(2, 3-dioleoyloxy)propyl)-N,N,N-trimethylammonium sulphate)-DNA lipoplexes, although both these complexes showed lower transfection in Caco2 cells, with TMOs taking the lead over DOTAP.^[67]

Galactosylated chitosan-graft-dextran (GCD) was prepared and characterized for Hepatocyte-targeting and complexed with DNA by Park and coworkers.^[68] Lactobionic acid-bearing galactose group was coupled with chitosan for liver specificity, and dextran was grafted to galactosylated chitosan (GC) for stability in water. The structures of GCD and GC are as shown in Fig. 9. Park et al. found the GCD/DNA complex to be more stable compared to the GC/DNA complex, and found that the particle size of the GCD/DNA complex becomes smaller as the charge ratio of GCD to DNA increased. They observed transfection of GCD/DNA complexes only in Chang Liver cells. They also found the transfection of Hep G2 having asialoglycoprotein receptors (ASGR), indicating the specific interaction of cells and galactose ligands on chitosan.^[68]

Okamoto et al.^[69] adopted a supercritical carbon dioxide technique to make chitosan-plasmid complex powders, which they applied as a pulmonary gene delivery system in vivo. The luciferase activity in mouse lung was evaluated after pulmonary administration of the powders or pCMV-Luc solutions. The chitosan-pDNA powders increased the luciferase activity in mouse lung compared with pCMV-Luc powders without chitosan or pCMV-Luc solutions with or without chitosan. Okamoto et al. found a drastic increase of luciferase activity (up to 2700%) when chitosan-pDNA powder with an N/P ratio = 5 in comparison to that of the pCMV-Luc solution.

TISSUE ENGINEERING

The tissue-engineering approach to repair and regeneration is based on the use of polymer scaffolds that serve to support, reinforce, and in some cases organize the regenerating tissue.^[70–72] The scaffold may be required to release bioactive substances at a controlled rate or to directly influence the behavior of incorporated or ingrowing cells. A number of natural and synthetic polymers are currently employed as tissue scaffolds.^[73–75] The microstructures of these systems range from hydrogels, to open-pore structures, to fibrous matrices. Because the range of potential tissue-engineered systems is broad, there is a continuous ongoing search for materials which either possess particularly desirable tissue-specific properties, or which may have broad applicability and can be tailored to several tissue systems. Chitosan finds application in tissue engineering because of its biocompatibility and capacity to deliver drugs at a

Fig. 8 PEGylation of chitosan-DNA nanoparticles and conjugation of transferring through a PEG spacer.

controlled rate. From a survey of the literature, it is evident that chitosan forms approximately one of every 50 reports on tissue engineering. (See Fig. 6.) One of the most promising features of chitosan is its excellent ability to be processed into porous structures for use in cell transplantation and tissue regeneration. Francis Suh and Matthew^[76] recently reviewed the application

of chitosan-based polysaccharide biomaterials in cartilage tissue engineering.

Chitosan has been thoroughly investigated in tissue engineering; several researchers have examined the response of tissue to various chitosan-based implants.^[77,78] These materials have generally been found to evoke minimal foreign body reaction. In most cases, no major fibrous encapsulation has been observed.^[79] Porous chitosan structures can easily be formed by freezing and lyophilizing chitosan-acetic acid solutions in suitable molds.^[80] The mechanical properties of chitosan scaffolds depend mainly on pore sizes and orientation.

Zhang and Zhang^[81] synthesized and characterized macroporous chitosan scaffolds reinforced by β -tricalcium phosphate (β -TCP) and calcium phosphate invert glass by a freeze-drying technique via thermally induced phase separation for tissue-engineering applications. They observed the composite scaffolds to be porous and the pore structures of the scaffolds with β -TCP and the glass to be very different. The bioactivity tests showed a continuous decrease in both Ca and P concentrations of a simulated body fluid (SBF) after the scaffolds with β -TCP were immersed in the SBF for more than 20 hours, suggesting the formation of an apatite layer on the scaffolds (which was not the case with pure chitosan scaffolds or scaffolds incorporated with glass due to the absence of nucleation sites on scaffold surfaces).^[81] There are, however, positive reports of chitosan scaffolds used alone without any

Table 2 Transfection efficiency in 292 cells and particle sizes of different chitosan/pDNA complexes at their optimal charge ratios

Chitosan ^c	Charge ratio ^a (+/-)	Gene expression ^b (pg/ μ g protein)	Particle size (nm)
C(1;31)	3.6:1	6.0 \pm 2.8	131 \pm 9
C(1;170)	3.6:1	5.0 \pm 2.0	174 \pm 23
C(15;190)	3.0:1	7.2 \pm 1.5	144 \pm 12

C(49;98)	3.6:1	0.1 \pm 0.04	229 \pm 2

^aCharge ratios covering the range 0.6:1–4.2:1 (+/-) were investigated.

^bCells were analyzed for CAT gene expression 48 h after transfection. Data are expressed as mean values \pm s.d. from one representative experiment ($n=4$) of three performed.

^cChitosan represented by previously published nomenclature. The numbers in parentheses are degree of deacetylation expressed in %, followed by the molecular weight in kDa.

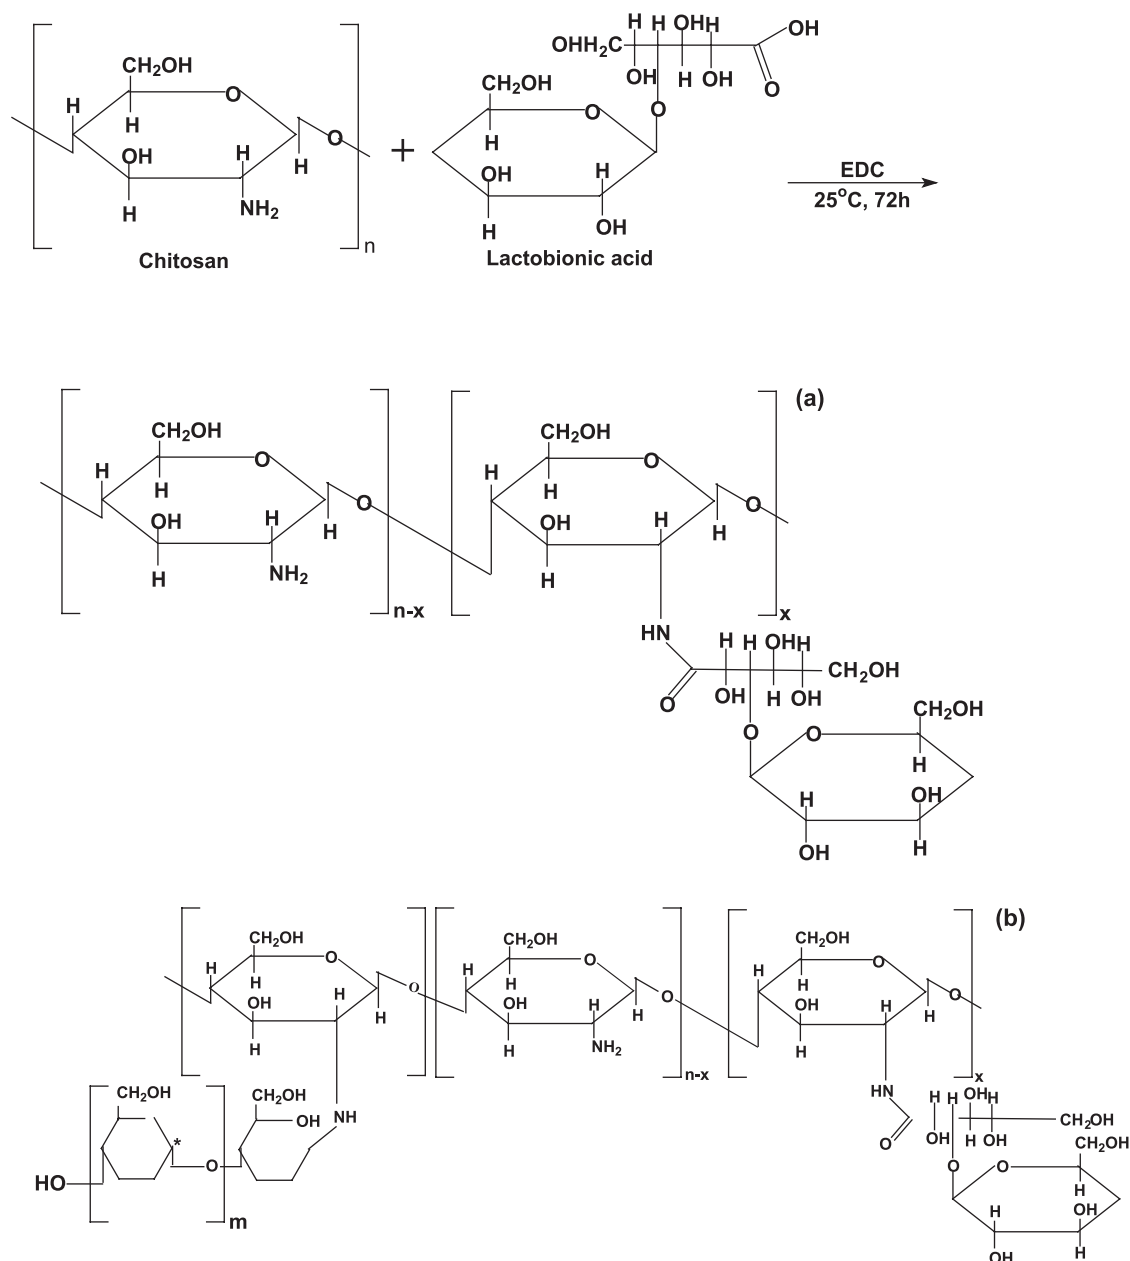

Fig. 9 Chemical structures of (a) galactosylated chitosan (GC); and (b) galactosylated chitosan-graft-chitosan (GCD).

modification.^[82] Lee and coworkers^[83] studied bone formation by controlled growth factor delivery from chitosan, chitosan-poly(L-lactide) (PLLA) matrices, and chitosan coated on PLLA matrices.

FOOD TECHNOLOGY

Chitin and chitosan have been materials of interest over the past decades due to the broad range of their potential applications, as discussed in the foregoing. However, only limited attention has been paid to the food application of these versatile biopolymers. The

conversion of processing discards into edible by-products and alternative specialties is a timely challenge for food research and development. Chitosan finds application in various sectors of the food industry, as shown in Table 3. Shahidi et al.^[84] reviewed the food application of chitin and chitosan.

A most intently investigated food industry application of chitosan stems from its antimicrobial activity. The growing consumer demand for foods without chemical preservatives has led to the discovery of chitosan's antimicrobial properties.^[85] The cationic nature of chitosan is expected to influence the mechanism of the antimicrobial activity through binding

Table 3 Applications of chitinous materials in food technology

Area of application	Examples
Antimicrobial agent	Bactericidal Fungicidal Measure of mold contamination in agricultural commodities
Edible films	Controlled moisture transfer between food and surrounding environment Controlled release of antimicrobial substances Controlled release of nutrients, flavors, and drugs Reduction of oxygen partial pressure Controlled rate of respiration Temperature control Controlled enzymatic browning in fruits Reverse osmosis membranes
Additive	Clarification and deacidification of fruits and beverages Natural flavor extender Texture controlling agent Emulsifying agent Food mimetic Thickening and stabilizing agent Color stabilization
Nutritional quality	Dietary fiber Hypocholesterolemic effect Livestock and fish food additive Reduction of lipid absorption Production of single cell protein Antigastritis agent Infant feed ingredient
Recovery of solid materials from food processing waste	Affinity flocculation Fractionation of agar
Purification of water	Recovery of metal ions, pesticides, phenols, and PCBs Removal of dyes

sialic acid in negatively-charged phospholipids, thus restraining the movement of microbiological substances.^[84] Oligomeric chitosan penetrates into the cells of microorganisms and prevents the growth of cells by prohibiting the transformation of DNA into RNA.^[86] Jung et al.^[87] synthesized amphiphilic chitosan copolymers by grafting two anionic soluble monomers,

mono(2-methacryloyl oxyethyl) acid phosphate and vinylsulfonic acid sodium salt. The antimicrobial properties of these copolymers were tested and indicated improved activity. The antimicrobial activity was found to depend largely on the amount and type of grafted chains and on changes of pH against *Candida albicans*, *Trichophyton rubrum*, and *Trichophyton violaceum*. Enhanced activity was determined at pH 5.75 with strain selectivity against *Candida albicans* and *Trichophyton violaceum* due to a difference in affinity between the cell walls of fungi and chitosan or its derivatives.^[87]

Jumaa et al.^[88] investigated the antimicrobial activity of chitosan in lipid emulsion as well as in aqueous solutions using different deacetylated chitosan (92% and 73%). They studied the influence of pH on antimicrobial activity by incubating the microorganisms at different pH in lactic acid solution (1% w/v) containing different concentrations of chitosan up to 1.5% (w/v). Both types of chitosan were pH-dependent; optimal activity was found at pH 5 for *P. aeruginosa* and pH 5.3 for *S. aureus*. This study revealed that lipid emulsions containing 0.5% (w/v) chitosan displayed antimycotic efficacy, conforming to the requirements of the preservation efficacy test for topical formulations.^[88]

CONCLUSION

From the foregoing sections it is evident that chitosan is a material of choice for versatile applications. The problem of chitosan's ineffectiveness at neutral pH can be dealt with by derivatization to render the polymer soluble. Although much research and development have been accomplished during the past few decades, untiring efforts are still in progress to develop increasingly versatile applications.

Chondroitin Sulfates

Nicola Volpi

Department of Biologia Animale, Biological Chemistry Section, University of Modena and Reggio Emilia, Modena, Modena, Italy

INTRODUCTION

The study of chondroitin sulfate (CS) and related proteoglycan (PG) structure and function has significantly influenced our understanding of a wide variety of biological processes and pharmacological applications. Historically, these cellular and extracellular macromolecules were generically designated as “ground substances” or “mucopolysaccharides” and, owing to their carbohydrate content and heterogeneity, were extremely difficult to study in relation to proteins. The advent of the field of glycobiology with tools and techniques for studying glycosaminoglycans (GAGs) has done much toward furthering appreciation of how carbohydrate moieties can affect cellular responses to a variety of stimuli.

Despite their wide distribution and common synthetic pathway to heparan sulfate, CS and dermatan sulfate (DS) have attracted less attention than heparan sulfate and heparin. Growing evidence suggests, however, that CS and DS chains have intriguing functions in central nervous system (CNS) development, wound repair, infection, growth factor signaling, morphogenesis, and cell division, in addition to their conventional structural roles. Furthermore, from a pharmacological point of view, CS produces a slow but gradual reduction of the clinical symptoms of osteoarthritis (OA) and these benefits last for a long period after the end of treatment. In fact, many animal studies and clinical trials have proved the efficacy of CS as a structure-modifying OA drug agent able to reverse, retard, or stabilize the pathology of OA, thereby providing symptomatic relief in the long-term treatment.

Chondroitin sulfate and DS are synthesized as GAG side chains of PGs and, as a consequence, many of their biological functions are related to these macromolecules. Furthermore, the recent molecular cloning of the various genes encoding the glycosyltransferases and sulfotransferases required for the synthesis of GAG chains has outlined major biosynthetic pathways that are common to vertebrates and invertebrates.

The aim of this entry is to focus on the structure and activity of CSs also as components of more complex PGs and to discuss recent advances in their pharmacological applications and their possible use as biomaterials. The

main arguments focused on in this entry will be the structure of CSs, their role in the structure and functions of PGs, their biological and pharmacological activities, and their applications as biomaterials.

STRUCTURE OF CS/DS

Glycosaminoglycans are complex natural heteropolysaccharides distributed among all organisms.^[1,2] These biological molecules are major structural components of PGs, the main macromolecular complex of the extracellular matrix, but also localized at the cellular level as intracellular components and distributed on the cellular membrane.^[3] Evidence derived from recent glycobiology studies in the fields of biochemistry, cell and developmental biology suggests that PGs are not only structural components, but they participate in and regulate many cellular events and physiological processes, such as cell proliferation and differentiation, cell–cell and cell–matrix interactions.^[4] The strong capacity of GAGs to be interactive at the molecular and cellular levels is due to their great structural diversity, such as the GAG type, size, composition and charge density, as well as the degree of substitution and domain arrangement.

Chondroitin sulfate chains are polymers constructed from 40 to more than 100 repeating disaccharide units comprising GlcA and GalNAc, whereas DS, known as CS type B, chains contain varying proportions of IdoA in place of GlcA. In addition, the two chains are often found as CS/DS copolymeric structures. Chondroitin sulfate and DS have the potential to display an enormous structural diversity, comparable to that of heparan sulfate, by embedding multiple overlapping sequences constructed with distinct disaccharide units modified by different patterns of sulfation. This diversity is the basis for their wide variety of functions.

Chondroitin sulfate and DS chains are formed by the repeating unit $[-\rightarrow 4\text{GlcA}\beta 1 \rightarrow 3\text{GalNAc}\beta 1 \rightarrow]$, which is then variously sulfated in different positions of the hexosamine unit and/or uronic acid. Some, but very few, of these positions remain unsulfated. The regular disaccharide sequence of CS type A, chondroitin 4-sulfate, is constituted by the repeating unit sulfated in position 4 of the GalNAc unit, while CS type C, chondroitin 6-sulfate, is mainly composed of a disaccharide unit

sulfated in position 6 (Fig. 1). Disaccharides with a different number and position of sulfate groups can be located, in different percentages, within the polysaccharide chains, such as the disulfated disaccharides in which two sulfate groups are O-linked in position 2 of GlcA and position 6 of GalNAc (disaccharide D) or in positions 4 and 6 of GalNAc (disaccharide E) (Fig. 1). In the case of DS, further enzymatic modifications complete the final structure, such as C-5 epimerization of GlcA to IdoA, and O-sulfation at C-2 of IdoA. As a consequence, polysaccharide chains of DS consist of a prevailing disaccharide unit [$\rightarrow 4$ IdoA $\beta 1 \rightarrow 3$ GalNAc $\beta 1 \rightarrow$] sulfated in position 4 of the hexosamine unit with a minor concentration of disulfated disaccharides, in particular sulfated in position 4 of GalNAc and position 2 of the IdoA unit (Fig. 1).

These heterogeneous structures are responsible for different and more specialized functions of these GAGs (see below). L-Iduronic acid imparts conformational flexibility to the DS chain, altering the shape and spatial

orientation of sulfate residues, endowing the chain with a higher negative charge content than the GlcA.^[5] Although the principles of the biosynthetic process have not yet been fully elucidated, it is well known that this process results in the generation of highly modified oligosaccharide domains within the polymer chain, which are separated by regions of relatively low-degree structural modifications. Thus, the DS chain has a hybrid copolymeric structure consisting of low modified (CS) and highly modified (DS) domains. The IdoA-containing units are often sulfated at C-4 of the GalNAc residue, while sulfation at C-6 is frequently associated with GlcA-containing disaccharides.^[6]

CHONDROITIN SULFATE/DERMATAN SULFATE PGs

Proteoglycans are macromolecules that consist of a protein backbone to which GAG chain(s) and

Fig. 1 Six typical disaccharide units found in CS and DS chains.

oligosaccharides are covalently attached. In view of the considerable complexity of PG structure and composition, we need to know the identities of the constituent GAGs but also the core-protein sequences to organize a logical classification scheme for PGs.

Chondroitin Sulfate PGs that Aggregate with Hyaluronic Acid

The large aggregating PGs in cartilage represent the most studied of all PGs (Table 1). They are characterized by their very large size. A hyaluronic acid-binding region (HABR) is located at the N-terminus and constitutes about one-quarter to one-third of the total core protein.^[7,8] This region can bind specifically to hyaluronic acid with the formation of macromolecular aggregates. Interaction of the PG with hyaluronic acid is stabilized by a link protein that binds to the HABR in a molar ratio of 1:1.

Some molecules contain a region where keratan sulfate chains are concentrated and that is adjacent to the HABR. To the remainder of the core protein are attached most of the CS chains.^[7] The very high charge density reached by aggregated cartilage PGs permits these molecules to imbibe reversibly large quantities of water. They can occupy a solution volume of 30–50 times their dry weight but in cartilage this swelling is limited by the network of collagen fibrils. The resulting pressure after swelling endows cartilage with its compressive rigidity and its ability to sustain repeated loading during articulation.

When cartilage develops, the structures of these PGs change. The molecule synthesized in the fetus initially lacks keratan sulfate. In man, this is added mainly after

birth and increases in amount with age. This is accompanied by a shortening of CS chains, with an increase in the proportion of 6-sulfate, a reduced molecular size, and an increase in the proportion of core protein. The significance of these GAG changes remains to be established.

Aging of human cartilage is accompanied by an accumulation of the HABR and partially fragmented link proteins. In rabbits there is a decrease in link-stabilized PG aggregates with age. These observations indicate that there is progressive degradation in cartilage with aging, which would favor the development of osteoarthritic changes where a net loss of PG is associated with macroscopic degenerative changes. In inflammatory arthritis, PGs can act as autoantigens and have been implicated in the immunopathology of the disease.^[7]

The aorta also contains large CS-PGs that aggregate with hyaluronic acid (Table 1). A link protein similar in size to the larger of the two major species found in cartilage is also present in the aorta. As in cartilage, aggregates of these PGs probably play a key role in maintaining shape and sustaining the repeated loading due to blood flow. A large aggregating CS-PG is also present in tendons and may perform an important role in dispersing load because it is more abundant in those parts of the tendon subjected to increased pressure.^[7]

Large Nonaggregating CS PGs

Skin contains a large nonaggregating CS-PG (Table 1). Its amino acid composition is similar to that of the large aggregating cartilage PG but it lacks cystine and methionine. This is consistent with the lack of aggregation, because both of these amino acids are present

Table 1 Chondroitin sulfate proteoglycans

Type	M_r	Glycosaminoglycans		Core protein		Tissue
		Chain number	M_r	M_r	Binds to HA	
Aggregating	2.5×10^6	100 CS	20,000	200,000	Yes	Cartilage
		30–60 KS	6,000			
	$1-2 \times 10^5$	12	43,000	200,000	Yes	Aorta
	$1-2 \times 10^6$	50	17,000	>200,000	Yes	Tendon
	nd	nd	nd	250,000	Yes	Melanoma
Large nonaggregating	150,000	1–2	30,000	70,000	Yes	Brain
	1×10^6	50	20,000	50,000	No	Skin

in the HABR of the cartilage molecule where cystine disulfide linkages are essential for the functional integrity of this region.

Another large PG is present in the soft tissue mesenchyme of the metaphysis lying between the trabeculae of forming bone (Table 1). It has a protein core similar in size to that of the aggregating cartilage PGs and cross-reacts with antibodies raised against these cartilage molecules.

Small Nonaggregating CS PGs

A major PG of bone is a molecule of small size and is similar to the small widely distributed DS-PG. It is present in osteoblasts and bone, but not in cartilage (Table 1). The major difference between the small PGs is probably whether DS or CS chains are synthesized.

Another similar small CS-PG is found in cartilage. Immunochemical analysis and peptide mapping have revealed that it is different from the small DS-PGs of cornea, sclera, and tendon, but similar to a small PG isolated from the aorta.

Dermatan Sulfate PGs

A number of PGs bearing DS have been described (Table 2). They vary in size and iduronic acid content. A small PG with an M_r of 70,000–100,000 and a

protein core probably of M_r 38,000 is widely distributed (Table 2).^[7] The core protein can constitute from 30% to 60% of the total weight. This molecule may have one or possibly two DS chains which, within a tissue, can vary in iduronate content from 45% to 85% of the total hexuronate. The length of this chain also shows tissue variations from M_r 15,000 to 45,000. In both skin, cartilage, and placenta, position 4 of the core protein is a serine residue and in each case there is probably either a DS chain or an O-linked oligosaccharide attached to it. Some PGs may have the same or very similar core proteins to which either CS or DS chains are attached, depending on whether glucuronic acid is epimerized to iduronic acid during synthesis. Several studies have indicated that this small DS-PG is bound to type I collagen. Because the PG can inhibit fibrillogenesis of type I and type II collagens, it may play a key role in the regulation of collagen fibril assembly and in the biomechanical strength of collagen fibrils.

Dermatan sulfate chains with a high iduronic acid content, e.g., those found in the small DS-PG, can self-associate to form multimeric PG complexes.^[7] This is a property of the arrangement of the glucuronic acid and iduronic acid components and may indicate that DS-PGs on adjacent collagen fibrils can reversibly associate through their GAGs, assuming that they are bound to collagen by their core proteins, as indicated. Such DS chains also show high-affinity binding to low-density lipoproteins and this may be of importance in

Table 2 Dermatan sulfate proteoglycans

M_r	Glycosaminoglycans			Core protein

HA, hyaluronic acid; nd, not determined.
(From Ref. [7].)

atherosclerosis if these molecules are synthesized in excess in atheromas. A small glucuronic acid-rich DS-PG is also present in the cornea (Table 2). The core protein is immunologically related to the small DS-PG of cartilage and sclera and has the same size. The molecular size of this corneal PG enables it to fit between the collagen fibrils, permitting corneal transparency.

Fibroblasts secrete the small DS-rich PG into culture medium but retain a larger molecule that is cell associated and can bind to hyaluronic acid (Table 2). A large glucuronic acid-rich DS-PG is also found in the sclera (Table 2). Like the aggregating PGs of cartilage, aorta, and tendon, this molecule may play a key role in maintaining shape (of the eye) and sustaining intraocular pressure.

The other DS-PG of cartilage (DS-PGI) has an overall size and core protein similar to the smaller molecule (Table 2). Although it has a similar iduronic acid content to the smaller molecule, only the larger species can self-associate, probably through its DS chains.

BIOLOGICAL PROPERTIES OF CS

Chondroitin sulfate exhibits a wide variety of biological functions reviewed in Ref. [9,10], mainly owing to the presence of rare oversulfated structural building units forming domain structures interacting specifically with other molecules, inducing the modulation of several biological functions, such as the regulation of neuronal patterning in the retina, interactions with fibronectin, neurite outgrowth promoting activity, modulation of the adhesive function of $\alpha_4\beta_1$ integrin, monocyte and B-cell activation, plasminogen activation, binding of *Plasmodium falciparum*-infected erythrocytes, and upregulation of the antigen-specific Th1 immune response of murine splenocytes sensitized with ovalbumin in vitro and to suppress the antigen-specific IgE responses.

Highly sulfated PG is correlated with axon boundaries in the developing CNS, which suggests that these molecules affect neural pattern formation. In the developing mammalian retina, gradual regression of CS may help control the onset of ganglion cell differentiation and the initial direction of their axons. Changes induced by the removal of CS from intact retinas in culture confirm the function of CS in retinal histogenesis.

Interactions between fibronectin and GAGs are essential for extracellular matrix morphology and cell adhesion. Recombinant fibronectins (deminectins) containing the carboxyl-terminal cell, heparin, and fibrin domains bind specifically to CS in affinity chromatography assays.

A mouse brain PG-CS epitope was shown to possess neurite outgrowth promoting properties. Several

hexasaccharides isolated from commercial shark cartilage CSD, which contains a higher proportion of characteristic D units (GlcA2S β 1 \rightarrow 3GalNAc6S), has a tetrasaccharide sequence composed of an A disaccharide unit (GlcA β 1 \rightarrow 3GalNAc4S) and a D disaccharide unit. The CSD promoted neurite outgrowth of embryonic day 18 hippocampal neurons. Eight octasaccharide fractions were isolated from CS type D after partial digestion with bacterial chondroitin ABC lyase to investigate the frequency and the arrangement of the tetrasaccharide unit in the polymer sequence. Structural analysis demonstrated that the isolated octasaccharides shared the common core structure Δ hexA (Glc/Ido) α 1 \rightarrow 3GalNAc β 1 \rightarrow 4(GlcA β 1 \rightarrow 3GalNAc)₃, with four, five, and six sulfate esters at various hydroxyl groups in different combinations.

Melanoma CS-PG plays a role in modulating the adhesive function of $\alpha_4\beta_1$ integrin. A peptide from within α_4 integrin termed SGI binding to cell surface melanoma CS-PG was identified. Soluble SGI inhibits $\alpha_4\beta_1$ integrin-mediated human melanoma cell adhesion to CS. These results demonstrate that $\alpha_4\beta_1$ integrin interacts directly with CS through the SGI site, and that this site can affect the ligand binding properties of the integrin.

At inflammatory sites, PG are both secreted by activated mononuclear leukocytes and released as a consequence of extracellular matrix degradation. Chondroitin 4-sulfate PGs constitute the predominant ones produced by activated human monocytes/macrophages. Two chondroitin 4-sulfate forms, CSA and CSB, can activate distinct peripheral blood mononuclear cell types. Whereas CSA activates monocytes (to secrete monokines), CSB activates B-cells (to proliferate). In contrast, the chondroitin 6-sulfate CSC and heparin do not exert these functional effects. These findings point to GAGs, and specifically chondroitin 4-sulfates, as a novel class of immunological mediators at inflammatory sites. Furthermore, the data link CD44 to B-cell activation, paralleling the established roles of CD44 in T-cell and monocyte activation.

CS type E markedly enhanced plasminogen activation by tissue plasminogen activators (t-PAs) and urinary plasminogen activator (u-PA) in vitro. Though the potentiation activity of CSE gradually decreased when it was depolymerized by chondroitinase ABC, the specific disaccharide from CSE still showed significant activity. These results suggested that the minimal structural requirement in CSE to enhance plasminogen activation by plasminogen activators is GlcA β 1-3GalNAc(4S,6S) and that additional branching sugars abolish the activity.

Plasmodium falciparum infection in pregnant women results in chondroitin 4-sulfate-mediated adherence of the parasite-infected red blood cells (IRBCs) in the placenta, adversely affecting the health

of the fetus and the mother. The unusually low sulfated CS-PGs in the intervillous spaces of the placenta are the receptors for IRBC adhesion, which involves a chondroitin 4-sulfate motif consisting of six disaccharide moieties with approximately 30% 4-sulfated residues. The placental CS-PGs are a mixture of two major populations, which are similar by all criteria except for their differing sulfate contents. The majority of the sulfate groups in the CS-PGs are clustered in CS chain domains consisting of 6–14 repeating disaccharide units. While the sulfate-rich regions of the CS chains contain 20–28% 4-sulfated disaccharides, the other regions have little or no sulfate. The oligosaccharides corresponding to the sulfate-rich domains of the CS chains efficiently inhibited IRBC adhesion. Finally, the unique distribution of sulfate groups in the CS chains of placental CS-PGs and the sulfate-clustered domains have the necessary structural elements for the efficient adhesion of IRBCs.

Chondroitin 4-sulfate was shown to upregulate the antigen-specific Th1 immune response of murine splenocytes sensitized with ovalbumin in vitro, and CS was able to suppress the antigen-specific IgE responses. In a further recent study, a specific sulfation pattern of the CS was demonstrated to be necessary for the Th1-promoted activity, suggesting that the GlcA(β -3)GalNAc(4,6-*O*-disulfo) sequence in CSE is important for Th1-promoted activity.^[11] These findings describe a new mechanism for the anti-inflammatory and chondroprotective properties of CS.

BIOLOGICAL ACTIVITIES OF DS

Dermatan sulfate proteoglycans bind a diverse range of molecules including matrix molecules, growth factors, protease inhibitors, cytokines, chemokines, and pathogen virulence factors.^[12] The precise binding site has neither been identified for many of these proteins, nor has the binding affinity for different structural variants of DS been thoroughly investigated.

Table 3 lists a number of DS-binding proteins. Although many of these interactions were first identified using other GAGs, it has been appreciated that many proteins can interact with more than one type of GAG chain albeit with differing affinities. The characterization of GAG/PG-protein interactions is complicated by the fact that many interactions are between the PG protein core and the binding protein rather than the GAG. It is conceivable that certain GAG/PG-protein binding interactions involve both the GAG side chain(s) and the PG protein core.

One particularly well-investigated DS binding interaction, reviewed by Trowbridge and Gallo, occurs with heparin cofactor II (HCII).^[12] This serpin homolog of antithrombin III acts by inhibiting the procoagulative effect of thrombin. This effect is enhanced 1000-fold in the presence of DS or heparin. It is postulated that the GAG forms a stable ternary complex between the serpin and the protease. Dermatan sulfate fragments reported to bind HCII include octasaccharides and hexasaccharides with the

Table 3 Binding interactions of dermatan sulfate and dermatan sulfate proteoglycans

Binding protein	Binding sequence	Physiologic effect
Heparin cofactor II	IdoA-2S-GalNAc-4S Hexasaccharide	Enzymatic inactivation of thrombin

(From Ref. [12].)

highest-affinity fraction bearing a sulfate on IdoA C2 and on the C4 of GalNAc. Interestingly, this species represents only about 5% of porcine skin DS. Despite its high binding affinity, the purified fraction was estimated to be 20 times less active than unfractionated DS in a thrombin inhibition assay. With a different source of DS (bovine mucosa), the total charge of the DS disaccharide subunits appears to matter more than the IdoA content per se. Two disaccharide species (IdoA 2S-GalNAc-4S and GlcA-GalNAc-4,6diS) were primarily identified in DS that activated HCII.

Heparin has been shown to have a fivefold greater affinity for HCII than DS, but the complex formed between heparin, fibrin, and thrombin is different from that formed by DS. It was postulated that heparin binds both thrombin and fibrin, thereby forming a ternary complex and causing a change in the HCII active site of thrombin such that it is no longer sensitive to inhibition. On the contrary, DS binds directly to thrombin only, not to fibrin, and the bound thrombin retains sensitivity toward the serpin. This suggests that DS might be a useful clinical tool for specifically treating or preventing thrombosis.

Dermatan sulfate may also influence coagulation by enhancing the effects of activated protein C (APC), an endogenous inhibitor of the clotting cascade. Other CS samples (CSA and CSC) also enhance APC activity. At a physiologically relevant concentration, DS enhanced APC activity more than the other GAGs tested. Moreover, when fractions of DS separated on the basis of charge density were tested, the fraction containing the highest charge density enhanced APC activity more than unfractionated DS. These findings further suggest that DS oligosaccharide size and sulfation determine binding affinity and lead to different physiological consequences.

PHARMACOLOGICAL EFFECTS OF CS

Chondroitin sulfate has anti-inflammatory activity and affects cartilage metabolism (reviewed in Ref. [9,10]). Oral administration of CS was shown to significantly decrease the granuloma formation secondary to cotton, pellet, or sponge implants, the inflammatory response in adjuvant arthritis, and lysosomal enzyme release in carrageenan pleurisy. Furthermore, CS and its fractions inhibit the directional chemotaxis induced by zymosan-activated serum, are able to decrease the phagocytosis and the release of lysozyme induced by zymosan and to protect the plasma membrane from oxygen reactive species. When the effects of CS on chymopapain-induced articular cartilage injury in rabbits were investigated, it was found that rabbits that were given intramuscular or oral doses of CS before

injection of chymopapain demonstrated less PG loss from the articular cartilage than the controls.

The antioxidant activity of chondroitin 4-sulfate was tested on a rat model of collagen-induced arthritis (CIA). Arthritis was induced in Lewis rats by multiple intradermal injections of emulsion containing bovine type II collagen in complete Freund's adjuvant at the base of the tail and into three to five other sites on the back. Treatment with CS, starting at the onset of arthritis for 10 days, limited the erosive action of the disease in the articular joints of knee and paw, reduced lipid peroxidation, restored the endogenous antioxidants, reduced glutathione (GSH) and superoxide dismutase, decreased plasma TNF-alpha levels, and limited synovial neutrophil infiltration. These data confirm that erosive destruction of the joint cartilage in CIA is due at least in part to free radicals released by activated neutrophils and produced by other biochemical pathways. Furthermore, in another study, CS treatment was found to reduce the damage in carbon tetrachloride-induced acute rat liver injury.

Chondroitin sulfate efficacy and tolerance have been evaluated and demonstrated in many clinical studies (Table 4) reviewed in Ref. [9,10]. Oliviero et al. conducted a clinical trial, lasting 6 mo, performed on 200 patients. The results showed a considerable improvement both in pain and in mobility. No relevant side effects were found; only 3% of patients, with oral administration, noticed slight nausea and found it necessary to interrupt treatment.

Mazieres et al. treated 120 patients with CS in a placebo-controlled study. Significant improvement of joint pain and physician global assessments was evident in the CS-treated group. Morreale and coworkers evaluated 146 patients with knee OA. Seventy-four patients received 400 mg CS three times a day for 3 mo, followed by 3 mo without treatment. These patients were compared with 72 patients who were treated with 50 mg of diclofenac three times a day for 1 mo, followed by 5 mo of treatment. Those treated with diclofenac had a decrease in joint pain at 10 days, which disappeared shortly after discontinuation of treatment; those treated with CS had a significant response at 30 days, which lasted for 3 mo after discontinuation of the drug. Thus, the effects of CS treatment persisted longer after discontinuation than those of traditional therapy.

In a study by Bucsi and Poor, 40 patients treated with 800 mg of CS were compared with 40 who received placebo. The CS group showed significant improvement in the Lequesne index, visual analog pain scale, 20 m walk time, and patient and physician efficacy ratings. All these results strongly suggest that CS acts as a symptomatic slow-acting drug in knee OA.

Bourgeois et al. evaluated 40 patients with knee OA who were treated with CS in the form of a 1200 mg

Table 4 Summary of results in chondroitin sulfate trials

Author(s)	Year	No. of patients	Follow-up period	Complications	Results
Rovetta	1991	40	25 wk	Well tolerated	Higher therapeutic effect on all symptoms of OA
Oliviero et al.	1991	200	6 mo	3% Mild adverse effects	Considerable improvement in both pain and mobility
Mazieres et al.	1992	120	3 mo	Well tolerated	Slowly effective against symptoms of OA and reduction of the need for NSAIDs
Morreale et al.	1996	146	3 mo	Minor	Benefits of CS appeared later but lasted for up to 3 mo after end of treatment
Fleish et al.	1997	56	1 yr	Well tolerated	Improvement in mobility, joint effusion, and swelling
Bucsi and Poor	1998	80	6 mo	Minor	43% reduction in joint pain
Bourgeois et al.	1998	127	3 mo	No adverse events	Significant reduction in joint pain
Uebelhart et al.	1998	42	1 yr	None	Decreased joint pain and improved mobility
Verbruggen et al.	1998	119	3 yr	Not documented	Radiographic demonstration of decrease in number of patients with "new" erosive finger-joint OA
Uebelhart et al.	2004	120	1 yr	Minor adverse events	Decreased pain and improved knee function. Reduction of the progression of medial femoro-tibial joint space
Rovetta et al.	2004	24	2 yr	Not documented	Efficacy of oral CS in improving some aspects of erosive OA of the hands

(From Ref. [10].)

dose oral gel. The Lequesne index and pain score (visual analog scale) decreased significantly in both CS groups, compared with the placebo group, and patient and physician global assessments significantly favored the CS-treated group.

A computerized technique was used to measure medial tibiofemoral joint space in patients treated with 800 mg CS per day or with placebo. After 1 yr, tibiofemoral joint space width had decreased significantly in placebo-treated patients but had not changed from the baseline value in the CS treatment group. The aim of this study was to assess the clinical, radiological, and biological efficacy, and tolerability of the chondroitin 4- and 6-sulfate, in patients suffering from knee OA.

Verbruggen and colleagues evaluated hand radiographs of 119 patients with OA (Table 4). Thirty-four patients who received CS 400 mg three times a day were compared with 85 patients who received placebo. Radiographs were performed annually over a 3 yr period. A total of 119 patients were included in a randomized, double-blind, placebo-controlled trial to assess the properties in OA of CS. In the CS group, a significant decrease in the number of patients with new erosive OA finger joints was observed.

In a very recent randomized, double-blind, multicenter study, the efficacy and tolerability of oral CS in knee OA patients in a 3 mo duration, twice yearly,

intermittent treatment was investigated (Table 4). Radiological progression at month 12 showed significantly decreased joint space width in the placebo group with no change in the CS group. Tolerability was good with only minor adverse events identically observed in both groups. This study provides evidence that oral CS decreased pain and improved knee function.

PHARMACOLOGICAL USE OF DS

As previously reported, although the anticoagulant activity of DS is significantly lower than that of heparin, its venous antithrombotic activity appears to be significantly higher. Thus, the hemorrhagic properties of DS are greatly reduced when compared to heparin. This has made DS an interesting target in developing new therapeutic agents for the prevention of thrombosis.^[13] Dermatan sulfate has two major pharmacokinetic problems, a relatively short half-life and low bioavailability, when compared to heparin delivered by subcutaneous or intramuscular routes. However, DS does not bind to the endothelium and thus gives simpler pharmacokinetics than those observed for heparin.

The use of DS in clinical trials has been extremely limited. A pharmaceutical preparation of DS has been used in healthy volunteers and patients under

treatment for renal failure by dialysis, venous thromboembolism, disseminated intravascular coagulation syndrome, and arterial atherothrombotic diseases. In all cases (more than 300 patients) no serious bleeding complications have occurred. Furthermore, DS has been used to prevent deep vein thrombosis in hip fracture patients. In another study, the efficacy of moderate intravenous doses of DS was compared to heparin for the treatment of disseminated intravascular coagulation in acute leukemia patients. Dermatan sulfate was as effective as heparin in preventing deep vein thrombosis. Moreover, new bleeding complications were less frequent with DS than heparin and no patient experienced thromboembolic complications.

CHONDROITIN SULFATE APPLICATION IN BIOMATERIALS

Several materials are used for regeneration therapies in orthopedics and dentistry, such as heterologous graft of frozen or lyophilized bone, both demineralized or not, use of biomaterials, reabsorbable or not, or combinations of the above-mentioned materials with organic macromolecules composing the extracellular matrix such as proteins and GAGs. Apatites and bioglass are excellent biomaterials with good biocompatibility and associated with a lack of toxicity or proinflammatory activity.

As previously reported, mineralized connective tissues predominantly contain small CS-PG species. For these reasons, GAGs and in particular CS, have received major attention as molecules implicated in the absorption process onto hydroxyapatite. This biomaterial has been used for the construction of artificial bone and as bone-substitute biomaterial used to fill bone defects around immediate implants in humans.^[14] Furthermore, material composed of gelatin, CS, and hyaluronic acid was utilized for cartilage tissue engineering, and GAG hydrogel films, formed of hyaluronic acid and CS, were applied as biointeractive dressings for wound healing.^[15]

CONCLUSIONS

The rapidly accumulating evidence obtained in these last decades suggests that CS/DS have crucial biological functions in growth factor signaling, axonal growth and regeneration, neuritogenesis during CNS development, morphogenesis, and cell division. In addition, the involvement of cell-surface CS/DS chains in infection has been recently reported. Although the evidence is fragmentary and immature, future analysis will help reveal the molecular mechanisms underlying these functions.

The study of CS will certainly extend well into this new century with so many questions still left unanswered. Some focal points in the near future include: 1) improved preparation and synthesis of CS/DS; 2) new DS-based anticoagulants with improved properties; 3) new therapeutic applications for CS/DS; 4) new biomaterials; and 5) development of an improved understanding of physiology and pathophysiology through glycomics.

The preparation of CS from mammalian tissues creates concern particularly after the recent appearance of bovine spongiform encephalopathy in Europe. As a consequence, there are growing concerns about CS prepared by alternative routes, defined, recombinant mammalian cell lines capable of being cultured in large-scale fermentations, or non-mammalian tissues, offer an exciting alternative to the present preparations.

New anticoagulants based on DS structure might provide enhanced specificity, targeting one or selected groups of coagulation proteases and avoiding undesired interactions with other proteins, thus decreasing the side effects associated with the use of heparins. These new potential applications of DS/CS may be strictly associated with molecules possessing a peculiar and unusual structure, such as those isolated from invertebrates.

Finally, one of the most important future directions of CS research is driven by the recent sequencing of the human genome and the field of genomics. While much attention is currently focused on the proteome encoded by the genome and the rapidly developing field of proteomics, the glycome has attracted little attention. Glycomics is the study of the structure and function of the glycome, the most important and complex of the posttranslation modifications that proteins undergo. An improved understanding of the glycome should be beneficial in better understanding genetic diseases, offering new therapeutic approaches to treat these very serious pathologies. Moreover, improved knowledge of glycomics, in vertebrate and invertebrate species, should lead to a better understanding of physiology and pathophysiology, offering new approaches to drug development.

ABBREVIATIONS

APC	Activated protein C
CNS	Central nervous system
CS	Chondroitin sulfate
CIA	Collagen-induced arthritis
DS	Dermatan sulfate
GalNAc	N-acetyl-D-galactosamine

INTRODUCTION

Collagen is the most abundant protein in the human body, accounting for 30% of the total protein. In normal tissues, collagen provides tensile strength and structural integrity. Collagen has a structure of splendid hierarchical order. The structural complexity involves numerous types of collagen associated with tissue-specific expression, organization into heteropolymeric or homopolymeric fibrils of uniform size, unique posttranslational processing and interaction with proteoglycans, adhesion glycoproteins, cells, and other collagens. When tissues are disrupted following injury, collagen is needed to repair the defect and restore structure and function. Too much collagen deposited in a wound site results in loss of normal anatomical structure, function, and fibrosis. Conversely, if insufficient amounts of collagen are deposited, the wound is weak and may dehisce. Therefore, to fully understand wound healing, it is essential to understand the basic biochemistry of collagen.

Collagen forms the extracellular matrix that defines the ground substance for all connective tissues and is a major functional component of skin, bone, cartilage, and other tissues to be discussed. There are over 1000 commercial products on the market today that contain collagen and collagen enhancers. These products are represented by body and hand lotions, nail treatments, firming gels, wrinkle injections, eye pads, and even anti-cancer treatments, to name but a few. In recent years, new high tech wound dressing materials and skin substitutes have become available for the treatment of partial and full thickness dermal injuries and chronic dermal ulcers. Future applications of collagen products hold promise in the fields of drug delivery and tissue engineering.

COLLAGEN STRUCTURE AND FUNCTION

Collagen provides structural integrity for connective tissues such as dermis, bone, cartilage, tendon, ligament,

and internal organs.^[1,2] Due to the wide distribution throughout various tissues, collagen represents one of the most abundant naturally occurring proteins on earth.^[3] The collagen super-family includes over 30 different gene products that assemble into at least 20 genetically distinct collagen types which may be homotrimeric or heterotrimeric in nature.^[4,5] The ubiquitous nature of collagen is such that a single cell may co-express several collagen types. For example, skin fibroblasts are able to synthesize six highly homologous but genetically distinct procollagen chains necessary for the assembly of fibrillar collagen. The ability of individual procollagen chains to discriminate between each other is a central feature of the assembly process by ensuring that each collagen molecule has the correct complement of pro chains. Collagens I–V are the five major types, and those which are the main focus of this review (Table 1). The predominant form is type I collagen, found in bone, and is by far the major single protein. Type I collagen is also found in other tissues such as skin, dentin, cornea, blood vessels, fibrocartilage, and tendon. The fibrillar form of collagen represents over 90% of our total collagen and is composed of three very long protein chains. In type I collagen, each protein chain is referred to as an alpha chain (α -chain). Two of the α -chains are identical and are called α 1-chains whereas the third chain is slightly different and is labeled the α 2-chain. The three chains are twisted with each other to form a triple helical structure called a collagen monomer or a gamma structure (γ -structure) (Fig. 1a). The equivalent configuration imparts tremendous strength to the protein. The overall structure of the collagen molecule can be compared to the reinforcement rods (called rebar) used in concrete construction. The scaled molecular dimensions of a collagen molecule would be one inch in diameter and 17 feet in length. Collagen is indeed nature's rebar due to its incredible strength and provision of structural integrity for connective tissues and organ structures.

Table 1 Collagens

Type ^a	Composition	Tissue distribution
I	($\alpha 1(I)$) ₂ $\alpha 2(I)$, trimer ($\alpha 1(I)$) ₃	Dermis, bone cornea, tendon, fibrocartilage, vessels, intestine, dentin, skin, uterus
II	($\alpha 1(II)$) ₃	Cartilage, notochord, vitreous humor, nucleus pulposus
III	($\alpha 1(III)$) ₃	Dermis, intestine, gingiva, heart valve, uterine wall, vessels
IV	($\alpha 1(IV)$) ₂ $\alpha 2(IV)$	Basement membranes
V	$\alpha 1(V)\alpha 2(V)(\alpha 3(V))$ or ($\alpha 1(V)$) ₂ $\alpha 2(V)$ or ($\alpha 1(V)$) ₃	Cornea, placental membranes, bone, vessels, cartilage, gingiva
XI	1 $\alpha 2\alpha 3\alpha 1$ or $\alpha 1(XI)\alpha 2(XI)\alpha 3(XI)$	Cartilage, intervertebral disc, vitreous humor

^aI-V are the most abundant; I, II, III, V, and XI are capable of fibril formation.

All of the collagens share the triple-helical molecular structure. However, the various other types of collagens have slightly different amino acid compositions and provide other specific functions in our bodies. Type II collagen is the form found exclusively in cartilaginous tissues. It is usually associated with water, proteoglycans, glycoproteins, and noncollagenous proteins. The collagen provides for the tensile integrity of the tissue whereas the water and proteoglycans are responsible for the swelling. Type II collagen acts as a shock absorber in our joints and vertebrae. Type III collagen is found in our skin as well as in ligaments, blood vessels, and internal organs. In the adult, the skin contains about 80% type I and 20% type III collagen. In newborns, the type III content is greater than that found in the adult and may contribute to the supple nature of newborn skin. Type III also contributes to the flexibility of blood vessels and is expressed during the initial period of wound healing.^[6]

Type IV collagen is found in basement membranes and basal lamina structures and functions as a filtration system. The complex interactions between type IV collagen and the noncollagenous components of the basement membrane form a meshwork that filters cells, molecules, and light. For example, the basement membrane in the lens capsule of the eye plays a role in light filtration. The glomerulus basement membrane of the kidney is responsible for filtration of the blood to remove waste products. The basement membrane form in the walls of blood vessels controls the movement of oxygen and nutrients out of circulation and into the tissues. Likewise, the basal lamina in the skin delineates the dermis from the epidermis and controls the movement of materials in and out of the dermis.

Type V collagen is found in essentially all tissues and is associated with types I and III. In addition it is often found around the perimeter of many cells and functions as a cytoskeleton. It is of interest to note that there appears to be a particular abundance of type V collagen in the intestine compared to other tissues.^[7] The remaining types of collagen play minor but

important roles participating as extracellular signaling molecules and eliciting intracellular responses.

Primary Structure

The collagens most involved in forming fibrillar structures include types I, II, III, V, and XI.^[8] The structures are assembled in precise combinations utilizing 10 varying polypeptide chains that include, $\alpha 1(I)$, $\alpha 2(I)$, $\alpha 1(II)$, $\alpha 1(III)$, $\alpha 1(V)$, $\alpha 2(V)$, $\alpha 3(V)$, $\alpha 1(XI)$, $\alpha 2(XI)$, and $\alpha 3(XI)$ (Table 1). The chains derive from a common ancestral gene containing a nucleotide segment that encodes a peptide representing strings of five or six amino acid triplets comprised of Glycine-X-Y, where the residues for X and Y are frequently the amino acids proline (Pro) and lysine (Lys). At the nucleotide level this corresponds to a 45- or 54-nucleotide segment that is repeated several times uninterrupted and provides a common feature within the highly conserved collagen family (Fig. 1b). At the amino acid level, there is extensive posttranslational modification that takes place, which includes hydroxylation of Lys and Pro residues into hydroxylysine and hydroxyproline. More variable is the glycosylation of hydroxylysine residues into galactosyl- or glucosyl-galactosyl-hydroxylysine, and oxidation of some Lys and hydroxylysine residues into an aldehyde group. In diabetic patients sometimes the collagen in tendons and basement membranes becomes glycosylated by nonenzymatic mechanisms and this abnormal collagen is responsible for the many pathologic characteristics associated with the disease such as blindness, kidney failure, neuropathy, and atherosclerosis.^[9]

Secondary Structure

The α -chains form tight left-handed α -helices. The peptide bond backbone forms with the side chains of the amino acids pushing to the outside of the helix. Approximately three residues form a turn in the helix

Fig. 1 The structure of collagen: (a) The basic structural unit of collagen is a triple-stranded helical molecule, and each basic unit is approximately 300 nm in length. (b) Collagen fibrils are formed with collagen units oriented side by side and adjacent strands positioned to overlap and form covalent cross-linking bonds (in dark) between the N-terminus of one strand and the C-terminus of the adjacent strand. The periodic pattern of collagen formation in fibril packing creates 67 nm end-to-end separations. (c) The periodic pattern gives an appearance of striations as seen in a scanning electron micrograph (SEM) of embryonic chick tendon. (SEM scan reproduced from *Molecular Cell Biology*, Fourth Ed. Lodish, Berk, Zipursky, Matsudaira, Baltimore, and Darnell, eds. New York: W. H. Freeman and Company, 2000, with permission of the publisher.)

with glycine positioned at every third residue in the (Gly-X-Y) motif. The Gly-residues align and form what is known as the clear line that winds in a left-handed fashion on the surface of the molecule.

Tertiary Structure

The Gly-clear line is a left-handed formation that helps stabilize the reciprocal formation of right-handed threads and vice versa.^[10] The triple helix between three collagen fibers occurs in the C- to N-terminal direction and is facilitated by a lack of steric hindrance due to the glycine rows forming a central axis. Point mutations in the X or Y positions can be tolerated, whereas mutations that replace Gly impair the formation of the triple helix, and most often result in one of many forms of connective tissue disorders collectively referred to as osteogenesis imperfecta.^[11] The type of triple helix that forms is dictated by the collagen and tissue type and can be either a homotrimer or a heterotrimer triple helix formation (Table 1).^[12] As collagen forms into its triple helix it resembles a rodlike structure that is both stiff and flexible (Fig. 1c), and can be over 300 nm long (~1.5 nm wide), with globular domains capping both N- and C-terminal ends. This form of secreted collagen is termed procollagen.

COLLAGEN SYNTHESIS

The biosynthetic pathway responsible for collagen production is complex.^[4,13] Each specific collagen type is encoded by a specific gene; the genes for all of the collagen types are found on a variety of chromosomes. As the messenger RNA (mRNA) for each collagen type is transcribed from the gene, or DNA blueprint, it undergoes many processing steps to produce a final code for that specific collagen type, called mRNA processing. Translation occurs once the final pro- α -chain mRNA is produced and attaches to the site of actual protein synthesis. The site of pro- α -chain mRNA translation is found on the membrane-bound ribosomes called the rough endoplasmic reticulum (rER) for function in the extracellular environment (Fig. 2).

Collagen, like most proteins that are destined for transport to the extracellular spaces for their function or activity, is produced initially as the larger precursor molecule called procollagen.^[14] Procollagen contains extension proteins on each end called amino and carboxy propetides that are unlike collagen.^[14] These nonhelical portions of the molecule increase solubility for ease of movement within the cell as it undergoes production. While inside the cell and when the procollagen peptides are intact, the molecule is about 1000 times more soluble than it is at a later stage when the extension peptides are removed.^[15] This high degree of solubility allows the procollagen molecule to be transported easily within the cell. It is moved by means of specialized structures called microtubules to the cell

Fig. 2 The intracellular and extracellular events involved in the formation of a collagen fibril.

surface where it is secreted into the extracellular spaces.^[16] As the procollagen is secreted from the cell, it is acted upon by specialized enzymes called procollagen proteinases that remove the extension

peptides from the ends of the molecule.^[17] Portions of these digested end pieces are thought to reenter the cell and regulate the amount of collagen synthesis through a feedback type mechanism.^[18,19] The newly processed

molecule is referred to as collagen and now begins the important process of fiber formation.

On the amino- or N-terminal end, special disulfide bonds are formed among three procollagen chains and insure proper alignment of the chains. This step is called registration. Once registration occurs, then the three chains wrap around each other forming a stringlike structure. As collagen molecules are produced, they undergo many posttranslational modifications that take place in the Golgi compartment of the ER.^[4,13]

One of the first modifications to take place is the very critical step of hydroxylation of selected Pro and Lys amino acids in the newly synthesized procollagen protein (Fig. 2). Specific enzymes called hydroxylases are responsible for these important reactions needed to form hydroxyproline and hydroxylysine. The hydroxylase enzymes require vitamin C and iron as cofactors and molecular oxygen as a cosubstrate.^[20] If a patient is vitamin C deficient, the hydroxylation reaction is inhibited. In the absence of hydroxyproline, the collagen chains cannot initiate hydrogen bond formation to form a proper helical structure and the resultant molecule is weak and quickly destroyed.^[21] The end result is poor wound healing and the clinical condition is called scurvy.^[22] The current Recommended Dietary Allowance for vitamin C is 60 mg per day; however, research has shown 200 mg may be optimal.^[23,24]

Some of the newly formed hydroxylysine amino acids are glycosylated by the addition of sugars such as galactose and glucose.^[25] The enzymes that catalyze the glycosylation step, galactosyl and glucosyl transferases, require the trace metal manganese (Mn^{+2}). The glycosylation step imparts unique chemical and structural characteristics to the newly formed collagen molecule and may influence fibril size.^[26] It is of interest to note that the glycosylation enzymes are found with the highest activities in the very young and decrease as we age.^[27]

Fibrillogenesis

In the extracellular spaces, another posttranslational modification takes place as the triple helical collagen molecules (see Fig. 1) line up and form fibrils and then

fibers. The cross-link formation is promoted by another specialized enzyme called lysyl oxidase.^[28] The reactions place stable cross-links within (intramolecular) and between (intermolecular) the molecules (Fig. 3). Cross-link formation is the critical step giving the collagen fibers, on a per weight basis, tensile strength approaching that of steel.

The structural hierarchy of collagen can be visualized as resembling a piece of sewing thread for the individual collagen molecules. Many of these threads are wrapped around one another to form a string or fibril. The strings form cords, which associate to form ropes, and then interact to form cables or fibers. The structure can be compared to the steel rope cables on the Golden Gate bridge. The highly organized structure is responsible for the strength of tendon, ligament, bone, and dermis.

When the normal collagen in our tissues is injured and replaced by scar tissue, the connective tissue does not regain the original highly organized structure and is weaker. The maximum tensile strength of scar tissue is about 70 to 80% of the original.^[29] Collagen synthesis and remodeling continue at the wound site long after the injury. The body is constantly trying to remodel the scar tissue to achieve the original collagen ultrastructure. This remodeling involves ongoing collagen synthesis and collagen degradation. Interference with protein synthesis can cause the synthesis/degradation equilibrium to shift allowing increased collagen degradation. For example, patients who are malnourished or patients receiving chemotherapy may experience wound dehiscence because the wound site will become weak due to a shift in the balance toward collagen degradation. It is of interest to note that when wounds in the fetus heal, they do so in such a manner that the original collagen ultrastructure is achieved.^[30] If only we understood more about the biology and mechanisms responsible for the rapid and optimal wound healing response seen in the fetus, we would have greater insight into the management of adult wounds.^[31]

Spontaneous aggregation of the collagen molecules begins with the formation of microfibrils which aggregate to form fibrils. Fibrillogenesis is dependent on the glycoprotein content and the distribution of the glycosylated residues along the molecule. Any effects

Fig. 3 The intramolecular and intermolecular cross-links formed within a collagen fibril.

Fig. 4 D-Period banding of collagen molecules. (From Ref. [32].)

of copolymerization with different collagen Types within the fibril also contribute to differences in fibrillogenesis.^[32,33] The aggregation is also controlled by periodic distribution of polar charged amino acid residues and amino acids with hydrophobic side chains along the triple helix.^[33–36]

The differing types of amino acid R-groups include:

- nonpolar, i.e., glycine, alanine, proline.
- cationic, i.e., lysine, arginine.
- anionic, i.e., free carboxyls of aspartic and glutamic acid.
- polar ionic, i.e., residues of serine and hydroxyproline.^[35]

The collagen fibrils are the major source of strength for all connective tissue and range from 16 to 200 nm in diameter.^[34] The nonanastomosing fibrils form a $\frac{1}{4}$ stagger arrangement with a 67 nm periodic banding pattern which is termed D-period banding. D is equivalent to $\frac{1}{4}$ the molecular length of the collagen molecule, approximately 234 residues.^[35,37,38] There is a 0.4 D overlap which contributes to the D-period banding pattern and also contains the functional groups for cross-linking (see Figs. 3 and 4). The D4 period contains amino acid sequences critical for cell motility.^[39] The potential nonpolar and ionic interaction between the collagen molecules is optimized at multiples of D.^[32,35,36,40]

The kinetics of fibril formation is also dependent on pH, ionic strength, temperature, cross-links, aldehydes which form cross-links, the concentration of phosphate, and the telopeptide region.^[32] In cartilage, Type II collagen forms fibrils approximately 20 to 30 nm in diameter but does not form fibers as found in tendons. The tissues composed of collagen Type II are comprised of a network of thin fibrils.^[32,37] The $\alpha 1(\text{II})$ chain contains 6% hydroxylysine-linked carbohydrates

which is a comparatively large amount of hydrophilic carbohydrate groups when compared with other collagen molecules. The increase in the lateral spacing produced by the carbohydrate groups allows twice as much water to be dispersed among the molecules and the fibrils than does a typical collagen Type I molecule.^[32,35] The lateral spacing is achieved by a layering effect of collagen molecules in a microfibril. The most popular model for microfibril arrangement is the Smith model, in which five molecules are staggered by a D period in a layer (see Fig. 5).^[32,34] Recent advancements upon this theory have been demonstrated using atomic force microscopy.^[41] With this technology one can study fully hydrated tendon specimens to simultaneously demonstrate fibril-bound material and surface cross-binding, at the same time excluding artifacts typically associated with fixation and dehydration. This work predicts a compressed microfibril model forming a fibril of five-stranded microfibrils. The molecular segments follow an individual path within the gap zone and pack tightly in the overlap zone.

Cross-Links

The inherent tensile strength of the collagen fibrils is primarily dependent on the covalent nondisulfide cross-linking. Disulfide bonds are found in the propeptide regions of the procollagen molecule and play no role in intermolecular cross-linking; however, the aldehyde-derived cross-links are multifunctional.^[34] Although the cross-links are not visible by scanning electron microscopy (SEM), the cross-links can be thought of as welds used to bind and direct the building blocks of collagen molecules into a rope-like unit.^[35,40] Inhibition of cross-linking significantly increases the diameter and the volume density of collagen fibrils. However, the mechanical integrity of the

Fig. 5 Smith Model—Collagen Microfibril Arrangement. (From Ref. [33].)

thicker under-cross-linked fibrils is significantly less than that of normal collagen fibrils.^[42] A decrease in the percentage of cross-linking also contributes to an increased susceptibility to proteolytic degradation and subsequent solubilization.^[35,37] Cofactors are necessary to induce cross-linking of the fibrils by the conversion of lysine and hydroxylysine to allysine and hydroxyallysine. The cofactors include pyridoxal phosphate, Cu^{++} , O_2 , and lysyl oxidase.^[34-36] The spontaneity of the condensation reactions is mediated by the physical location of the molecules with respect to each other and their correct alignment. The aldimine product is a combination of lysine and hydroxylysine in which the lysine has been altered to allysine by the cofactors and subsequently combines with the hydroxylysine to form a terminal group.^[34] The aldehydes are restricted to the N-telopeptide and the helical region.^[36,37] The initial condensation reactions produce difunctional cross-links capable of linking two separate polypeptide chains.

COLLAGEN DEGRADATION

Of equal importance in the total picture of collagen metabolism is the complex process of collagen degradation. Normally the collagen in our connective tissues turns over at a very slow and controlled rate. However, during rapid growth and in disease states such as arthritis, cancer, and chronic non-healing ulcers, the extent of collagen degradation can be quite extensive. In normal healthy tissues where the collagen is fully hydroxylated and in a triple helical structure, the molecule is resistant to attack by most proteases. Under these normal healthy conditions only specialized enzymes called collagenases can attack the collagen molecule.^[43] The group of collagenases belongs to a family of enzymes called matrix metalloproteinases (MMP).

Many cells in our bodies can synthesize and release collagenases including fibroblasts, macrophages, neutrophils, osteoclasts, and tumor cells. One of the reasons that some neoplastic cells can be so invasive is because they release potent collagenases and can break down the collagen around them. They degrade the basement membranes of blood vessels and spread throughout the body. In chronic pressure ulcers, there is a massive invasion of neutrophils releasing a very potent collagenase called MMP-8 which is responsible for connective tissue breakdown and delayed healing.^[44] Some exciting new research suggests that members of the tetracycline family of antibiotics, such as doxycycline, when given systemically, and at low doses, may be useful to treat pressure ulcers by inhibiting MMP-8.^[45]

Collagen is particularly resistant to attacks by neutral proteases due to its function as the primary structural protein in the body. At neutral pH only specific collagenases cleave the native helix at a position about three-quarters of the way from the N-terminus.^[46] They are zinc-containing MMP of approximately 40–50 kDa and generally require calcium as a cofactor for full activity.^[47] Fibrils as aggregates of collagen molecules are degraded starting from the exterior. Collagenase binds tightly to triple helices at or near the surface, whereas molecules in the interior become accessible to enzymes in the course of the progressive degradation from the outside.^[48] The various types of collagen show different susceptibility to collagenolytic degradation.^[49] After the triple helix is disrupted, further degradation of the collagen molecules is facilitated by enzymes such as gelatinases and non specific proteinases which cleave the primary fragments into small peptides and amino acids. Elastases and cathepsins assist in proteolysis of collagen fibers with a higher degree of natural cross-linking based on their ability to digest nonhelical telopeptide regions.^[50]

Synthetic Cross-Linking

Naturally occurring intramolecular cross-links are disrupted during collagen extraction purification procedures. Upon subsequent processing, collagen does not molecularly re-cross-link; therefore, a synthetic cross-linking process must be performed.

Synthetic cross-linking prevents material degradation, increases resistance to cell-mediated contraction, and in some cases decreases immune reaction responses.^[51-55] Physical cross-linking methods involve processes allowing the collagen to polymerize without cytotoxic products, but may degrade or fragment the collagen. Chemical cross-linking methods involve polymerization with reagents potentially forming cytotoxic products.

Different methods of cross-linking affect the collagen material characteristics regarding cell adhesion qualities, degeneration, and mechanical properties which must be considered depending on the application.^[56]

Physical cross-linking methods included dehydrothermal treatments (DHT) and ultraviolet light (UV). DHT forms intermolecular cross-links by removing water from the collagen through condensation reactions.^[51,54,57] The high temperature required for cross-linking may partially denature the collagen.^[51,58] UV exposure produces radicals of unpaired electrons located in the nuclei of aromatic amino acid residues located on the α -chains, which then band to form cross-links.^[55,57] The process is limited by the number of aromatic amino acids and the attenuation of the UV

light by the collagen fibers.^[57] Overexposure to the UV light may partially denature the collagen fibers.^[55]

Chemical cross-linking methods include glutaraldehyde (GTA), 1-ethyl-3-(3-dimethylamino-propyl) carbodiimide (EDC or EDAC), or diphenylphosphorylazide (DPPA). GTA reacts with amino groups to form methylene bridges capable of spanning large intermolecular spaces. Disadvantages of this process include its reactivity during foreign body reactions in which the cross-links are dissolved and absorbed, unsealing the collagen material.^[54] The inflammatory response is associated with continued hydrolysis of free monomeric GTA, thereby increasing cytotoxicity.^[56,59] EDC involves many functional groups by forming amide bonds in the presence of lysine or hydroxylysine.^[51,55] In vivo testing has shown biocompatibility with the unbound carbodiimide eliminated from the collagen through simple washes and the conversion of the bound EDC into the form of nontoxic urea.^[56,59,60] DPPA synthesizes acryl azide on lateral carboxyl groups of aspartic and glutamic acid which then react with amino groups of lysine and hydroxy lysine to produce cross-links.^[61]

Extraction

Although collagen is ubiquitous in the mammalian body, those tissues rich in fibrous collagen such as skin and tendon are generally used as starting materials to generate collagen for use in implants, wound dressings, or drug delivery systems. The major impediment to dissolution of collagen type I from tissue is the presence of covalent cross-links between molecules. Collagen is an extremely stable protein and resists action of nonspecific proteases.^[62] In order to extract the protein from tissue it is necessary to solubilize and appropriate the covalent cross-links. One way to aid in extraction is to inhibit the cross-links from forming. Inhibitors of cross-links include a copper deficient diet, carbonyl reagents such as phenyl hydrazine and hydroxyl amine, and lathyrogens such as β -aminopropionitrile.^[34] In general, however, three different solvent reactions exist to extract collagen. The first employs a salt solvent (0.15–2.0 M NaCl, pH 7.5), the second uses a dilute organic acid (0.5 M acetic acid), and the third uses a dilute organic acid in conjunction with an acid protease (pepsin).^[34]

Neutral Salt-Soluble Collagen

The most commonly used solvents are neutral salt solution (0.15–2.0 M NaCl) or dilute acetic acid.^[63] Neutral salt solutions will extract freshly synthesized and negligibly cross-linked collagen molecules present in the tissue. The extracted material is purified by

dialysis, precipitation, and centrifugation. Most tissues have little or no salt-extractable collagen.

Acid-Soluble Collagen

Dilute acidic solvents, e.g., 0.5 M acetic acid at 4°C, citrate buffer, or hydrochloric acid at pH 2–3, are more efficient than neutral salt solutions. The intermolecular cross-links of the aldimine Type of collagen are dissociated by the dilute acids, and the repelling charges on the triple helices lead to swelling of fibrillar structures.^[64] Dilute acids will not disassociate less labile cross-links such as keto-imine bonds. Therefore, collagen from tissues containing higher percentages of keto-imine bonds, such as bone, cartilage, or material from older animals, has a lower solubility in dilute acid solvents.

Alkali- and Enzyme-Treated Collagen

Additional collagen material can be solubilized by treating connective tissue with an aqueous solution comprised of alkali hydroxide and alkali sulfate, for example, approximately 10% sodium hydroxide and 10% sodium sulfate, for approximately 48 h.^[65] Much higher yields than with acidic extraction can be achieved by taking advantage of the fact that the collagen triple helix is relatively resistant to proteases, that is, pronase[®], ficin, pepsin, or chymotrypsin, below approximately 20°C.^[66] The pepsin cleaves at carboxylic groups of aromatic amino acids such as phenylalanine and tyrosine. It will not cleave at bonds with valine, alanine, or glycine, which allows for the maintenance of the triple helix.^[67] Therefore, the selective cleavage of pepsin occurs at the N- and C-telopeptide nonhelical regions breaking the peptide bonds near cross-links and forming an atelopeptide collagen molecule capable of dissolving in aqueous solution.^[34,68] Polyacrylamide gel electrophoresis in sodium dodecyl sulfate is used extensively to identify collagens. Performed with relative ease, speed, and a high degree of sensitivity, it is capable of identifying microgram quantities instead of the milligram quantities necessary for other analyses.^[34]

Denaturation

Denaturation of a protein is a result of damage to the internal structure of the molecule. The rearrangement of peptide chains is due to rupture of weak interchain bonds by heat, urea, collagenases, or acids.^[62] The melting temperature (T_M) of collagen is proportional to the body temperature of the particular species. The T_M is stable enough to remain native at common

temperatures but not so stable as to prevent collagen degradation and turnover. The T_M is regulated by the proline and hydroxyproline content.^[34,62] Mammalian collagenases separate the α -chain at specific and limited sites (i.e., Gly-Ile) to denature the molecule, and nonspecific proteolytic enzymes take over and digest the collagen fragments.^[32,34] Bacterial collagenases sever the α -chain at several sites.^[32] As stated, collagen is slightly susceptible to proteolytic enzymes under physiological conditions, and resorption of collagenous tissues does occur normally. However, resorption is dependent on the ability of the collagenase to degrade the collagen fibril and upon other proteases to depolymerize the collagen fibrils. Highly cross-linked collagens are resistant to digestion, but can be degraded with an increase in temperature.^[34,40] Due to the amino acid sequence, the degree of glycosylation, and the number of cross-links, type II collagen degrades five to six times more slowly than either type I or type III collagen.^[34]

CONCLUSION

Collagen metabolism is indeed one of the most complex and highly regulated processes in our bodies. As we move forward in the future to design new strategies and technologies to treat the many challenging clinical problems associated with wound healing, we need to keep in mind how our connective tissues are assembled and how they are remodeled. Collagen is an attractive biomaterial because it is a natural material of low immunogenicity and is therefore seen by the body as a normal constituent rather than as foreign matter.^[69] The versatility of the collagen matrix allows for it to be processed into a number of forms such as sheets, tubes, sponges, electrospun matrices, powders, fleeces, injectable solutions, and dispersions, all of which have extensive potential in medical procedures.^[70-72] Future work with collagen-based products will be at the forefront of a variety of applications in systems for drug delivery, ophthalmology, wound and burn dressing, tumor treatment, and cartilage and musculoskeletal tissue engineering.

Collagen Fixation

Thomas J. Koob

Skeletal Biology Section, The Centre for Research in Skeletal Development and Pediatric Orthopaedics, Shriners Hospitals for Children, Tampa, Florida, U.S.A.

INTRODUCTION

Collagenous tissue grafts and artificial constructs produced from reconstituted collagen fibers have been examined for potential use as bioprostheses for over forty years. Tissues, both allografts and xenografts, have warranted systematic investigation because the inherent collagen fiber system retains its tissue-specific shape and organization coupled with functional biomechanical properties. Grafts generally require processing to eliminate undesirable and potentially problematic compounds such as cell-associated molecules, enzymes, nucleotides, fats, etc. Methods to render grafts more biocompatible and long lasting have been developed over the past several decades and remain an active area of research. In contrast to grafts, reassembled fibers can be fabricated to satisfy mechanical requisites of the intended tissue replacement with the added advantage of allowing incorporation of additional macromolecules, therapeutic agents, and autologous or stem cells. Numerous innovative methods using diverse forms of collagen have been developed and optimized recently for fabricating functional collagen-based structures.

Both forms of bioprosthesis, whether a tissue or engineered construct, must be treated to reduce antigenicity and foreign body response, to attenuate degradation by host cells, or to enhance biomechanical properties. The basic strategy of most treatment protocols developed to date centers on the introduction of stable, covalent, intermolecular cross-links between collagen fibrils. Two related criteria are essential for the implementation of this strategy. The collagen fibrils must contain the reactive group, typically an amino acid side chain, targeted by the chemistry of the cross-linking agent and coupling mechanism. Second, the conditions, including temperature, pH, and nature of the solvent, must not adversely affect the inherent collagen molecules, fibrils, fiber systems, or properties of the bioprosthesis. Additional considerations might also be necessary depending on the cross-linking agent employed, e.g., residual reactants, unreacted intermediates, and byproducts of the reaction, all of which might be detrimental to the performance of the bioprosthesis in vivo.

What has proven most demanding is designing treatment strategies that are entirely biocompatible,

particularly with respect to cytotoxicity, antigenicity, and induction of a foreign body response. Chemical cross-linking agents such as formaldehyde, glutaraldehyde, and epoxy compounds, while effective at cross-linking collagen matrices, are themselves cytotoxic, and their reaction products in the cross-linked bioprostheses can be problematic in vivo. Nevertheless, advanced research on these strategies may in the future provide novel materials for biomedical engineering. New strategies incorporating natural biological cross-linking compounds or inducing cross-link formation without assimilation of foreign agents are emerging that may be as biomechanically effective as conventional cross-linking agents. Plant-derived compounds such as genipin and nordihydroguaiaretic acid are two examples of biological compounds that not only effectively improve the functional properties of collagenous materials but also appear to be biocompatible. An alternative method is to catalyze cross-link formation between reactive groups within the collagen fibrillar system. Such treatments include carbodiimide induction of isopeptide bond formation, ultraviolet light, and dehydrothermal treatments, all of which improve the properties of collagenous constructs crucial for use as bioprostheses.

Research and development of fixation strategies for collagenous materials have escalated enormously concomitant with the burgeoning fields of biomedical and tissue engineering. New strategies employing natural chemistries and biomimetic approaches will emerge that may supersede traditional methodologies. The present article reviews the current status of traditional approaches and describes potentially applicable novel fixation strategies.

COLLAGENOUS TISSUES AND MATERIALS

Fibrous assemblies of collagen molecules provide the major structural support of all vertebrate tissues. The molecular type of collagen and organization of these assemblies, however, are tissue-specific. In tendon and ligament, the predominantly type I collagen fibrils form fibers and fiber bundles that are aligned nearly parallel to the direction of load. In dermis, fibrils of type I collagen form loose networks. In bone, type I collagen forms the fibrillar phase of the mineralized

cortical and trabecular composites. Type II collagen in cartilage forms a dense network array of individual thin fibrils that constrain the proteoglycan-rich, inter-fibrillar matrix. In cornea, the thin type I collagen fibrils (co-polymerized with type V collagen) are arrayed parallel in each lamella with alternating layers arranged orthogonally with respect to the orientation of the fibrils. These examples illustrate the diverse arrangements of natural collagenous scaffolds to attain specific physicochemical properties and serve as archetypes for bioengineering designs.

Natural Collagen Fiber Systems

In order to devise strategies for using collagen in the development of advanced biomaterials for biomedical engineering, it is first necessary to understand the natural mechanisms underlying collagen fibril assembly and cross-linking pathways, the physicochemical properties of assembled fibril systems, and, thereby, appropriate means of obtaining diverse and potentially exploitable collagenous materials. Of principal concern here are the fibril-forming collagens that make up the extracellular matrices in collagen-dominated tissues and that can be obtained and purified in relatively large amounts (the interstitial collagen types I, II, and III). Other fibril-forming collagens,

types V and XI, are beyond the scope of the present article, as are the other twenty or more genetic types of collagen that are present in humans.^[1,2]

Interstitial collagen molecules within fibrils consist of a triple helix of three polypeptide chains (α -chains) with short, flanking, nonhelical telopeptides (Fig. 1). These molecules spontaneously assemble into fibrils with the characteristic D-period cross-striated repeat pattern measuring approximately 67 nm. Following incorporation into the fibril, covalent, intermolecular, lysine-derived cross-links form between the telopeptides and helical domains of neighboring molecules. The cross-linked fibril is the fundamental unit of mature collagen fiber systems within all connective tissues.

Collagen fibrils are organized into tissue-specific suprafibrillar architectures.^[3] Individual fibrils form a network in tissues such as skin, cartilage, and cornea. Fibrils are aligned and bundled into fibers and these in turn are aligned and bundled into fascicles in tissues such as tendon and ligament. Intact, native collagen fibrils have never been isolated from normal vertebrate tissues, indicating that their hierarchical organization is crucial to the tissues' structural properties. In addition, noncovalent as well as covalent interactions may provide additional stabilizing bridges linking fibrils where they are appropriately aligned. The nature of functionally relevant interfibrillar interactions remains an active area of connective tissue research and may

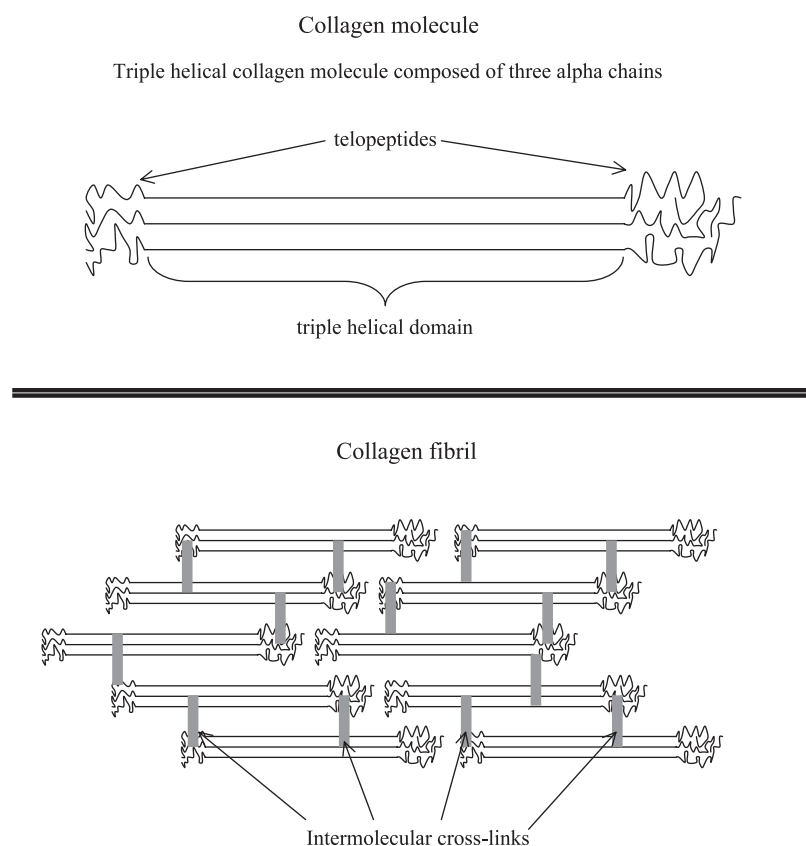

Fig. 1 Representative structure of fibril-forming, interstitial collagens and the organization of the fibrils they form.

eventually have important ramifications for collagen fixation strategies.

Collagen Scaffolds

Tissue grafts

Various forms of collagen have been examined for potential use as bioprosthetic devices and scaffolds for biomedical engineering. In the absence of synthetic mechanisms or molecular techniques to produce biomimetic collagen in any of its forms, the principal means of taking advantage of collagen is to use the native structure. Three forms are readily applicable for biomedical applications: collagenous fibril systems as they exist in tissue grafts, processed insoluble collagen, and purified collagen molecules that can be reassembled to satisfy specific geometrical and biomechanical objectives. Techniques to use each of these natural biomaterials have been optimized to various degrees. Before describing the strategy underlying implementation of these techniques, the distinct properties of each class of material must be understood.

Tissue grafts for use in humans can be obtained from several sources and each of these has advantages as well as drawbacks or limitations. Host-derived autogenous grafts function quite well in many instances and eliminate complications associated with immune reactions, foreign body response, and eventual rejection. They retain the native biomechanical properties of the extracellular matrix. Therefore, autogenous grafts do not require chemical fixation. However, autografting of collagenous tissues is limited by the paucity of sources with the added consideration that the source of the grafted tissue must not be compromised by resection of the graft itself. Examples of autogenous grafts used with success include skin grafts for treating severely burned patients, tendons for anterior cruciate ligament repair, and blood vessels for replacement of atherosclerotic arteries.

Tissue grafts derived from human cadaveric donors, i.e., allografts, constitute a potentially plentiful source of structural materials for use in the surgical repair of the musculoskeletal system. In contrast to vital organs for transplantation that are harvested alive and sterile, and utilized without modification, structural tissues such as bone and soft connective tissues—tendons, ligaments, and knee menisci—must be processed to remove blood, cells, soluble proteins, and enzymes before they can be used *in vivo*. Nevertheless, if treated properly, allografts retain much of their intrinsic structural and biomechanical properties. However, processed allografts must also be treated to eliminate immunogenic reactions and to reduce host-mediated breakdown. The only FDA-approved allografts that

are in general use today are bone-derived materials including bone chips and demineralized bone powder. No soft skeletal tissue has attained acceptable performance, due primarily to inflammatory responses and premature catabolism by invading cells.

Grafts originating from nonhuman species, termed xenografts, offer yet another source of collagenous scaffolds for use in tissue augmentation and repair. In contrast to allografts, there is potentially an unlimited supply of xenograft materials from a variety of animals, but they present a greater challenge *in vivo* with respect to antigenicity and induction of a foreign body response, including rapid degradation and removal. Xenografts must be processed even more stringently than allografts to eliminate potentially antigenic compounds and fixed to mask antigenic sites and to reduce host-mediated biodegradation. Fixation strategies to render xenografts more biocompatible have focused on methods for removal of nonstructural elements and chemical fixation of the collagen scaffold.

Although there has been a great deal of clinical and laboratory work exploring the potential use of fixed xenografts for musculoskeletal and vascular system applications, glutaraldehyde-fixed pig heart valves are the only xenograft bioprostheses in general use in humans at this time. Development and verification of the protocols that have enabled use of pig heart valves have a long and successful history. The most relevant advances will be described under specific fixation strategies to follow.

Collagen fibers

Naturally cross-linked collagen fibers purified to remove noncollagenous compounds provide effective starting materials for fabrication of collagen-based bioprostheses. This material is generally referred to as insoluble collagen and is commercially available. As long as the collagen is not denatured by the extraction procedure, the purified fibers retain the biomechanical properties that give tissues their particular functional properties and are thus like allografts. Concerns about biocompatibility are minimized due to the exhaustive extraction that leaves only the terminally cross-linked collagen. Unlike allografts, however, the tissues from which the fibers are obtained are mechanically fragmented, producing small segments of the fiber system. Fabrication of bioprostheses from these segments requires reassembly and fixation. Tissues that are used to produce insoluble collagen include tendons (Achilles) and corium, and these are predominantly from nonhuman species. The possibility of using human allograft tendons or other collagen-rich tissues as a source of insoluble collagen has not been systematically examined.

Because biomaterials created from insoluble collagen are essentially xenografts, they must be treated or fixed to reduce antigenicity and retard degradation *in vivo*. The same methods that have been applied to allografts and xenografts have been examined for their effects on insoluble collagen and its derivatives. In addition, following assembly of the fiber segments, the construct must be fixed to join the segments and thereby augment its biomechanical properties. One significant advantage of using insoluble collagen as opposed to grafts is that the fibers can be assembled into variably sized structures with geometries that satisfy specific physical or mechanical requirements. Another advantage is that other structural macromolecules or therapeutic agents can be incorporated into the construct during the fabrication process. Insoluble collagen fibers have been used to produce biomaterials for ligament and tendon repair, ocular implants and dressings, drug delivery vehicles, and as scaffolds for tissue engineering.

Reconstituted fibrils

Intact native collagen molecules containing the telopeptides can be obtained from tissues of fetal and growing vertebrates by acid extraction. Extraction of the newly synthesized collagen is possible because the mature intermolecular covalent cross-links have not yet formed or have progressed on the allysine pathway to a stage where they remain acid-labile. Since acid extraction is limited to the newly incorporated molecules, only a small proportion of the collagen is extractable from the tissues. More collagen is extracted from growing animals; only small amounts of collagen can be extracted from mature animals.

Substantially more collagen can be obtained from fetal and neonatal animals by enzyme extraction. The triple helical domain of the native collagen molecule is obtained from connective tissues by pepsin treatment in acid. Pepsin cleaves in the telopeptide region of the molecule inside the cross-linking domain but outside the helical domain, thereby liberating the molecule.

Acid-extracted and pepsin-solubilized collagen is purified by salt fractionation in acetic acid. The extract containing acid-soluble or pepsin-extracted collagen is brought to 0.7 M NaCl by addition of solid or dissolved NaCl in acetic acid. The major fibrillar collagens precipitate and are collected by centrifugation. The collagen is redissolved in acetic acid and precipitated a second time. The precipitate is redissolved in acetic acid and residual salt is removed by dialysis. The purity of the collagen preparation is assessed by polyacrylamide gel electrophoresis and amino acid analysis. Of note here is that bovine collagen prepared

in this way does not elicit significant antigenic response and has been FDA-approved for use in humans.

Both intact and pepsin-solubilized collagen molecules spontaneously form fibrils *in vitro* at neutral pH at 37°C. These fibrils are ultrastructurally identical to native fibrils *in vivo*. The purified collagen molecules dissolved in acid are neutralized, generally by dialysis, into phosphate-buffered saline. The molecules are soluble at neutral pH at 4°C. To form fibrils, the temperature of the collagen preparation is increased to 37°C. Because the initial collagen solution is a viscous liquid, it can be easily loaded into molds, vessels, or chambers for specific geometries. Following fibrillogenesis, the viscous liquid is transformed into a loose gel. However, gels formed this way are relatively dilute and fragile. The subsequent treatment of reconstituted collagen gels depends on the intended use of the biomaterial. However, in virtually all cases, fixation is required at some stage to stabilize the collagen phase of the construct and improve its biomechanical properties. Reconstituted collagen fibrils have been used to fabricate fibers for tendon and ligament repair and for collagen scaffolds for tissue engineering.

COLLAGEN FIXATION STRATEGIES

There are four fundamental strategies for fixing collagenous tissue grafts and biomaterials constructed of processed fibers or purified collagen. The traditional approach involves the introduction of exogenous chemical cross-linking agents that covalently couple neighboring collagen fibrils using targeted reactive moieties in the collagen fibrillar system and the cross-linking molecules themselves. Such agents include glutaraldehyde, epoxy compounds, and isocyanates. The exogenous agents themselves are incorporated as part of the cross-link (Fig. 2). These treatments result in formation of chemical entities that are not normally present in biological tissues and, therefore, care must be taken to ensure that the cross-linked materials are not cytotoxic, are not inflammatory, do not induce a foreign body response, and, if biodegradable, the mobilized products do not cause immunogenic reactions and do not impact organs involved in their metabolism or excretion.

Another approach is based on catalyzing cross-link formation by physicochemical means that covalently join collagen fibrils via the naturally occurring reactive amino acid side chains. Included in this class of fixation methods are photo-oxidation, microwave irradiation, dehydration, and dehydrothermal treatment. Physicochemical methods eliminate concerns centering on nonbiological cross-linking agents, residual cross-linking precursors and intermediates, and the products derived from reactions of these agents

Fig. 2 Structure of chemical cross-linking agents that are themselves incorporated into the cross-link and the structure of the cross-links that form between collagen fibrils. It should be noted that the scheme for glutaraldehyde fixation is an extremely simplified representation of only the primary reaction product generated by glutaraldehyde. The extremely complex nature of glutaraldehyde cross-linking is described in Refs. [4] and [5] and these should be consulted for a full understanding of glutaraldehyde fixation and for further reading.

with collagen. It is assumed that the cross-links formed with these protocols are similar to naturally occurring biological adducts thereby reducing potential adverse effects *in vivo*. Physicochemical methods such as UV light irradiation may adversely affect the integrity of the collagen fibrillar system, so care must be taken to ensure that the design of the treatment protocol reduces detrimental reactions.

The third strategy is to chemically catalyze intermolecular cross-links between reactive amino acid side chains on the collagen fibrils. The advantage of this strategy is that the catalytic agent does not become incorporated into the cross-link and can be completely washed out of the biomaterial. Carbodiimide and the azyl azide method are two treatments that fix collagenous tissue grafts in this way.

The fourth strategy is based on polymerizing compounds that are mixed with collagenous assemblies and form polymeric interactions that do not chemically react with the collagen fibrils. These interactions can be either noncovalent or covalent. Materials produced with this approach can be considered polymer-reinforced composites. While the collagen is not chemically altered, the polymer formed may or may not be problematic *in vivo*.

Implementing one or another of the collagen fixation strategies described above involves distinct considerations based on the type of collagen scaffold to be

fixed, its inherent properties, and intended use *in vivo*. Allografts and xenografts require fixation to limit adverse reactions *in vivo*, including a foreign body response, an inflammatory reaction, and immunogenicity. A fixation strategy that retards biodegradation and absorption during the repair phase is also necessary in most cases. Premature debilitation of the biomaterial's functional properties must be avoided during the repair phase. The objective of most strategies is to design a fixation strategy that produces a biodegradable biomaterial, the rate of degradation of which is closely tuned to the repair process and the development of normal properties in the repair tissue. Since these grafts retain their natural biomechanical properties, less emphasis need be placed on fixation methods that are designed to improve physical properties. However, fixation will inevitably alter the graft's biomechanical properties, and this must be taken into account when designing graft fixation strategies.

Biomaterials produced from insoluble and reconstituted collagen also require fixation for biocompatibility and attenuation of biodegradation. However, of equal importance for these bioprotheses is fixation to achieve appropriate biomechanical performance. In practice, the principal goal in the design and development of collagen-based biomaterials is optimization of the fixation strategy for the desired functional properties. Nonetheless, only fixation methods that

result in biocompatible materials need be applied. In the best case scenario, the fixation method not only produces a mechanically competent biomaterial, but also renders the construct biocompatible. Some of the methods described below are capable of this dual effect.

Standard methods are used to measure the effectiveness of the fixation strategy, and these relate directly to the intended use of the biomaterial. The temperature at which collagenous structures shrink, the thermal shrinkage temperature, is generally taken as a measure of the density of intermolecular cross-links. The technique is simple to set up and reliably measures differences in effective cross-link density. If the fixation method creates new cross-links, the shrinkage temperature should increase over that of the untreated biomaterial. Differential scanning calorimetry is a more sensitive and informative tool to quantify thermal stability of the cross-linked collagen, but it requires costly equipment.

Biodegradability can be assessed initially in the laboratory by assessing the susceptibility of the cross-linked material to bacterial collagenase. The treated biomaterial is incubated with commercially available collagenase and the amount of degraded collagen released over time is compared to that of the untreated control. This method is employed primarily as an assessment of the effectiveness of the fixation method, although decreased susceptibility to collagenase *in vitro* indicates that the biomaterial will be less degradable *in vivo*. In the final analysis, the fixed biomaterial must be tested *in vivo* for biodegradability by implanting it, usually subcutaneously, and following its fate histologically.

Biocompatibility can be tested *in vitro* with isolated cells to determine whether the fixation agents or the cross-links they produce are cytotoxic. In addition, the response of specific cell types to the fixed biomaterial can be assessed. As with biodegradability, biocompatibility must be determined *in vivo*. Following implantation, the local tissue is analyzed histologically over time for inflammatory reactions, including the presence of T-cells, monocytes and macrophages, and multinucleated giant cells. Antigenicity can be evaluated by biochemical analysis for antibodies to the fixed biomaterial.

The functional properties of the fixed biomaterial must also be evaluated. The type of test will depend on the intended use of the fixed biomaterial. For example, cross-linked collagen fibers for tendon and ligament repair are tested with uniaxial tensile tests to failure. These tests yield tensile strength, stiffness, and strain at failure, which can be compared to the natural tensile properties of tendon and ligaments. The stiffness of fixed pig heart valves and pericardium is measured to determine whether they will perform *in vivo* similarly

to the natural valves. Beyond structural and mechanical properties, biochemical analyses are generally required to determine the nature of the reaction products formed by fixation protocols and to monitor the efficacy of the cross-linking conditions. Many of the fixation strategies described below involve free amines. Relatively straightforward colorimetric analyses of free amines, e.g. with picrylsulfonic acid (TNBS), can be employed to evaluate the cross-linked biomaterials.

Aldehyde-Based Fixation

Glutaraldehyde is an effective cross-linking agent that is used primarily to fix biological tissues for electron microscopy. Fixation is based on the introduction of covalent cross-links between neighboring proteins; however, the mechanism of bond formation and exact nature of the introduced bonds are not entirely clear. Glutaraldehyde contains two reactive aldehyde groups flanking a short 3-carbon aliphatic chain ($\text{OH}-\text{C}-(\text{CH}_2)_3-\text{C}-\text{HO}$). An aqueous solution of glutaraldehyde contains a mixture of the free aldehydes, monomeric and polymeric cyclic derivatives, and unsaturated polymers. At neutral pH, glutaraldehyde and its derivatives react with primary amines ($\text{R}-\text{NH}_2$) and, if the amines are constituent side chains of separate proteins, then glutaraldehyde cross-links these proteins. The number of cross-links formed depends on the number of available primary amines coupled with their intermolecular distance. It should also be noted that glutaraldehyde reacts with other functional groups in proteins, including carboxy and amido groups, though adducts formed from this reaction appear to play only a minor role in glutaraldehyde fixation.

Though simple in theory, glutaraldehyde fixation is encumbered with potential difficulties. First, glutaraldehyde in aqueous solutions polymerizes with time, forming polymers that contain fewer free aldehydes available for cross-linking. This problem can be minimized by using fresh solutions prepared from concentrated (>25%) electron microscopy-grade glutaraldehyde that has been stored frozen until dilution to the appropriate concentration. Second, the effectiveness of fixation varies with glutaraldehyde concentration and treatment duration. There is no straightforward general formula to apply to all tissue. The optimal concentration for any particular application must be empirically determined. There is good evidence that lower concentrations or short durations are more effective for some tissues, whereas high concentrations produce better outcomes for others. Third, coupled with concentration and duration is the size of the tissue or biomaterial to be fixed.

Complete and effective fixation relies on thorough penetration into the tissue, which can be problematic in large structures. Despite these potential problems, glutaraldehyde is one of the most investigated of the collagen fixation schemes and remains the standard to which new fixation schemes are systematically compared.^[4,5]

Glutaraldehyde reacts with ϵ -amino groups of lysine residues in collagen, thereby forming cross-links between collagen molecules, presumably at all hierarchical levels.^[5] Greatest biomechanical stability would result when cross-links occur between neighboring collagen fibrils. Interfibrillar cross-links can occur only where fibrils are within the cross-linking distance of glutaraldehyde and where lysine side chains are juxtaposed. Thus, glutaraldehyde is most effective in achieving the highest cross-link density in structures with high concentrations of collagen or aligned collagen fibrils.

Glutaraldehyde has been used extensively for treating allografts and xenografts, in which the primary objective is to make the graft more biocompatible and less biodegradable. Bioprosthetic bovine pericardium and porcine heart valves fixed with glutaraldehyde have been used in humans for over twenty-five years with success.^[4] The principal shortcoming of glutaraldehyde as applied to heart valves is that the cross-link products facilitate calcium deposition. Calcification is the major cause of failure as it results in stiffening the valves to an extent that they no longer function properly. Nevertheless, bioprosthetic heart valves fixed with glutaraldehyde remain the only such bioprosthesis in use today, largely because a suitable alternative, differently fixed heart valves, valve biomaterials, or synthetic substitutes, have yet to achieve adequate performance.

Glutaraldehyde fixation has been applied to a variety of other collagenous allografts and xenografts, including vascular grafts, pericardium, knee menisci, tendons, and ligaments.^[4] Research on other potential applications of glutaraldehyde fixation has been aimed at cross-linking reassembled collagenous constructs for fabricated bioprostheses, tissue repair scaffolds, and drug delivery vehicles.^[4-7] Despite the long history and large body of empirical work on glutaraldehyde-fixed collagenous biomaterials, problems associated with the cytotoxic, inflammatory, and antigenic effects resulting from this fixation strategy have yet to be resolved adequately to allow general use of these biomedical devices.

Polyepoxy Compounds

Polyepoxy compounds have been examined as potential collagen cross-linking agents for fixation of grafts

with the idea that they could serve as alternatives to glutaraldehyde and ameliorate the adverse reactions, e.g., cytotoxicity and calcification, associated with glutaraldehyde-fixed tissues. These compounds consist of short branched polymers that terminate in reactive epoxy functionalities. Both the number of epoxy groups, and therefore potential cross-linking sites, and the molecular distance separating them can vary significantly. The most commonly employed group of multifunctional epoxy reagents, the glycerol ethers, is based on glycerol, the hydroxyl side chains of which having been modified by the addition of alkanes of varying length. Other polyepoxy compounds include glycol and glycerol polyglycidyl ethers.^[5,8]

Cross-linking is based on the terminal epoxy functionality, a three-atom cyclic ether, the high strain energy of which favors ring opening, especially in the presence of nucleophiles. Polyepoxy compounds react primarily with the free amines of lysine side chains on neighboring proteins. Fixation is relatively straightforward in that the reaction takes place in aqueous solutions at neutral pH at room temperature. However, rates and degrees of cross-linking vary depending on the chemistry and size of the branched polymer. Experimental studies on specific tissues must be carried out in order to optimize the effectiveness of fixation. Epoxy compounds have been used to fix bovine pericardium, arteries, aortic valve cusps, and tendons.^[8] Cytotoxicity of the fixation strategy is equal to or less than that of glutaraldehyde.^[5]

Isocyanates

Isocyanates (R-NCO) react with primary amines to form the urea bond (R-NH-CO-NH-R). Difunctional isocyanates thus have the ability to cross-link collagen via its lysine side chains. One such compound, hexamethylene diisocyanate, in which the two reactive isocyanate groups are separated by a linear ten atom chain (OCN-(CH₂)₈-NCO), has been used to cross-link bovine pericardium,^[9] sheep dermal collagen,^[10] and processed collagen fibers.^[11]

In principle, isocyanates can be the terminal groups on a variety of polymers with distinct chemistries. For example, a polyurethane polymer with terminal isocyanate groups has been examined as a fixation strategy for porcine pericardium.^[12] Though effective at cross-linking the surface, it failed to penetrate the deep layers of the pericardium, likely due to the relatively large size of the polyurethane polymer, which prevented diffusion. An advantage of using polyurethane polymers with isocyanates is that the chain size separating the cross-linking moieties can be varied and thereby potentially result in differential

cross-linking effects. The potential use of difunctional isocyanates has not been systematically examined.

The major concern in designing fixation strategies using isocyanates is the solvent in which the reaction takes place. Aqueous solvents largely favor destruction of the isocyanate over reaction with collagen. This can be eliminated by using nonaqueous solvents. In the case of hexamethylene diisocyanate, iso-propanol was used effectively as the solvent. Dimethyl sulfoxide was used as the solvent for polyurethane diisocyanate treatment. Use of these non-aqueous reagents, however, requires additional considerations, as they will affect the collagen scaffold itself.

Studies to date, though few, have clearly established that diisocyanate treatment effectively cross-links collagenous materials. However, whether isocyanate and its derivatives are more or less biocompatible than other covalent cross-linking agents remains an open question. In-vitro experiments indicated that hexamethylene diisocyanate-treated sheep collagen was less cytotoxic than that treated with glutaraldehyde.^[13] In-vivo experiments with hexamethylene diisocyanate-fixed synthetic collagen fibers as anterior cruciate ligament replacements in sheep showed that they were less cytotoxic than glutaraldehyde-fixed fibers, and the degradation products were minimally cytotoxic.^[11] More work is necessary to determine the full range of biocompatibility with isocyanate-fixed materials.

Carbodiimide cross-linking

The recognition that exogenous cross-linking agents that become incorporated into the cross-link can cause serious complications in vivo has led to the development of strategies to catalyze cross-link formation with agents that act as catalysts only and are subsequently removed from the treated tissue following the reaction. The cross-links formed mimic chemical structures normally present in vivo and therefore could potentially eliminate concerns with biocompatibility. One such strategy that has recently received considerable attention is carbodiimide-generated iso-peptide bond formation.

Carbodiimide, 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide (EDC) being the most widely used, reacts with the carboxyl groups of aspartic and glutamic acid side chains in collagen to form the *o*-isoacylurea derivative.^[5] This then reacts by nucleophilic attack with primary amines of lysine side chains on collagen, generating the amide cross-link and liberating the urea derivative of the carbodiimide, which can be readily washed out of the biomaterial. With the addition of N-hydroxysuccinimide (NHS), internal rearrangement of the activated isoacylurea

derivative is minimized resulting in little remaining reaction intermediates and more efficient cross-linking. No residual cross-linking agent remains in the biomaterial, and the resulting iso-peptide bond mimics the natural peptide bond in proteins, except that it bridges neighboring peptides. The reaction takes place in aqueous solution at pH 5. The extent of cross-linking can be controlled by adjusting the ratio of carbodiimide to collagen since the first step proceeds to completion.

Both tissues and collagenous biomaterials have been fixed with carbodiimide, although the predominant use of carbodiimide is to cross-link biomaterials created from insoluble and reconstituted collagen fibers. Its effect on tissues include stabilization of the collagen fibrillar network, enhancement of biomechanical properties, and a decrease in biodegradability.^[14] Carbodiimide cross-linking strengthens fibers produced from insoluble collagen. [15, 16] Recently, carbodiimide has been the cross-linking agent of choice for production of collagen scaffolds for tissue engineering, either alone or in combination with other macromolecules, primarily because properly washed carbodiimide-fixed scaffolds are not cytotoxic and they are entirely permissive to incorporation of cells (see, e.g., Refs. [17, 18] and [19]). Biomaterials cross-linked with carbodiimide are in general significantly more biocompatible than those cross-linked with glutaraldehyde; however, carbodiimide fixation would not necessarily reduce antigenicity.

Acyl azide-based cross-linking

As with carbodiimide treatment, the acyl azide method produces covalent bond formation between the carboxylic acid side chains of aspartic and glutamic acids and the ϵ -amino groups of the lysines of collagen (Fig. 3).^[20] Following esterification of the carboxyl groups in which a methyl group is added to the acid, the biomaterial is treated with hydrazine to form the corresponding hydrazide. Sodium nitride is added to react with the hydrazide forming the acyl azide. These reactive acyl azides then spontaneously couple with the primary amines of lysine to form the cross-link. The cross-linked biomaterial is washed thoroughly to remove all of the reactants, leaving the collagen with the newly formed iso-peptide bonds. A somewhat simpler one-step acyl azide method that uses diphenylphosphoryl azide has been reported, but this method requires a nonaqueous environment. While the acyl azide method has been shown to effectively stabilize collagenous biomaterials that are biocompatible,^[21] it is more difficult to carry out and has been superseded by the much simpler carbodiimide method.

Fig. 3 Structure of the isopeptide cross-links formed between collagen fibrils by carbodiimide and acyl azide method.

Other Strategies

Dehydration

The aforementioned cross-linking strategies require that the molecular distance between the targeted functionalities in the collagen fiber system have the proper spatial dimension in order for cross-links to form. Both the side-to-side and lateral spacing must be in the proper register, and optimal spacing will depend on the fixation method employed. The three-dimensional configuration of the collagen fibers will thus dictate the cross-link distance. Fixation agents that become incorporated into the cross-link vary in length and therefore occupy a portion of the intermolecular distance. Glutaraldehyde is a straight chain molecule five atoms long; multifunctional epoxy compounds can vary between three and 46 carbons; hexamethylene diisocyanate spans twelve atoms and polyurethane diisocyanates can vary immensely in length. Isopeptide bond formation catalyzed by carbodiimide treatment or the acyl azide method requires that the carboxylic acid group be directly adjacent to the primary amine.

In order to facilitate optimal cross-link number and density, methods to concentrate and align collagen

fibers have been examined. These methods are generally applied to bioprostheses produced from purified insoluble collagen fibers and reconstituted collagen fibrils. The simplest method is to air dry the construct at room temperature. Not only do the collagen fibrils become closely apposed, it is likely that both covalent and noncovalent cross-links form among juxtaposed fibers during drying. This has proven most effective in the production of cross-linked fibers with advanced tensile properties for tendon and ligament repair (see, e.g., Refs. [15] and [16]). The addition of heat (110°C) and vacuum, dehydrothermal shrinkage, has been reported to produce concentrated cross-linked fibers with improved mechanical properties.^[22] However, dehydrothermal treatment must be used with caution because of progressive denaturation of the collagen triple helix and degradation.

UV irradiation

Another physicochemical cross-linking method that avoids introduction of exogenous agents into collagen scaffolds is ultraviolet light irradiation.^[22,23] Dry collagenous materials are exposed to UV light at 254 nm wavelength. Both the distance from the source and the duration of exposure can be adjusted to vary cross-link density and optimize the intended biomechanical properties. The extent of irradiation must be well controlled because UV light has two competing effects, cross-linking and fragmentation of the collagen triple helix. At the appropriate intensity, cross-linking proceeds rapidly and achieves its maximum effect before significant fragmentation occurs. Intense and prolonged UV treatment will not only break up the collagen but will also denature it, thereby eliminating the effect of cross-linking. UV treatment has been shown to increase the mechanical strength of collagenous materials, but it is not as effective as other cross-linking schemes at reducing degradation of materials *in vivo*.

Glycation and UV irradiation

Glucose-mediated cross-linking of collagen, termed glycation, is a well recognized process that occurs in connective tissues with aging and is accelerated in diabetic humans and laboratory animals. Experimental studies have established that glycation of collagen alters the mechanical properties of connective tissues such as tendon and skin and it reduces susceptibility of these tissues' collagen to enzymatic degradation. Both of these properties are beneficial for collagen-based bioprostheses. Initial attempts to take advantage of collagen glycation met with mixed success, primarily because of the relative inefficiency of cross-linking by

conventional in-vitro incubations with glucose alone.^[24] Of note, however, was that glycated collagen materials implanted subcutaneously did not cause an inflammatory response and allowed integration of host cells. Glycated collagen scaffolds have also been shown to provide a permissive environment in vitro for tissue engineering.^[25] Increased levels of glycation cross-links have been produced by UV treatment of glucose-saturated collagen films that resulted in improved biomechanical properties.^[26]

Biological cross-linking compounds

Genipin and its related iridoid compounds are natural products isolated from the fruits of the gardenia plant (*Gardenia jasminoides*). It is used in herbal medicines as an antiphlogistic and cholagogue, for dyeing food products, in the preparation of gelatin capsules, and immobilizing enzymes. Its capacity to cross-link proteins plus being a naturally occurring biological

compound make it potentially applicable and particularly interesting for collagen fixation. The protocol for cross-linking of collagen-based biomaterials with genipin is straightforward and has no adverse effects on the collagen matrix. Cross-linking is carried out in aqueous buffers such as phosphate at room temperature and neutral pH. The putative mechanism by which genipin cross-links collagen involves aldehydes and primary amines, similar to glutaraldehyde cross-linking, except that in aqueous solutions genipin is a dialdehyde.^[27] The aldehydes react with ϵ -amino groups on lysine side chains of neighboring collagen molecules. The genipin molecule becomes incorporated into the cross-link. Pericardium treated with genipin demonstrated increased stability to enzymatic degradation, improved biomechanical properties, and overall was comparable or superior to pericardium fixed with glutaraldehyde.^[27,28] In addition, genipin-fixed tissues are significantly more biocompatible and less cytotoxic than those fixed with glutaraldehyde and epoxy compounds.^[29]

Catechol-quinone tanning systems are prevalent in a wide variety of animals wherein they strengthen otherwise vulnerable extracellular matrices. In all cases the catechol is derived from tyrosine. In insect cuticle, a chitin-based material, circulating tyramine is hydroxylated forming 3,4-dihydroxytyramine, which enters the newly secreted and assembled cuticle where it polymerizes with the chitin to form the hard exoskeleton. Mussel byssus threads are collagenous structures by which the animal secures a firm holdfast to the substrate. The foot gland produces an amalgam of collagenous material and catechol containing proteins. The catechol in this case is 3,4-dihydroxyphenylalanine produced intracellularly by hydroxylation of tyrosine in the polymerizing proteins. Skate egg capsules are polymerized by a quinone tanning mechanism that involves conversion of tyrosine in the structural proteins to 3,4-dihydroxyphenylalanine in the assembled biomaterial. In all these structures, polymerization is induced by enzymatic oxidation of the catechol moieties to the corresponding quinones, which subsequently form covalent adducts.

Nordihydroguaiaretic acid (NDGA), isolated from the creosote bush, is a small molecular weight dicatechol containing two *ortho*-catechols that are located

at either end of a short alkane chain, 3,4 dimethylbutane (2,3-bis(3,4-dihydroxyphenylmethyl)butane) (Fig. 4). The two catechols on NDGA will slowly autooxidize in aqueous solutions at neutral pH forming reactive quinones. Oxidized NDGA thus has the potential to fix collagenous biomaterials. However, the fixation mechanism differs from those described above. The NDGA-quinone does not form cross-links with side chains of collagen, but rather polymerizes to form an NDGA bisquinone polymer interpolated within the collagen network.^[30] The NDGA treatment protocol is suitable for collagenous biomaterials in that it occurs in aqueous buffers at neutral to slightly basic pH.^[31]

Fibers produced from reconstituted collagen treated with NDGA exhibit mechanical properties superior to collagen fibers fixed with glutaraldehyde, carbodiimide, epoxy compounds, and the acyl azide method.^[31] NDGA-collagen fibers were reported to be biocompatible *in vitro* and *in vivo*.^[30,32,33] They created little foreign body response or inflammatory reaction when placed subcutaneously in an animal model.^[30] NDGA fixation establishes that strategies other than those based on forming covalent cross-links between collagen molecules are potentially viable for producing collagen-based biomaterials.

CONCLUSION

The burgeoning research on collagen fixation strategies is both a testament to the need to devise safe and effective methods for the biomedical use of biologically based, collagenous materials, be they grafts or engineered constructs, and a clear indication that a wholly biocompatible and biomechanically competent fixation method has yet to be developed. Collagen fixation strategies continue to evolve. Traditional cross-linking methods such as glutaraldehyde could be improved by modifying the problematic properties that result from fixation. For example, much research has focused on efforts to mitigate calcification in glutaraldehyde-fixed pig heart valves.^[5] Synthetic mechanisms for producing novel cross-linkers may derive from developments in the industrial and chemical engineering sectors, similar to polyurethanes and isocyanates. New fixation chemistries will no doubt be coopted from other disciplines, in the same way carbodiimide cross-linking was transferred from analytical biochemistry to biomedical applications. As more is discovered about natural cross-linking mechanisms in collagen, such as glycation, these reactions might be mimicked to develop an entirely biomimetic collagen fiber. Though still far from realization, molecular biology could devise cellular techniques to produce natural collagens with cross-linking precursors built in. Perhaps the most enticing is the potential to capture and adapt stabilization chemistries from biological materials with unique and exploitable physical properties.

Finally, it should be pointed out that several excellent reviews on the use and treatment of collagen-based biomaterials have been published recently (Tables 1 and 2). These reviews provide more in-depth treatment of specific aspects covered in this chapter and should be consulted by those who wish to learn more about particular cross-linking strategies and their applications. Moreover, an extensive introduction to the literature on collagen fixation strategies as well as biomaterials development can be found in these papers.

INTRODUCTION

The transformation of animal dermis into useful products predates recorded history. Primitive people who lived during the Ice Age approximately 500,000 years ago were likely the first to use animal skins to protect their bodies from the elements. Just as leather today is a by-product, our ancient ancestors hunted animals primarily for food. But, once they had eaten the meat, they would clean the skin by scraping off the flesh and then slinging it over their shoulders as a crude coat. They also made footwear by using smaller pieces of animal skin that were made to fit loosely over the foot and tied it at the ankle with thin strips of skin or vines to protect their bare feet from rocks and thorns. The main problem that primitive man encountered was that, after a relatively short time, the skins decayed and rotted away. With his limited knowledge and experience, primitive man had no idea how to preserve these hides. As centuries passed, it was noticed that several processes could slow down the decay of the skins. If the skins were stretched out and allowed to dry in the sun, even though they became stiff and hard, they lasted much longer. Various oily substances were then rubbed into the skins to soften them. As time passed, it was eventually discovered that the bark of certain trees contained tannin or tannic acid, which could be used to convert raw skins into what we recognize today as leather. It is quite hard to substantiate chronologically at exactly what time this tanning method materialized, but the famous Iceman, which dates from at least 5,000 BC that was discovered in the Italian Alps, was clothed in very durable leather.

Techniques used by the American Indians were very similar to those used in this early period. Indians soaked ashes from their campfires in water and then soaked the skins in this solution. In a few weeks, the hair and bits of flesh came off and only the raw hide was left. The hide was then tanned in a solution made from a mixture of hemlock and oak bark. This took about three months to complete. After which, the leather was worked by hand to make the hide soft and pliable.

THE MAKING OF LEATHER GOODS

The tanning of leather was used by mankind in numerous geographical areas during early periods of human civilization. As certain leather characteristics began to emerge, man realized that leather could be used for many purposes besides footwear and clothing. The uses and importance of leather increased greatly. For example, it was discovered that a leather bag acts as an insulator that keeps water fresh and cool. It was also found suitable for items such as tents, beds, rugs, carpets, armor, and harnesses. Ancient Egypt, one of the most developed civilizations in this early period, valued leather as an important item of trade. The Egyptians made leather sandals, belts, bags, shields, harnesses, cushions, and chair seats from tanned skins. Many of these items are still made from leather today.

The Greeks and Romans also used leather to make many different styles of sandals, boots, and shoes. When the Roman legions marched in conquest across Europe, they were well-attired in leather armor and capes. In fact, right up until the early 18th century, the shield carried by the ordinary soldier was more likely to be made of leather than metal.^[1]

Today, many items of clothing are still made from leather. However, other uses have been developed for collagen, the primary component of leather. These include food substances in addition to medical devices and therapies. In this article, we will cover various aspects of collagen processing, recovery, and fibrillogenesis that allows collagen to be used as an industrial raw material and in biomedical applications.

COLLAGEN RECOVERY

The goal of collagen processing is to isolate collagen from cellular and extracellular material for use as a unique polymeric material. All procedures used to isolate collagen rely heavily on several key processing variables, including temperature–time, pH, and ionic strength. The ionic strength on a concentration basis is defined as $I_c = 1/2 \sum c_B z_B^2$. The sum goes over all the

ions B . z_B is the charge number of ion B . Time itself is not a process variable, but it becomes important in diffusion of ions through the collagen articles and the temperature–time history of the collagen.

COLLAGEN PRODUCTION FOR INDUSTRIAL APPLICATIONS

Initial Processing

Freshly killed bovine steers which are up to 18 months old, are hooked onto a chain conveyor and transported into the processing area (5°C winter and 35°C summer, ambient conditions). The hide is removed in the skinning area and allowed to fall into a water bath (10°C winter and 30°C summer, ambient conditions). It is then cooled from a normal body temperature of 39°C. The hides are removed from the water bath, trimmed to remove extraneous flesh, and boxed (5°C winter and 35°C summer, ambient conditions) for shipment to the tannery by dedicated refrigerated truck (4°C).

Beamhouse

Once received at the tannery, the hides are washed for 30–120 minutes in potable water (30°C) that contains a small amount (0.2 wt%) of NaHCO_3 ($\text{pH}=9.0$, $\text{IS}=0.01$). The water is drained and refilled for a second wash or soak. Soaking is accomplished by adding $\text{Na}(\text{CO}_3)_2$ at 0.2 wt% which is based on wet hide weight, ($T=27^\circ\text{C}$, $\text{pH}=9.0$, $\text{IS}=0.01$) for 3.5 hours. Surfactant may be added at this time to help remove the fat from the hides. The soak water is drained, and the hides are washed for a third time in 27°C water for 30–60 minutes to rinse off the $\text{Na}(\text{CO}_3)_2$.

Hair Removal

Hair is removed from the hides in the hair burn step. Water is added to equal 50 wt% of the wet hide weight. Then, 0.6 wt% $\text{Na}(\text{CO}_3)_2$, 2.0 wt% $\text{Ca}(\text{OH})_2$, and 4.3 wt% NaHS is added and mixed for two hours to remove all of the hair from the exterior of the hide ($T=30^\circ\text{C}$, $\text{pH}=13.0$, $\text{IS}=0.09$). After 30 minutes in the hair burn, more water can be added if the hides swell and absorb all of the available water. The hair burn treatment is drained, and the hides are limed. Water is added at 1.5 to 2.0 times the wet hide weight and then 2 wt% $\text{Ca}(\text{OH})_2$ is added and mixed for seven hours. ($T=27^\circ\text{C}$, $\text{pH}=12.5$, $\text{IS}=0.4$). The liming solution is drained, and the hides are washed in water for 90 minutes. The final treatment in the beamhouse is with 0.1 wt% sodium metabisulfite solution for

20 minutes ($T=27^\circ\text{C}$, $\text{pH}=12.5$, $\text{IS}=0.1$). From the beamhouse, the hides are transported to the tannery.

Tannery

In the tannery, the hides are stacked on pallets and then split. Splitting is accomplished by feeding the hide pieces through a continuous knife that separates the top grain from the corium and flesh layers of the hide. The top grain is then further processed into leather goods for products such as shoes, belts, briefcases, car upholstery, and other industrial uses. Leather making is beyond the scope of this text. The top grain layer of the hide is unsuitable for use in food and medical collagen applications because of highly developed nonacid labile crosslinking. After splitting, the corium layer is stripped of any remaining flesh or subdermal tissue. The corium layer is then transferred to the white room for further processing.

White Room

In this step, the hide amide–N concentration is established. This is a critical determinant in the production of collagen. Amide–N is an indication of the extent of treatment with base. The hides are again treated with 3 wt% $\text{Ca}(\text{OH})_2$ for 90 minutes ($T=15^\circ\text{C}$, $\text{pH}=12.5$, $\text{IS}=0.6$). The goal is for the hide to absorb and retain 1.0–2.0 wt% lime based on the total amount of solids. Typical solids content at this point is 24.0 wt%. The hides are returned to a 3.0 wt% $\text{Ca}(\text{OH})_2$ solution in the temper step, removed from the lime, stacked in shipping containers, and sent to cold storage for use in industrial applications. The hides are good for up to 12 days in storage before the collagen begins to significantly degrade into gelatin. Again, amide–N content will be a good indicator of the state of the material (Fig. 1).

Treatment with base, usually lime, drastically changes the characteristics of the collagen. The treated collagen will associate a great deal more water than untreated collagen (Fig. 2). This process is commonly referred to as opening up of the hide, which means that treatment with lime allows much faster and more consistent absorption of tanning chemicals than before treatment.

There are a number of changes that take place during treatment with base or liming of the collagen tissues. The addition of salts, sulfur compounds, and amines controls the degree of swelling of the collagen. The swelling state influences the mass transport of noncollagenous cellular and extracellular materials from the hide. Any remaining cells are destroyed. The content of proteoglycans and carbohydrates is greatly reduced. Ammonia is liberated from glutamine

Fig. 1 Bovine hide amide concentration at various stages of processing the hide for leather or other applications. As the hide becomes more chemically treated, the lower the hide amide content. (From Ref. [2].)

and asparagine—forming additional carboxyl groups. This is indicated by a drop in the amide nitrogen content.^[2]

Deliming

$\text{Ca}(\text{OH})_2$ is effectively removed from the hides by acid treatment. Deliming begins with a water wash at 28°C

Fig. 2 Collagen swelling characteristics before and after treatment with lime. After treatment with lime, the collagen swells much more strongly with changes in pH. Swelling is maximized around pH 2.5 and above pH 13. This behavior is useful for further treatment by tanning chemicals or prior to dissociation of the collagen fibrils. Adapted from de la Burde (1961).

and a pH of 12.5, which results from residual lime, for 95 minutes. The wash water is drained, and the vessel is refilled with water at 50.0 wt% of the total hide weight. Salt can be added at this point—up to 1 M—to facilitate the removal of $\text{Ca}(\text{OH})_2$ from the hides. Salt increases the ionic strength of the solution and causes a partial shrinking of the hides and opening of the pore structure. Different salts have been used. Two of the most effective are NaCl and NH_4Cl . During deliming, acid, and which is usually concentrated HCL, is added to slowly and consistently drop the pH from 12.5 to roughly 5.5. It is critical that the acid be added stepwise and the pH of the solution monitored. The hides should be allowed to equilibrate with the aqueous solution. If the acid is added too quickly, as indicated by the solution's pH being below 5.5, the hide pieces will swell on the outside, which essentially traps calcium on the interior and results in a high ash content and poor subsequent processing performance. Deliming can be accomplished in roughly 600 minutes ($T=28\text{ C}$, $\text{pH}=12.5\text{--}5.5$, $\text{IS}=0.36$). The deliming solution is drained, and the hides are washed in ice water to reduce their temperature. At this point, hide pieces may be split, and the internal pH checked is by using a surface pH probe. Targets for sufficient lime removal are an internal pH between 6.0 and 6.8. The delimed hides may now be stored at 4°C for up to 72 hours or frozen for up to one year.

Size Reduction

Bovine hides have dimensions of about 1.5 meters \times 1.2 meters and must be reduced in size for further processing to extract the collagen. The delimed hide is a tough, fibrous material that can be a very challenging task for the size-reduction equipment. Several types of mills have been tried, including rotary knife, hammer, rotating discs, and ball. Rotary knife mills work best because they can shred the collagen hide without overheating it. Size-reduction processing can cause intense, localized heating of the material being reduced and, thus, can be detrimental to the collagen. This can be minimized by adding ice during the size-reduction process.

Mixing

Ground hide pieces have a solids content of 20.0 to 25.0 wt%. For most applications, the collagen solids content is set between 3.0 and 9.0 wt%. At these concentrations, the collagen's consistency is between that of thick batter (3.0 wt%) and stiff dough (9.0 wt%). For industrial purposes, the collagen hide particles can now be acidified to dissociate the collagen molecules. It is unlikely that the collagen will dissociate

completely into individual triple helix molecules. It is much more likely that the collagen will dissociate into sub- and microfibrils rather than completely to individual collagen molecules. Mixing, in this case, is usually a two-step process. First, there is usually a bulk mixing of acidified water into the comminuted hide particles. This can be accomplished in planetary or sigma blade type mixers that are designed for high-bulk flow of viscous materials. Upon acidification, the collagen swells associates water with the protein molecules, and the collagen fibrils will then dissociate from each other. The viscosity will greatly increase at this stage. The second mixing step is usually a high-shear local mixing. This step is necessary to help break apart clumps of collagen that are stuck together and improve the overall distribution of the acid within the mixture. Localized heating can be a significant problem for this step; therefore, cooling is required. ($T=11^{\circ}\text{C}$, $\text{pH}=2.5\text{--}3.0$, $\text{IS}=\text{low}$). The ionic strength should be kept to a minimum during the swelling and dissociation processes because excess ionic strength will shrink the collagen and make it difficult to create a smooth aqueous dispersion.

Homogenization

The collagen dispersion requires 24–48 hours for the acid to diffuse into the hide particles and complete the swelling and dissociation. Further high-shear intensity mixing is required to complete the processing of the dispersion. A two-stage homogenizer operating at pressures of 4000–6000 psi is used for this mixing. After homogenization, the dispersion is filtered to remove any collagen aggregates that did not disintegrate during the processing (40–60 micron slotted stainless steel type filter). Homogenization is a two-step storage, homogenization, and filter process. The dispersion is now ready for shaping.

Shaping

Shaping the collagen dispersion is the same as for any polymer system. It can be molded, extruded in tubes and sheets, spun into fibers, etc. Treatment after shaping can be a dry or wet process, depending on the type and properties of the desired final product. Post shaping and drying in the acidic state followed by neutralization and cross-linking is considered the dry process and neutralization followed by cross-linking and drying is considered the wet process. The dry process produces a tough film that has a very small pore structure and low water permeability. The wet process produces a collagen film that has a much more open pore structure that behaves more like a fabric than a polymer film.

Dry Process

The collagen dispersion is shaped and then dried at a maximum temperature of 50°C . Higher temperatures will cause irreversible denaturation of the collagen molecules and turn it into gelatin. Drying is completed when the moisture content is very low at approximately 7.0 wt% water. This extreme drying develops some dehydrothermally induced cross-links. After drying, the collagen is neutralized in a water bath containing 0.3 wt% NaHCO_3 . After neutralization, the collagen is washed in water to remove the bicarbonate salt. It then can be treated with cross-linking agents, such as glutaraldehyde 200–1000 ppm, pH approximately 7.2–7.5, water-washed, and dried again. For thin films under 3 millimeters thick, 10-second exposure time is sufficient to produce measurable changes in the modulus and ultimate tensile properties of collagen films. Longer times may be required for thicker films or higher cross-link densities.

Wet Process

The collagen dispersion is shaped at temperatures between 4°C and 10°C and then quickly heated to 37°C while simultaneously neutralizing the pH in either an anhydrous ammonia chamber or ammonium sulfate bath that is saturated with ammonia to a pH between 8.0 and 12.0. Further processing includes water washes that lower the dispersion pH to between 5.5 and 7.0 to remove residual salt. The collagen can then be air-dried or treated with cross-linking agents such as aldehydes. Air-drying can be accomplished at temperatures up to 135°C . These are much higher temperatures than can be used in the dry process because the collagen is at a much more neutral pH. The collagen is dried to moisture contents as low as 7.0 wt% to induce chemical and dehydrothermal cross-links. Collagen can then be rehydrated to the desired final moisture content of 20.0–25.0 wt% water.

Further postprocessing cross-linking can be accomplished by treatment with UV radiation or drying to a very low moisture, such as 7.0 wt%, and then holding at an elevated temperature of 80°C for up to 48 hours.

Collagen Extraction for Laboratory Uses

Research in the medical field and other industries frequently requires that collagen be extracted from noncollagenous tissues, cells, and extracellular matrix components.^[3] During this procedure, intact bovine dermis is obtained from slaughterhouses, the hair removed, and all subdermal tissue is scraped off. The top grain is then split from the hide with a sharp knife

to reveal the corium layer. At this point, the hide can be cut into smaller pieces and stored at -20°C for up to one year.

Unless otherwise noted, all subsequent processing is performed at 4°C . Once ready for processing, the hides are partially thawed and ground into small particles of approximately 5 millimeters diameter to generate sufficient surface area to maximize subsequent chemical processing while minimizing mechanical degradation of the collagen fibrils. The most frequently used processing method involves a 24-hour treatment of the particles with 0.5 N acetic acid (10:1 based on solids) and pepsin (1:100 based on wet hide weight) while mixing with a high-shear mixer. Acetic acid (0.5 M to glacial) is used in this step because it is a very effective solvent for collagen. Other solvents that may be used include mineral acids such as HCl, which is less expensive than acetic acid but is a significantly poorer solvent. The addition of pepsin to the reaction mixture is for two important reasons. First, pepsin is active against noncollagenous peptides, but it does not attack collagen. Second, pepsin is active at a low pH (2.5–3.5) in which the collagen molecule has unfolded and associated significant amounts of water. While the collagen is unfolded and at a low pH, pepsin will cleave any noncollagenous telopeptides from the collagen triple helix and leave the two $\alpha 1$ and the $\alpha 2$ chains intact.^[4] This significantly removes noncollagenous components from the mix. It is important to prevent localized heating of the collagen dispersion during this step, and ice may be incorporated into the mixture as necessary to maintain a temperature of 4°C .

Following the 24 hours in the acetic acid: pepsin mixture, the collagen dispersion should be centrifuged at 20,000 g for 50 minutes, which will result in the separation of the solubilized collagen and the nonacid-labile cross-linked collagen in the pellet that can be discarded. The solubilized collagen should be mixed in a high-flow, low-shear mixer while solid NaCl is slowly added to a final concentration of 2 M. Once all of the salt is added, subsequent mixing is not required. If the NaCl is added too rapidly, the collagen fibrils will clump around the salt and significantly slow dissolution. If done properly, the collagen will form a white precipitate in the mixture that should be complete in 24 hours. The collagen can then be collected by either centrifuging (20,000 g for 50 minutes) or filtration through a 50–100 μm filter.

Residual salts can be removed from the collagen by dissolving the pellet or filtrate in 0.5 N acetic acid (10:1 based on wet solids weight) and dialyzing in 0.5 N acetic acid (30:1 based on wet solids weight). The dialysis solution should be changed a minimum of three times over a 24-hour period. Once dialysis is complete, the pH of the solution should be adjusted to

6.0 with 1 M NaOH while maintaining the temperature of the solution between 0 and 4°C . The collagen can then be recovered by centrifugation or filtration as described above.

At this point, it is necessary to separate the neutral from the nonneutral salt soluble collagens. Neutral salt soluble collagen can be collected by dialyzing the neutralized collagen dispersion versus 0.05 M tris buffer containing 1 M NaCl at a pH of 7.5 (30:1 buffer based on sample weight). As above, the buffer should be changed a minimum of three times in a 24-hour period. The solution should then be centrifuged, which will result in the precipitation of the nonneutral salt soluble collagen that should be discarded.

To further separate types I and III collagen, the solution is dialyzed versus 0.05 M tris buffer containing 1.8 M NaCl at pH 7.5 for 48 hours at 4°C with a minimum of at least three changes of buffer. Type III collagen can be removed by centrifugation at 35,000 g for 50 minutes. To precipitate type I collagen, the collagen solution is dialyzed vs 0.05 M tris containing 3.5 M NaCl at pH 7.5 for 48 hours at 4°C while changing the buffer at least three times. Type I collagen can then be collected by centrifugation at 35,000 g for 50 minutes.

Degradation

There are three main methods that cause degradation of the intact collagen triple helix: proteolysis, thermal, and chemical. Proteolysis occurs when bacteria, mold, or yeast contaminates the collagen material during processing and secrete collagenase enzymes that degrade the collagen. Most bacteria are killed during the pH shifts from very basic to very acidic levels. Molds and especially yeasts can be very tenacious by surviving and adapting to pH extremes. Preservatives can be added to inhibit microbial growth. Sodium benzoate (500–1000 ppm) can prevent growth of almost all microorganisms, including yeast, bacteria, and fungi. It operates best in an acidic environment at a pH below 3.5 and works synergistically with other preservatives especially potassium sorbate (500–1000 ppm).

The second common cause of degradation of collagen is when it is exposed to high temperatures. In the extreme case of thermal degradation, the collagen triple helix will lose its conformation and become a random coil. The collagen will become gelatin with significantly different physical properties than intact collagen. The most common thermal degradation case causes hydrolysis of the peptide bonds along the backbone of the collagen triple helix. The triple helix is damaged and, thus, causes changes in the physical characteristics of the collagen and its performance in

the final product. It is important to note that thermal degradation is usually manifested as low molecular weight oligomers breaking away from the collagen triple helix rather than complete denaturation of the triple helix into gelatin. Finally, strong concentrations of mineral acids such as HCL and H₂SO₄ can cause irreversible chemical degradation that is similar to thermal degradation.

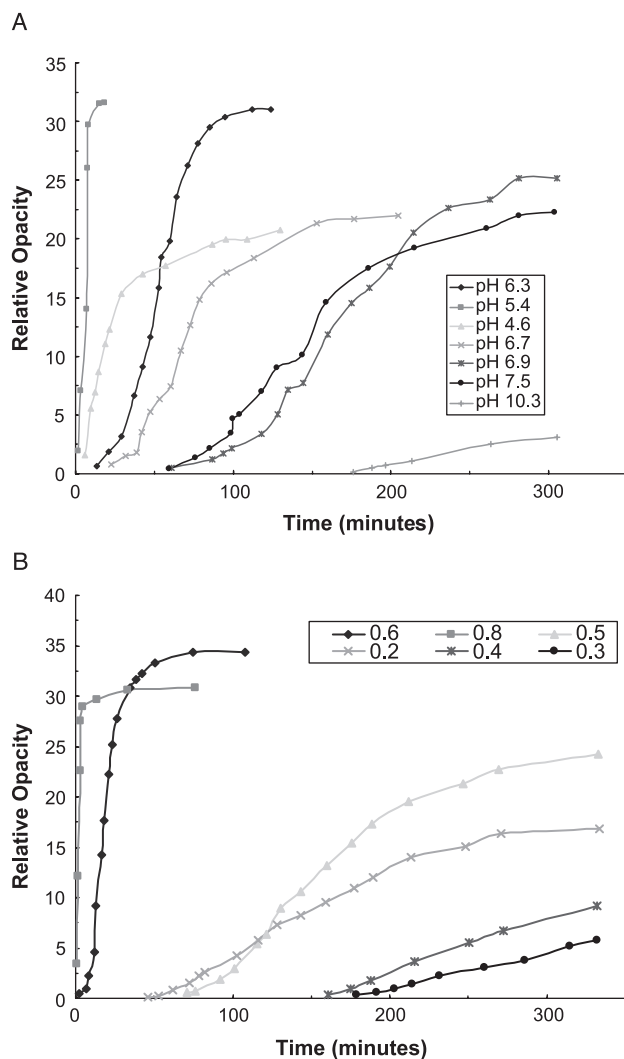

Fig. 3 A) The effect of pH on the rate of fibrillogenesis. These data are for a 0.1% solution at constant temperature of 23°C and IS of 0.4. Note that the rate of fibrillogenesis is fastest near the isoelectric pH, 5.5, of the collagen and not at physiological pH conditions. B) The effect of ionic strength on collagen fibrillogenesis. These data are for 0.1% collagen solutions at constant temperature of 23°C and pH of 7.5. Increasing the ionic strength of the buffer has the effect of neutralizing the ionic repulsions present within the triple helix allowing hydrophobic/hydrophilic interactions to predominate. In both cases, the buffer used was sodium phosphate buffered saline. (From Ref. [6].)

Fibrillogenesis

The self-assembly of collagen fibrils has been studied extensively in vitro for many years. Studies have measured the effect of temperature, pH, ionic strength, and the types of ions on the rate of fibrillogenesis and the size and type of fibrils obtained under various experimental conditions.^[1,4-18] These investigations have demonstrated that proteoglycans, glycosaminoglycans, and carbohydrates alter the rate of fibrillogenesis and the size and type of fibrils obtained.^[19-21] The general procedure for these investigations is to mix the collagen solution with an equal part of double strength buffer, heat it to reaction temperature, and monitor the increase in opacity or absorbance with respect to time. The absorbance curve has three distinct phases: a lag phase with no increase in absorbance; a growth phase; and a plateau phase in which the reaction has come to completion. These investigations show that the rate of collagen fibrillogenesis increases with increasing temperature occurring between 16°C and 37°C, reacts readily in the pH range of 6.0–8.0, and increases with increasing ionic strength, as can be seen in Figs. 3A and 3B. Some studies have been done showing the effect of specific ion type on the length of the lag phase of the reaction. In general, near physiological conditions, increasing the ionic strength or lowering the pH lengthens the lag phase. The lengthening effect of the salt is both anion and cation specific with anions having the greater effect. The anion effect is in the order $\text{SCN}^- < \text{HCO}_3^- < \text{I}^- < \text{Br}^- < \text{SO}_4^{2-} < \text{S}_2\text{O}_3^{2-}$ and cations in the order $(\text{K}^+, \text{Na}^+, \text{Li}^+) < (\text{Ba}^{2+}, \text{Mg}^{2+})$.^[17]

CONCLUSION

Humankind has benefited from the use of collagen for thousands of years. From crude protection from the elements to scaffold materials for tissue engineering applications, collagen has proven itself to be a remarkably versatile and useful material. There are several means to isolate collagen, which depends on the desired end product though, most methods are based on either removing noncollagenous materials from the intact collagen matrix (leather and food applications) or extracting the collagen from noncollagenous material and then recovering the collagen from this extract. Both methods have benefits and drawbacks. Most recently, collagen has seen a revival in the field of tissue engineering in its use as a scaffold material. Tissue engineering is advancing at a rapid pace, which thus results in some exciting findings. It is conceivable that, in the near future, numerous pathological conditions will be treated by implantation of biologically engineered devices. Some of which will likely have collagen as a major component.

INTRODUCTION

Composite materials can be generally defined as those materials having two or more distinct material phases. With the advent of advanced polymeric composite materials, the term composite became somewhat synonymous with engineered carbon-epoxy, Kevlar-epoxy or ceramic- or metal-matrix composites, though this term later came to refer to a broader set of materials; more recently, the descriptor heterogeneous has been used to characterize study of such materials. Porous materials may also be considered composite materials, with one phase composed of void or air spaces. Examples of composites include the familiar carbon-epoxy airframe skins, and glass/epoxy or glass/polyester structural materials, e.g., helicopter rotor blades, or even furniture. Sporting goods, e.g., golf clubs, tennis rackets, and skis are also often constructed of advanced composites. Even wood, which contains reinforcing cellulose fibers, bone, which may be considered a porous reinforcement, at a smaller scale, extracellular matrices, reinforced by structural proteins such as collagen, that are surrounded by ground substance (Fig. 1) constitute composites. There is a large body of literature available on both properties^[1-5] and manufacturing^[6] of many types of engineered composite materials, and much of this work has found, and will continue to find application in improved understanding of heterogeneous biomaterials and design of biocompatible materials.^[7] As an example, of the 20–30% of the human body that is composed of proteins, up to 50% is collagen;^[8] collagen's precursors have been on the planet nearly as long as multicellular life.^[9] Undoubtedly, the need for improved micro and nanoscale models for the behavior of such critically important fibrous biomaterials will continue, and will support new insights into biochemistry and evolutionary science.

HISTORICAL BACKGROUND

General modeling of the properties of heterogeneous materials is of great importance to almost all engineering and scientific disciplines, and can be traced to the

mid-19th century (Table 1), in work on properties of gases.^[10-53] Closed-form solutions for effective properties in gases led to similar analyses for conductivity and stiffness in composite solids. Determination of engineering properties, from conductivity to stiffness, was classically accomplished via solution of Laplace's equation, whose linearizing field assumption allows simultaneous solution of a number of important problems using the same partial differential equations, rescaled using appropriate material constants (Tables 2 and 3, following the description in Ref. [54]). Other techniques that have been widely used to determine, or bound, properties of heterogeneous materials, include solutions of stress fields in representative volume elements (RVEs), models of anisotropic sheets, and models of continuum anisotropic phases. In this article, we do not attempt to survey each of these areas thoroughly; we aim, however, to give an overview of approaches in modeling composite materials, with specific results of classic models, and an eye toward the modeling of biological materials. Thus, we omit discussion of manufacture of composite materials (see, for example, Refs. [6,55,56]). Instead, we emphasize analysis of elastic and transport properties, both for their common roots in the literature, and also their importance in study of biomaterials. We begin with general formulations of anisotropic elasticity, and discuss simplifications for layered structures, which are abundant both in engineered and biological materials. Bounds on elastic properties are also discussed, since they allow estimation of material response (important in analysis of damage and growth modeling of bone, skin, and other tissues). And, a discussion of the role of phase geometry and percolation, relative to transport properties, is presented for its usefulness in estimation of both mechanical response and permeability of specific phases (e.g., structural proteins) in biomaterials.

CONTINUUM AND MICROMECHANICS OF COMPOSITE MATERIALS

Composite materials may be isotropic or anisotropic, depending on the shapes, locations, and relative sizes

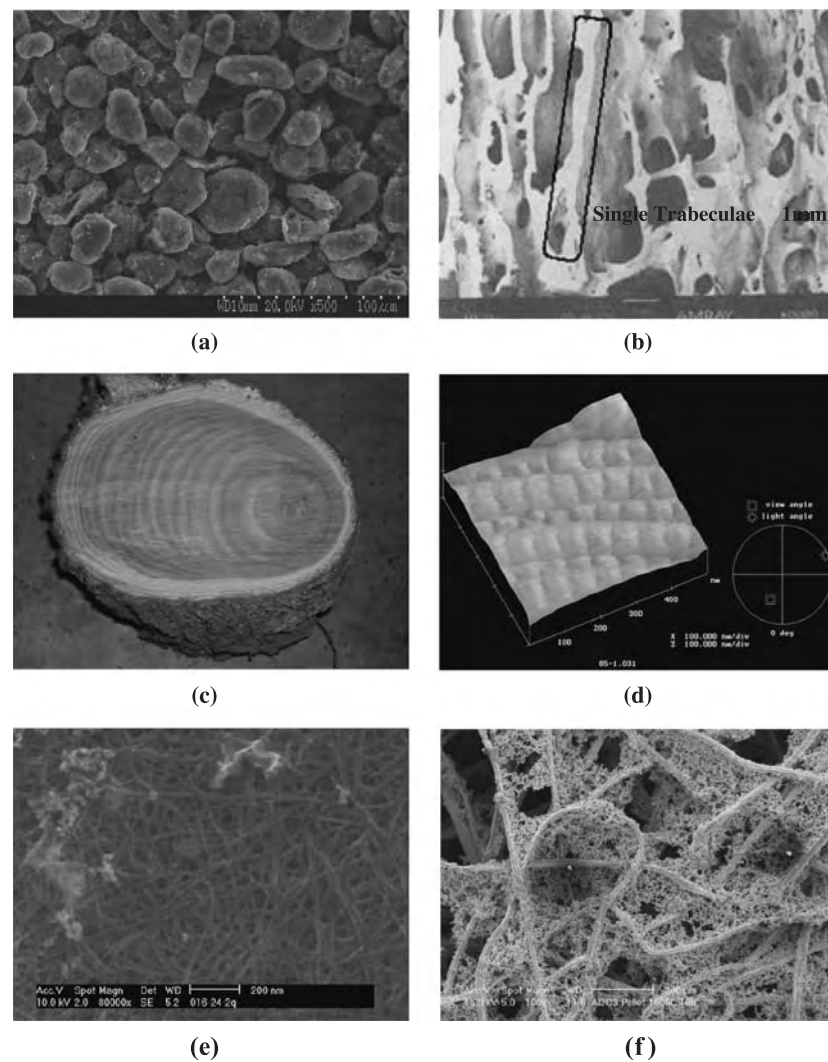

Fig. 1 Examples of composite materials, including (a) an anode of a Li-ion battery, containing carbon particles and polymeric binder, (b) trabecular bone (courtesy Dr. Scott Hollister, University of Michigan), (c) wood of an elm tree, and (d) collagen fibrils of the rat sciatic nerve perineurium, (e) carbon nanotube sheet, and (f) substrate of NiMH electrode.

of the material phases. Many particulate, porous, or short-fiber systems, for example, exhibit isotropic stiffness and conductivity; long-fiber and fabric-reinforced systems generally exhibit some degree of anisotropy.

Broadly, analysis of composite materials can be divided into two categories. Work that incorporates anisotropy into material models without detailed modeling of each phase is termed continuum mechanics, and can be used to predict effective properties of a heterogeneous material (see Ref. [57] for example). Work that directly models the shapes, locations, and relative sizes of model phases in a material is termed micromechanics, and more recently, nanomechanics, though the latter properly includes atomistic or molecular dynamics modeling and often is applied only to very small volumes due to its inherent computational intensiveness. Micromechanics is generally used to determine the details of stress, current, or other distributions

(Table 2) within a heterogeneous material, along with effective properties (e.g., Refs. [1,58]). The units of the common parameters used in the derivation of effective properties and their governing equations are listed in Table 3 and Table 4. Though theories for failure of material have been developed using continuum mechanics,^[59,60] understanding of specific failure mechanisms often requires analysis of the load sharing among the constituent materials, especially for brittle reinforcements. Statistical approaches have been shown to be useful in developing scaling rules for failure (e.g., Refs. [61–65]). The subject of failure of heterogeneous materials is quite broad and spans modeling of ductile failure, fracture, fatigue, and creep, to name a few key phenomena. Here, we introduce modeling of constitutive properties of elastic, heterogeneous materials, from the continuum to microscale, and comment on applications for both constitutive and failure modeling.

CONTINUUM, ANISOTROPIC STIFFNESS

The number of stiffnesses required to fully characterize a material’s response depends upon the degree of its anisotropy. Counterintuitively, tensorial stiffnesses are denoted C_{ijkl} , and tensorial compliances are denoted S_{ijkl} . An elastic constitutive relation (using the notation of Fig. 2) can be expressed as either

$$\sigma_{ij} = C_{ijkl}\epsilon_{kl} \tag{1}$$

or

$$\epsilon_{ij} = S_{ijkl}\sigma_{kl} \tag{2}$$

respectively, where ϵ_{kl} is the infinitesimal strain tensor and σ_{ij} is the stress tensor. We note that 2-D sections of the internal structure of a composite material depend on the plane examined, but models using 3-D ellipsoidal or cylindrical inclusions can be used to represent a wide range of reinforcement shapes (Fig. 3), from particles (2-D circles or ellipses, or 3-D spheres or ellipsoids) to fibers (1-D lines, 2-D ellipses or circles, or 3-D cylinders or ellipsoids).

The number of nonzero components of the stiffness tensor and the relationships among its components can be determined using material symmetry and equilibrium considerations. As a first cut, the 81 coefficients in the C_{ijkl} tensor can be seen immediately to have only 36 independent coefficients due to the symmetry of σ_{ij} and ϵ_{kl}

$$\sigma_{ij} = \sigma_{ji} \text{ and } \epsilon_{kl} = \epsilon_{lk}$$

We can then write the constitutive rule in matrix form (e.g., Refs. [66,67] for notation and general methods

Table 4 Common governing equations for modeling physical phenomena

Equation	Formula	Phenomena	Solution

that follow) as

$$\begin{bmatrix} \sigma_1 \\ \sigma_2 \\ \sigma_3 \\ \sigma_4 \\ \sigma_5 \\ \sigma_6 \end{bmatrix} = \begin{bmatrix} C_{11} & C_{12} & C_{13} & C_{14} & C_{15} & C_{16} \\ C_{21} & C_{22} & C_{23} & C_{24} & C_{25} & C_{26} \\ C_{31} & C_{32} & C_{33} & C_{34} & C_{35} & C_{36} \\ C_{41} & C_{42} & C_{43} & C_{44} & C_{45} & C_{46} \\ C_{51} & C_{52} & C_{53} & C_{54} & C_{55} & C_{56} \\ C_{61} & C_{62} & C_{63} & C_{64} & C_{65} & C_{66} \end{bmatrix} \begin{bmatrix} \varepsilon_1 \\ \varepsilon_2 \\ \varepsilon_3 \\ \varepsilon_4 \\ \varepsilon_5 \\ \varepsilon_6 \end{bmatrix} \quad (3)$$

where C_{ij} are the elastic stiffness coefficients, and

$$\begin{aligned} \sigma_1 &= \sigma_{11}; \sigma_2 = \sigma_{22}; \sigma_3 = \sigma_{33}; \sigma_4 = \sigma_{23}; \sigma_5 \\ &= \sigma_{13}; \sigma_6 = \sigma_{12} \\ \varepsilon_1 &= \varepsilon_{11}; \varepsilon_2 = \varepsilon_{22}; \varepsilon_3 = \varepsilon_{33}; \varepsilon_4 = 2\varepsilon_{23}; \varepsilon_5 \\ &= 2\varepsilon_{13}; \varepsilon_6 = 2\varepsilon_{12} \end{aligned} \quad (4)$$

The requirement of symmetry in C_{ij} further reduces the number of independent coefficients to 21.

Further, nontrivial reductions of the stiffness tensor (i.e., for a number of independent coefficients greater than 2) can be obtained for aligned fibrous materials, wherein the transverse arrangement of fibers determines the degree of anisotropy (Fig. 4). Materials containing square-packed fibers (Fig. 4a) are termed orthotropic, since they contain at least two mutually orthogonal planes of symmetry; in this case, the number of elastic coefficients is reduced to 9, as

$$\begin{bmatrix} \sigma_1 \\ \sigma_2 \\ \sigma_3 \\ \sigma_4 \\ \sigma_5 \\ \sigma_6 \end{bmatrix} = \begin{bmatrix} C_{11} & C_{12} & C_{13} & 0 & 0 & 0 \\ C_{12} & C_{22} & C_{23} & 0 & 0 & 0 \\ C_{13} & C_{23} & C_{33} & 0 & 0 & 0 \\ 0 & 0 & 0 & C_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & C_{55} & 0 \\ 0 & 0 & 0 & 0 & 0 & C_{66} \end{bmatrix} \begin{bmatrix} \varepsilon_1 \\ \varepsilon_2 \\ \varepsilon_3 \\ \varepsilon_4 \\ \varepsilon_5 \\ \varepsilon_6 \end{bmatrix} \quad (5)$$

Materials containing aligned, hexagonally packed fibers or randomly arranged fibers (Figs. 4b and 4c) are termed transversely isotropic, since the elastic properties are invariant with respect to an arbitrary rotation about an axis parallel to the fibers' axis; in this case, the

number of independent stiffness coefficients is reduced to 5, as

$$\begin{bmatrix} \sigma_1 \\ \sigma_2 \\ \sigma_3 \\ \sigma_4 \\ \sigma_5 \\ \sigma_6 \end{bmatrix} = \begin{bmatrix} C_{11} & C_{12} & C_{13} & 0 & 0 & 0 \\ C_{12} & C_{11} & C_{13} & 0 & 0 & 0 \\ C_{13} & C_{13} & C_{33} & 0 & 0 & 0 \\ 0 & 0 & 0 & C_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & C_{44} & 0 \\ 0 & 0 & 0 & 0 & 0 & \frac{C_{11} - C_{12}}{2} \end{bmatrix} \begin{bmatrix} \varepsilon_1 \\ \varepsilon_2 \\ \varepsilon_3 \\ \varepsilon_4 \\ \varepsilon_5 \\ \varepsilon_6 \end{bmatrix} \quad (6)$$

Composites composed of layers of fibrous sheets, or laminae, are termed laminates or laminated composites. Analysis of the elastic properties of a stack of such layers (Fig. 5) requires modeling of both the in-plane properties of each layer and an assumed for an out-of-plane displacement function for the stack. Classically, this is accomplished using the well known laminate theory, in which an elastic stiffness matrix, the ABBD matrix, is assembled for the stack. A standard notation is shown in Fig. 5; the laminate code is enclosed in brackets, with sequential plies designated by the in-plane orientation of their fibers. Subscripts s and t are used to denote symmetric or total, respectively. Symmetry in the orientations of the layers about the midplane prevents bend-twist coupling in the laminate, discussed later. Also, many laminates are designed to have in-plane properties that are independent of rotation (quasi-isotropy), as in the example of Fig. 5.

Plane stress is assumed in each layer. Normal stress resultants in the x direction, N_x , in the y direction, N_y , and in shear, N_{xy} , are defined as

$$\begin{aligned} N_x &= \int_{-H/2}^{H/2} \sigma_x dz \\ N_y &= \int_{-H/2}^{H/2} \sigma_y dz \\ N_{xy} &= \int_{-H/2}^{H/2} \sigma_{xy} dz \end{aligned} \quad (7)$$

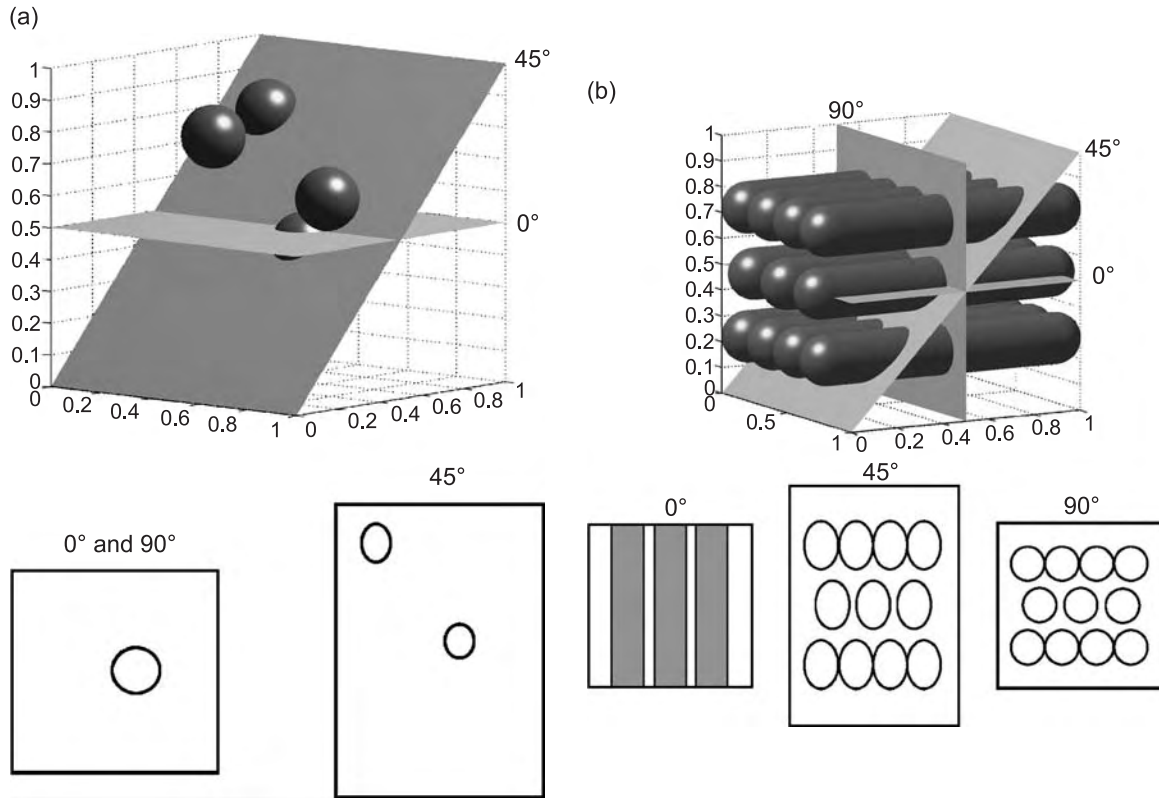

Fig. 3 Cross-sections of (a) particulate and (b) fibrous composite materials.

and moment resultants, M_x , M_y , and M_{xy} , are defined as

$$M_x = \int_{-H/2}^{H/2} \sigma_x z dz$$

$$M_y = \int_{-H/2}^{H/2} \sigma_y z dz$$

$$M_{xy} = \int_{-H/2}^{H/2} \tau_{xy} z dz$$

Fig. 4 Several classical transverse arrangements assumed for aligned-fiber composites, including (a) square packing, (b) hexagonal close-packing and (c) random packing.

Fig. 5 Notation for laminated composites, with in-plane orientation of fibers in each layer designated in degrees. The example shown is a symmetric, quasi-isotropic laminate, $[0/\pm 45/90]_s$.

The plane stress assumption (σ_3 , τ_{23} , and $\tau_{13}=0$) results in the 2-D reduction of Eq. 3 to

$$\begin{bmatrix} \sigma_1 \\ \sigma_2 \\ \tau_{12} \end{bmatrix} = \begin{bmatrix} Q_{11} & Q_{12} & 0 \\ Q_{12} & Q_{22} & 0 \\ 0 & 0 & Q_{66} \end{bmatrix} \begin{bmatrix} \varepsilon_1 \\ \varepsilon_2 \\ \gamma_{12} \end{bmatrix} \quad (9)$$

where

$$\begin{aligned} Q_{11} &= C_{11} - \frac{C_{13}^2}{C_{33}} \\ Q_{12} &= C_{12} - \frac{C_{13}C_{23}}{C_{33}} \\ Q_{22} &= C_{22} - \frac{C_{23}^2}{C_{33}} \\ Q_{66} &= Q_{66} \end{aligned} \quad (10)$$

We note that for the 2-D case, these relations apply to both transversely isotropic or orthotropic laminae. Transformation of stiffnesses (Eq. 9) to a global coordinate system is required for each layer, where the transformed stiffness are denoted \bar{Q}_{ij} , as in

$$\begin{bmatrix} \sigma_x \\ \sigma_y \\ \tau_{xy} \end{bmatrix} = \begin{bmatrix} \bar{Q}_{11} & \bar{Q}_{12} & \bar{Q}_{16} \\ \bar{Q}_{12} & \bar{Q}_{22} & \bar{Q}_{26} \\ \bar{Q}_{16} & \bar{Q}_{26} & \bar{Q}_{66} \end{bmatrix} \begin{bmatrix} \varepsilon_x \\ \varepsilon_y \\ \gamma_{xy} \end{bmatrix} \quad (11)$$

and are obtained from the Q_{kl} by

$$\begin{aligned} \bar{Q}_{11} &= Q_{11} \cos^4 \theta + 2(Q_{12} + 2Q_{66}) \sin^2 \theta \cos^2 \theta \\ &\quad + Q_{22} \sin^4 \theta \\ \bar{Q}_{12} &= (Q_{11} + Q_{22} - 4Q_{66}) \sin^2 \theta \cos^2 \theta \\ &\quad + Q_{12}(\sin^4 \theta + \cos^4 \theta) \\ \bar{Q}_{16} &= (Q_{11} - Q_{12} - 2Q_{66}) \sin \theta \cos^3 \theta \\ &\quad + (Q_{12} - Q_{22} - 2Q_{66}) \cos \theta \sin^3 \theta \\ \bar{Q}_{22} &= Q_{11} \sin^4 \theta + 2(Q_{12} + 2Q_{66}) \sin^2 \theta \cos^2 \theta \\ &\quad + Q_{22} \cos^4 \theta \\ \bar{Q}_{26} &= (Q_{11} - Q_{22} - 2Q_{66}) \sin^3 \theta \cos \theta \\ &\quad + (Q_{12} - Q_{22} + 2Q_{66}) \sin \theta \cos^3 \theta \\ \bar{Q}_{66} &= (Q_{11} + Q_{22} - 2Q_{12} - 2Q_{66}) \sin^2 \theta \cos^2 \theta \\ &\quad + Q_{66}(\sin^4 \theta + \cos^4 \theta) \end{aligned} \quad (12)$$

Use of the Kirchhoff–Love hypothesis, that plane transverse sections remain plane during loading,

results in

$$\begin{aligned} u &= u_o - z \frac{\partial w_o}{\partial x} \\ v &= v_o - z \frac{\partial w_o}{\partial y} \\ w &= w_o \end{aligned} \quad (13)$$

for the displacement (u , v , w) of a point at (x, y, z) , given midplane displacements (u_o , v_o , w_o). The strains can then be calculated via

$$\begin{aligned} \varepsilon_x &= \frac{\partial u}{\partial x} = \frac{\partial u_o}{\partial x} - z \frac{\partial^2 w_o}{\partial x^2} = \varepsilon_x^o - z \frac{\partial^2 w_o}{\partial x^2} \\ \varepsilon_y &= \frac{\partial v}{\partial y} = \frac{\partial v_o}{\partial y} - z \frac{\partial^2 w_o}{\partial x^2} = \varepsilon_y^o - z \frac{\partial^2 w_o}{\partial x^2} \\ \gamma_{xy} &= \frac{\partial u}{\partial y} + \frac{\partial v}{\partial x} = \frac{\partial u_o}{\partial y} + \frac{\partial v_o}{\partial x} - 2z \frac{\partial^2 w_o}{\partial x \partial y} \\ &= \gamma_{xy}^o - 2z \frac{\partial^2 w_o}{\partial x \partial y} \end{aligned} \quad (14)$$

Assuming small rotations, displacements u and v in Eq. 13, the strains, can expressed as

$$\begin{aligned} \varepsilon_x &= \frac{\partial u}{\partial x} = \frac{\partial u_o}{\partial x} - z \frac{\partial^2 w_o}{\partial x^2} = \varepsilon_x^o + z\kappa_x^o \\ \varepsilon_y &= \frac{\partial v}{\partial y} = \frac{\partial v_o}{\partial y} - z \frac{\partial^2 w_o}{\partial x^2} = \varepsilon_y^o + z\kappa_y^o \\ \gamma_{xy} &= \frac{\partial u}{\partial y} + \frac{\partial v}{\partial x} = \frac{\partial u_o}{\partial y} + \frac{\partial v_o}{\partial x} - 2z \frac{\partial^2 w_o}{\partial x \partial y} \\ &= \gamma_{xy}^o + z\kappa_{xy}^o \end{aligned} \quad (15)$$

and Eq. 11 can be rewritten as

$$\begin{bmatrix} \sigma_x \\ \sigma_y \\ \tau_{xy} \end{bmatrix} = \begin{bmatrix} \bar{Q}_{11} & \bar{Q}_{12} & \bar{Q}_{16} \\ \bar{Q}_{12} & \bar{Q}_{22} & \bar{Q}_{26} \\ \bar{Q}_{16} & \bar{Q}_{26} & \bar{Q}_{66} \end{bmatrix} \begin{bmatrix} \varepsilon_x^o + z\kappa_x^o \\ \varepsilon_y^o + z\kappa_y^o \\ \gamma_{xy}^o + z\kappa_{xy}^o \end{bmatrix} \quad (16)$$

Finally, a global stiffness matrix for both in-plane displacements and out-of-plane moments can be expressed in terms of the ABBD matrix as

$$\begin{aligned} \begin{bmatrix} N_x \\ N_y \\ N_{xy} \end{bmatrix} &= \begin{bmatrix} A_{11} & A_{12} & A_{16} \\ A_{12} & A_{22} & A_{26} \\ A_{16} & A_{26} & A_{66} \end{bmatrix} \begin{bmatrix} \varepsilon_x^o \\ \varepsilon_y^o \\ \gamma_{xy}^o \end{bmatrix} \\ &\quad + \begin{bmatrix} B_{11} & B_{12} & B_{16} \\ B_{12} & B_{22} & B_{26} \\ B_{16} & B_{26} & B_{66} \end{bmatrix} \begin{bmatrix} \kappa_x^o \\ \kappa_y^o \\ \kappa_{xy}^o \end{bmatrix} \end{aligned} \quad (17)$$

$$\begin{bmatrix} M_x \\ M_y \\ M_{xy} \end{bmatrix} = \begin{bmatrix} B_{11} & B_{12} & B_{16} \\ B_{12} & B_{22} & B_{26} \\ B_{16} & B_{26} & B_{66} \end{bmatrix} \begin{bmatrix} \epsilon_x^o \\ \epsilon_y^o \\ \gamma_{xy}^o \end{bmatrix} + \begin{bmatrix} D_{11} & D_{12} & D_{16} \\ D_{12} & D_{22} & D_{26} \\ D_{16} & D_{26} & D_{66} \end{bmatrix} \begin{bmatrix} \kappa_x^o \\ \kappa_y^o \\ \kappa_{xy}^o \end{bmatrix} \quad (18)$$

where

$$\begin{aligned} A_{ij} &= \int_{-H/2}^{H/2} \bar{Q}_{ij} dz \approx \sum_{k=1}^N \bar{Q}_{ijk} (z_k - z_{k-1}) \\ B_{ij} &= \int_{-H/2}^{H/2} \bar{Q}_{ij} z dz \approx \sum_{k=1}^N \bar{Q}_{ijk} (z_k^2 - z_{k-1}^2) \\ D_{ij} &= \int_{-H/2}^{H/2} \bar{Q}_{ij} z^2 dz \approx \frac{1}{3} \sum_{k=1}^N \bar{Q}_{ijk} (z_k^3 - z_{k-1}^3) \end{aligned} \quad (19)$$

The matrices represent extensional stiffness (A), bending (D), and bend-twist coupling (B). If each layer of laminate is thin, the terms A_{ij} , B_{ij} , and D_{ij} can be approximated from the sums shown in Eq. 19, and we can write the laminate constitutive law as

$$\begin{bmatrix} N_x \\ N_y \\ N_{xy} \\ M_x \\ M_y \\ M_{xy} \end{bmatrix} = \begin{bmatrix} A_{11} & A_{12} & A_{16} & B_{11} & B_{12} & B_{16} \\ A_{12} & A_{22} & A_{26} & B_{12} & B_{22} & B_{26} \\ A_{16} & A_{26} & A_{66} & B_{16} & B_{26} & B_{66} \\ B_{11} & B_{12} & B_{16} & D_{11} & D_{12} & D_{16} \\ B_{12} & B_{22} & B_{26} & D_{12} & D_{22} & D_{26} \\ B_{16} & B_{26} & B_{66} & D_{16} & D_{26} & D_{66} \end{bmatrix} \begin{bmatrix} \epsilon_x^o \\ \epsilon_y^o \\ \gamma_{xy}^o \\ \kappa_x^o \\ \kappa_y^o \\ \kappa_{xy}^o \end{bmatrix} \quad (20)$$

We note that the dimensions of these parameters are scaled per unit length of the laminate, i.e., N_i and A_{ij} are expressed in force per unit length, M_i and B_{ij} , in force, and D_{ij} as force \times length. As usual, ϵ is dimensionless; curvature κ is dimensioned as inverse length.

These relations have been widely implemented in free and commercially available codes, and are a cornerstone of laminate design. However, though laminate theory can satisfactorily model the behavior of the composite at the lamina or laminate scale, the details of load sharing among the constituent materials and many aspects of failure require more detailed modeling of the phases.

MICROMECHANICS OF ORDERED AND DISORDERED COMPOSITES

Micromechanical approaches take specific account of each phase in modeling. Classical approaches (Fig. 6a) span simple strength-of-materials series^[68] and parallel^[69] models, to early 2-D elastic field solutions for stresses around elliptical particles (e.g., Ref. [70]). All of these stemmed, along with much other work in the field, from the classical work of Eshelby.^[27] To model polymeric systems having viscoelastic behavior, elements in each model can be replaced with Voigt–Kelvin (parallel spring-dashpot) or Maxwell (series spring-dashpot) elements, as illustrated in Fig. 6b. In present applications, modeling of the details of even elastic load transfer in constituent phases (with engineering fibers of O(10–100 μ m)) in a simulation of structural properties (of components of O(>1 cm)) is still somewhat beyond computational capability, though

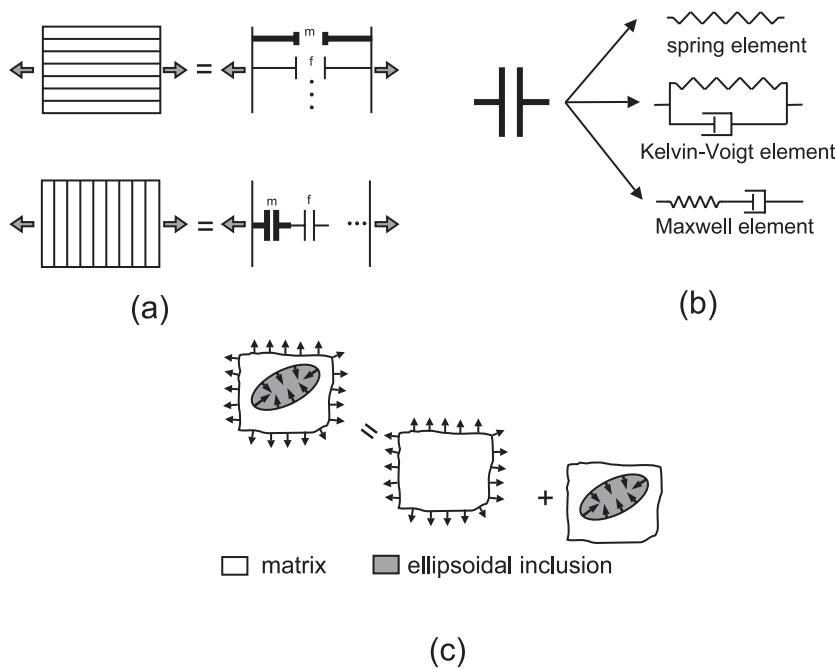

Fig. 6 Possible levels of detail in micromechanical models, from (a) simple rule of mixtures in series and parallel for stiffness modeling, (b) the element in (a) can be represent for spring, Kelvin–Voigt (spring-dashpot in parallel) element, or Maxwell (spring-dashpot in series) element, to (c) derivation of the stress fields around elliptical particles.

detailed finite element analyses of load transfer have found great utility in informing less-detailed models of structural response and failure (e.g., Ref. [67]). Here, we emphasize the classical work in analytical elasticity (Fig. 7), employing simplifying assumptions for the shapes of the phases in composite media in order to directly perform energy and mechanics of materials analyses to derive field solutions for stresses, strains, and stiffnesses.

Though many fibers are anisotropic, especially with regard to thermal expansion (e.g., many carbon fibers have a slightly negative axial coefficient of thermal expansion and a positive transverse CTE), the classical micromechanics models view each phase as isotropic. Thus, we complete the reduction of the stiffness tensor described earlier for single, isotropic phases to (see below)

$$\begin{bmatrix} \sigma_1 \\ \sigma_2 \\ \sigma_3 \\ \sigma_4 \\ \sigma_5 \\ \sigma_6 \end{bmatrix} = \begin{bmatrix} C_{11} & C_{12} & C_{12} & 0 & 0 & 0 \\ C_{12} & C_{11} & C_{12} & 0 & 0 & 0 \\ C_{12} & C_{12} & C_{11} & 0 & 0 & 0 \\ 0 & 0 & 0 & (C_{11} - C_{12}) & 0 & 0 \\ 0 & 0 & 0 & 0 & (C_{11} - C_{12}) & 0 \\ 0 & 0 & 0 & 0 & 0 & (C_{11} - C_{12}) \end{bmatrix} \times \begin{bmatrix} \varepsilon_1 \\ \varepsilon_2 \\ \varepsilon_3 \\ \varepsilon_4 \\ \varepsilon_5 \\ \varepsilon_6 \end{bmatrix} \quad (21)$$

for which there are only two independent components of C_{ij} . Engineering constants, such as Young's modulus E , shear modulus μ , and bulk modulus K can be readily obtained from these tensorial stiffnesses. For example, if we specify

$$\varepsilon_1 = \varepsilon_2 = \varepsilon_3 = \varepsilon \quad (22)$$

and

$$\sigma_1 = \sigma_2 = \sigma_3 = \sigma \quad (23)$$

we can find from the definition of bulk modulus K ,

$$\sigma = 3K\varepsilon \quad (24)$$

that

$$K = \frac{1}{3}(C_{11} + 2C_{12}) \quad (25)$$

The shear moduli are defined as

$$\mu = \mu_{12} = \mu_{31} = \mu_{23} = \frac{1}{2}(C_{11} - C_{12}) \quad (26)$$

and Young's modulus and Poisson's ratio can be then determined by bulk modulus K and shear modulus μ as

$$E = \frac{9K\mu}{3K + \mu} \quad (27)$$

and

$$\nu = \frac{3K - 2\mu}{2(3K + \mu)} \quad (28)$$

Both somewhat realistic and purely theoretical constructs have been used to derive effective properties (both conductive and mechanical) using micromechanical analyses, and both classes of RVEs have contributed to literature on the bounding of effective properties. In the first category, wherein fibers or particles are somewhat literally represented in 2-D as circles or ellipsoids (see Fig. 3), the derivations of Maxwell^[14] and Rayleigh^[15] were among the first to allow calculation of effective conductive properties based on relative fraction of materials packed in a regular fashion. Later, Bruggeman analyzed both a "symmetric effective medium" and an "asymmetrical effective medium" by assuming a wide distribution for the sizes of inclusions.^[22] In 1962, Hashin introduced a composite sphere model (see Fig. 7c) using Eshelby's energy approach (Fig. 6b) to develop a closed-form solution for effective stiffness of a continuous matrix phase infused with a variable-diameter sphere.^[31] The ratio of radii a/b for the phases was taken as a constant, proportional to the volumetric ratio of each composite sphere and independent of their absolute size.

Schemes involving theoretical material constructs have also allowed for solution of the field equations to estimate effective properties; these so-called self-consistent domains are analyzed by matching average stress and strain in the inclusion phases and the uniform stress and strain in the surrounding, infinite, isotropic medium. The first self-consistent formulations were developed by Hershey^[71] and Kröner^[72] in modeling polycrystalline media (Fig. 7d). Later, Budansky extended their work in order to determine

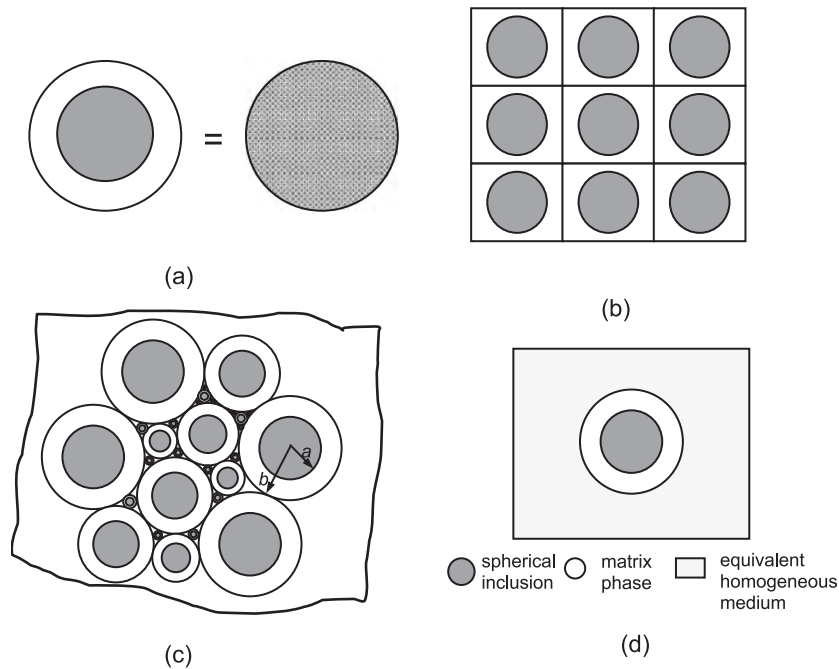

Fig. 7 Micromechanical models of ordered composite materials, including representative volume elements for the effective medium theories of (a) Maxwell's model (see Ref. [14]), (b) Rayleigh's rectangular array (see Ref. [15]), (c) Hashin's composite sphere model (see Ref. [31]) and (d) Christiansen and Lo's three phases model (see Ref. [46]).

bounds on shear and bulk moduli of multiphase materials.^[37] Hashin and Shtrikman used a variational method to minimize potential energy in a model domain and provide rigorous bounds on effective magnetic permeability, shear, and bulk moduli of multiphase materials.^[32,73-75] Christensen and Lo later devised a three-phase self-consistent approach to calculate effective shear moduli of materials containing spherical and cylindrical inclusions.^[46]

Importantly, many classical results for effective conductivity and effective bulk modulus coincide for both physical and self-consistent RVEs. Effective elastic properties can be found for these arrangements via minimization of potential energy, or minimization or work principles, expressing stored elastic energy as either

$$U_C = \frac{1}{2} \sum_{i=1}^6 \sum_{j=1}^6 \varepsilon_i C_{ij} \varepsilon_j \quad (29)$$

or

$$U_S = \frac{1}{2} \sum_{i=1}^6 \sum_{j=1}^6 \sigma_i (S_{ij}/m_i m_j) \sigma_j \quad (30)$$

These two expressions result in different magnitudes for the total stored elastic energy in heterogeneous domains due to simplifying assumptions regarding stress and strain fields. Together, they allow calculation of bounds on properties of anisotropic fields of fibrous (Table 5) and particulate (Table 6) materials, with assumed geometry and volume fraction of phases (summarized in compact form, for example, by McCullough,^[76] following work by Hashin and Shtrikman^[74,75]). These

estimates are useful for design for stiffness, in both fibrous and particulate materials, and can be readily used to model a wide range of materials, and compare well with elastic finite element simulations in prediction of stiffnesses^[67] we note that these models assume transverse isotropy in the composite, with isotropic fiber and matrix.

Though effective properties can be estimated and bounded using these simplified elastic estimates, however, the importance of disorder in material geometry at the scale at which the material is used must frequently be considered. Such disorder can create internal non-uniformities in material response, and thus variability among devices or structures created from the material. Also, variability in location of reinforcement phases can result in higher stress concentrations in the material, producing earlier-than-expected failure (Fig. 8^[77-79]).

Indeed, real, disordered, or stochastic materials exhibit a range of values in material response, and attempts have been made for various geometries (e.g., randomly laid fibers or particles, as in Fig. 9) to bound these properties. Work of this type models disorder in a material specifically, rather than through use of an energy approach, as described in the previous section, to simply bound properties of an ordered, representative arrangement. In early work, Bergman devised an analytical method to determine bounds for dielectric conductivity^[80] Lurie and Cherkaev^[81] and Milton and Kohn^[82] presented bounds for macroscopically anisotropic media by extending the work of Hashin and Shtrikman.^[32,73,74] Gibiansky and Torquato used a "translation method" to determine the rigorous bounds for the relation between conductivity and elastic moduli of two-dimensional, globally isotropic

Table 5 Summary of the rigorous bounds of physical properties for transverse isotropic composites materials

Property	Lower bound	Upper bound
\mathbf{E}_1	$E_1^L = \mathbf{v}^f E_1^f + \mathbf{v}^m E_1^m + \frac{4 \left(\mathbf{v}_{12}^m - \mathbf{v}_{12}^f \right)^2 k^f k^m G_{12}^m}{\left[k^m k^f + G_{12}^m (\mathbf{v}^f k^f + \mathbf{v}^m k^m) \right]}$	$E_1^U = \mathbf{v}^f E_1^f + \mathbf{v}^m E_1^m + \frac{4 \left(\mathbf{v}_{12}^f - \mathbf{v}_{12}^m \right)^2 k^f k^m G_{12}^f}{\left[k^m k^f + G_{12}^f (\mathbf{v}^f k^f + \mathbf{v}^m k^m) \right]}$
$\nu_{12} = \nu_{13}$	$\nu_{12}^L = \nu_{13}^L = \mathbf{v}^m \nu_{12}^m + \mathbf{v}^f \nu_{12}^f + \frac{\left(\mathbf{v}_{12}^m - \mathbf{v}_{12}^f \right) (k^f - k^m)}{\left[k^m k^f + G_{12}^m (\mathbf{v}^m k^m + \mathbf{v}^f k^f) \right]}$	$\nu_{12}^U = \nu_{13}^U = \mathbf{v}^m \nu_{12}^m + \mathbf{v}^f \nu_{12}^f + \frac{\left(\mathbf{v}_{12}^f - \mathbf{v}_{12}^m \right) (k^m - k^f)}{\left[k^m k^f + G_{12}^f (\mathbf{v}^m k^m + \mathbf{v}^f k^f) \right]}$
\mathbf{G}_{12}	$G_{12}^L = \frac{G_{12}^m \left[\left(G_{12}^f + G_{12}^m \right) + \mathbf{v}^f \left(G_{12}^f - G_{12}^m \right) \right]}{\left[\left(G_{12}^f + G_{12}^m \right) - \mathbf{v}^f \left(G_{12}^f - G_{12}^m \right) \right]}$	$G_{12}^U = \frac{G_{12}^f \left[\left(G_{12}^f + G_{12}^m \right) + \mathbf{v}^m \left(G_{12}^m - G_{12}^f \right) \right]}{\left[\left(G_{12}^f + G_{12}^m \right) - \mathbf{v}^m \left(G_{12}^m - G_{12}^f \right) \right]}$
\mathbf{G}_{23}	$G_{23}^L = \frac{G_{23}^m \left[k^f \left(G_{23}^f + G_{23}^m \right) + 2G_{23}^f G_{23}^m + \mathbf{v}^f k^m \left(G_{23}^f - G_{23}^m \right) \right]}{\left[k^m \left(G_{23}^f + G_{23}^m \right) + 2G_{23}^f G_{23}^m - \mathbf{v}^f \left(G_{23}^f - G_{23}^m \right) \right] \left(k^m + 2G_{23}^m \right)}$	$G_{23}^U = \frac{G_{23}^f \left[k^m \left(G_{23}^f + G_{23}^m \right) + 2G_{23}^f G_{23}^m + \mathbf{v}^m k^f \left(G_{23}^f - G_{23}^m \right) \right]}{\left[k^f \left(G_{23}^f + G_{23}^m \right) + 2G_{23}^f G_{23}^m - \mathbf{v}^m \left(G_{23}^f - G_{23}^m \right) \right] \left(k^f + 2G_{23}^f \right)}$

$\mathbf{E}_2 = \mathbf{E}_3$	$E_2^L = E_3^L = \frac{1}{\frac{1}{4G_{23}^L} + 4k^L + \frac{1}{E_1^L}} \frac{1}{\left(\nu_{12}^U \right)^2}$	$E_2^U = E_3^U = \frac{1}{\frac{1}{4G_{23}^U} + 4k^U + \frac{1}{E_1^U}} \frac{1}{\left(\nu_{12}^L \right)^2}$
ν_{23}	$\nu_{23}^L = \frac{2E_1^L k^L - E_1^L E_2^L - 4 \left(\nu_{12}^U \right)^2 k^L E_2^L}{2E_1^L k^L}$	$\nu_{23}^U = \frac{2E_1^U k^U - E_1^U E_2^U - 4 \left(\nu_{12}^L \right)^2 k^U E_2^U}{2E_1^U k^U}$

Superscripts “L” and “U” indicate lower and upper bounds, respectively, for corresponding physical properties. Superscripts “f” and “m” indicate fiber and matrix phases, respectively. All formulae adapted from Ref. [76].

Table 6 Summary of rigorous bounds physical properties for particulate-filled composite materials

Property	Lower bound	Upper bound
K	$k^L = \frac{k^m(k^f(1 + (v^f)^2(2v^f - 2v^m) + v^m) + 2k_m((v^f)^2 - 1)(v^m - v^f))}{k^f(v^m)(1 + v^m) + k^m(2 + v^f + (v^f - 4)v^m)}$	$k^U = \frac{k^f \{ 2k^f (v^f)^2 (v^f - v^m) + k^m [(2v^f + v^m)(3v^m - 3v^f + 4(v^f)^2)] \}}{-k^m v^f (v^m + 2v^f) + k^f [v^f (5v^f + 4v^m) - 3]}$
G	$G^L = -\frac{G^m [G^m (v^m)(7v^f + 2v^m) + G^f (8 + 7v^f - 5(2 + v_f)v_m)]}{2G^f (v^m)(v^m - 4v^f) + G^m (-7v^f - 2v^m + 2v^f (v^m - 4v^f))}$	$G^U = \frac{G^f [G^f (v^f) (7v^m - 2v^f) + G^m (15 + 7v^f (5v^f - 22))]}{2G^m v^f (4v^m - v^f) + G^f (15 + v^f (10v^f - 23))}$
E	$E^L = \frac{9k^L G^L}{3k^L + G^L}$	$E^U = \frac{9k^U G^U}{3k^U + G^U}$
v	$v^L = \frac{3k^L - 2G^L}{2(3k^L + G^L)}$	$v^U = \frac{3k^U - 2G^U}{2(3k^U + G^U)}$

Superscripts “L” and “U” indicate lower and upper bounds, respectively, for corresponding physical properties. Superscripts “f” and “m” indicate filler and matrix phases, respectively. Physical properties of filler phase are assumed to be superior to those of the matrix phase. All formulae adapted from Ref. [76].

Fig. 8 2D models of transverse stress distributions in an elastic, carbon-epoxy, fiber-reinforced composites. For the simulations shown, $E_f = 231 \text{ GPa}$, $E_m = 3.4 \text{ GPa}$, $\nu = 0.28$, $\nu_m = 0.36$ and $f = 0.1$; both simulations are subjected to a biaxial tension of 1%, resulting in far field von Mises stresses of 26 MPa. In the regular array (a), the highest stress is 51 MPa at both matrix and fiber phases, whereas in the disordered array (b), the highest stresses are 87 MPa in matrix phase and 80 MPa in fiber phases between the closely-spaced fibers. Material constants for AS4C Hexel[®] Carbon fibers were obtained from Refs. [77,78]. Material constants for Hercules 3501-6 epoxy were obtained from Refs. [6,79].

composite materials.^[83] Later, Torquato and coworkers used a discrete network and homogenization theory to determine the effective mechanical and transport properties of cellular solids.^[84] Studying fibrous materials, Lu, Carlsson, and Andersson used a micromechanical approach to obtain rigorous bounds on elastic properties.^[85–87] And Ostoja-Starzewski et al. developed network techniques to simulate effective properties of generalized composites by changing the

spring constants of individual springs within the network to model multiphase material properties.^[88] Sastry and coworkers studied the stochastic fibrous networks to determine both conductivity and variance in conductivity in battery materials.^[89,90] This work was later extended to model fiber type bonding conditions, and failure mechanisms in greater detail^[90,91] and was also extended to include the effects of fiber waviness on material mechanical properties^[92–94] to model variance in electrical conductivity of porous networks with elliptical particles.^[95]

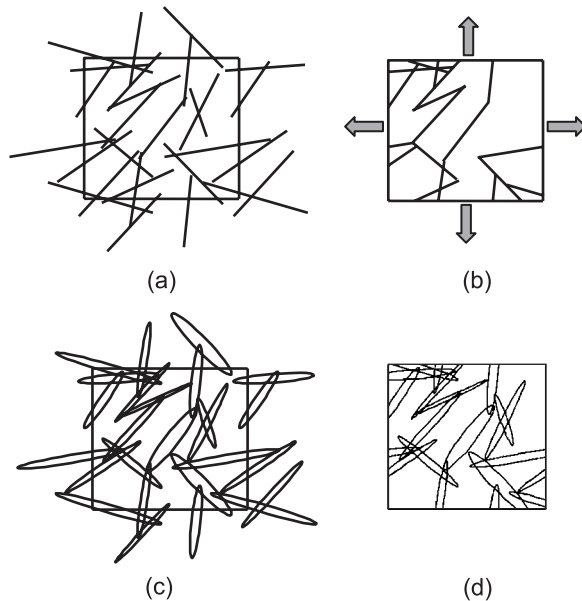

Fig. 9 Micromechanical models of disordered composite materials, including disordered 1D fibrous inclusions, with (a) randomly-laid, and (b) reduced, and periodic geometry, and 2D, fibrous or particulate inclusions, with (c) randomly-laid and (b) reduced, and periodic geometry.

PHASE CONTINUITY AND PERCOLATION IN DISORDERED COMPOSITES

All of these efforts further underscored the importance of variance in properties in real materials. Indeed, a key requirement in producing dramatic changes in material transport properties (e.g., thermal and electrical conduction) is percolation of the additive phase. We can define percolation as the formation of at least one, continuous, domain-spanning path of the percolating phase in the material. Dramatic improvements in computing speeds from the 1980s to the present have allowed direct, stochastic simulation of transport in disordered arrays.

Key features of such models include physically realistic simulation domains and use of many statistically equivalent realizations, i.e., domains in which the statistical parameters describing particles, sizes, etc. are the same for all, but the locations, sizes, etc. are different in each. As a result, the minimum amount of a phase required to produce dramatic improvements in composite properties can be determined, along with

Fig. 10 Percolating and non-percolating arrays of circles, with volume fractions (a) 32.7%, (b) 51.2%, and (c) 64.0%.

discrete and averaged predictions of material properties. Percolation concepts have been used not only in design of materials for mechanical^[96–98] properties, but also in filtration^[99–101] and conductive^[89–103] properties.

Classic work by Kirkpatrick, who studied site and bond percolation using a resistor network, pointed out the importance of the percolation threshold, or threshold volume fraction above which a percolating phase would form at least one single, domain-spanning path (Fig. 10).^[104] In 1988, McLachlan introduced a more general effective-media equation for binary conductivity media.^[47] The fact that higher aspect ratio phases percolate at lower volume or area fractions than lower aspect ratio phases has been well documented. In early work, Kirkpatrick's simulations showed that the percolation threshold ρ_c , i.e., the density or volume fraction of the fiber phases at percolation onset, exhibited a power law dependence upon bond fraction v .^[104] Pike and Seager also examined conduction and percolation phenomena in stick networks

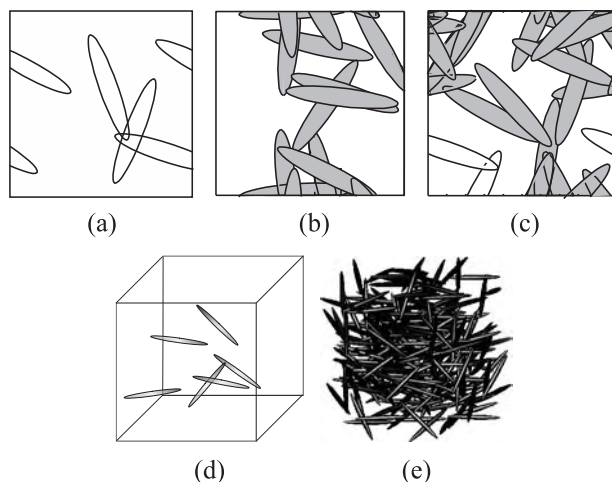

Fig. 11 Two-dimensional percolating and nonpercolating arrays of ellipses of aspect ratio 6 and volume fractions (a) 17.9%, (b) 31.6%, and (c) 50.7%. Three-dimensional percolating and nonpercolating arrays of ellipsoids are also shown, of aspect ratio 10, and volume fraction (d) 6%, and (e) 20%.

(among others), using 2-D and 3-D Monte Carlo simulations.^[105]

Recently, analytical approximations of the percolation points have been developed for both 2-D and 3-D arrays of generalized ellipses and ellipsoids of uniform shape and size,^[106,107] which verified and extended earlier results on simulation of simpler 2-D networks of 1-D fiber percolation,^[97,98] 3-D networks of 2-D ellipsoids, and other analytical approaches for determination of percolation of circular arrays;^[108–114] combined results^[91,106] are shown in Fig. 11. These illustrate that the percolation point in realistic materials is probabilistic (i.e., only a statistical estimation of percolation point can be made, for any given volume fraction of particles), and also that 2-D fiber models in models are quite satisfactory for determining percolation properties for aspect ratios greater than 100, as shown in Fig. 12. Similarly, Fig. 13 shows that percolation probability of ellipsoid models in 3-D model is also strongly dependent upon of aspect ratio.

APPLICATION OF COMPOSITE THEORIES TO BIOMATERIALS

Modeling of the shapes and effects of various phases in materials is tremendously important in understanding the combined mechanical and physiological role of biomaterials. Natural materials exhibit a high degree of variability, and use of statistical theories touched upon in this chapter can be helpful in anticipating differences in clinical results of both in-vitro and in-vivo tissue response. Generalized domains, particularly fields of ellipses and ellipsoidal particles, can be used to describe a wide variety of materials and bound a number of important effective engineering properties. Percolative properties have important implications

Fig. 12 Probability of percolation in 2D arrays, for various particle-fiber geometries. (Adapted from Ref. [106].)

Fig. 13 Simulation results for percolation probability versus particle size, for arrays of overlapping ellipsoids of revolution. In this figure, 'a' represents the semi-axis length, and the aspect ratio of the ellipsoids is 10. (Adapted from Ref. [107].)

for understanding the role of particulates (either voids or material phases) and fibers, both adaptation and selection, in biomaterials (Fig. 12).

Thus, in conclusion, the modeling of heterogeneous domains performed by the composites community has broad application in modeling biomaterials. Elasticity provides an initial estimate of properties, and percolation theories provide a method of determining the connectivity of phases, and thus their importance in transport.

ACKNOWLEDGMENTS

The authors wish to acknowledge the invaluable assistance of Dr. Yun-Bo Yi, Dr. Bradley Layton, Dr. Hui Wang, and Dr. Scott Hollister, who provided simulation data and/or images for this chapter, and of Mr. Taeyong Kim, in helping to collect materials.

Compression of Digital Biomedical Signals

Tapio Grönfors

Department of Computer Science, University of Kuopio, Finland

Martti Juhola

Department of Computer Sciences, University of Tampere, Finland

INTRODUCTION

This article introduces compression methods for biosignals routinely used in clinical work, electrocardiography (ECG), electromyography (EMG), electrooculography (EOG), and electroencephalography (EEG), including brain auditory evoked potential (BAEP). The compression of ECG signals is the most studied biosignal compression approach, with hundreds of published scientific papers. The compression of BAEP signals is far less studied, with only a few published papers. This article discusses some less studied biosignals, such as EMG and EOG, and determines fundamental quality questions regarding biosignal compression methods.

The article begins with a brief background introduction to compression methods and quality evaluation. Selected, cited application examples are presented after the Introduction. In every case, remarks are made from the most typical methods and most prominent results. However, the aspect is kept on an abstract level, without technical details of the methods. A concise conclusion is drawn about these methods and their applicability.

MOTIVATION FOR BIOSIGNAL COMPRESSION

Several electrophysiological signals of humans are used routinely in clinical work. Many of these signals fulfill one or more of the following conditions: high sampling rate (≥ 1 kS/sec), high precision (12 bits or more), multichannel recording (four channels or more), or long-term recording (≥ 24 hr). Based on these figures, hundreds of megabytes of data can be easily evoked per recording.

Although large portions of these recordings are disposable, growing portions are archived for scientific purposes and clinical use in electronic patient documents. Notable numbers of recordings change positions in information networks. Novel biosignal recording technologies are made to utilize wireless measuring processes.^[1] Typically, these portable, wearable, or even implantable recording devices use a radio system with limited transmission capabilities.

Both archiving and telecommunication benefit from data compression. However, demands of the task and available approaches are quite specific. Requirements exist to work with novel biosignal recording technologies for low-power computing and real-timing in tandem with computationally reduced hardware.

ASPECT FOR BIOSIGNAL COMPRESSION: LOSSLESS, NEAR LOSSLESS, AND LOSSY

Lossless compression methods are the footing for compression. As the name suggests, these methods are totally reversible and there is no information loss in the compression process. These methods are based on the results of information theory^[2] and compression is attained by setting the length of codes according to their probability. For compressing a text or computer program, the lossless property is an obvious requirement. Lossless methods are also widely used for biosignals for fear of losing critical information.

The main methods of lossless compression are^[2] Huffman coding and its variations, such as Golomb coding, arithmetic coding, and dictionary techniques, including well-known LZ77/LZ78 approaches and predictive coding. Arithmetic coding is computationally more complex than Huffman coding, but can code sequences of data and effect better performance and adaptability on changing data statistics. Dictionary techniques are most useful when frequently occurring structural patterns in data are a small subset of all possible structural patterns, like in text. However, this is not typical with biosignals. Predictive methods, which use past values of the data sequence to predict the actual value of the current data, are endogenously suitable for signal compression.

In the group of near-lossless compression methods, the main requirement is ensuring that the maximum error between the original and the processed data does not exceed a fixed threshold. This kind of a bound on the error magnitude can apply to biosignals on a sample-by-sample basis.

In the group of lossy compression methods, there is an unlimited error between the original and the

processed data. Typically, the error increases while a better compression ratio is attained. The lossy methods are based on models. Via the model, worthless, or at least non-critical, information is lost in the compression process. This approach is acceptable for recorded biosignals, because they contain extra data beside the information.

A variety of lossy compression approaches are available. The main methods are^[2] scalar and vector quantization with multiple variations on the theme, differential encoding, transform methods, subband coding, and wavelet-based methods. Differential encoding does not provide as high compression as quantization methods, but it is very simple and suited to implementation for signal-like data.

In a practical biosignal compression system, few consecutive compression stages can follow each other. In every stage, the results of the preceding stage are compressed with another method, gaining more compression. Some methods are lossless and some are lossy. Compression methods can also be dynamic, adapting to local variations of data.

EVALUATION OF EFFICIENCY OF COMPRESSION METHODS

The most obvious measurement for a compression method is the attained ratio between the original and the compressed data. This is simply the ratio between the original size and the compressed size, expressed, for example, in the form 5:1, meaning that the original data was five times as large as the compressed data. The compression ratio can also be represented by a reduction in the amount of data required as a percentage of the size of the original data, for example, 80%. From a telecommunications aspect, the compression ratio can be referred to as the rate, or the average number of bits per sample in the compressed representation.

Obtaining the desired compression ratio requires computational effort. The algorithmic complexity is the second measure of a compression method. Algorithmic complexity can be represented as the relative structural complexity of an algorithm, required amount of memory, required sophistication of a processor, or fastness of an implementation with a given processor. In novel challenging applications the algorithmic complexity of compression methods is emphasized.

With lossy compression methods, the third measure is how closely the reconstruction resembles the original data. This is the compression error. With lossless methods, this is omitted. With lossy methods, the measure is computed by investigating the influence of compression. First, the signal data is compressed and then decompressed. The decompressed signal data is compared with the original, uncompressed data. The

natural objective is that their difference be as small as possible. On the other hand, the more effective the compression, the larger such a difference tends to be. The compression error is often called the distortion.

The compression errors of biosignals are typically evaluated using the measures^[2] mean squared error (MSE), average of absolute differences, or mean absolute error (MAE), maximum value of the error magnitude (MEM), signal-to-noise ratio [SNR, including its logarithmic representation in decibels, SNR(dB)], peak signal-to-noise ratio (PSNR), and normalized root-mean-square error (NMRS). In biosignal-related studies, the NMRS value is represented as a percentage and is called the percent root-mean-square difference (PRD) for original signal samples o_i and processed samples p_i and their variances, σ_o^2 and σ_p^2 :

$$MSE = \frac{1}{N} \sum_{n=1}^N (o_n - p_n)^2 \quad (1)$$

$$MAE = \frac{1}{N} \sum_{n=1}^N |o_n - p_n| \quad (2)$$

$$MEM = \max_n |o_n - p_n| \quad (3)$$

$$SNR = \frac{\sigma_o^2}{\sigma_p^2} \quad (4)$$

$$SNR(dB) = 10 \log_{10} \frac{\sigma_o^2}{\sigma_p^2} \quad (5)$$

$$NMRS = \sqrt{\frac{\sum_{n=1}^N (o_n - p_n)^2}{\sum_{n=1}^N o_n^2}} \quad (6)$$

All of the above-mentioned measures are used to summarize the error of the sequence of signal samples. Sometimes the differences are also examined on a sample-by-sample basis tracking the values of squared or absolute difference measures. Nevertheless, these measures only express the general changes of an entire signal affected by compression. Thus, they cannot directly reveal the risk of the loss of useful clinical information. Such a risk has to be separately clarified for each medical parameter, as we will describe in the later sections.

FIDELITY OF BIOSIGNALS AND CLINICAL QUALITY

Audio and video compressions are well-known areas of lossy methods for signal-like data. The fidelity and the quality of processed signals are evaluated via human

perception of distortion: if they sound or look agreeable, compression is valid. When the compression is optimized for perception, the data are inaccurate for computational processing.

Visual similarity is sometimes used as a criterion for biosignals. This can be a sufficient condition only if the clinical use is based on visual inspection. A fundamental criterion of fidelity is that the processed biosignal is not allowed to lead a physician to a wrong or insufficient diagnosis.

Most biosignals are interpreted via medical parameters and the time evolution of medical parameters. The medical parameters are typically calculated from a time-domain or frequency-domain representation of biosignals. Although the measured compression errors between the original and processed biosignals correlate with errors of medical parameters, the dependency is not straightforward. A novel and fruitful aspect involves inspecting the medical parameter values of processed signals against original signals over the whole clinically interesting range.

APPLICATION EXAMPLES OF SELECTED BIOSIGNALS

Compression of ECG Signals

Perhaps the most important, or at least most used, biomedical signal is ECG, which is applied to the diagnosis of heart problems and even leisure-time heart pulse recorders. Numerous articles investigated compression of ECG signals since the 1960s. Presumably, the majority of all biosignal compression investigations consider ECG signals. The investigators concentrated on lossy compression, or ECG signals, which are typically explored in time domain. An ECG signal is usually composed of rather clear waves, segments, and QRS complexes, which create a successful basis for effective lossy compression. It suffices to keep the main features of the ECG signal components almost intact or only slightly deformed by compression. Therefore, there has not been much reasonable cause to study lossless compression for ECG signals. Several different methods were introduced in the past. The methods can be divided into two main categories: direct and transformation techniques. Another method, called the parametric method, is performed on the basis of statistical models applying signal distribution. The latter category is seldom applied to ECG signals.

Direct compression methods were introduced first because several such methods are fairly straightforward and, therefore, fast. In fact, investigations mostly focused on compression effectiveness, but their computational effectiveness, which materializes as running time, was only briefly considered. The quality of compression

was usually understood to include (normalized) MSE, PRD, or the measures mentioned above. Instead, investigators rarely dealt with the issue of how a compression method can exactly deform ECG signal components in detail. A statistical value like PRD might look fairly good, but it does not express much, e.g., how amplitudes of QRS complexes could have been decreased by compression. Later research mainly addressed transformation methods. Transformation methods seem promising in order to compress efficiently and, at the same time, handle information content of signals conservatively, i.e., not deform ECG signal components too strongly.

Several direct compression methods are applied to ECG signals. Typically, they are designed on the basis of signal segmentation in a suitable way to change a signal curve into broken lines of best fit corner data-points and to represent the curve as a sequence of such segments. Segments can also be accomplished with nonlinear short, e.g., third-degree, curves. However, short linear segments are more typically applied because their consideration is simpler, faster, and possibly equally useful in the sense of compression.

Perhaps one of the oldest direct compression methods is differential pulse code modulation, which utilizes a polynomial predictor like

$$\hat{u}_i = u_{i-1} + \Delta_1 u_{i-1} + \Delta_2 u_{i-2} + \dots + \Delta_k u_{i-k},$$

where \hat{u}_i is the i th predicted sample, u_{i-1} is the $(i-1)$ st sample, $\Delta_1 u_{i-1}$ is equal to $u_{i-1} - u_{i-2}$, and generally $\Delta_k u_{i-k}$ is equal to $\Delta_{k-1} u_{i-k} - \Delta_{k-1} u_{i-k-1}$. Usually either the zero-order predictor of

$$\hat{u}_i = u_{i-1}$$

or the first-order predictor,

$$\hat{u}_i = u_{i-1} + (u_{i-1} - u_{i-2}) = 2u_{i-1} - u_{i-2},$$

is used. For example, for the former the first-difference signal or amplitude between successive samples, $e_i = u_i - \hat{u}_i$, is replaced for the original signal. Because a magnitude of e_i is clearly smaller than that of u_i , it spares storage counted in bits. To decode the compressed data, the reverse procedure is performed. Several methods are derived from this approach,^[3] where typically the prediction procedure is developed further. The basic differential pulse code modulation (DPCM) is naturally suitable for any type of signal. It is also used as a preprocessing method and then built for some other compression, which obtains successive differences e_i as input. In other words, first DPCM is performed as preprocessing for a signal and then another compression method is executed for the output of DPCM.

Other simple direct methods are often based on various segmentation procedures of ECG signals. Fan and scan-along polygonal approximation (SAPA) are algorithms^[3,4] in which linear slopes are fitted on a signal. In Fan the longest possible line was set between the current start sample and a new end sample so that all intermediate samples were within a given small error limit. In SAPA, this technique was developed slightly further. Another idea was to take advantage of peaks, maxima, and minima in ECG signals. By recognizing maxima and minima, slope changes, and zero-crossings it was possible to approximate ECG signals.^[3] These simple methods can be fast, but can lose more information from ECG signals than more sophisticated segmentation algorithms. Information loss is understood to mean inaccurate decoding with considerable sample (amplitude) differences between the original and the decoded (returned or decompressed) signal. There may also be differences along the time axis after decompression. These features are even visually considerable. In principle, they could slightly affect frequency domain properties, but this has been little explored in compression literature. After the aforementioned early ECG compression methods, more sophisticated segmentation algorithms were introduced. A simple idea starts from the computation of linear regression slopes, which are successively set on the signal to approximate this signal. However, this way is not very effective. The regression procedure implies an optimization task along with a vertical axis, which may cause extra amplitude errors in segmentation, because the shortest distance between a line and a sample is not along the vertical axis, but is equal to the Euclidean distance between them. Such a distance to be minimized is obtained by assigning a normal (perpendicular segment of a line) between the sample and the line. This is computationally harder than linear regression. We constructed such a method, which also used error distributions to predict for the minimization purpose.^[5]

Transformation-based compression methods cover a large area, which can loosely be described at the highest level as a signal that is transformed into another form, from which its information content (frequencies, waveforms, peaks, and phenomena in general) can be extracted and effectively returned via an inverse transformation or corresponding procedure to almost equivalent representation compared with the original signal. Compared with direct methods, transformations are more complicated and probably more time consuming, but capable of yielding high compression ratios with tolerance to the decay of information content. In short, a more complicated and sophisticated method may perform better than a simple method.

Several available transformations are applicable to ECG and other biosignal compression, such as discrete fast Fourier, cosine, Walsh, Haar, and Karhunen–Loeve

(principal components) transforms. The Karhunen–Loeve transform is optimal in a theoretical sense, but requires heavy computation. It results in decorrelated transform coefficients, minimizing total entropy. The computationally hard task of its eigenvalue process supports the use of other theoretically suboptimal techniques, in which the basis vectors of a transform are other than the eigenvectors (derived from eigenvalues) of the covariance matrix. Instead, they are based on simple sines and cosines (Fourier and cosine transforms), squares, or other waves or sequences.

Although articles on ECG compression are numerous, we mainly restrict ourselves to a small collection of recent publications. A comprehensive review of the ECG compression of “traditional” methods is provided by Jalaeddine et al.^[3] Chen et al. introduced a method on the basis of pattern recognition using heartbeat segmentation and normalization, two-stage pattern matching with template updating, and residual beat coding as Huffman or run-length coding or vector quantization.^[6] A Max-Lloyd quantizer was developed for the ECG compression of a telemetry system for dolphins and human divers.^[7] Because of the application context, i.e., allowing low computational complexity, the traditional quantizer was employed to code differences of current and predicted samples given by a first-order differential pulse modulation. Ambulatory ECG compression was studied with average beat subtraction and residual differencing.^[8] Fast Fourier transform was adopted by Kulkarni et al.^[9] Vector quantization was used by Mammen and Ramamurthi^[10] and Cárdenas-Barrera and Lorenzo-Ginori.^[11] Miaou and Larn discussed adaptive vector quantization of ECG.^[12] Discrete cosine transform was applied to model heartbeats.^[13] Sun and Tai explored vector quantization for residuals after QRS detection and segmentation of heartbeats.^[14]

Wavelet transforms have been at the forefront of current research. Alesanco segmented an ECG signal into beats, subtracted a template from them, and applied wavelet compression tuned with thresholds as usual.^[15] A filter bank-based algorithm was introduced,^[16] in which a cosine-modulated filter bank was compared with a wavelet packet technique. Tohumoglu and Sezgin utilized embedded zero-tree wavelets.^[17] Wavelet-based vector quantization was considered by Miaou and Chao.^[18] Wavelet-based compression for the purpose of telecardiology was presented.^[19] Signal-dependent wavelet compression was employed to adapt wavelets to a signal according to signal distortion rate determined by the desired compression ratio.^[20] This method was applied to EMG and EEG as well. We tested and compared discrete cosine transform with enumerative coding, a Daubechies-6 wavelet with γ run-length coding or enumerative coding, and a Daubechies-6 wavelet packet with γ run-length coding

or enumerative coding.^[21] The four wavelet compressions were virtually equally good and slightly but clearly better than the discrete cosine transform. For ECG signals recorded at the sampling frequency of 400 Hz and amplitude resolution of 13 bits, average PRD values were approximately 0.5% for the wavelets and 1% for the cosine transform when the compression ratio was 6.5:1. For a compression ratio equal to 13:1, average PRD values were, respectively, about 1.5% and 5.5%.

Neural networks were used for prediction in ECG compression.^[22] A genetic segmentation algorithm for compression was presented.^[23] Two-dimensional coding techniques for ECG signals were investigated by Alexandre et al.^[24] and Lee and Buckley.^[25] A Markov process was used to consider the coding redundancy and intersample redundancy, which yielded better results than Huffman coding.^[26]

It is not straightforward to liken the efficacy of the compression methods considered, because their data materials vary greatly. Most studies used their own signals, but some utilized the MIT-BIH arrhythmia signal database (Massachusetts Institute of Technology, 1992). Compression effectiveness clearly depends on recording parameters. The parameters are sampling frequency, amplitude resolution, and filtering mode, which are usually 100–1000 Hz, 8–16 bits, and lowpass filtering with a cutoff frequency of 30–100 Hz. There are numerous ways to design suitable filters, which may somewhat affect compression results. The use of a high sampling frequency may naturally cause better compression results than a low sampling frequency. This is assumed to be a roughly direct linear relation: by doubling the sampling frequency, the compression ratio can approximately be doubled if everything else is similarly performed in the compression process. Amplitude resolution may follow this property. However, these ideas are simplified approaches, because in reality there is always more or less noise present in signals; even after lowpass filtering, frequency bands of actual information and noise overlap. Increased sampling frequencies and amplitude resolutions also manifest more noise in addition to actual signal phenomena. We must remember that noise is mostly random, with the exception of some systematic types of noise, such as that caused by surrounding electric devices using a main current of 50 or 60 Hz.

The lossy compression literature regarding ECG signals reports compression ratios between 2:1 and 12:1 depending on the methods and types of ECG signals. Lossless compression has seldom been studied with regard to ECG signals. A compression ratio of 2:1 was obtained for ECG signals at a 400-Hz sampling frequency and 13-bit amplitude resolution.^[27] Thus, this value can be taken as the baseline ratio for lossy compression. Compression quality was then evaluated

according to the measures, e.g., PRD, listed at the beginning of the chapter. Nevertheless, these techniques only compare decompressed and original signals in a general sense, because they deal with parallel samples. Such a general view does not express precisely what may happen to amplitudes of QRS peaks or waves in ECG signals. This conception is strongly supported by Blanco-Velasco et al.,^[28] who pointed out that relying merely on PRD or corresponding measures may result in wrong conclusions.

The quality of ECG signal compression statistical measures other than those given above has been little investigated. The statistical measures provide an overall influence of compression on ECG signals, but more precise scrutiny is also affordable. A subjective evaluation of cardiologists was used by Hilton^[29] for ECG signals of the MIT-BIH database. A diagnostic distortion measure was prepared and tested by Zigel et al.^[30] to assess the impact of compression on several medically interesting ECG attributes such as magnitudes of QRS complex and T and P waves. A wavelet-based measure was suggested for the quality assessment of ECG compression.^[31] Kulkarni et al. clarified how many fast Fourier transform coefficients were necessary for the reliable compression validated with differences of ECG attributes like QRS peaks between original and decompressed signals.^[9] Likewise, we explored ECG attributes regarding amplitudes and durations of QRS peaks and that of T waves. For our four wavelet compression modes named above,^[21] we determined that, for instance, for a compression ratio of 13:1, the two T-wave attributes received tolerable average errors of 5–7% evaluated as PRD values. Correspondingly, QRS amplitude errors were 2% and 3% on average, but QRS duration errors were as large as 10–12%. To diminish the latter to 5%, the compression ratio should be reduced to about 4:1. Taking these in-depth evaluations into account, better compression ratios than 4:1 to 8:1 cannot be recommended for ECG signal compression, depending on the compression methods and other factors described.

Compression of EMG

The recording of muscle activity is widely used in clinical neurophysiology, sports medicine and rehabilitation, sleep studies, and even psychophysiology to measure emotions. EMG is best suited to examining the way in which tension develops within a muscle. EMG can reveal onset and offset of activities too small to produce visible movements. Via EMG, muscular force and fatigue can be assessed. EMG recording can be made intramuscularly with needle electrodes or on the skin with surface electrodes. Non-invasive surface myoelectric signals are relatively simple to record.^[32]

EMG recordings are noisy-like signals generated by the complex non-linear system of skeletal muscles. EMG, like regular patterns, is not typical. The amplitude of the surface EMG signal is typically a few hundred microvolts and most of the activity is between 50 and 150 Hz. Hence, 1000 samples/sec is a suitable sampling frequency. Depending on the application area of the EMG signal, different medical parameters can be computed^[33]: spectral parameters such as the mean frequency (MNF) and the median frequency (MDF) of power spectra and amplitude parameters such as the averaged rectified value (ARV) and the root mean square value (RMS).

Different lossy compression methods were widely tested^[34] and results evaluated via compression ratio versus SNR(dB). Differential pulse code modulation, a multipulse coder, a code excited linear predictive coder, discrete cosine transform discarding non-significant components, and wavelet-based subband coding were used. Both needle-electrode and surface-electrode recordings were used for testing. Compression ratios varied up to 13:1. The wavelet transform outperformed other compression methods in the compression ratio range of 5:1 to 9:1.

Wellig et al.^[35] used two modified wavelet-based methods (single-tree and zero-tree wavelet coder) and evaluated results via both compression ratio versus SNR(dB) and percentual distortion PRD versus bitrate. The modified zero-tree wavelet algorithm gives better results than the single-tree wavelet algorithm. Berger et al.^[36] also used wavelet-based methods. Orthogonal wavelet transformations (DWT) with Daubechies wavelets are compared with discrete cosine transformation. In assessments between methods based on compression ratio and energy-based SNR(dB), DWT methods demonstrate better performance than discrete cosine transform methods and Daubechies-4 demonstrates the best performance within DWT methods with a compression ratio of 10:1.

Chan et al. first published a paper in which evaluation was based on the medical parameters MDF and variance.^[37] They used a variation of differential encoding, the adaptive differential pulse code modulation (ADPCM) technique, in a real-time system and achieved compression ratios up to 4:1.

Carotti et al. used a compression method based on the algebraic code excited linear prediction.^[38] The test procedure utilized a fixed 87.3% compression ratio and the quality was assessed in two ways: MSE provided a global indicator of the quality and medical parameters ARV, RMS, MNF, and MDF and spectral skewness calculated for several force levels provided detailed quality indicators. Both simulated and recorded EMG signals were used.

We studied lossy compression of EMG signals^[39,40] with different variations of vector quantization: basic

vector quantization (VQ), mean residual VQ, gain shape VQ, and classified VQ for signal segments. In all our studies the behavior of MNF and MDF parameters played a central role. The fidelity depended on the size of the codebook and segment length. Longer segments presented attenuating lowpass filter effects and shorter segments added segment junction impulse noise. The gain shape method was most advantageous and was able to reach agreeable quality up to a compression ratio of 10:1.

Compression of EOG Recordings

We shed light on biosignal compression by exploring eye movements measured at otoneurological clinics applied to balance investigations. These signals were electro-oculographically recorded with surface electrodes on the canthi of each subject. We recorded many eye movement signals at a sampling frequency of 400 Hz and amplitude resolution of 13 bits. They were filtered with a median-hybrid lowpass filter to suppress noise above about 70 Hz. To study lossless compression of eye movement signals,^[41] the following algorithms were programmed: γ and exponential Golomb universal codes, LZSS, LZW, and LZ77 dictionary methods, Huffman algorithm, arithmetic coding, and adaptive Rice and exponential Golomb coding. All were implemented with the zero-order predictor. For the unfiltered signals the four latter techniques performed best, yielding average compression ratios of 2.2–2.3:1 when MAE and MSE were computed to output reasonably low values. After filtering, the compression ratios of the same signals were 2.6–2.7:1.

We also studied lossy compression methods.^[42] We implemented compression methods on the basis of wavelets, wavelet packets, and discrete cosine transform, similar to that described above.^[21] In addition, Walsh–Hadamard was used. Results of these transform methods were compared with simple pure scalar quantization (levels up to 64) and differential pulse code modulation with the zero-order predictor. For the unfiltered eye movement signals, the latter two simple methods gave low compression ratios of 2.2–3.2:1, with average PRD values no higher than 5%. Using compression ratios as high as 18:1, the wavelet and wavelet packet methods reached average PRD values of less than 4%, the Walsh–Hadamard transform obtained 8%, and the discrete cosine transform produced the best PRD values, at 3%. We continued this research by analyzing precisely how the best methods (discrete cosine transform and wavelet packet) affected eye movement attributes such as amplitudes and durations and maximum velocities and gains derived from the preceding amplitudes and durations.^[43] Fast eye movement types, i.e., saccades and fast phases of nystagmus,

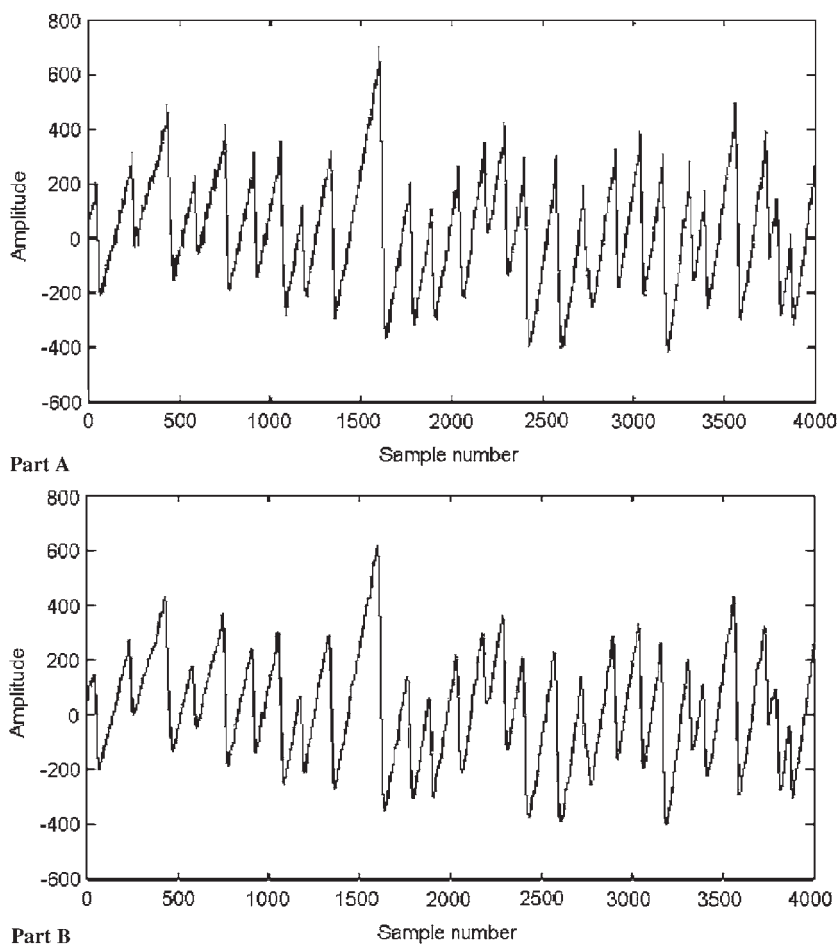

Fig. 1 A 10-sec segment of a fast nystagmus eye movement signal (A) was compressed with the discrete cosine transform using a very high compression ratio of 19:1 and then decompressed (B). Note how, for example, the highest beat at the approximate location of sample 1500 in (B) is lower than that in (A).

were more sensitive to compression than slower eye movement types like tracking eye movements (Fig. 1). In conclusion, we were able to compress and decompress eye movement signals with a compression ratio of 8:1 with reliable analysis results, including average errors of at most 5% for critical attributes of fast eye movements and less for others. Even a compression ratio as high as 18:1 produced average errors below 5% for slow eye movements.

Compression of EEG Including BAEP

EEG is a technique for recording the summation of electrical activity from the scalp as related to cortical activity. It is widely used in neurology, clinical neurophysiology, sleep studies, and even novelty areas like biofeedback and human-computer interfaces. Spontaneous EEG signals are interpreted with rhythms: α activity (about 8–12 Hz), β activity (13 Hz and larger), δ activity (0.5–4 Hz), and θ activity (5–7 Hz), λ waves, K-complex waves, and sleep spindles, which are not defined solely in terms of frequency.^[32]

Counterpoints to spontaneous EEG recordings are evoked responses (ER). ER are time locked to specific

sensory stimulus and response, alternations in cortical or neuronal pathway activity, following that stimulus. BAEP are a sequence of electrical potentials generated in the brainstem and the central auditory pathway after stimulation of the ears with various kinds of sounds. A brief repeated click delivered through earphones is the stimulus most often used. The response can be characterized by a series of peaks within 10 msec after a stimulus onset, e.g., so-called Jewett components (Fig. 2).^[44] BAEP recordings have been used in audio- and otoneurological clinics to evaluate symptoms and dysfunctions related to auditory pathways.

The amplitude of an EEG signal on the scalp is typically only a few microvolts. A common sampling frequency for EEG recordings is between 125 Hz and 200 Hz, although the newest technology allows sampling frequencies up to 1 kHz. A sampling frequency for evoked responses is higher, even 20 kHz for short potentials. Both spontaneous EEG and ER recordings use multichannel setups.

A summary paper^[45] provides a good background to lossless EEG compression techniques. Lossy methods are passed, because clinicians consider exact EEG reconstruction an essential requirement. Widely employed compression algorithms (repetition count and

Fig. 2 A typical 10-msec BAEP signal of a healthy subject with Jewett I–VII components

Huffman coding), VQ, transformation compression, and techniques based on signal predictors (linear predictors, maximum likelihood, and neural networks) were evaluated and presented.^[45] Data compression was represented in percentage format, comparing it with two widely used compression programs: *gzip* (38.8%) and *lharc* (38.9%). Huffman coding resulted in the same compression ratio as *gzip* and *lharc*, 39.5%. Also, the authors used Huffman coding on the compression of prediction error of predictor-based techniques and the difference between the original signal and the processed signal in transformation compression was run with discrete cosine transform. The VQ method includes the use of error vectors to ensure losslessness. The best compression ratios achieved were 59.0% with VQ and 59.7% with linear predictive coding.

A substantial number of EEG compression studies use only lossless methods. Magotra et al. used a two-stage technique: a reversible filter or recursive least-squares lattice filter followed by arithmetic coding.^[46] The best results with reversible (high-pass) filters approached a factor of 2. An instantaneous adaptive bit-assignment algorithm for lossless compression of multichannel EEG was used.^[47] This real-time technique approximated a compression ratio of 2:1. Neural network-based techniques were used.^[48] Lossless compression through neural network is achieved using the net of a predictor and coding the prediction error in a lossless manner with Huffman or arithmetic coding. The best results exceeded a compression ratio of 6:1. Lossless wavelet transformation was utilized for multichannel real-time EEG compression.^[49] The system also performs denoising, spike detection, and sorting. The achieved compression ratio could exceed 10:1.

Cinkler et al. and Memon et al. performed a versatile and thorough comparison study on lossless and near-lossless EEG compression methods.^[50,51] The motivation for near-lossless methods is to improve the bit rate and preserve diagnostic accuracy. For lossless compression, methods include a range from simple dictionary-based approaches to more sophisticated context modeling techniques. For near-lossless compression the authors used a context-based trellis-searched DPCM technique that minimizes the entropy of the quantized prediction error sequence. They proved that dictionary-based techniques do not work

well when applied to EEG signals because of the inherent nondeterministic nature.

In a study by Mitra and Sarbadhikari, an interactive function system- and genetic algorithm-based lossy compression method was used.^[52] The fidelity of the compression process was evaluated with SNR and PSNR and by examining the cross-correlation and the power spectra of original and processed signals. The authors concluded the quality was sufficiently good for clinical purposes with 85% compression. Computationally effective ADPCM subband coding was used.^[53] The authors achieved a compression ratio of 70% with very little distortion.

We studied lossy compression of BAEP signals^[42] with scalar quantization (SQ), DPCM combined with SQ, combinations of discrete cosine transformation (DCT) and successive approximation quantization (SAQ) with different bits per sample (bps) rates, and combinations of wavelet transforms and SAQ with different bps rates. The results were evaluated via MAE of latencies (in milliseconds) and amplitudes between original and processed signals for Jewett components I and V and mean NMRS between the original and processed signals. Results demonstrated that both DCT and SAQ with the bps 1 approach and wavelets and SAQ with the bps 1 approach could keep the fidelity at a compression ratio of 12:1.

CONCLUSIONS

If the biosignal is clinically interpreted via well-defined medical parameters, the use of lossy compression method is easier, because the effect of processing is measurable. Confidence in correct diagnosis remains. A good counterexample is EEG signals: they are visually inspected by human experts and automatically analyzed via signal processing algorithms in the time domain.

Provided that signal compression is carefully accomplished, fairly high compression ratios such as 4–8:1, and even up to 10:1, can be applied to biosignals in the case of lossy compression. However, compression ratios depend on the types of signals. For slow changes in signals, i.e., for low frequencies, even greater compression ratios could be used. The most effective

methods to compress biosignals and yet preserve their main features seem to be methods-based wavelet transforms. In the case of lossless compression, compression ratios are essentially smaller, e.g., 2–3:1. Compression ratios also depend on sampling frequencies, amplitude resolutions, and the filters employed. Thus, no direct comparison between reports of various tests is reasonable. A more general measure than the compression ratio is actually the average number of bps used in a compressed signal, but we only used it secondarily here because the great majority of the literature regarding biosignal compression does not apply it.

Computer-Assisted Surgery

Thomas L. Husted
Timothy J. Broderick

Department of Surgery, University of Cincinnati College of Medicine, Cincinnati, Ohio,
U.S.A.

INTRODUCTION

Computer-assisted surgery has naturally evolved from surgical applications of improved computer and robotic technology within the minimally invasive surgical revolution. Computer-assisted surgery addresses several shortcomings of present day minimally invasive surgery (MIS) and thereby enables an intuitive return to more traditional surgical practice. Currently, computer-assisted surgery is gaining acceptance as the standard of care in several complex surgical procedures. Specific esophageal, cardiac, and pelvic operations have been improved with the use of surgical robots and, with time, the benefit of surgical robots in the performance of many more operations will become apparent. The brightest star in the rapidly expanding horizon of computer-assisted surgery is the use of the robotic platform to integrate digital technology into surgical training, practice, and quality improvement. As the integration of surgery with computers and robots continues to evolve, this article offers a broad overview of the potential of surgical robotics.

EVOLUTION OF COMPUTER-ASSISTED SURGERY

While computer and robotic technologies have continually increased in sophistication, surgeons have only recently begun to exploit these advancements. The latest innovations in surgical practice represent a complex amalgamation of advanced computer technology, robotic engineering, and paradoxically, a return to traditional surgical techniques. “Robot” is derived from the Czech word *robota* and is defined as slave labor.^[1] Therefore, the use of the term “surgical robot” is a misnomer. The correct description is surgical telemanipulator, as surgical robotic systems lack significant or sufficient autonomy in their subservient role. Currently, anatomic variability, difficulty in registering imaging data of deformable tissues in real time, and complex decision-making processes prohibit automation of most operations. For this reason, in the clinical arena, surgical robots function as slaves under

control of their human masters. Despite master–slave functionality, the surgical and lay communities continue to refer to these systems as surgical robots as opposed to telemanipulators. As such, surgical robotics is used interchangeably with computer-assisted surgery throughout the remainder of this article.

The introduction of video technology into surgical practice in the late 1980s resulted in a MIS revolution. One of the initial minimally invasive surgical procedures performed was the laparoscopic cholecystectomy (use of video equipment within the abdominal cavity to remove the gallbladder). During laparoscopic cholecystectomy, the surgeon operates through several small incisions into which are introduced a small diameter video camera and elongated surgical instruments. The laparoscopic cholecystectomy demonstrated significant advantages over traditional open cholecystectomy which included decreased tissue injury, decreased blood loss, decreased postoperative pain, faster recovery, and improved cosmetic result. Surgeons soon realized the benefit of performing a wide variety of procedures through such small incisions. Minimally invasive surgery has grown quickly and broadly to include such areas as laparoscopy (instruments and viewing optics inserted into the abdomen through small incisions), endoscopy (instruments and viewing optics inserted into the body through existing orifices), and angiography (catheters inserted through the skin to diagnose and treat abnormalities within blood vessels).

Minimally invasive surgery has several limitations, and computer-assisted surgery has been developed in part in an attempt to overcome these restrictions. The minimally invasive surgeon does not directly see or feel the tissues on which he or she operates; impaired visual and haptic perception limits the application and performance of MIS procedures. By separating a surgeon’s hands and eyes from the tissues, MIS imposes a conceptually awkward operative presence and requires a steep learning curve to master the techniques. Other limitations of MIS include a decreased range of motion with the elongated instruments, an abdominal wall fulcrum effect that requires counterintuitive hand movements, reliance on two-dimensional (2D) viewing

Table 1 Description of degree of freedom

-
- DOF is an important concept as it defines the number of independent motions of which an instrument is capable. Robotic instruments allow 7 DOF, similar to the human hand holding a surgical instrument. These seven degrees are motion in any of x, y, or z planes as well as any rotation in pitch, yaw, or roll. The seventh degree is achieved with the ability of the instrument to pinch (Fig. 1).
 - How this translates into the operative environment is that the first 2 DOF are the ability to pivot about the entry port in two planes (similar to the human wrist rotating a fist). The next 2 DOF are of the ability to move the instrument in and out of the entry port as well as rolling the instrument (similar to moving the human forearm forward and back plus pronation and supination of the forearm). The next 2 DOF allow for an arbitrary choice of position and orientation of the jaws of the instrument, a freedom not permitted with traditional endoscopic instruments (similar to the human hand being positioned in any orientation). The final degree of freedom is gained from the grasping ability of the instrument (achieved with the human hand holding a surgical instrument.)
-

with a narrow field of vision and instruments which convey only 4 degrees of freedom (DOF) (Table 1). Additionally, elongated instruments magnify hand tremors and reduce tactile feedback.

Computer-assisted surgery has successfully addressed several of these limitations, while ignoring some limitations and creating several limitations of its own. The current commercially available robotic devices have instruments with the same 7 DOF as the surgeon's hand (Table 1). Moreover, the view is stereoscopic [three-dimensional (3D)], the computer is able to filter natural hand tremor, the motion can be scaled to suit the surgeon and operation, and the fulcrum effect is eliminated. As robotic surgery approximates the traditional surgeon-patient interaction experienced in open surgery, many surgeons perceive robotic surgery as more intuitive than laparoscopic surgery.

CURRENT COMPUTER-ASSISTED SURGERY PLATFORMS

At present there are two robotic surgical systems used clinically, although one of these system is no longer manufactured or supported. The research, development, government approval, and production costs of new surgical robot systems are extremely high. In addition, intellectual property issues have stifled collaboration and development. Unfortunately, financial collapse of robotic surgical companies has been the rule rather than the exception.

Zeus System

The Zeus robotic system is a telemanipulator comprised of three robotic arms and a surgeon's console. The surgeon operates two instrument arms and a camera arm from a remotely located console usually positioned in the same room. The robotic arms individually attach

to the operating room table, and the latest version of a 5-mm-diameter-articulating instrument allows 6 DOF.

The surgeon operates the Zeus system based upon a video image that can be provided by a variety of different video systems. The video system most widely utilized with Zeus provides either high quality 2D or lower quality 3D image. Stereoscopic vision is

Fig. 1 A da Vinci intracorporeal operating instrument, illustrating the similar range of motion and DOF with the surgeon's hand.

provided by viewing polarized images specific for each eye on a monitor while wearing polarized glasses. This video system permits magnification to increase surgical precision. The surgeon uses voice commands to direct the robotic arm holding the camera. The voice-controlled robotic arm that positions the video camera was originally marketed as a stand-alone product for laparoscopic surgery as the automated endoscopy system for optimal placement (AESOP). This Robotic platform permits adjustable motion scaling and tremor filtration. Additionally, the Zeus system affords the option to use instruments as small as 3.5 mm diameter. These smaller diameter instruments are well suited to pediatric surgery.

A significant shortcoming of this robotic system was the lack of haptic feedback. Furthermore, the original design did not include articulated instruments and thus did not increase the DOF beyond traditional laparoscopic surgery. Subsequently, an articulated version was introduced, but the man-machine interface was shown to be more difficult to use than the rival commercial system described later in this entry. The performance characteristics of the Zeus system led surgeons to conclude that this computer-assisted device was more similar to laparoscopic surgery than it was to traditional open surgery.^[2] The lack of demonstrable clinical benefit over laparoscopic surgery combined with high system cost limited the adoption of this technology.

A landmark event for the Zeus system came in September 2001. A successful transoceanic operation was performed, demonstrating the feasibility of remote presence surgery or telesurgery.^[3] From a surgeon's console located in New York, U.S.A., surgeons connected via a broadband telecommunication link to a Zeus robotic system in Strasbourg, France, were able to perform a telerobotic laparoscopic cholecystectomy. This expensive, proof of concept operation was successful and the patient recovered nicely. Significantly, the surgeons demonstrated that they could overcome latency—or communication time delay—and effectively remotely operate on patients. Most importantly, they demonstrated the value of the robotic platform as a means to introduce advanced technology—in this case telecommunication technology—into the surgical process. Despite these successes, intellectual property battles and competition within a limited market forced a merger of the two major robot manufacturers and the Zeus system is no longer produced or supported.

da Vinci System

While being similar to Zeus, the da Vinci system is currently produced and supported for clinical use. The

system is made up of two major components. The first is the control console (Fig. 2). The surgeon operates while seated at the control console with his head tilted forward and eyes peering down; the surgeon's hands are in an ergonomic position and inserted in the system's master interface. The optics deliver a high-resolution 3D image through display of stereoscopic images on separate monitors directed to the right and left eyes (Fig. 3). The position of the camera can be adjusted by the surgeon to achieve the optimal view, with the possibility of magnification (2–10X). The control console is located up to 3 m from the patient-side cart positioned at the operating table. The 3 m distance is required secondary to direct cable connections between the components; although, in theory, this distance may be extended or even wirelessly transmitted.

The second component is the patient-side cart, which, in addition to the robotic arm holding the camera, also has three arms for tissue manipulation (Fig. 4). The surgeon can toggle the console to simultaneously control any two of the three instrument arms. The surgeon uses one static instrument arm to assist with exposure and retraction and the remaining two arms to operate. These complex manipulating

Fig. 2 The da Vinci control console at which the operating surgeon is seated.

Fig. 3 Dual channeled camera of the da Vinci surgical robot, delivering stereoscopic vision to the operating surgeon.

arms have cable-driven joints and are able to achieve 7 DOF. The surgeon's hand movements at the console are digitized, sampled >1300 times per second, and sent to the slave components of the manipulators. Any nonpurposeful oscillations (tremor) are filtered. Additionally, motion scaling (up to 5X) can translate comfortable and natural hand motions into precise and delicate instrument movements. The stereoscopic imaging, intuitive interface, and articulated instruments of the da Vinci system permit the use of operative techniques very similar to traditional open techniques. The novice MIS surgeon learns MIS techniques more quickly with use of the da Vinci robot.^[2] Ongoing research has demonstrated that the da Vinci system also can serve as a platform to introduce digital technologies that enable functionality such as virtual reality simulation and telesurgery.

However, da Vinci has limitations when compared to traditional open and MIS surgery. The most significant disadvantage is the cost. A four-armed da Vinci Surgical System currently sells for approximately 1.25 million US dollars. Operating costs include a maintenance contract (10% annually) and the semi-reusable instruments (\$2000 for an individual 10-use instrument). The cost for a noncomplex robotic operation has been factored to be an additional \$2000 as compared to a traditional open operation.^[4] Another disadvantage of the da Vinci is the lack of haptic feedback. The surgeon receives limited haptic feedback from gross interactions such as forceful instrument collision, but fine haptic feedback is not obtained from interaction with soft tissues. When using this robot,

Fig. 4 The da Vinci patient side-cart, illustrating the camera and three manipulation operating arms.

surgeons cannot feel tissues and it can be difficult to diagnose and localize pathology. Proper surgical technique also mandates gentle handling of tissues and sutures. While haptic feedback is currently an area of intense research, the present day system relies on exceptional imaging to provide clues to the motion and strength of the robotic arms as they stress the operative tissues. Fortunately, the possibility of tissue injury and suture breakage from the lack of haptic feedback can be partially compensated for by training. A robotic surgeon quickly learns to use visual cues to compensate for the lack of haptic feedback.

Additional limitations are the complexity of the system. It takes longer to prepare and set-up the da Vinci system than traditional surgical equipment. Use of the da Vinci also requires specialized training for the operating room staff. A result of these limitations is the practical limitation of robotic surgery to large academic medical centers: "Centers of Excellence." In these centers, volume of use allows economy of scale to support computer-assisted surgery with clinical, technical, and financial expertise. Robotic surgery can become more expedient and effective as the surgeons and staff become familiar with the technology and procedures.^[5]

CURRENT USE OF COMPUTER-ASSISTED SURGERY

The historically glacial pace of change in medicine and the conservative nature of surgeons have translated into slow integration of computer-assisted surgery into clinical practice over the last decade. Initial experience has demonstrated safe and effective application of surgical robots in a variety of cardiac, abdominal, and pelvic operations. In addition, recent data suggest that robotic surgery benefits patients who require selective procedures as compared to standard MIS.

Esophageal Surgery

Esophageal surgery has traditionally been technically demanding, owing in part to the location of the esophagus in the posterior thoracic and abdominal cavities. Conventional open esophageal surgery has been performed through the abdomen or the chest and has been associated with significant scarring and prolonged rehabilitation. The development of advanced laparoscopic techniques enabled better visualization and manipulation of the esophagus while decreasing recovery time and improving the outcome of the surgery. However, the application and effectiveness of MIS esophageal surgery is limited by the use of rigid laparoscopic instruments.

The da Vinci system has proven itself useful in esophageal surgery. While a number of robotic esophageal operations have been demonstrated to be safe, one of the most promising applications of the da Vinci system has been the esophageal myotomy (in which the surgeon divides an unusually tight lower esophageal muscle to allow the patient to swallow normally). In a multicenter study, surgeons performed nearly 100 esophageal myotomies with no perforations (the most serious complication) and only minor complications not attributable to the use of the robotic system. The researchers credit this success to the magnified 3D visualization and the enhanced range of motion of the high DOF articulating instruments.^[6-8]

Additionally, robotic application in antireflux surgery has been validated in two controlled clinical trials in which it was found that computer-assisted fundoplication (wrapping the stomach around the lower esophagus to create a valve that will limit heartburn caused by the reflux of stomach contents into the esophagus) to be feasible and safe in a series of 21 and 40 patients, respectively.^[9,10] However, these studies did find that the use of the robot resulted in longer operative time and increased the cost when compared to conventional laparoscopic fundoplication. With more frequent use of the device, robotic operative times approach laparoscopic operative times.

Cardiac Valve Surgery

As early as in 1998, the first truly endoscopic mitral valve repair was performed using a prototype of the da Vinci system.^[11] Evolution of cardiac valve repair has seen the requirement for an assistant's hand eliminated with the totally robotic mitral valve repair using only one-centimeter ports as a routine choice for patients having isolated mitral valve pathology.^[12]

Initial experience with robotic mitral valve repair during Food and Drug Administration (FDA) Phase Two trials showed good success for 112 patients among 10 centers.^[13] Despite a 5.4% reoperation rate, the study demonstrated that multiple surgical teams could perform robotic mitral valve surgery safely early in the development of this technique, thus predicting a flattened early learning curve.^[12]

After receiving FDA approval for mitral valve surgery, the da Vinci system has been used successfully in several series of patients.^[12,14,15] The largest series report 150 robotic mitral valve repairs with one operative death (0.67%) from a medication reaction and no device-related complications. Operative times continued to decrease until 100 operations had been performed, attributed to improved set up and deployment of the robot and closer working relations among the operating room staff. As technology advances, there will be an increased use of surgical robot in such cardiac operations as coronary artery bypass grafting and correction of arrhythmias (irregular heart beat). Innovative robotic and anastomotic technology currently under development will spur the application of MIS in cardiac surgery.

Pelvic Surgery

Removal of the prostate for localized prostate cancer is the most commonly performed robotic operation. A traditional approach to cancer of the prostate requires a large abdominal incision to remove the prostate, but the laparoscopic approach uses several small incisions and provides similar results with regard to tumor resection and side effects. With both of these approaches, however, visualization of and suturing the bladder to the urethra after removal of the prostate remain problematic. The difficulty in carefully dissecting the prostate and avoiding the adjacent neurovascular bundle and sphincter complex has led to life altering side effects: retained tumor, loss of urinary continence, and sexual impotence. Surprisingly, incisional pain and operative discomfort are minor complaints among men undergoing this procedure.^[16]

Computer-assisted surgery has demonstrated significant advantages in removal of the prostate in completeness of tumor resection as well as in decreasing the

side effects of loss of continence and sexual potency. Superior visualization and articulated instruments allow more precise dissection of the prostate from the surrounding nerves and vessels. Improved dissection leads to more complete tumor resection and preservation of the nerves responsible for sexual potency. Additionally, suturing facilitated by the articulated instruments allows a more accurate anastomosis of the urinary bladder and urethral sphincter, preserving urinary continence.^[16]

The largest series to date include over 250 patients who received robotic-assisted radical prostatectomy with less intraoperative blood loss, fewer positive tumor margins, decreased length of stay in hospital, and only a 4% complication rate. Furthermore, sexual potency was preserved in 78% of patients and urinary continence was preserved in 96% patients.^[16,18] Better patient outcomes confirm that surgical robots provide benefit primarily by enabling the surgeon to dissect and suture better in this difficult anatomic region.

Additional Applications

In every facet of surgery where laparoscopy has taken a foothold, the use of surgical robots has been introduced and has been favorably received by some surgeons and patients. Surgeon acceptance originates from excellent 3D visualization, and improved capability to dissect and suture with high DOF instrumentation. A broad range of operations have been successfully performed with the robot including cardiac, thoracic, esophageal, gastric, intestinal, biliary, hepatic, pancreatic, gynecologic, pediatric, and urologic procedures.^[19] Only time will reveal whether robotic systems will evolve sufficiently to permit application in the few remaining specialties such as trauma and transplant surgery.

FUTURE OF COMPUTER-ASSISTED SURGERY

The potential of computer-assisted surgery is nearly limitless. The next step is correction of the current list of shortcomings. Initial improvements will include adaptation of common surgical instrumentation for use with the robot. These instruments include suction-irrigators, multifire clip appliers, and surgical staplers. Improvements will also address the increased length of time required to perform robotic surgery as the result of longer set up and instrument exchange times. Adapting the platform to make it more “plug and play” will decrease the set up and disassembly time. Additionally, multifunction instruments should decrease operative time by decreasing instrument exchange time. Another limitation that hopefully will be

addressed in the near future is the lack of tactile sensation. Providing haptic feedback to the surgeon should improve surgical performance and quality. In the short term, surgeon compensation for the lack of haptics through visual clues is promising.^[17]

Keeping in step with ever quicker and more powerful computer technology, surgical assist devices will decrease their footprint despite increasing capability. Eventually, the ever-increasing portability and capability of modern computers will be translated into new robotic platforms. This development is eagerly awaited by the military and National Aeronautic and Space Administration. Small, portable, deployable robotic systems could serve as a platform to improve surgical treatment in hostile environments. Despite the lack of a local surgeon, remotely guided expert treatment provided at the point of injury could save the life and limbs of soldiers on the battlefield. From a centralized location and out of the direct line-of-fire, a single surgeon could become the battlefield medic for countless combat troops. Networked robotic platforms could become a force multiplier for limited surgical assets. A working model of telesurgery has been attempted using the internet as the communication network. Surgeons in Cincinnati, Ohio have mentored and guided Surgical and Urological Residents in Sunnysvale, California, through robotic procedures using porcine models. While the latency of the internet transmissions was cumbersome, the teams were able to compensate for the delay and the principle was proven possible. As developments in transmission bandwidth are advanced, the latency issue should be overcome.

As we further explore space in the upcoming decades, robust surgical capabilities are required to insure crew health and mission success. While an earth-bound surgeon could successfully operate on a sick astronaut in earth orbit, distance and corresponding communication latency dictate that autonomous surgical care will be required in planetary exploration. Exploration enabling surgical technology is currently being developed. Astronauts on a Martian mission in the upcoming decades could benefit from a robotic platform that enables autonomous surgical care that includes just-in-time virtual reality training, planning, and practice of an operation on patient specific data, and semiautonomous and autonomous function of some surgical tasks.

In the future, robotic technology could facilitate development of intraluminal surgery (operating inside structures such as the intestinal tract or blood vessels). Natural orifice surgery is thought to represent the next frontier of surgery by some surgical thought leaders. Robotics could allow surgeons to perform such “natural orifice” surgery as taking a gallbladder out through the mouth. In the longer term, deployable miniaturized robotics and intraluminal endovascular

therapy could revolutionize minimally invasive therapy of organs such as the heart or brain. Surgeons have begun to explore the use of early versions of such systems.

Future surgical robots will also be used to facilitate surgical training. Similar to the use of virtual reality simulators in the aviation industry, surgical robotic systems will serve as the platform and interface through which surgeons obtain training. Surgical education will move from a time-based apprenticeship to a proficiency-based educational process. Trained surgeons will use such systems to plan and practice complex operations on virtual representations of the patient and thereby optimize surgical performance and patient outcome.

As all the information transmitted via the robot and optical console is digitized, there is incredible potential for integrating patient, surgeon, and procedure related data. Surgeon controlled inputs, endoscopic video, radiologic imaging, and physiologic data are available as digital media. As the digital interface between the surgeon and patient, the robotic system is the information platform that will integrate these data. For example, “augmented reality” that is similar to the onlay of images seen in a fighter pilot’s heads-up display could allow the surgeon to safely remove a tumor within a solid organ by “viewing” the tumor with fused radiological and video images. Aviation’s digital “fly-by-wire” systems are finally reaching medicine as digital “surgery-by-wire” systems.

The ultimate evolution of robotic surgery is a true surgical robot. A database of human anatomy, human physiology, and operative procedures will be combined with improved robotics and artificial intelligence to allow transition of the robot from a slave to a colleague. Its role will broaden from reducing surgical error (establishing and preventing known common errors) to eventually replacing the surgeon as a truly automated robot. Eliminating the surgeon from robotic surgery is considered by many to be science fiction, but the rapid development and application of computers and robotics in the last century suggest this is probably better considered science eventuality.

CONCLUSIONS

The last half century has seen amazing developments in technology and the integration of computers, robotics, and medicine is natural. Current robotic surgical systems deliver two advantages: greatly improved visualization and high DOF instruments that continue to push the application and performance of MIS. Computer-assisted surgery will continue to evolve and further improve surgical quality and safety.

While still suffering from growing pains and limitations, computer-assisted surgery has proven itself useful, safe, and effective in esophageal, cardiac, and urologic surgery. While these operations have little in common anatomically or procedurally, robotic surgery has proven of benefit secondary to improved 3D visualization and dexterity in manipulation of tissues. Increasing collaboration between creative surgeons and engineers will push development and application of robotic surgery and thereby improve surgical practice.

The future of surgery will increasingly incorporate robots, as new devices prove themselves to be safe, easy to operate, capable, and cost effective. Although faced with several issues, robotic surgery will ultimately demonstrate its value with superior safety and performance of a variety of minimally invasive procedures.

Conductive Polymers

Gordon Wallace
Leon Kane-Maguire

Intelligent Polymer Research Institute, University of Wollongong,
Wollongong, New South Wales, Australia

INTRODUCTION

The use of electrical stimuli to control and promote the adhesion of living cells and biomolecular events occurring within such structures is not a new area of study. Previous studies have involved the use of inorganic (metal) or simple organic (carbon) electrodes as conduits for electrical stimulation to facilitate bone regrowth wound healing and nerve regeneration.

Although the mechanism of operation is not clearly understood, it is believed that changes in surface hydrophobicity, interfacial pH, and ionic strength contribute to the overall effects observed. In summary, it is not only the ability to provide a conduit for electron transfer reactions that may be important in biomolecular events but also the ability to induce appropriate interfacial chemistries. This makes the use of inherently conducting polymers (ICPs) as biomaterials a very exciting prospect. In recent years an understanding of the dynamic interfacial chemistry that accompanies the oxidation/reduction of ICPs has been established and is now being used to advantage in designing revolutionary new biomaterials.

WHAT ARE ICPs?

A large array of organic polymeric structures capable of functioning as electronic conductors are now available.^[4,5] To date most attention has been paid to the easily prepared and relatively stable ICP structures based on polypyrroles, polythiophenes, and polyanilines, shown as Chemical Structures 1, 2, and 3 (where A^- = counteranion, n determines the level of doping (normally between 3–4 for PPy and PTh), and m determines the molecular weight)

1
Polypyrrole (PPy)

2

Polythiophene (PTh)

3

Polyaniline (PAN)

These simple ICP materials typically have electrical conductivities in the range of $1\text{--}200\text{ S cm}^{-1}$. For comparison, copper (an excellent conductor) exhibits a conductivity of $5 \times 10^5\text{ S cm}^{-1}$. The simplest ICP materials formed are generally neither solution- nor melt-processable.

However, even within these simple materials the chemistry available is rich and diverse (discussed later). Polypyrrole or polythiophene backbones can be chemically modified to covalently attach groups (R) capable of inducing organic solvent solubility or alkyl sulfonate groups inducing solubility in aqueous media. With polyanilines, attachment of alkyl or alkoxy groups to the aromatic ring can similarly induce organic solvent solubility. Alternatively, the aromatic ring can be directly sulfonated to induce water solubility after polymer synthesis, or sulfonated monomers (shown in Chemical Structure 4) can be used to produce water-soluble sulfonated polyanilines.

4

An alternative, highly flexible, and often facile route to functionalizing ICPs is by varying the nature of the counteranions (A^-) incorporated along the polymer chains. These dopant anions may vary from simple ions

(such as Cl^- or BF_4^-) to complex biochemicals, including proteins, enzymes, antibodies, ATP, DNA, and even a whole living cell (discussed later).

The organic nature of these ICP structures provides a potential molecular-level compatibility with living systems, and the versatile chemistry currently available provides the biomaterials engineer with an array of approaches to the design of appropriate structures for particular bioenvironments. The unique ability of ICPs to conduct charge at charge densities comparable to or greater than conventional electrodes (see Cellular Communications) and the ability to tune the chemistry or biochemistry of these surfaces in situ explains the excitement of materials scientists and engineers working in this field.

SYNTHESIS OF ICPs

ICPs such as polypyrrole, polythiophene, and polyaniline are most commonly prepared via the chemical or electrochemical oxidative polymerization of the respective monomers. However, a range of polymerization techniques has now been developed, including 1) electrochemical polymerization; 2) chemical polymerization; 3) photochemically-initiated polymerization; and 4) enzyme-catalyzed polymerization.

Both aqueous and organic solvents have been widely employed for the synthesis of polypyrroles and polythiophenes, whereas aqueous solutions are typically used for synthesizing polyanilines. A counteranion (A^-) is incorporated during synthesis in order to balance the positive charges that are generated on the developing polymer chains. With pyrrole and thiophene oxidations, the counteranions can be added to the polymerization solutions as neutral salts. However, for polyaniline syntheses, acidic conditions ($\text{pH} \leq 3$) are usually required, and the counteranions are often introduced as the corresponding acids (HA). These acidic conditions are necessary to solubilize the aniline monomers in the aqueous solvent and to ensure the deposition of the electrically conducting emeraldine salt form of the polyaniline.

Depending on the conditions employed, the ICPs can be produced as films, powders, colloids, or water-soluble materials.

Electrochemical Synthesis

Electrochemical syntheses of ICPs are usually carried out in a three-electrode cell, with the polymer products depositing as films on the working electrode (anode), as illustrated in Fig. 1 for polypyrrole syntheses. A variety of working electrodes may be used, including platinum or gold plates, glassy carbon, and reticulated vitreous

Fig. 1

carbon, as well as glass coated with indium-tin-oxide (ITO). Use of the optically transparent ITO-coated glass working electrodes allows the measurement of the absorption (UV-visible) and circular dichroism spectra of the ICP films.

Constant potential (potentiostatic), potentiodynamic (potential cycling), or galvanostatic (constant current) techniques may be employed. The rate-determining step (requiring the highest positive potential) in these electropolymerizations is the oxidation of the monomers to their respective radical cation species (shown in Fig. 2 for pyrrole ($\text{X}=\text{NH}$) and thiophene ($\text{X}=\text{S}$)). The anodic potential required to achieve monomer oxidation increases along the series, pyrrole, aniline, thiophene. Dimeric and higher oligomeric species formed in subsequent steps are considerably easier to oxidize (e.g., bithiophene has an oxidation potential 0.76 lower than thiophene itself). This has given rise to some problems with overoxidation of the polymer products, especially in the case of polythiophenes.^[6] At the potential required to oxidize the thiophene monomer, the polythiophene product becomes overoxidized, causing a deterioration in its physical and chemical properties. An approach that has been successfully employed to overcome this problem is the addition of small amounts of bi- or ter-thiophenes to reduce the polymerization potential.^[7] Defects arising from overoxidation of polyaniline can also occur, which may be associated with crosslinking or the opening of the chains after the formation of a paraquinone.^[8] Therefore, the use of potentiostatic growth conditions is recommended for polyaniline syntheses in order to minimize the likelihood of overoxidation.

An important requirement for the oxidative formation of ICPs with extended π -conjugation and high conductivity is regioselective coupling of the initially

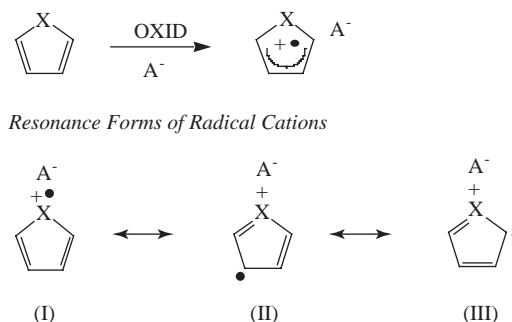

Fig. 2

formed radical cations. For example, this involves coupling of the alpha-sited radicals (III, Fig. 2) for pyrrole and thiophene.

A useful recent advance for the electrochemical synthesis of water-soluble or -dispersible ICPs has been the development of an electrohydrodynamic technique, employing a flow-through electrochemical cell with porous working electrodes such as reticulated vitreous carbon.^[9]

Chemical Polymerizations

The most common oxidants employed in the chemical oxidation approach to ICPs are FeCl_3 and $(\text{NH}_4)_2\text{S}_2\text{O}_8$, which provide Cl^- and $\text{HSO}_4^-/\text{SO}_4^{2-}$, respectively, as the dopant anions (A^-). An attractive feature of chemical polymerization is its experimental simplicity and ready scale-up to produce bulk quantities of ICPs. However, the alternative electrochemical oxidation route has the advantage of greater control over the oxidation potential applied (thereby limiting over-oxidation) and greater flexibility in terms of the anions that can be incorporated from the electrolyte (MA salt or HA acid).

Properties of ICPs such as their morphology, electrical conductivity, molecular weight, and stereoregularity are sensitive to the polymerization conditions employed (as well as to the nature of the monomer and dopant anion).^[10] For example, it has recently been shown from circular dichroism spectral studies that electrochemically and chemically generated PAn.(+)-HCSA polymers (where the CSA^- dopant is the chiral camphorsulfonate anion) possess different conformations/structures for their polyaniline chains.^[11]

Photochemical Polymerizations

Alternative photochemical routes to ICPs have been reported. Using either $[\text{Ru}(\text{bipy})_3]^{2+}$ (bipy = 2,2'-bipyridine) or $[\text{Cu}(\text{dpp})_2]^+$ (dpp = 2,9-diphenyl-1,10-phenanthroline) as the photosensitizer and an appropriate electron acceptor (sacrificial oxidant), pyrrole has been successfully polymerized to polypyrrole by irradiation with visible light.^[12] More recently, Kobayashi et al.^[13] reported the photopolymerization of aniline (in the presence of a small amount of dimer) via the visible irradiation of films containing $[\text{Ru}(\text{bipy})_3]^{2+}$ and methylviologen (MV^{2+}) as sacrificial oxidant. Using appropriate masks, these photochemical routes have been used to generate patterns of ICPs on substrates (with definitions as low as $2\ \mu\text{m}$). We have recently found^[14] that by employing $[\text{CoX}(\text{NH}_3)_5]^{n+}$ ($\text{X} = \text{Cl}$ or H_2O) as the sacrificial oxidant instead of MV^{2+} , aniline can be readily polymerized in the presence of $[\text{Ru}(\text{bipy})_3]^{2+}$ to polyaniline without the need to add

aniline dimer. We have employed the route to produce conducting polyanilines as bulk powders and as polyaniline-impregnated fabrics.

Enzyme-catalyzed Polymerizations

Enzymes such as horseradish peroxidase have seen limited employment as catalysts in the synthesis of polyanilines and polypyrroles.^[15] For example, Samuelson et al.^[16] used polyelectrolytes such as poly(styrenesulfonate) as templates in enzyme-catalyzed polymerizations to induce more structural order during polyaniline growth. Another advantage of this enzyme-catalyzed route is the considerably higher pHs that can be employed, compared to chemical and electrochemical polymerization methods. The mild (pH 4.3) conditions for these HRP-catalyzed syntheses have permitted the use of more delicate biological polyelectrolytes such as DNA as the aligning templates.^[17]

Adding Biological Functionality to ICPs

The presence of substituents such as alkyl, alkoxy, or sulfonate groups on the monomer repeat units of polypyrroles, polythiophenes, and polyanilines can lead to markedly enhanced solubility in organic solvents or water (as discussed earlier). Related modifications of ICPs have improved their biocompatibility and provided them with a range of biological functions. Three approaches have typically been employed to achieve this additional functionality: 1) covalent attachment of specific groups to the CEP backbone (either pre- or postpolymerization); 2) incorporation of specific dopant anions during polymerization; and 3) formation of hybrid ICP/biopolymer composites.

In the first approach, a monomer containing the appropriate biologically active group is synthesized and then oxidized to produce the modified ICP.^[18] For example, the covalent attachment of amino acids to the β -ring position of pyrrole and thiophene monomers prior to their oxidation has provided routes to substituted ICPs, as shown in Chemical Structure 5, ($\text{R} = \text{CH}_2\text{OH}$, CHMe_2 , Ph).^[19] The presence of the chiral substituents is believed to induce a one-handed helical structure on the polymer backbones of the polypyrroles and polythiophenes formed. *N*-substituted polypyrroles possessing main chain chirality, as shown in Chemical Structure 6, have also been generated via the covalent attachment of chiral groups (e.g., sugars) to the N center of the pyrrole monomer prior to polymerization.^[20] In some cases, e.g., the polymers, shown as Chemical Structures 5 and 6, these optically active polypyrroles and polythiophenes have been shown to possess the ability to discriminate between the enantiomers of chiral molecules and ions.

A drawback to this approach to functionalized ICPs is potential difficulties in the synthesis of the initial substituted monomer. Furthermore, subsequent oxidation to the desired polymer may prove difficult due to steric hindrance by the functional group or electronic effects, causing an increase in the oxidation potential of the monomer. A useful development in this regard is the recent report of a route involving the facile modification of preformed polypyrroles containing good leaving groups such as *N*-hydroxysuccinamide.^[21] Using this approach, oligonucleotides have been covalently attached to polypyrrole backbones and their hybridization with appropriate base pairs used for direct hybridization detection and nucleotide sequencing information.^[22] This has led to the development of DNA biochips for biochemical sensing.^[23,24]

Others^[25] have attached 3-*N*-hydroxyphthalimide to polypyrrole or polythiophene backbones to provide facile leaving groups for attachment of antigens. Enzymes (e.g., GOD) have been covalently attached to polypyrroles^[26] or polythiophenes^[27] containing carboxy functional groups. A range of poly(3,4-ethylenedioxythiophene) (PEDOT) derivatives containing hydroxyl groups have been used to covalently attach GOD.^[28] Covalently attached biotin groups have been similarly used to facilitate immobilization of biological entities.^[29,30]

The second approach to adding biological functionality to ICPs avoids the synthetic problems of the first method by entrapping the desired biologically active group as the dopant anion (A^-) or via physical entrapment into the conducting polymer chains during synthesis. These dopants may be relatively small biomolecules such as adenosine triphosphate (ATP). For example, Reynolds et al. have reported the

synthesis of PPy.ATP species.^[31] They showed that the ATP could be released via electrochemical stimulation, suggesting that such ICP-based materials may be useful as ATP supply devices.

Enzymes have also been directly entrapped during the electropolymerization process carried out in the presence of additional electrolyte. This approach has been used to incorporate glucose oxidase,^[32,33] sulfatase,^[34] and urease.^[35] The use of specific monomers (see Chemical Structure 7) to induce a chemical environment to increase trapping efficiency has been demonstrated.^[36] Antibodies have also been incorporated directly into conducting polymers at the point of electrosynthesis. Incorporation of antihuman serum albumin,^[37] an antibody to thaumatin,^[38] and anti-isoproturon^[39] are examples of immunopolymers fabricated using this approach.

A range of polyelectrolyte biological dopant anions (A^-) have also been successfully incorporated into ICP chains. In the synthesis of polyaniline-based biomaterials, the polyelectrolyte provides the additional benefit of binding to and preferentially aligning with the aniline monomers prior to polymerization, thereby facilitating the desired head-to-tail coupling of the monomer units, as described by Samuelson et al. in the template-assisted synthesis of PAn.DNA. In related studies, salmon sperm DNA has been incorporated into polypyrrole chains, producing PPy.DNA membranes that could be employed for electrochemically controlled transport of simple ions.^[40]

Similarly, biologically active polyelectrolytes such as the anticoagulant heparin have been incorporated into polypyrrole^[41] (see Chemical Structure 8.) During redox cycling, these large biological dopants are retained in the polymer film and instead cations are reversibly incorporated from solution. Oligonucleotides have also been employed as dopants in ICPs,^[42] and the hybridization of these oligonucleotides with the appropriate base pair gives rise to useful electronic signals that can be used for diagnostic purposes.

The third approach is related to the second, but the polymeric biological entities are not necessarily entrapped physically or as dopants, but may form blends via interactions such as H-bonding or hydrophobic or dispersion forces. For example, hybrid biomaterials have been reported that combine the biologically active polysaccharide chitosan with both polypyrrole and polyaniline.^[43,44] These were prepared via the oxidation of the pyrrole and aniline monomers, respectively, in the presence of 2% (w/w) chitosan in 2% (v/v) acetic acid.

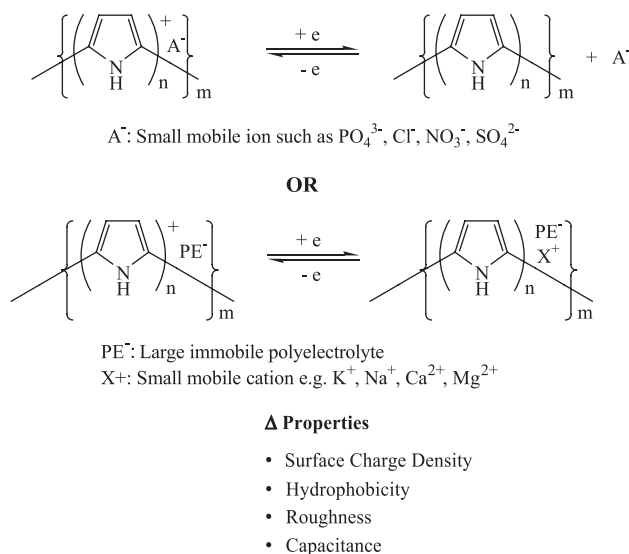

Polypyrrole-collagen composites have been similarly synthesized that contain between 4% and 35% (w/w) of the protein collagen.^[45] The solid products resemble polymer blends and show good electrical conductivity (e.g., 62 and 1.4 S cm⁻¹ for composites containing 4% and 26% collagen, respectively). It has been suggested that these solid hybrid biomaterials may be useful for applications of collagen in areas such as artificial nerves and blood vessels where charge or electrical conductivity are necessary. Using a water-soluble pyrrole derivative (bearing a butanesulfonate substituent) as monomer, related substituted polypyrrole-collagen hybrids have been generated as gels.^[46] As well as thereby achieving improved processability, the collagen was found to be more strongly bound to its ICP partner due to additional possibilities for electrostatic and hydrogen-bonding interactions between the two polymeric components.

ELECTROCHEMICAL PROPERTIES OF ICPs

In addition to their electrical conductivity, a characteristic of ICPs most useful in many bioapplications is their ability to be readily and reversibly switched between different oxidation states, as illustrated in Fig. 3 for polypyrrole. These reversible oxidations/reductions may be achieved by the simple application of an electrical potential. The oxidized and reduced species have markedly different chemical and physical properties. Such redox switching therefore provides an in situ mechanism of control over chemical, electronic, and physical properties (Fig. 3).

Besides providing a route to incorporate specific bioactive dopants (such as antibodies or enzymes) into the ICPs, the choice of dopant is also critical in determining a number of other important factors that govern behavior during electrochemical switching.^[5] These include initial conductivity, morphology, switching potential (i.e., the nature of the electrochemical processes occurring), hydrophobicity/hydrophilicity, water content, and mechanical properties (tensile strength/elongation to break).

It has been shown that the strength of individual molecular interactions occurring on ICPs is determined

(All expected to impact on extracellular protein/cell adhesion)

Fig. 3 Oxidation/reduction of polypyrrole.

by the initial composition (polymer backbone and dopant), and can be altered by electrical stimulation. For example, the ion exchange capacity of polypyrrole is obviously diminished in the reduced state, making it a more hydrophobic material.

Secondary effects (such as reduction of oxygen in solution with a subsequent increase in pH at the polymer solution interface) will also influence the molecular interactions that take place on the polymer surface. With some ICPs (e.g., polyaniline), these secondary (solution) effects are amplified by the fact that the change in oxidation state of the polymer involves release/uptake of protons.

It is presumed that the effect of applied potential (and the subsequent redox state of the polymer) on these primary molecular interactions results in the ability to control the adsorption of larger molecules such as proteins on ICP surfaces.^[47,48]

ICP electrode substrates have also been used to demonstrate the ability to provide in situ control over how some proteins interact with each other. It has been shown^[37,38] that antibody protein molecules can be incorporated directly into ICPs during electrodeposition (shown as the dopant A⁻ in Fig. 1). These antibody-containing materials retain the ability to selectively interact with the target (antigen) molecule. It is particularly interesting that the degree and reversibility of this interaction can be modulated using appropriate electrical stimuli.

CELLULAR COMMUNICATIONS USING ICPs

The earliest report involving cells and inherently conducting polymers was in 1990 by Deshpande and

Hall,^[49] wherein whole banana cells were immobilized into polypyrrole to create a biosensor for detection of dopamine. The enzyme polyphenol oxidase (contained in banana cells) converts dopamine to quinone, involving oxygen consumption that can be monitored to provide the sensing signal. The whole cells were incorporated during electropolymerization (Fig. 1) from a phosphate buffer-containing solution.

Aizawa and coworkers^[50] demonstrated the ability to modulate the acid phosphatase gene expression in *Saccharomyces cerevisiae* (yeast cells) using inherently conducting polymer platforms. Expression of the PHO5 gene, which codes for the major acid phosphatase in *Saccharomyces cerevisiae*, is inversely proportional to the phosphate concentration in the medium, coming out of repression when external phosphate levels fall below ca. 700 μM . The application of appropriate electrical stimuli to conducting polymers in contact with yeast cells was found to modulate the gene's expression via localization of ions. Aizawa et al. also demonstrated the use of the conducting polymer to facilitate electron transfer and hence control enzyme activity (fructose dehydrogenase).^[50]

Yeast cells have also been brought into contact with polypyrrole surfaces by introducing an agarose layer containing the cells.^[51] A change in pH resulting from metabolic activity of the cells caused a change in the electronic properties of the polypyrrole platform, which could then be used to monitor metabolic activity and to detect the presence of metabolic inhibitors (Fig. 4).

A more recent example^[52] of utilizing molecular events within cells as the basis of a biosensor involves the immobilization of red blood cells (RBCs) in polypyrrole (Fig. 5). These studies found that the use of a polyelectrolyte as the dopant (represented by A^- in Fig. 1) resulted in a cell-compatible environment for the red blood cells. The use of a polyelectrolyte essentially produced an electronic hydrogel whose resultant material had water content greater than 90%. The biomolecular event of interest here was the binding of anti-D to the D antigen in the RBC membrane. It was established that in the presence of anti-D, the electronic properties of the polymer containing RBCs changed.

Fig. 4 Factors affecting protein adsorption on ICP surfaces.

Fig. 5 Polypyrrole-containing red blood cells fixed in glutaraldehyde (0.15%)/phosphate buffer immediately postsynthesis. Scale bar 10 μm . (Courtesy of T. Campbell, Ph.D. thesis, University of Wollongong, 1999.)

Others^[53] have electrodeposited polypyrroles with polystyrene sulfonate as dopant onto the gold or indium electrodes of micromachined neural probes. It was found that the impedance of the coated electrode decreased with polymer thickness up to at least approximately 13 μm . Acute in-vivo recording tests were conducted on the cerebellum of a guinea pig, and high-quality neural signals were obtained.

ICPs have also been employed as platforms for cell adhesion and proliferation. Langer and coworkers^[54] showed that the adsorption of extracellular matrix molecules—namely fibronectin—is a critical step in facilitating cell attachment. When aortic endothelial cells were cultured, an oxidized polypyrrole coated with fibronectin cells spread normally and synthesized DNA as expected. When the polymer was reduced (Fig. 3), cell extension and DNA synthesis were inhibited, but cells remained viable. In other studies^[55] it was shown that the presence of vitronectin was critical for adhesion of endothelial cells to heparin-containing polypyrroles. With this conducting polymer platform the involvement of fibronectin was less critical.

In studies^[56] using polystyrene sulfonate as dopant in polypyrrole, the use of electrical stimulation was shown to enhance fibronectin adsorption on the polymer if it was stimulated immediately upon exposure to the protein-containing solutions. Subsequently, adhesion of nerve cells to the substrate and neurite and outgrowth were improved. However, if the electrical stimulation was delayed (e.g., applied after only a two-hour period of exposure to the Fn-containing solution), no increase in protein adsorption was observed.

The adhesion of PC-12 nerve cells to polypyrroles containing polyelectrolytes as dopants has also been demonstrated,^[57] and the incorporation of nerve growth factor and the electrically controlled release of this to trigger cell growth and differentiation has been demonstrated.^[58]

Langer and coworkers^[59] utilized polypyrrole platforms for PC-12 cell adhesion and proliferation. In-vitro studies revealed that neurite excursions from PC-12 cells were more pronounced than on tissue culture polystyrene, and that application of an electrical stimulus resulted in a significant increase in neurite length. In the same work,^[59] polypyrrole discs laminated with PLGA poly(lactic acid-co-glycolic acid) were also implanted into adult male Lewis rats in the subcutaneous and intramuscular regions. It was found that inflammation was not as severe as when PLGA alone was inserted. It was also found that the conducting polymer conduits facilitated sciatic nerve regeneration over a 10 nm gap, with no application of electrical stimulus and no apparent adverse effects observed.

Other workers^[60] have carried out in-vivo studies using polypyrrole tubes to facilitate regrowth of a severed (14 mm gap) sciatic nerve in rats. In other studies^[61] using PC-12 cells, it was shown that the medium nerve outgrowth was 18.1 μm with electrical stimuli applied and 9.5 μm for controls. These latter studies from

200% compared to nonpolymer coated titanium was observed.^[64]

Others^[65] have incorporated the nonapeptide (CDPGYIGSR) during electrodeposition of polypyrrole. This peptide is a laminin fragment proven to mediate in cell attachment and to promote neurite outgrowth. The study showed that neuroblastoma cells grew preferentially on the PPy-polypeptide materials.

Even a biodegradable ICP has recently been devised.^[66] The polymer consists of conducting oligomers of pyrrole and thiophene connected via degradable ester linkages (see Chemical Structure 9). An electrical conductivity on the order of $10^{-4} \text{ S cm}^{-1}$ was obtained. It was verified that the material was biodegradable and was subject to degradation by enzymes normally found in the body. Nerve cells adhered to the new polymer structures, and neurite outgrowth was observed after one day. In-vivo biocompatibility was determined by subcutaneous implantation into rats. Inflammation was mild and similar to that observed with PLGA at 29 days.

9

Langer's group also involved the use of a polyelectrolyte (polystyrene sulfonate) as dopant. Biologically derived polyelectrolytes (shown earlier in Chemical Structure 8, heparin) have also been included as dopants in ICPs used as platforms for cell growth.^[62] The advantage of such dopants is that they not only result in cellularly compatible electronic hydrogels, but also bring additional biofunctionality to the platform. For example, heparin is a powerful anticoagulant and is a component of the extracellular matrix of blood vessels promoting endothelial cell growth. In these studies the growth of endothelial cells was indeed sustained on the conducting polymer composites. The effect of the dopant on cell densities observed during growth was obvious. Accessibility to the incorporated heparin moiety was also shown to be dependent on the electrical stimuli applied to the conducting polymer composite. (Composites remained stable after autoclaving to sterilize.)

Protocols to enable covalent attachment of polypeptides to polypyrrole backbones have been developed.^[63] These techniques were used to attach the polypeptide Cys-Gly-(Arg-Gly-Asp)-Ser-Pro-Lys to polypyrroles coated on titanium or platinum. This polypeptide (RGD) contains the cell adhesive region of fibronectin. Increase in osteoblast cell adhesion on the order of

Zhang and coworkers^[67] recently investigated the biocompatibility of PPy-coated polyester fabrics for possible use as vascular prostheses. The fabrics were coated in two ways: 1) using phosphorylation to bind pyrrole groups to the polyester surface, with subsequent gas-phase polymerization; or 2) through plasma-activated polymerization of pyrrole. No adverse effect on hemolysis or coagulation time was observed. Low cell adhesion for endothelial cells was found for both coated textiles at 24 hours, but no cytotoxicity was detected at 72 or 168 hours. Further confirming biocompatibility the fabrics did not activate polymer phagocytic cells (PMN) (i.e., inflammatory cells).

CONCLUSION

Inherently conducting polymers—polypyrrole in particular—provide an organic environment capable of efficient charge transfer that is compatible with biological systems. The incorporation of enzymes, antibodies, and even whole living cells during polymerization (while retaining molecular biological function) verifies the high degree of compatibility. Further evidence is provided by the ability to culture mammalian cells on polypyrrole

surfaces. The exciting possibilities of controlling cell adhesion and proliferation and the direction of neurite outgrowth have been demonstrated.

The mechanisms underpinning such control are yet to be fully elucidated. Once understood, they will provide a sound basis for the design of new biomaterials based on ICPs. In parallel, the rapid advances in ICP processing and device fabrication are particularly pertinent to the biomaterials engineering field. The ever-expanding ability to generate ICPs in aqueous solution or as aqueous dispersions that can be used to fabricate structures of different sizes, shapes, and configurations is important for the biomaterials engineer.

Such solutions and dispersions can be used to create patterned two-dimensional surfaces using traditional methods such as ink-jet printing, or three-dimensional structures using electrospinning techniques. The development of protocols that result in ordered structures at the nanodomain will also impact the biomaterials field.^[68] This is a rapidly developing field, in which strategies to enable synthesis of nanocomponents of controlled dimensions and the assembly of nanodimensional structures are being developed at an accelerating rate.^[69]

Confocal Microscopy

Denis Semwogerere

Eric R. Weeks

Department of Physics, Emory University, Atlanta, Georgia, U.S.A.

INTRODUCTION

A confocal microscope creates sharp images of a specimen that would otherwise appear blurred when viewed with a conventional microscope. This is achieved by excluding most of the light from the specimen that is not from the microscope's focal plane. The image has less haze and better contrast than that of a conventional microscope and represents a thin cross-section of the specimen. Thus, apart from allowing better observation of fine details it is possible to build three-dimensional (3D) reconstructions of a volume of the specimen by assembling a series of thin slices taken along the vertical axis.

BACKGROUND

Confocal microscopy was pioneered by Marvin Minsky in 1955 while he was a Junior Fellow at Harvard University.^[1] Minsky's invention would perform a point-by-point image construction by focusing a point of light sequentially across a specimen and then collecting some of the returning rays. By illuminating a single point at a time Minsky avoided most of the unwanted scattered light that obscures an image when the entire specimen is illuminated at the same time. Additionally, the light returning from the specimen would pass through a second pinhole aperture that would reject rays that were not directly from the focal point. The remaining "desirable" light rays would then be collected by a photomultiplier and the image gradually reconstructed using a long-persistence screen. To build the image, Minsky scanned the specimen by moving the stage rather than the light rays. This was to avoid the challenge of trying to maintain sensitive alignment of moving optics. Using a 60 Hz solenoid to move the platform vertically and a lower-frequency solenoid to move it horizontally, Minsky managed to obtain a frame rate of approximately one image every 10 sec.

MODERN CONFOCAL MICROSCOPY

Modern confocal microscopes have kept the key elements of Minsky's design: the pinhole apertures and

point-by-point illumination of the specimen. Advances in optics and electronics have been incorporated into current designs and provide improvements in speed, image quality, and storage of the generated images. Although there are a number of different confocal microscope designs, this entry will discuss one general type—the other designs are not markedly different.^[2]

The majority of confocal microscopes image either by reflecting light off the specimen or by stimulating fluorescence from dyes (fluorophores) applied to the specimen. The focus of this entry will be on fluorescence confocal microscopy as it is the mode that is most commonly used in biological applications. The difference between the two techniques is small. There are methods that involve transmission of light through the specimen, but these are much less common.^[3]

Fluorescence

If light is incident on a molecule, it may absorb the light and then emit light of a different color, a process known as fluorescence. At ordinary temperatures most molecules are in their lowest energy state, the ground state. However, they may absorb a photon of light (for example, blue light) that increases their energy causing an electron to jump to a discrete singlet excited state.^[4] In Fig. 1, this is represented by the top black line. Typically, the molecule quickly (within 10^{-8} sec) dissipates some of the absorbed energy through collisions with surrounding molecules causing the electron to drop to a lower energy level (the second black line). If the surrounding molecules are not able to accept the larger energy difference needed to further lower the molecule to its ground state, it may undergo spontaneous emission, thereby losing the remaining energy, by emitting light of a longer wavelength (for example, green light).^[5] Fluorescein is a common fluorophore that acts this way, emitting green light when stimulated with blue excitation light. The wavelengths of the excitation light and the color of the emitted light are material dependent.

Microscopy in the fluorescence mode has several advantages over the reflected or transmitted modes. It can be more sensitive. Often, it is possible to attach fluorescent molecules to specific parts of the specimen,

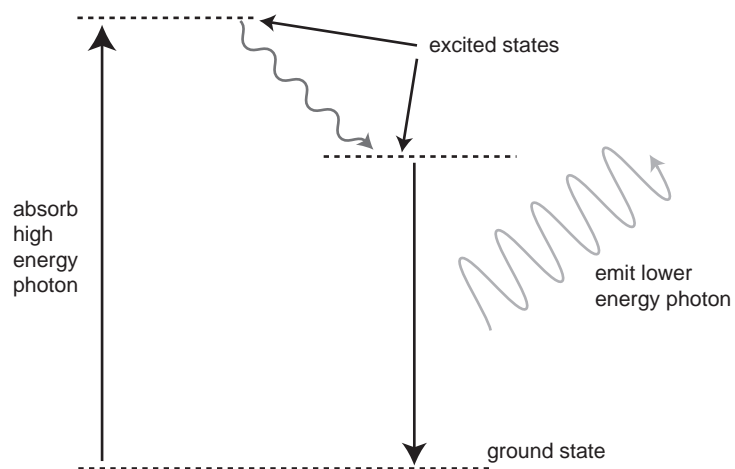

Fig. 1 Mechanism of fluorescence. The horizontal lines indicate quantum energy levels of the molecule. A fluorescent dye molecule is raised to an excited energy state by a high-energy photon. It loses a little energy to other molecules and drops to a lower excited state. It loses the rest of the energy by emitting light of a lower energy.

making them the only visible ones in the microscope and it is also possible to use more than one type of fluorophore.^[6] Thus, by switching the excitation light different parts of the specimen can be distinguished.

FLUORESCENCE MICROSCOPY

In conventional fluorescence microscopy a dyed specimen is illuminated with light of an appropriate wavelength and an image is formed from the resulting fluorescent light. In Fig. 2 the excitation light is blue and the emitted light is green. The microscope uses a dichroic mirror (also called a “dichromatic mirror”) that reflects light shorter than a certain wavelength but transmits light of longer wavelength. Thus, the light from the main source is reflected and passes through the objective to the sample, while the

longer-wavelength light from the fluorescing specimen passes through both the objective and the dichroic mirror. This particular type of fluorescence microscopy, in which the objective used by the illuminating light is also used by the fluorescing light in conjunction with a dichroic mirror, is called epifluorescence. In the case of reflected light microscopy, a beamsplitter is used in place of the dichroic mirror.

CONFOCAL MICROSCOPY

To understand confocal microscopy it is instructive to imagine a pair of lenses that focuses light from the focal point of one lens to the focal point of the other. This is illustrated by the dark blue rays in Fig. 3. The light blue rays represent light from another point in the specimen, which is not at the focal point of the

Fig. 2 Basic setup of a fluorescence microscope. Light from the source is reflected off the dichroic mirror toward the specimen. Returning fluorescence of a longer wavelength is allowed to pass through the dichroic mirror to the eyepiece.

Fig. 3 Rejection of light not incident from the focal plane. All light from the focal point that reaches the screen is allowed through. Light away from the focal point is mostly rejected.

left-hand-side lens. (Note that the colors of the rays are purely for purposes of distinguishing the two sets—they do not represent different wavelengths of light.) Clearly, the image of the light blue point is not at the same location as the image of the dark blue point. (Recall from introductory optics that points do not need to be at the focal point of the lens for the system of lenses to form an image.)

In confocal microscopy, the aim is to see only the image of the dark blue point.^[1] Accordingly, if a screen with a pinhole is placed at the other side of the lens system, then all of the light from the dark point will pass through the pinhole.^a Note that at the location of the screen the light blue point is out of focus. Moreover, most of the light will get blocked by the screen, resulting in an image of the light blue point that is significantly attenuated compared to the image of the dark blue point.

To further reduce the amount of light emanating from “light blue” points, the confocal microscope setup minimizes how much of the specimen is illuminated. Normally, in fluorescence microscopy the entire field of view of the specimen is completely illuminated, making the whole region fluoresce at the same time. Of course, the highest intensity of the excitation light is at the focal point of the lens, but the other parts of the specimen do get some of this light and they do fluoresce. Thus, light at a “dark blue” point may include light that has been scattered from other “light blue” points, thereby obscuring its fluorescence. To reduce this effect the confocal microscope focuses a point of light at the in-focus dark blue point by imaging a pinhole aperture placed in front of the light source.^[1] Thus, the only regions that are illuminated are a cone of light above and below the focal (dark blue) point (Fig. 9A).

Together the confocal microscope’s two pinholes significantly reduce the background haze that is typical

^aActually not all the light from the focal point reaches the pinhole. Some of it is reflected and absorbed by the optics in between.

of a conventional fluorescence image, as shown in Fig. 5. Because the focal point of the objective lens forms an image where the pinhole/screen is, those two points are known as “conjugate points” (or alternatively, the specimen plane and the pinhole/screen are conjugate planes). The pinhole is conjugate to the focal point of the lens, hence the name “confocal” pinhole.

HOW DOES A CONFOCAL MICROSCOPE WORK?

The confocal microscope incorporates the ideas of point-by-point illumination of the specimen and rejection of out-of-focus light.

One drawback with imaging a point onto the specimen is that there are fewer emitted photons to collect at any given instant. Thus, to avoid building a noisy image each point must be illuminated for a long time to collect enough light to make an accurate measurement.^[1] In turn, this increases the length of time needed to create a point-by-point image. The solution is to use a light source of very high intensity, which Minsky did with a zirconium arc lamp. The modern choice is a laser light source, which has the additional benefit of being available in a wide range of wavelengths.

In Fig. 4A the laser provides the intense blue excitation light. The light reflects off a dichroic mirror, which directs it to an assembly of vertically and horizontally scanning mirrors. These motor-driven mirrors scan the laser across the specimen. Recall that Minsky’s invention kept the optics stationary and instead scanned the specimen by moving the stage back and forth in the vertical and horizontal directions. As awkward (and slow) as that method seems it does have among others the following two major advantages:^[7]

- The specimen is everywhere illuminated axially, rather than at different angles as in the case of the scanning mirror configuration, thereby avoiding optical aberrations. Thus, the entire field of view is illuminated uniformly.

Fig. 4 Basic setup of a confocal microscope. Light from the laser is scanned across the specimen by the scanning mirrors. Optical sectioning occurs as the light passes through a pinhole on its way to the detector.

- The field of view can be made larger than that of the static objective by controlling the amplitude of the stage movements.

In Fig. 4 the dye in the specimen is excited by the laser light and fluoresces. The fluorescent (green) light is descanned by the same mirrors that are used to scan the excitation light (blue) from the laser and then passes through the dichroic mirror. Thereafter, it is focused onto the pinhole. The light that makes it through the pinhole is measured by a detector such as a photomultiplier tube.

In confocal microscopy, there is never a complete image of the specimen because at any instant only one point is observed. Thus, for visualization the detector is attached to a computer, which builds up the image

one pixel at a time. For a 512×512 -pixel image this is typically done at a frame rate of 0.1–30 Hz. The large range in frame rates depends on a number of factors, the most important of which will be discussed below.

The image created by the confocal microscope is of a thin planar region of the specimen—an effect referred to as optical sectioning. Out-of-plane unfocused light has been rejected, resulting in a sharper, better-resolved image. Fig. 5 shows an image created with and without optical sectioning.

THREE-DIMENSIONAL VISUALIZATION

The ability of a confocal microscope to create sharp optical sections makes it possible to build 3D

Fig. 5 Images of cells of spirogyra generated with and without optical sectioning. The image in (B) was created using a slit rather than a pinhole for out-of-focus light rejection. Most of the haze associated with the cell walls of the filamentous algae is absent, allowing clearer distinction of the different parts.

renditions of the specimen. Data gathered from a series of optical sections imaged at short and regular intervals along the optical axis are used to create the 3D reconstruction. Software can combine the 2D images to create a 3D rendition. Representing 3D information in a meaningful way out of 2D data is nontrivial, and a number of different schemes have been developed. Fig. 6 shows a 3D reconstruction, from slices of a suspension of 2 μm diameter colloidal particles using “alpha blending”—a technique that combines images by first making each of their individual pixels less or more transparent according to a computed weight called the “alpha” value.^[8] The result is a 3D-like structure.

OTHER CONSIDERATIONS

A confocal microscope, as with every instrument, has some limitations and often compromises must be made to optimize performance. The following is an outline of some of the most important of them.

Resolution

As with conventional microscopy, confocal microscopy has inherent resolution limitations due to diffraction. In the discussion above it is assumed that the point source used produces a point of light on the specimen. In fact it appears in the focal plane as an Airy disk, whose size depends on the wavelength of the light source and the numerical aperture of the objective lens.^[9] (The numerical aperture of a lens is a measure of how well it gathers light.) The graph of Fig. 7B shows a plot of the intensity of light as a function of

Fig. 6 Three-dimensional reconstruction of a series of 2D images of PMMA spheres suspended in a cyclohexylbromide and decalin solution. The image was created using “alpha blending.”

radius of an Airy disk—the image is circularly symmetric, as shown in Fig. 7A.

The Airy disk limits the maximum resolution that can be attained with the confocal microscope—the best resolution is typically about 200 nm. Ideally, the image of a point would just be a single intense point right at radius = 0. However, the finite size of the Airy disk sets the scale for which details can be resolved. According to the Rayleigh criterion, the minimum separation between two Airy disks for which they are distinguishable is equal to their radius. This corresponds to the maximum of one Airy disk superimposed on the minimum of the other.

Resolution along the optical axis is also limited by diffraction effects. As in the lateral direction there is a periodic, but elliptical distribution of intensity in the shape of an Airy disk.^[10]

Pinhole Size

The optical sectioning capability of a confocal microscope derives from having a pinhole to reject out-of-focus light rays. In turn, the strength of the optical sectioning (the rate at which the detected intensity drops off in the axial direction) depends strongly on the size of the pinhole.^[11]

It is tempting to assume that making the pinhole as small as possible is the best choice. However, as the pinhole size is reduced, so too are the number of photons that arrive at the detector from the specimen. This may lead to a reduced signal-to-noise ratio. To offset the weaker signal more fluorescence is needed from the specimen. This usually can be done, to a limit, by raising the intensity of the excitation light. But high intensities can damage the specimen, and in the case of fluorescence, also degrade the fluorophore. Moreover, it has been shown that optical sectioning does not improve considerably with the pinhole size below a limit that approximates the radius of the first zero of the Airy disk.^[2,11] (Note that the study considered imaging in coherent mode; however, the result still qualitatively applies to inherently incoherent confocal fluorescence microscopy.) Thus, a good approximation is to make the pinhole about the size of the Airy disk.

Intensity of Incident Light

An important component of a confocal microscope is the photodetector that captures light from the specimen. In confocal fluorescence imaging the pinhole along with the optics preceding it significantly reduce the intensity of the emission that reaches the detector. Thus, the detector’s sensitivity and noise behavior are vitally important.^[3] The sensitivity is characterized by the quantum efficiency, which, as in any measurement

Fig. 7 Airy disk similar to that of an image of a very small particle. (A) The image is “overexposed” and in reverse color to allow distinction of the faint secondary peak. (B) A graph of the intensity change with radius.

involving quantum interactions, is limited by Poisson statistics.^[12] That is, the accuracy of the measurement is improved by increasing the number of photons arriving at the detector. In practical terms this can be done by averaging data from many frames—which has the drawback of slowing down the effective frame rate of the microscope. Or, it can be done by increasing the intensity of the fluorescence signal.

Fluorescence can be increased by dyeing the specimen with a larger concentration of fluorophore molecules or by raising the intensity of the excitation light. However, each of these methods increases excitation up to some limit. For high fluorophore concentrations, the individual molecules can quench each other.^[5] They may also reduce the amount of fluorescence deep inside the specimen—fluorophores nearest the light source can absorb enough light to significantly reduce the portion available to the rest of the specimen.^[3] Increasing fluorescence by increasing the excitation light intensity leads eventually to saturation of the fluorophore. Higher intensities drive a larger fraction of fluorophore molecules into excited states, which in turn leads to a smaller fraction of ground state molecules. Ultimately, the rate at which fluorophores are excited matches their decay rate, causing ground state depopulation. Fluorescence then ceases to increase with excitation intensity.^[13]

Fluorophores

Among the most important aspects of fluorescence confocal microscopy is the choice of fluorophore. It is

typically influenced by several factors. The fluorophore should tag the correct part of the specimen. It must be sensitive enough for the given excitation wavelength. For living specimens it should not significantly alter the dynamics of the organism; and an extra consideration is the effect of the specimen on the fluorophore—its chemical environment can affect the position of the peaks of the excitation and emission spectra.^[14]

Photobleaching

A major problem with fluorophores is that they fade (irreversibly) when exposed to excitation light (Fig. 8). Although this process is not completely understood, it is believed in some instances to occur when fluorophore molecules react with oxygen and/or oxygen radicals and become nonfluorescent.^[13,15] The reaction can take place after a fluorophore molecule transitions from the singlet excited state to the triplet excited state. Although the fraction of fluorophores that transitions to the triplet state is small, its lifetime is typically much longer than that of the singlet state. This can lead to a significant triplet state fluorophore population and thus to significant photobleaching.^[5]

Several strategies have been developed to reduce the rate of photobleaching.^[5,13] One method is to simply reduce the amount of oxygen that would react with the triplet excited states. This can be done by displacing it using a different gas.^[5] Another method is by the use of free-radical scavengers to reduce the oxygen radicals. Shortening the long lifetime of the triplet excited state has also been shown to be effective.^[16] Other ways

Fig. 8 Dyed suspension of densely packed polymethyl-methacrylate beads with significant photobleaching. The rectangular region near the center faded after about 30 sec of exposure to excitation light.

include using a high numerical aperture lens to collect more fluorescence light and thus use less excitation light.^[17] Also, keeping the magnification as low as is permissible spreads the excitation light over a larger area, thereby reducing the local intensity.

While photobleaching makes fluorescence microscopy more difficult, it is not always undesirable. One technique that takes advantage of it is fluorescence photobleaching recovery (FPR) or fluorescence recovery after photobleaching (FRAP). It involves exposing a small region of the specimen to a short and intense laser beam, which destroys the local fluorescence, and then observing as the fluorescence is recovered by transport of other fluorophore molecules from the surrounding region. Quantities such as the diffusion coefficient of the dyed structures can then be determined.^[18]

LIVING CELLS

Confocal microscopy has been used effectively for the 3D study of dynamics in living cells. However, the imaging of living specimens adds the challenge of maintaining the life and normal function of the organism.^[19] There are of course difficulties involved in preparing the sample for viewing as is the case in conventional microscopy. But on top of that the effect of photodamage on the specimen caused by the focused high-intensity excitation light must be taken into account. This is compounded by the repeated exposure required for tracking the cellular dynamics—a problem that is worsened for 3D data collection.

Fluorescence also introduces the problem of the fluorophore influencing the cell behavior as well as the risk that oxygen molecules reacting with fluorophores in triplet excited states may generate free radicals that damage the cell.^[19]

Despite the challenges, a wide variety of sophisticated fluorophores have been developed to study different aspects of cell biology. They are designed to mark specific parts of the cell interior and often can simply be introduced to the cell wall.^[19] The fluorophore molecules make their way into the cell and attach to the intracellular structures of interest such as the mitochondria and the Golgi apparatus. This is not always the case, however, as some fluorophores must be injected directly into the cell.^[19] Labeling is even applied to the study of “nonphysical” structures of the cell—some fluorophores have been developed for the measurement of dynamic processes such as membrane potentials and ion concentrations.^[5]

Multicolor Fluorescence

To distinguish between small features such as proteins within a cell it is useful to tag them with different fluorophores and image them as separate colors. There are two ways to do this: in one method fluorophores are selected to correspond with the wavelengths of a multiline laser and in the other their response to the same excitation wavelength causes emission at different wavelengths.^[20] In both cases the resulting emission is separated with appropriate filters and directed to different detectors. However, there can be cross talk between channels of the emitted light.^[14] For most of the commonly used fluorophores there is usually some overlap between their emission spectra, making perfect channel separation impossible by filtering alone. To first order this can be corrected by determining the level of overlap of emission of each individual fluorophore into the channels of the other fluorophores and subtracting it out mathematically.

FAST CONFOCAL MICROSCOPY

Most confocal microscopes generate a single image in 0.1–1 sec.^[21] For many dynamic processes this rate may be too slow, particularly if 3D stacks of images are required. Even for a single 2D image, slow frame rates translate into long exposure times of the specimen to intense laser light, which may damage it or cause photobleaching. Two commonly used designs that can capture images at high speed are the Nipkow disk confocal microscope and a confocal microscope that uses an acousto-optic deflector (AOD) for steering the excitation light.

Acousto-Optic Deflector

Speeding up the image acquisition rate can be achieved by making the excitation light beam scan more quickly across the specimen. For most confocal microscopes, the limitation is the galvanometers that move the mirrors back and forth in the characteristic saw-tooth pattern. The usual configuration is a slow vertical scan combined with a rapid scan in the horizontal direction. For 512×512 -pixel images at a frame rate of ~ 30 frames per second the horizontal galvanometer would have to scan at a frequency of approximately $30 \times 512 = 15\text{kHz}$, which is beyond its normal capability of several kilohertz.^[21]

Fast horizontal scans are achieved using an AOD. An AOD is a device that deflects light by creating a diffraction grating out of a crystal using sound waves. The sound waves are high-frequency pressure waves that locally alter the refractive index of the crystal. Thus, when monochromatic light shines through the crystal, it forms sharp fringes at an angle of deflection that depends on the wavelength of the acoustic pressure waves. Rapidly changing the frequency, and hence the wavelength, of the sound waves allows quick and accurate steering.^[22]

The major disadvantage of AODs is that they are wavelength sensitive. That is, different wavelengths experience different degrees of deflection. This presents a problem for fluorescence microscopy because the light from fluorescence has a different wavelength from the excitation light and thus cannot be descanned by the AOD as is done in Fig. 4 with the mirrors. To get around this problem the confocal microscope is designed to descann only along the vertical direction that is controlled by the slow galvanometer and to then collect the light using a slit rather than a pinhole.^[21] The penalty is a reduction in the amount of optical sectioning and a very slight distortion in the image caused by the loss of circular symmetry. Nevertheless, it is possible to obtain high-quality images (Fig. 5B) using slits.^[10] Note that descanning is not a problem for monochromatic reflected light microscopy because the incident and reflected light are of the same wavelength.

Nipkow Disk

An even faster technique is the so-called Nipkow disk microscope. Instead of scanning a single point across the specimen the Nipkow disk microscope builds an image by passing light through a spinning mask of pinholes, thereby simultaneously illuminating many discrete points. In the setup by Xiao, Corle, and Kino the mask is a disk with thousands of pinholes arranged in interleaved spirals.^[23] At any given time only a small

section of the disk with a few hundred pinholes is illuminated. The light travels through the pinholes and onto the specimen and the returning light passes through the same pinholes for optical sectioning. As the disk spins, the entire specimen is covered several times in a single rotation. At a rotation of 40 revolutions per second Xiao, Corle, and Kino were able to generate over 600 frames per second.

The disadvantage of the Nipkow disk microscope is that only a small fraction ($\sim 1\%$) of the illuminating light makes it through the pinholes to the specimen.^[24] While that is not a major problem when operating in reflected light mode, it can lead to a weak signal and poor imaging in fluorescence mode. However, with strong fluorophores an image as good as that of a confocal laser scanning microscope can be obtained.^[24] Increasing transmission would require an increase in pinhole size, which would lead to less effective optical sectioning and xy resolution.

TWO-PHOTON MICROSCOPY

A fast-growing technique that is related to confocal microscopy and also provides excellent optical sectioning is two-photon microscopy. It addresses a fundamental drawback of confocal laser scanning microscopy: that the beam also excites the specimen above and below the focal-plane (Fig. 9A). For each 2D image created using confocal microscopy there is a significant nonimaged portion of the specimen that has been subjected to photobleaching and photodamage. Two-photon microscopy cleverly limits fluorescence to the focal volume while also reducing the average intensity of the excitation light.^[25] The lower amount of photobleaching and photodamage makes it particularly desirable for biological and medical imaging.

Two-photon microscopy is based on a novel method of exciting fluorophore molecules. In confocal microscopy, a single high-energy photon excites a fluorophore molecule while it takes two lower-energy photons absorbed simultaneously to achieve the same result in two-photon microscopy. By itself a single photon cannot be absorbed because it does not have enough energy to excite a fluorophore molecule and thus causes no fluorescence. It must reach the fluorophore molecule within approximately 10^{-16} sec of the arrival of another photon so that together they reach the energy threshold for excitation. Not surprisingly, this simultaneous absorption of light is a very low-probability event at moderate light intensities. To get a sense of how rare it is, a molecule of rhodamine B will absorb a single photon approximately once a second in bright sunlight, but will absorb a two-photon pair once every 10 million years.^[26] Because

Fig. 9 One-photon vs. two-photon emission from a solution of fluorescein. (A) One-photon emission shows strong fluorescence at the waist, but also fluorescence in a cone-like region above and below the focal volume. (B) In two-photon emission fluorescence is limited to the focal volume. (From Ref. [25].)

C

the probability of absorption is proportional to the square of the instantaneous light intensity, lasers that generate very short ($<10^{-12}$ sec) but intense pulses are used.^[26,27] Such lasers can be operated at low average power—typically, five orders of magnitude lower than for confocal microscopy—thereby causing less photo-damage.^[25]

How does the above help in microscopy? The key is that because two-photon excitation events are unlikely at low laser intensities, fluorescence only occurs within the focal volume of the objective where the intensity is highest (Fig. 9B). The hourglass-shaped region of fluorescence characteristic of one-photon excitation fluorescence confocal microscopy is instead a small volume at the focus, which needs no detector pinhole for optical sectioning.^[25,26]

A major advantage of two-photon microscopy is that it is possible to image deeper into a specimen than with confocal microscopy. The reason is that without the pinhole in front of the detector more of the fluorescence signal is collected. This is important because as the observation depth within the specimen is increased, fluorescent light from the focal volume becomes more likely to be scattered. In confocal microscopy, the pinhole will reject that scattered light if its trajectory makes it appear not to originate from the focal plane. To make matters worse, the pinhole may accept out-of-plane fluorescence light that is scattered and appears to come from the focal plane. Together the two effects significantly reduce the image contrast at depths of $\sim 100\ \mu\text{m}$. In two-photon microscopy all fluorescent light is from the focal volume and is thus acceptable. Plus it is much more likely to reach the detector because it does not have to pass through a pinhole.^[26] This arrangement allows imaging deeper than $\sim 400\ \mu\text{m}$.^[25]

Why not avoid the confocal microscope altogether in favor of a two-photon microscope? The main drawback with two-photon microscopy is the challenges associated with the type of laser it needs. Ultrashort pulse

lasers are still very expensive compared with the continuous wave lasers used in confocal microscopy. They are also typically more demanding to set up.^[27] For example, they have to be on the same optical table as the microscope because of difficulties in maintaining the pulse characteristics through an optical fiber. They need a stronger power supply and much more cooling—usually water pumped through it at several gallons per minute.

CONCLUSIONS

A confocal microscope provides a significant imaging improvement over conventional microscopes. It creates sharper, more detailed 2D images, and allows collection of data in three dimensions. In biological applications it is especially useful for measuring dynamic processes. A number of designs have been developed to achieve video-rate confocal microscopy, which enables the capture of short-timescale dynamics.

FURTHER READING

For detailed discussions about most aspects of confocal microscopy the book cited in Ref. [6] is an excellent source. Ref. [25] cites a book that along with providing insight and detail about confocal microscopy also gives plenty of information on two-photon microscopy.

Contact Lenses: Silicone Hydrogels

Paul C. Nicolson

Atlanta, Georgia, U.S.A.

Jürgen Vogt

CIBA Vision Corp., Duluth, Georgia, U.S.A.

INTRODUCTION

The subject of conventional soft hydrogel contact lenses has been covered previously in this encyclopedia.^[1] Further background can be found in the literature.^[2,3] This entry will discuss the exciting new family of contact lenses and the polymers of which they are composed. This new family of lenses, prepared from silicone hydrogels, offers the wearer a more ophthalmically compatible, more comfortable contact lens having a lower risk of adverse events, especially for those wearing lenses extended wear, which means wearing the contact lens continuously day and night for several days, or even weeks. The designations silicone and siloxane are essentially equivalent and can be used interchangeably, with “silicone hydrogel” used as the main terminology in the contact lens industry.

This entry will discuss the structural features of silicone hydrogels as contact lens polymers, including morphology and how innovators in this field have addressed the well-recognized problems of corneal hypoxia caused by contact lens wear and the notorious hydrophobic and lipophilic characteristics of silicone containing polymers.

BIOMATERIALS IN THE OCULAR ENVIRONMENT

The ocular environment places high demands on the performance of contact lenses as biomaterials. Ophthalmic compatibility of a contact lens requires that the lens maintain a stable, continuous tear film for clear vision, is resistant to deposition of tear film components, sustains normal hydration, is permeable to oxygen to maintain normal corneal metabolism, is permeable to ions to maintain movement, and is nonirritating and comfortable. Therefore, the lens must have excellent bulk and surface characteristics, being neither completely hydrophobic nor lipophilic, and must possess the appropriate polymer composition and morphology to be successful. The polymers must also be optically clear and homogeneous and have low modulus for comfort and sufficient mechanical strength for normal handling.

OXYGEN PERMEABILITY

The use of silicone hydrogel materials has been vigorously pursued in contact lens, as well as intraocular lens applications since the late 1970s. As greater understanding of the needs of human cornea for oxygen and for removal of metabolic products was gained, researchers sought materials that would better meet those needs. The cornea has no blood supply, and thus obtains oxygen predominantly from the air. Contact lenses reduce the amount of oxygen reaching the cornea, and thus can cause edema, microcysts, red eyes, and more serious and sight-threatening complications.

The permeability (Dk) of a specific gas through a given material is the product of the diffusivity D times the solubility of that gas in that material. For the diffusion of oxygen through contact lens materials, values of Dk are usually given in units of barrer = 10^{-11} [(cm³ O₂ STP) cm²/(cm³ s (mm Hg))]. The oxygen transmissibility Dk/t for a material of a given thickness is conveniently given in unit of barrer/(0.1 mm) = 10^{-9} [(cm³ O₂ STP)/(s (mm Hg))], thus the numerical value of the Dk of a material in barrer is equal to the same numerical value of a lens of 0.1 mm thickness, a typical value for soft contact lenses.

In conventional hydrogel contact lenses, the water contained in the lens is providing the pathway for oxygen transport through the lens. Thus, the achievement of higher oxygen permeability with hydrogels was first pursued through the development of high-water content (>50%) hydrogels that contained strongly hydrophilic monomers such as *N*-vinylpyrrolidone (NVP) and methacrylic acid (MAA). However, these endeavors soon reached their limit. Pure water has an oxygen permeability (Dk) of about 80 barrer. The revelation that a minimum oxygen transmissibility (Dk/t) of 87 barrer/(0.1 mm) was required for a lens to be worn safely overnight^[4] meant that thin, and thus more oxygen transmissible, designs were necessary in the high-water hydrogels, if they were to approach the required performance level for corneal health. But the use of extreme high water content (>80%) materials would have distinct disadvantages such as poor mechanical properties, difficult handling, difficult manufacture,

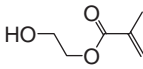

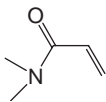

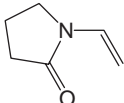

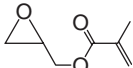

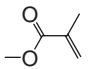

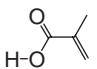

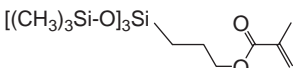

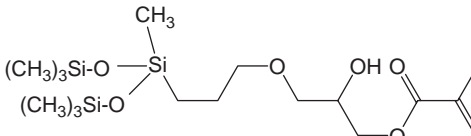

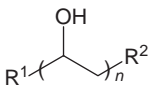

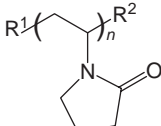

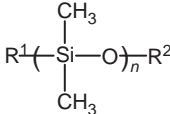

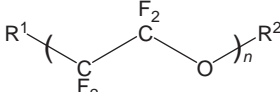

uptake of tear proteins, and care system components. Additionally, the findings of corneal desiccation with those material/design combinations eliminated them from serious consideration for extended wear.

Innovations in contact lens materials designed to better meet the oxygen needs of the eye appeared in 1978 through the efforts of Gaylord,^[5-7] scientists at Dow Corning^[8,9] and others in the rigid gas permeable (RGP) contact lens field. Those innovations included

the use of organosilicon-containing compounds, such as silicone acrylates composed of the tris-(trimethylsiloxy-silyl)-propyl methacrylate (TRIS) (Table1), polydialkyl- and/or diaryl-siloxane, as well as silicone resins. Since the focus of this paper will be soft contact lens materials, nothing further will be said concerning the rigid materials.

First, why is there so much interest in high oxygen permeability (Dk)? The work done by DeCarle^[10] in

England in the early 1970s, fitting contact lenses for overnight (extended wear), created a demand for the convenience that such a modality offered. Wearers were demanding “natural vision,” waking up and seeing the alarm clock, etc. without the hassle of daily lens removal and requisite cleaning and disinfection. However, it wasn't long before the negative physiological effects of the corneal oxygen deprivation created by extended wear of the lenses available at that time began to be realized, first in Europe^[11] in the late 1970s and then in the United States in the mid-1980s.^[12–14] As a result, in the United States in 1987, the Food and Drug Administration rescinded all 30 night extended wear approvals they had originally granted starting in 1981, leaving the only approved extended wear modality to be 6 nights' wear.^[15] However, researchers have shown that 6 nights of corneal compromise caused by wearing conventional hydrogels can still cause problems in some wearers.^[16–18]

A basic physical property of organosilicon-containing polymers is their high permeability to oxygen. The reported Dk of pure dimethylsiloxane is about 600 barrer, which is significantly higher than the 8–20 barrer of the average hydrogel. This high permeability to oxygen comes about by virtue of the bulkiness of the siloxane group generating free volume, and thus having high chain mobility that characterizes such materials, and which is responsible for the high diffusivity of oxygen through silicone-containing materials. The first commercial, soft silicone lens, elastofilcon A, was developed in 1980 by Dow Corning.^[19] This lens was a silicone elastomer containing no water and, as such, the lens manifested the typical rubbery behavior of silicone. These properties required the lenses be fabricated in small diameters, much like RGP lenses, to avoid binding or adhering to the cornea, and therefore were never able to deliver the comfort characteristics of hydrogels. Further, the inherent lipophilicity of the material required the lenses be surface treated. Elastofilcon A lenses are still available today, but only in aphakic powers for children and adults.^[20]

SILICONE HYDROGELS: BACKGROUND

The high oxygen permeability of polysiloxanes, offset by their characteristic hydrophobicity and rubbery character, led investigators to the design of a novel family of materials called silicone hydrogels. It was hypothesized that such materials would offer the softness, wettability and on-eye comfort of a conventional hydrogel, while at the same time providing the higher oxygen transmission required by the cornea.

The siloxane group can be represented structurally as follows: $-\text{Si}(\text{R})_2-\text{O}-$. It is a silicon atom bound to two oxygen atoms and is bonded to two R groups.

In contact lens technology the R's are most often CH_3 (methyl) groups or another siloxane group. However, in the general chemical literature, and in some silicone hydrogel contact lens patents, R can be a wide range of groups. n is the number of times the siloxane group is repeated in a “chain” structure. When n is greater than about five or six, then the term “poly(dimethyl siloxane)” (PDMS) is used to define the unit. Such units are usually linear. In some contact lens materials, n can be as large as 25 and even larger. When the R groups are siloxane groups, the entire unit becomes relatively bulky and space filling. A classic example of such a bulky siloxane can be seen in Gaylord's TRIS siloxane monomer. The end result of incorporating these groups into a polymer network is that significant free volume is created, especially when these units aggregate together to form a domain or phase. It is through this free volume that the relatively small oxygen molecules can pass, or diffuse, freely. The outcome is that the polymer network has a high permeability to oxygen and some other gases. The TRIS monomer, or closely related bulky siloxanes, are very frequently included in silicone hydrogel patents as part of mixtures or formulations of monomers and macromers that, when polymerized, form useful contact lens materials.^[21]

Both the linear PDMS and the bulky TRIS-type siloxanes can be incorporated as a part of a monomer. Again, that means the siloxane group is chemically bonded, through various linking groups, to a carbon-carbon double bond. Therefore the siloxane groups are present, pendant to the carbon backbone of the polymer network in the same fashion as hydrophilic groups are pendant in hydrogels.

In the authors' experience, particularly with linear PDMS groups, the longer the chain (i.e., the larger the value of n) the more efficient is the improvement in oxygen permeability. This is believed to be the case because larger PDMS groups more readily aggregate to form domains or phases within the polymeric material. For any polymer however, there is a practical upper limit to the length of the PDMS due to problems of macromer viscosity, ultimate phase size, compatibility with hydrophilic monomers, and optical clarity of the polymer.

There is a third means of incorporating siloxane groups into a polymer network. Macromeric hydrophiles can also contain silicone. Such combination macromers are disclosed in silicone hydrogel patents,^[22] but by far the most frequently disclosed means of incorporating siloxane into silicone hydrogel contact lens materials is through the use of silicone-only macromers that contain two double bonds. Such macromers are generally linear PDMS-containing, have large values of n (20–25 and higher) and serve two purposes. The first is, of course, to build into the polymer, large siloxane units that can more readily aggregate and form phases

for the facile transport of oxygen. Secondly, such bifunctional macromers serve as crosslinking agents that, in combination with carbon backbone polymer formed by the chains of all the monomers and macromers employed, form the polymer network. The siloxane chains from the macromer in this scenario can be considered “main-chain” siloxanes, in contrast to the pendant siloxanes discussed previously.

Bifunctional macromer silicones, because they form crosslinks within the polymer, tend to increase the modulus or stiffness of the resultant silicone hydrogel. In fact, 3 of the 5 current commercial silicone hydrogel contact lenses, demonstrate moduli or stiffness that is somewhat greater than most conventional hydrogel lenses. This is because those materials, balafilcon A and lotrafilcon A and B, contain silicone macromer crosslinkers.

The modulus of a crosslinked polymer generally increases proportionally with the number of crosslinks present and also decreases with increasing distance between crosslink points (the value of n in the bifunctional macromer) i.e., the points where crosslinking monomers or macromers connect to the carbon backbone. Therefore, longer silicone macromers are preferred when preparing silicone hydrogel materials for contact lenses. Structures of monomers and macromers commonly used in contact lens polymers are shown in Tables 1 and 2, respectively.

The higher modulus characteristic of the early silicone hydrogel polymers prompted polymer development to move in the direction of reduced modulus.^[23] In fact, a recent patent discloses a relationship between the modulus of the polymer, the thickness of the lens, and the clinical incidence of SEALs (superior epithelial arcuate lesion) observed with some lenses.^[24]

EARLY INNOVATIONS

Chang perhaps can be credited with the first patent dealing with polymers composed of siloxane-containing monomers combined with hydrophilic monomers that absorbed small amounts of water for use as contact lens materials.^[25]

Independently, in July and November 1977, and February 1978, CIBA-Geigy (Mueller, Kleiner),^[26] Toyo Contact Lens Company in Japan (Tanaka et al.)^[27] and Bausch and Lomb (Deichert et al.),^[28] respectively, each applied for patents on new families of high Dk polymers for contact lens polymers called silicone hydrogels. All three claimed these hydrophilic siloxane-containing materials as being novel compositions offering high oxygen permeability, thereby overcoming the shortcomings of conventional hydrogels for extended wear. Mueller and Deichert both employed macromers derived from bi- and/or poly-functional, methacrylated polydimethyl siloxane (PDMS) polyols, (main-chain siloxanes) in combination with hydrophilic monomers (NVP, HEMA). Chang^[25] and Tanaka,^[27] on the other hand, used monofunctional bulky siloxane-containing acrylates (pendant siloxanes). More recent patents describe the use of combinations of siloxane macromers with pendant siloxanes (e.g., TRIS). The use of TRIS in combination with linear macromeric PDMS is said to provide silicone hydrogel contact lens polymers with improved mechanical properties, compared to those using macromeric PDMS alone due to reduced crosslink density.^[21]

The macromer technologies disclosed by these early researchers differed largely in the linking groups employed. Condensation chemistries, namely urethane, ester, carbonate, thiourethane, urea, and amide group formation were the principle modes by which the final

Table 2 Macromonomers used in commercial silicone hydrogel contact lenses

Balafilcon A

Lotrafilcon A, B

Galyfilcon A, senofilcon A

structures were assembled. Urethanes were particularly popular in that no byproducts were formed, although they were criticized in some early patents as being undesirable for use in medical devices, particularly contact lenses.^[29] No reasons were given, however.

OTHER OXYGEN PERMEABILITY-ENHANCING MOIETIES

PDMS was not the only oxygen permeability enhancing component pursued for contact lens polymers. Rice at 3M presents novel macromers derived from perfluoropolyethers (PFPE).^[30,31] PFPE moieties function by increasing the oxygen solubility in polymers (the *k* in the *Dk* expression) while siloxanes increase diffusion (the *D* component) of oxygen. The PFPE technology appeared briefly on the contact lens market as fluorofacon A contact lenses, a terpolymer of a PFPE dimethacrylate, methyl methacrylate and NVP.^[32] Their mechanical properties fell somewhere between soft and rigid materials, thus they were termed flexible lenses. Lacking siloxane, fluorofacon A lenses did not manifest lipophilicity and their high *Dk* made them attractive for extended wear. However, because they were neither hard nor soft and they contained significant amounts of fluorochemicals that are relatively expensive, their unique fitting behavior and high cost contributed to their relatively short life on the market.

Building on the concept of permachor,^[33] the relationship of structure to oxygen permeability developed by the packaging industry, other nonsiloxane structures were studied. Patents on polyethylene/polypropylene oxide-containing soft polymers, with and without water, have issued.^[34,35] Although the *Dk* values reported are not as high as comparable materials derived from siloxanes, the materials did outperform conventional hydrogels with regard to oxygen permeability. There have not been any contact lens polymers derived from polyether technology that have been commercialized to our knowledge. To date, there have been no reports of other polymer materials for contact lens application that have the oxygen permeability characteristics of silicones or fluorosilicones.

SILICONE HYDROGELS: MORE RECENT DEVELOPMENTS

Following the earlier silicone hydrogel patents, a great number of patents have been issued in the field of silicone- and later fluorosilicone- and fluoro-hydrogels for contact lenses. The bulk of these patents, emanated from commercial enterprises, i.e., Bausch and Lomb, CIBA Vision, Johnson & Johnson, Vistakon, and a number of Japanese companies, such as Menicon and

Shin-Etsu, reflecting a commercial interest in developing new, better performing silicone and/or fluoro-silicone hydrogel polymers for contact lenses. For example, recent published applications by Alli et al.^[36] and Vanderlaan et al.^[37] disclose the use of a monofunctional macromer (mPDMS) as a means of incorporating siloxane into contact lens polymers. The benefit noted is that use of such monofunctional entities is the achievement of high oxygen permeability without the concurrent increase in modulus that occurs with the previously disclosed bifunctional macromers.

Historically, the use of TRIS in silicone hydrogel contact lens polymers has been very frequently disclosed in patents. A recent patent by McCabe et al. discloses a new, bulky siloxane acrylate monomer called SiGMA (2-propenoic acid, 2-methyl-2-hydroxy-3-[3-[1,3,3,3-tetramethyl-1-[(trimethylsilyloxy)-disiloxanyl]-propoxy] propyl ester).^[38] This new, bulky siloxane monomer shares a degree of similarity to that described by Tanaka, in that hydrophilicity in the form of hydroxyl and ether groups is incorporated in the linkage between the acrylate group and the siloxane group. This monomer is said to improve compatibility between the hydrophiles and siloxanes present in the polymers formed.

SILICONE MACROMER ARCHITECTURE

Silicone hydrogel materials development, based on a review of issued patents and patent applications, has followed different paths. Materials development strategies have included bifunctional macromers in large part, but the architecture of those macromers has been varied significantly. In the simplest form, silicone macromers were assembled by “capping” one mole of a PDMS diol with two moles of methacryloyl chloride. Alternatively, one mole of the PDMS diol could be reacted with exactly two moles of a diisocyanate, followed by consumption of the resulting diisocyanate with HEMA. Simple bi-functional PDMS derivatives such as those described by Deichert and Mueller have been chain extended^[39] in an effort to increase silicone content as well as to reduce modulus in such materials. Chain extension refers to the concept of linking two or more PDMS moieties together in a linear fashion. The starting PDMS units, generally available as α - ω diols or diamines, are reacted with a diisocyanate in a stoichiometry such that the PDMS units are joined to form an oligo-urethane or oligo-urea chain. The commercial availability of a new isocyanate methacrylate, isocyanatoethylmethacrylate (IEM), simplified the construction of methacrylate macromers for biomaterials.

Methacrylate end-capped, segmented hard–soft–hard polyurethane macromers have also been disclosed, offering improved mechanical strength according to the inventors.^[40] The soft segment of the materials contained

PDMS, as well as other long chain, flexible moieties, while the hard segment was composed of short chain diols linked through di-isocyanates such as isophorone di-isocyanate (IPDI).

Construction of methacrylate functional PDMS macromers by first reacting a di-isocyanate with the PDMS diol, followed by a monomer such as HEMA, inevitably lead to some chain extension even when exact stoichiometry was used. Use of IEM reduced the extent of that phenomenon and made macromer structure more controlled and predictable.

As mentioned earlier, monofunctional macromers have appeared more recently in patents. They allow the incorporation of blocks of PDMS to achieve oxygen permeability but they do not tend to increase modulus.

The hydrophobic and lipophilic character of PDMS led many investigators to explore more hydrophilic polysiloxanes. Patents^[22,41,42] report the preparation of amphiphilic segmented A–B–A-type block macromers, where A represents a hydrophilic segment such as polyethylene oxide or polyoxazoline with molecular weights in excess of 400, and B is a hydrophobic PDMS or PFPE segment with molecular weights of 1000–5000 or more. Since these macromers are inherently hydrophilic, homopolymers as well as co- and terpolymers, with other hydrophilic and hydrophobic monomers, have, in general, good soft contact lens bulk material properties, namely phase morphology, water content, and mechanical properties.

Keough et al. make a point in their patent about the troublesome incompatibility of PDMS-containing components and hydrophilic monomers leading to opaque, phase-separated products. To resolve this, they disclose the preparation of PDMS macromers with polar or hydrophilic side-chains.^[43] Such macromers are claimed to have enhanced compatibility with hydrophilic monomers. The hydrophilic side chains incorporate PEO or glycol moieties. An earlier investigator, LeBoeuf, discloses similar hydrophilic side-chain siloxanes, indicating the polymers derived from them are more wettable and that the siloxanes are compatible with hydrophilic monomers.^[44,45] Interestingly, Künzler reported problems of significant instability when the side chains are PEO, in contrast to when glycols are incorporated.^[46] A limited shelf lifetime was also reported by Nicolson in A-B-A lens polymers, where A is PEO. The materials manifested an inadequate shelf life for commercial purposes, whereas when A is poly-oxazoline, no such problems were observed.^[47]

Other strategies followed to obtain compatibility with hydrophilic components included PDMS macromers containing side chains with polar fluoro-substituents ($-\text{CF}_2\text{H}$). A second benefit of reduced lipophilicity, imparted by the fluoro-substituent, is claimed.^[23]

Bambury and Seelye introduced a new family of silicone hydrogel polymers employing vinyl carbonate- and

vinyl carbamate-functionalized compounds.^[48] They described silicone copolymer hydrogel films that contain NVP. Such vinyl-functional macromers co-polymerize more readily with NVP than do acrylate-functional macromers, improving NVP incorporation into the final polymer. Unique cross-linking agents containing both vinyl and acrylate functions have also been disclosed and have been claimed to improve co-polymerization of vinyl and acrylate-functional monomers and macromers.^[49]

SILICONE HYDROGEL COMPOSITION—THE HYDROPHILIC COMPONENTS

The hydrophilic monomers that can be, and are, used in silicone hydrogels are very much the same as those used in conventional hydrogels. However, a review of patents reveals that by far, the predominant hydrophilic monomers where the pendant group is small and contains a nitrogen atom. The monomers NVP and DMA appear much more frequently than does HEMA. This is, at first sight, strange due to the prevalent use of HEMA monomer in conventional hydrogels. What is essential in silicone hydrogel contact lenses, as in any contact lens, of course, is optical clarity. Clarity in polymers is a result of the achievement of a degree of compatibility amongst the hydrophilic- and silicone-containing components. Predominant citation of nitrogen containing hydrophilic monomers in patents suggests compatibility of significant amounts of HEMA with siloxane components, in a hydrogel polymer, may be more difficult to achieve.

A recent U.S. patent application filed by Menicon discloses a new hydrophilic monomer for silicone hydrogel contact lenses.^[50] It is based upon a methacrylate monomer, and the hydrophilic portion is triethyleneglycol, a member of the ether family, and does not contain nitrogen. Menicon does not yet have a commercial silicone hydrogel contact lens. Time will tell whether this new technology will emerge to compete within this exciting field of high *Dk* silicone hydrogels.

The amounts of hydrophilic components used in silicone hydrogels for contact lenses can vary widely, depending upon the amount of water desired in the final polymer. Since the intent of silicone incorporation into hydrogels is to significantly increase oxygen permeability, generally it is desirable to keep water contents as low as practicable to achieve high oxygen permeability, as well as other properties including low modulus, mechanical strength, comfort, etc. From our review of silicone hydrogel patents, hydrophilic component levels fall in the range from about 30% up to about 45% based on dry polymer weight.

Silicone Hydrogel Composition; Hydrophobic Comonomers

One would wonder why there might be a need for additional hydrophobic monomers in polymer systems already rich in hydrophobic siloxane monomers and macromers. Hydrophobic monomers have been described as being “toughening agents,” which improve mechanical strength, often at the expense of oxygen permeability. They also provide an additional means of fine tuning the final physical properties of polymers, impacting water content, refractive index, and modulus. Monomers containing fluorine offer the opportunity of maintaining oxygen permeability, while reducing the lipophilicity imparted by the silicones. The more common hydrophobic comonomers disclosed, however, are simple aliphatic esters of methacrylic acid, such as methyl methacrylate (MMA).

TRANSPORT PROPERTIES OF SILICONE HYDROGELS

It has been known for a long time that some polymeric materials possess excellent oxygen (and other gas) transport properties, one of the most prominent of such materials being silicone. Silicones are hydrophobic and do not take up significant amounts of water. Due to the bulkiness of the silicone polymer backbone ($-\text{Si}(\text{R})_2-\text{O}-$ chains), the amorphous silicone bulk material has a rather large “free volume,” or space, between the polymeric chains, through which small, nonpolar molecules, such as oxygen and nitrogen, can diffuse quite easily. This characteristic of silicone was exploited some 20 years ago in silicone elastomer lenses. But such lenses had profound disadvantages, including nonwettability and the need to fabricate the lenses in small diameters to avoid binding to the cornea. Even after appropriate surface coating or modification, such lenses were not sufficiently comfortable and biocompatible.

Attempts to improve the hydrophilicity and biocompatibility of silicones were numerous, mainly in chemical modification of the silicone polymer backbone with hydrophilic groups and in “blending” siloxane monomers with hydrophilic monomers. The former approach makes the overall polymer more hydrophilic, thus enabling water uptake. This approach, however, essentially fills up the free volume created by the siloxane groups in the polymer with water, rendering this type of silicone hydrogel a conventional homogeneous (mono-phase) hydrogel material. Oxygen molecules must still traverse the polymer network through the water. As discussed earlier, the oxygen permeability of such hydrogels is too low to be suitable as extended wear contact lens materials. The latter approach of blending silicone with hydrogel creates the water-and-oil

immiscibility dilemma: if forced to mix, the system forms an oil-in-water or a water-in-oil emulsion, turning opaque due to scattering of light by the droplets of the dispersed phase in the continuous phase.

Opacification of the biphasic system can be avoided by carefully designing the architecture of the polymer chains, controlling the domain size of the two immiscible polymer phases in such a way as to stay significantly below the wavelength of visible light (i.e., less than 400 nm).

Intensive research work in the authors' laboratories, with blending siloxane-containing and hydrophilic monomers, resulted in numerous optically clear silicone hydrogel lenses. The silicone hydrogel materials had excellent oxygen permeability, however they initially lacked sufficient comfort and movement on eye. This finding caused great consternation for our researchers until an unanticipated discovery concerning contact lens polymer morphology was made.^[51]

POLYMER PHASES IN SILICONE HYDROGELS

Up until 1995, literature and patents were silent on phases in contact lenses. If phases were mentioned, they were mentioned in the context of something that was to be avoided. Phase separation, and the resultant typical opacity associated with it, lies counter to the optical performance required by such products. The major message was that monomers employed in contact lenses should be as compatible as possible to avoid phase separation.

Silicones and most hydrophilic polymers are typically immiscible and when given the opportunity, they will phase separate. Phase separation occurs when cohesive interactions between chemically identical, or similar molecules, are stronger than the adhesive interactions between chemically different molecules. If mutual disliking groups are part of the same molecule, as exist in silicone hydrogel (amphiphilic) crosslinked networks, covalent bonds limit the maximal separation length between the phases. Separation lengths of about 100 nm or less generally lead to microphase separated systems. Such systems then are optically clear, as the phase size is significantly less than the wavelength of light. A recent publication by Gido describes the application of field emission gun scanning transmission electron microscopy (FEGSTEM) to the study of connectivity of domains in microphase separated polymer materials. Results obtained on CIBA Vision's Focus Night & Day lens (Iotrafalcon A) indicate a morphological length of about 20 nm.^[52]

In distinct contrast to prior conceptions about phase separation, Nicolson et al., in a series of comprehensive patents,^[51,53–56] describe the requisite properties for an ophthalmically compatible silicone hydrogel contact

lens, namely the need for separate, and cocontinuous ion/water permeable (ionoperm) hydrogel and oxygen permeable (oxyperm) pathways. An ophthalmically compatible lens is defined as a lens which has high oxygen transmissibility, moves on the eye, and does not accumulate significant lipid or protein deposits, as some of the necessary and desirable features.

The revelation that co-continuous phases or pathways are necessary to achieve an extended wear contact lens came about from the clinical evaluation of a large number of prototype silicone hydrogel-based contact lenses. Although generally, these test lens compositions had properties suitable for a soft extended-wear contact lens, clinical assessment revealed almost all of them ceased movement immediately or shortly after placement on the eye. It became clear that only those compositions manifesting a certain level of ion permeability (e.g, sodium chloride) would move on the eye. Differential scanning calorimetry (DSC) analysis of these compositions clearly showed the presence of separate silicone and hydrogel phases. The presence of micro-phases alone was clearly not sufficient however. The extent and continuity of both phases is key to on-eye movement and the achievement of high-oxygen permeability. A conceptual model illustrating cocontinuous phases is the cellulose sponge, with continuous sponge material and air "phases." Contrast this model with the Styrofoam cup, where the air "phase" is discontinuous.

ION PERMEABILITY AND THE PREDICTION OF ON-EYE MOVEMENT

Domschke et al. in a 1997 ACS presentation,^[57] described the research and the ion permeability test method developed to further elucidate the presence and nature of the continuity of the hydrogel phase. A percolation model can distinguish lens materials that bind on the cornea from those that will move.

Research is currently underway to determine just how water and ion permeability affect the ability of a lens to move on the eye. Tighe has proposed that the permeation of ions through the lens material allows for the maintenance of a hydrodynamic boundary layer between the lens and the cornea to avoid hydrophobic binding.^[58]

There does seem to be a level of ion permeability above which a lens material will move on the eye. The fact that greater permeability does not seem to promote greater movement supports the hydrodynamic boundary level theory and implies that once the layer is formed, its thickness is not critical. A previously accepted theory in the contact lens field is that surface characteristics of a lens will dictate its movement on the eye. It has been our experience that surface treatment of a lens is not enough to overcome the bulk polymers

physical performance with regard to movement. If a particular lens material did not move on the eye, application of various hydrophilic and wettable surfaces did not change the mobility on eye.

ON PHASES

Phase morphology can take many forms. Silicone hydrogels disclosed in patents are random, statistical polymers that can be best represented as isotropic structures, either as a dispersed system (only one phase is continuous) or as interpenetrating cocontinuous polymer phases (two phases continuous throughout the material) similar to an interpenetrating polymer network (IPN). Anisotropic structures typical of highly ordered systems are unlikely to work in contact lens application. One possible exception may be the polymer systems disclosed by Hirt, which may form mesophases.^[43]

A model analysis evaluation of phase-separated systems, using the parameters of phase volume fraction^[59] (Fig. 1), and the connectivity factor ξ ^[60] (Fig. 2), yields models allowing the prediction of oxygen permeability theoretically achievable (Fig. 3). Based on the analogy^[60] between the integrated Fourier law and Ohm's law, such calculations offer two boundary solutions, one representing the serial, the other the parallel arrangements of the conductors. Both solutions are shown in Fig. 3 as solid lines. The broken line in between represents the geometrical mean of those two solutions. As can be deduced from such calculations, a maximum oxygen permeability of 225 barrer could be obtained at 50% volume fraction of the PDMS phase, assuming the ideal connectivity $\xi = 1$. With the less ideal (but more realistic) $\xi = 0.5$, and the same PDMS volume fraction of 50%, the predicted Dk is still as high as 194 barrer. It becomes obvious from such model calculations that a material with dispersed, thus unconnected, oxygen transport phases would fall in its Dk value, far below the requirement for extended wear contact lenses (Fig. 3, right diagram). Furthermore, one can easily conclude from such simple model considerations that a complete phase separation (least amount of interphase regions) is essential for obtaining high oxygen permeabilities. Also, the continuity of the oxygen transport phase should be high ($\xi = 0.5$ to 1) for maintaining $Dk > 100$ barrer at a 50% volume fraction of PDMS. A similar treatment can be used to predict

Fig. 1 Finite element concept two phases, one parameter: volume fraction.

Fig. 2 Refined model showing connectivity.

the ion permeability. From such simple model treatment, one can predict the theoretical maximum oxygen permeability of a perfectly phase-separated (no inter-phase regions) silicone hydrogel contact lens, which will move on the eye. Achievement of such a polymer system is a goal for future polymer research.

The preparation of silicone or fluorosilicone hydrogel polymers with cocontinuous phases, in our experience, can be achieved either by careful design of the macromer architecture or by attention to polymerization kinetics, especially in polymers with relatively low water contents (<30%). Such systems are particularly advantageous for extended-wear contact lens polymers, as the lower water content allows for higher oxygen permeability to be achieved. Amphiphilic segmented macromers or prepolymers,^[43] composed of hydrophilic and hydrophobic segments bonded together, can provide spontaneous cocontinuous products. In polymer systems prepared from all-hydrophobic macromers, copolymerized with hydrophilic monomers such as DMA, inhibition of polymerization by oxygen has been shown to have a dramatic influence on continuous ionophase formation. Using ion permeability as a diagnostic

for the presence of a continuous hydrophilic phase, we have shown that continuity is achieved only when oxygen has been effectively excluded from the polymerizing mixture.^[51] However, differential scanning calorimetric (DSC) analysis shows no difference between two polymers cured in the presence and absence of oxygen, implying that two phases still exist. Apparently, kinetics of the complex competing polymerization reactions are sufficiently different in presence or absence of oxygen to hinder or allow the formation of the cocontinuous phases.^[47]

THE SURFACE OF SILICONE HYDROGEL CONTACT LENS MATERIALS

Neither silicones, nor fluorocarbon compounds, are hydrophilic, and silicones are highly lipophilic, neither of which are advantageous properties for the surface of a contact lens. The need for surfaces with excellent wettability and low deposition potential are well-understood in the contact lens field.^[61]

In soft hydrogel polymers, siloxane and fluorocarbon chain segments have the ability to move in the polymer matrix. Given the opportunity, these groups will migrate toward, and be enriched at, the lens surface in contact with air, which is hydrophobic, because “like-attracts-like,” thus lowering the surface energy. Siloxanes and fluorocarbons, lying at the lens-air interface, are energetically preferred over being immersed in the rather hydrophilic core of the hydrogel lens polymer. Siloxane chain segments in particular, enriched at a lens surface, will have a strong propensity to attract lipids from the tear film during lens wear. Little or no tear film stability, excessive deposits, discomfort, and poor vision would be the result of wearing a soft silicone hydrogel lens that

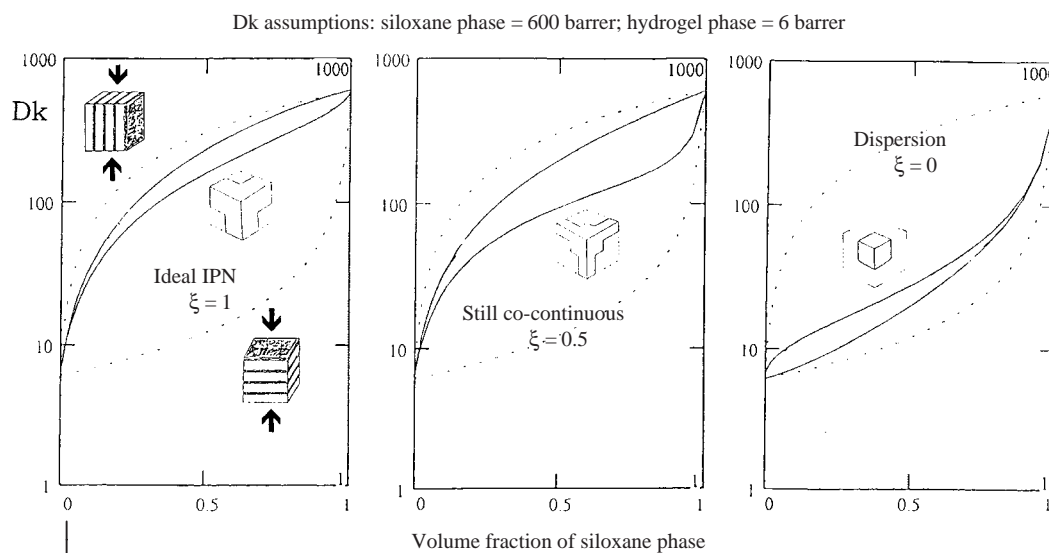

Fig. 3 Oxygen permeability prediction models.

does not employ some means of rendering the surface of the lens more hydrophilic than the core polymer.

This problem can also be considered an opportunity. In the case of conventional hydrogel contact lenses, the surface character of the lens is identical to the character of the core material, which is hydrophilic, and is thus easily wettable by water and tear fluid.

The necessity for some surface masking of the hydrophobic/lipophilic nature of silicone hydrogels and fluorosilicone hydrogels creates the opportunity to separately design and optimize the surface of the lens to achieve maximum ophthalmic compatibility. This is particularly important for silicone hydrogel contact lenses, since they are designed to provide high oxygen throughput to the cornea for overnight and continuous wear.

One of the major challenges facing researchers developing surface treatment technologies is to keep the desired changes at the surface of the lens material and not perturb the bulk properties. That is, one wishes not to alter or compromise the desired properties designed into the core material at the start.

Methods for surface treatment

Numerous methods for achieving and enhancing compatibility of silicone hydrogel contact lenses have been disclosed in patents and reported in literature. All the methods share one primary goal; that is to achieve a lens surface with minimum deposition of lipids and proteins, and one which will support a stable tear film on the anterior surface of the lens during wear.

Before a discussion of various means of surface treatments is offered, it is important to point out that the relative costs of the alternative surface treatment processes must be carefully considered by the researcher and the manufacturer. It is the nature of contact lenses that they are a challenge to handle individually in high volume and high yield. Most surface treatments require additional process steps in the overall manufacture of silicone hydrogel lenses, thus the need for careful cost considerations.

It is interesting to note that a review of early silicone hydrogel contact lens material patents seldom mention the need for surface treatment. It was believed that because the polymers absorbed water, they would be hydrophilic at their surface. During the 1980s, several patents appeared disclosing silicone hydrogel polymer materials that would be wettable. Approaches, including the inclusion of surface-active monomers,^[62] the incorporation of latent hydrophilic monomers, and the use of polar mold materials in the forming of the lens^[63] were disclosed. These very attractive, low cost means of achieving a wettable silicone hydrogel contact lens apparently did not deliver the desired results, as no commercial products ever emerged.

Plasma

Plasmas are considered to be the fourth state of matter. They can be described as a highly reactive gas, capable of reacting with any surface present. The gas is partially ionized, and thus rendered reactive by a strong, high-frequency electric field applied to it. Plasmas most often are employed under reduced pressure. Reactions in the ionized gas, and at the exposed surfaces, depend upon many factors, the most important being the composition of the gas, the electric power applied to the gas plasma reactor, the nature of the surface, the pressure in the reactor, and the frequency of the oscillating electric field. For contact lens silicone containing polymers, many different outcomes can be achieved. They are listed as follows:

1. Coating of the surface by compounds derived from the component(s) of the gas mixture
2. Etching of the surface manifested as a roughening of the surface
3. Ablation of the surface
4. Change of the chemical nature of the elements already present in the surface
5. Creation of chemically active sites on a surface; sites where subsequent reactions can occur

Illustrative examples of each of the above outcomes are:

- a. Coating of the surface with compounds containing carbon, and oxygen when the gas contains oxygen and methane, rendering the surface more hydrophilic.
- b. A loss of surface material and an observed roughening of the surface. The localized rate of etching can vary depending upon the local surface composition. Oxygen gas is often employed to achieve surface etching. A rough surface can be more wettable than a smooth surface. Higher energy electric fields are usually applied.
- c. A loss of surface material much like (b) above. Inert gases such as helium are sometimes used to achieve ablation in combination with higher energy electric fields.
- d. Conversion of chemical groups in the original surface. For example, conversion of hydrocarbon ($-\text{CH}_2-$) groups to $-(\text{C}-\text{OH})-$ or $-(\text{C}=\text{O})-$ containing groups which are more hydrophilic. Oxidizing plasma gases are generally used at higher energy to achieve such chemical conversions.
- e. This is a special case where a plasma reactor can be used to chemically activate the surface of a contact lens material. In this case, the activated lens is retrieved from the reaction chamber and subsequently treated with some hydrophilic chemical entity capable of reacting with that activated

surface. The reaction product is a lens with a more hydrophilic surface.

The authors hasten to point out that in most plasma processes more than one of the above a–e events occurs. For example, some change in the chemical nature of the substrate lens material may occur while a coating is being deposited.

The specific chemical reactions that take place in a plasma reactor are in most cases very complex and are not easily defined or characterized. It is up to the researcher to assure oneself that what has been achieved is safe, non-toxic, stable, durable, and reproducible. One of the particular advantages of plasma-based processes is that they are very reproducible when conditions in the reactor are maintained constant, the reactor is well maintained, and that the lens material being fed into the reactor is itself reproducible and constant.

While plasma systems that are appropriate for the high production volumes in commercial contact lens manufacturing require large initial capital investment, particularly when they are automated, the cost of operating the systems over time, both in dollars and in environmental costs, are competitive with other processes.

Chemical Coatings

In the patent literature, manufacturers and researchers have disclosed many methods of applying coatings to silicone hydrogel surfaces. One such process includes chemically linking a preformed hydrophilic polymer, for example poly-HEMA or PEG, to the surface using a class of chemical reagents known as carbodiimides.^[64] The preformed hydrophilic polymer can be applied to the lens substrate using methods such as lens immersion in a solution of the polymer, spraying, spin-coating etc. In some cases, patents disclose the preparation of unique hydrophilic polymers specifically designed by the researcher to deliver a desired surface quality.^[65]

Another method disclosed involves sequential adsorption onto the lens surface alternating cationic and anionic hydrophilic polymers.^[66] This is achieved by immersion of the lens into a series of solutions of hydrophilic polymers. Each polymer solution in the series bears opposite charges. That is, the first solution would be of an anionic polymer, the second would contain a cationic polymer, and so on. This process is known as the layer-by-layer method.

A third method of applying a preformed hydrophilic polymer is a method generally known as transfer grafting. In this procedure, the preformed polymer is applied to interior surfaces of the plastic molds used to form the lens. This application requires great care that the entire forming surfaces of the molds are uniformly coated.^[67] Then the monomer mixture that is to be

polymerized into the lens core is filled into the coated mold. The mold halves are brought together and polymerization commenced. As the lens polymer is formed in the coated mold, the preformed hydrophilic polymer on the mold surfaces is incorporated onto the surface of the formed lens.

A second general class of chemical coatings involves the initiation and growth of a new hydrophilic polymer directly from the surface of the substrate silicone hydrogel lens. This process, known as surface grafting, is challenging in that penetration of the hydrophilic monomers into the core of the lens substrate is difficult to control. If such penetration occurs, the properties and dimensions of the substrate silicone hydrogel can be significantly altered.

Surface Treatment from within the Core

A recent patent granted to J&J discloses a method of adsorption of a hydrophilic polymer from within the core lens that has been preloaded with the hydrophilic polymer.^[68] In this particular disclosure, an “internal wetting agent,” high molecular weight PVP, is incorporated into the initial blend or formulation of monomers used for the lens fabrication. The formulation, or blend, is polymerized, however the PVP may not be bonded or incorporated into the network silicone hydrogel formed. Rather the PVP may be “entangled” in the network, forming a kind of interpenetrating polymer network (IPN). It is suggested by the inventors that when the lens polymer is slowly cured, hydrated, and packaged in saline, the PVP may be able to migrate in the cross-linked network of the silicone hydrogel and adsorb onto the lens surface and provide wettability.^[68] A commercial conventional hydrogel, vifilcon A, also contains preformed PVP. Those lenses are known for their very slippery surface and that is due to the same phenomenon, that is, PVP migrating to the lens surface.

One can appreciate the economic attractiveness of such a treatment process from within the lens core. No additional processing steps for surface treatment are required.

In summary, as of today, silicone hydrogels require some surface treatment. It remains a major goal, to develop an inherently wettable silicone hydrogel polymer having high oxygen permeability.

CURRENT COMMERCIAL SILICONE HYDROGEL CONTACT LENSES

There are five commercial silicone hydrogel contact lenses available on the international market today. They are lotrafilcon A, as FOCUS Night&Day™ from CIBA Vision, balafilcon A as PureVision™ from Bausch and

Table 3 Commercial siloxane hydrogel contact lenses

Lomb, galyfilcon A as Acuvue Advance™ from Johnson & Johnson Vision Care, and most recently, lotrafilcon B as O₂Optix™ and senofilcon A as OASYS™ from CIBA Vision and Johnson & Johnson Vision Care, respectively. Some of the properties of these four products are listed in Table 3.

While the exact compositions of the core polymers and surfaces of these lenses are proprietary, general information is available. Patent disclosures offer additional insight.

Lotrafilcon A—the Core Polymer

This material has the highest oxygen permeability of the five materials, due likely, at least in part, to the lowest water content. It is reported to be composed of a fluorosiloxane difunctional macromer, DMA and TRIS. The difunctional macromer serves as a crosslinker in the polymer, thus the relatively high reported modulus. The polymer morphology of lotrafilcon A is reported to be biphasic, having fluoro-silicone rich pathways extending throughout the material, allowing facile transport of oxygen. The second phase is then hydrophilic and is also extending throughout the material.^[69] The hydrophilic phase allows the transport of ions and water from surface to surface, allowing for movement of the lens on the eye.

Balafilcon A—the Core Polymer

The patents claimed to cover this material disclose a different polymer system known as vinyl carbamate and vinyl carbonate polymers. It is sufficient to say here that

the monomers used to form vinyl polymers have carbon-carbon double bonds that are linked differently to the pendant groups than most all other monomers used in contact lens materials. Almost all other contact lens polymers are formed from acrylate carbon-carbon double bond containing monomers. A recent U.S. patent granted to B&L describes balafilcon A as containing a TRIS-like monomer, NVP, a bifunctional siloxane monomer and an amino acid derived hydrophilic monomer.^[65] This last ingredient is responsible for the classification of balafilcon A in FDA group III, namely as a low water, ionic polymer. Note the higher modulus of this material, again due to the siloxane crosslinking macromer. Balafilcon A has been reported to be a homogeneous polymer material.^[70] However, the high reported water permeability (twice the value of poly-HEMA) and the high *Dk* would tend to argue otherwise. Such high permeabilities would not be anticipated for a homogeneous silicone hydrogel. It is oxygen transport through the above described silicone phase which allows the attainment of high permeability.^[3]

Galyfilcon A—the Core Polymer^[71]

The polymer is composed of the monomer identified as SiGMA. Recent patents state SiGMA improves the compatibility of this monomer with hydrophilic monomers and the high molecular weight PVP and provides improved mechanical properties of the final polymer.^[38] The other monomers present include a monofunctional silicone macromer, DMA, HEMA and a crosslinker, ethyleneglycol dimethacrylate (EGDMA). The PVP is stated to be the “internal wetting agent” (termed

HYDRACLEAR™ in promotional material from J&J responsible for the wettability of the lens. Note the silicone macromer is monofunctional. This may be the primary reason why the galyfilcon A lens has a lower modulus than the other materials. No reports or literature have surfaced concerning the phase morphology of galyfilcon A.

Lotrafilcon B—the Core Polymer

Since this polymer shares the same generic name with lotrafilcon A, having only a different suffix, one can assume the same qualitative composition for both materials. The “B” indicates the materials differ in the amounts of the components present. The lower modulus measured on lotrafilcon B is a strong indication the amount of difunctional macromer in this material is less than that in lotrafilcon A. Because the macromer is hydrophobic, the lesser amount present has the predictable effect of higher water content (Table 3). The biphasic morphology is also anticipated to be present.

Senofilcon A—the Core Polymer^[72]

This is the newest silicone hydrogel-based contact lens to come to the market. The qualitative composition is identical to galyfilcon A, with the exception that the crosslinker is changed from EGDMA to the longer chain TEGDMA (tetra(ethyleneglycol) dimethacrylate), likely rendering the polymer slightly softer.

FOCUS Night&Day™ and O₂Optix™—the Surface

The surface applied to lotrafilcon A and lotrafilcon B to make FOCUS Night&Day™ and O₂Optix™, respectively, is reported to be a plasma-derived coating covalently and permanently bound to the lens polymer substrate.^[73] This process and outcome would fit best under subsection (a), under Plasma, above. Published images of the surface from atomic force microscopic (AFM) analysis reveal the surface to be smooth and homogeneous. Only insignificant scratches originating from tool fabrication are visible. The surface is reported to be low depositing.

PureVision™—the Surface

The surface of balafilcon A core material lenses is reported to be the result of partial plasma oxidation of the substrate polymer siloxanes to silicate. Silicate materials are hydrophilic. This process would be best described as falling under subsection (d), under Plasma, above. Published images and a patent clearly show the PureVision™ lens surface to be a surface of fragmented glassy islands.

Wettability is reported to be achieved as water “bridges over” the fissures between the glassy islands.^[73] As mentioned above under the plasma discussion, the plasma processes are usually carried out under partial vacuum; therefore, the lens is dry when coated. Perhaps the fissures develop as a result of the expansion of the substrate hydrogel as it swells with water to equilibrium.

Acuvue Advance™ and OASYS™, the Surface^[38]

The surface is enriched in PVP polymer by migration from within the core and adsorption on the lens surface.

CONCLUSION

There have been many exciting new innovations in the field of contact lens materials. The proliferation of these new silicone hydrogel products are likely only the beginning of a new generation of lenses that may render obsolete conventional hydrogels as technological advances continue to evolve. A major area of research activity, based on patents, involves lenses that diminish or eliminate bacterial growth on lens surfaces. Should these efforts prove successful, a greater margin of safety will be enjoyed by the contact lens wearer.

Control of Movement

Dejan B. Popović

Department of Health Science and Technology, Aalborg University, Aalborg, Denmark,
and Faculty of Electrical Engineering, University of Belgrade, Belgrade, Serbia

INTRODUCTION

The most remarkable attribute of movement is how easy it is. It is only when we face a sensory-motor disability that we are reminded of the problems associated with movement control with which our nervous systems copes so uncomplainingly. This becomes even more of a problem when we are faced with the task of designing an assistive system that would allow a disabled human to function like an able-bodied person in everyday activities. The biological control developed through the process of self-organization is impressive. This biological control is capable of encompassing the redundancy and richness of the anatomy. The basic concept presented here is that man-made control has to mimic as well as integrate into the biological control. The man-made control of movement should maximize the utilization of preserved sensory-motor mechanisms. The control has to consider the changes that have occurred to the sensory-motor systems as a result of a disability. The command interface between the biological and man-made control must be simple and intuitive, possibly at the subconscious level. The man-made control that we are describing here is based on the current understanding of life sciences and the technology that is available.

To learn more about the topics in this entry we recommend the book *Control of Movement for the Physically Disabled*.^[1] To learn in depth about neural control we suggest the book *Principles of Neural Science*.^[2] The biomechanics and motor control details can be found in *Biomechanics and Neural Control of Posture and Movement*.^[3]

BIOLOGICAL CONTROL OF MOVEMENT

The motor system in humans comprises three inter-related anatomical systems: the skeletal system; the muscle system, which supplies the power to move the skeleton; and the nervous system, which directs and regulates the activities of muscles. Man uses about 350 pairs of skeletal muscles of many shapes and sizes that are situated across more than 300 joints, being attached to bones via tendons. A shortening of the

muscle brings the muscle ends closer to each other, which changes the angle at the joint across which it acts. A muscle has three characteristic properties: contractility, excitability, and elasticity. Contractility is the capacity of the muscle to produce a force between its ends; relaxation is the opposite of contraction, which is entirely passive. Excitability is the ability of the muscle tissue to respond to stimulation. Elasticity relates to the ability of the muscle to be stretched by an external force and return to its original length. The muscle suffers no harm so long as it is not stretched in excess of its physiological limits.

A skeletal muscle is composed of two types of structural components: active contractile elements and inert compliant materials. The contractile elements are contained within the muscle fibers. Each muscle is composed of many muscle fibers, of which a medium-sized muscle contains approximately one million. The fibers vary in length from a few millimeters to more than 20 cm, and their width is between 50 and 150 μm . About 85% of the mass of a muscle consists of muscle fibers while the remaining 15% is composed largely of connective tissues, which contain variable proportions of collagen, reticular, and elastic fibers.

The muscle activation is linked to the activity of neural cells. The essential function of a nerve cell is to transmit excitation to other cells. This is achieved by releasing a chemical transmitter substance at its synaptic terminal. Many different kinds of stimuli may excite the neurons. The neurons normally carry trains of impulses. The motor neurons usually conduct at frequencies of 5–30 impulses per second although sometimes at higher rates. The upper-limit frequencies for sensory neurons are normally between 100 and 200 impulses per second. The motor neurons conduct at velocities between 50 and 80 m/sec. The nerves enter the muscle near the main arterial branch and divide to distribute both motor and sensory fibers to the muscle bundles. One motor neuron and all of the muscle fibers that are innervated by axon terminals constitute a motor unit. Small muscles and the muscles that are involved in the fine gradations of a contraction necessarily have smaller motor units compared with larger bulky muscles that are involved in the maintenance of a strong contraction.

The excitation of a muscle (contraction) can be described as follows. The nerve impulses arriving at the neuromuscular junction cause the release of a transmitter substance, which diffuses across the junction and chemically excites the muscle fiber. The action potentials travel along the fiber membrane at a speed of 1–5 m/sec and initiate the events that lead to the shortening of the contractile elements of the myofibrils and the consequent production of force in the muscle.

Movement results from the interaction of muscular force, gravity, and other external forces that impinge on skeletal levers. The muscles rarely act singly; rather, groups of muscles interact in several ways for the desired movement to occur. Whenever a muscle causes movement by shortening, it is functioning as a mover or agonist. If an observed muscle constitutes the major contribution to a movement, it is that muscle that is called the prime mover. Other muscles crossing the same joint on the same aspect, but that are less relevant for the movement, are termed secondary or assistant movers or agonists. The muscles that are in opposite action to the prime mover are called antagonists.

The sine qua non of the effective control of movement involves greater stabilization of the more proximal joints in order to provide greater freedom to the distal segments to move effectively. The greater the amount of force to be exerted by the open end of the system (whether it is the peripheral end of an upper or lower extremity), the greater the amount of stabilizing force that is needed at the proximal joints.

The natural control systems for human movements have a hybrid hierarchical structure and organization (Fig. 1). The control systems have a component that is

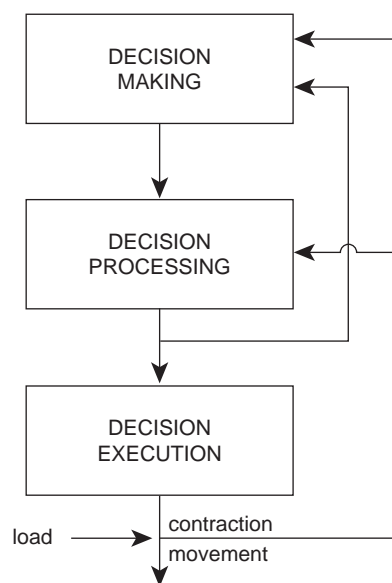

Fig. 1 Hierarchical hybrid model of control of movement in humans.

centrally programmed. For example, the entire act of signing a letter requires only one conscious thought: “Write the name.” The entire sequence of muscle activities and movements that follows occurs entirely automatically although the action can be changed at any time. Thus, it is possible to distinguish the *idea* (decision making in Fig. 1) from the *plan* that is used to carry it out. The movement plans are stored in the cortical parts of the central nervous system. The plans are developed mostly in childhood through a trial and error procedure, but they also develop later in life, especially when facing the loss of some sensory-motor mechanisms. The plans are likely composed of primitives (simple movement plans), which are placed into an integrated structure during each execution that is based on the visual or other information on the relation between the internal and external reference frames. The control systems also use feedback (arrows in Fig. 1).

The exteroceptors provide the control systems with information about the spatial coordinates of the objects. The proprioceptors relay information about the position of the body vs. the vertical, the angles of the joints, the length and tension of the muscles, etc. Via the proprioceptors, the control systems gain access to information about the condition of the muscles and skeletal parts that have to be moved. The control systems need information about the consequences of the motor systems’ actions. The sensory systems provide this information, which is thereafter used to calibrate the next series of motor commands. Thus, motor mechanisms are intimately related to and functionally dependent on central programming and sensory feedback.

Control of posture: Posture is characterized by the equilibrium of gravity and muscle generated forces. The multisegmental system has to be supported in an erect position with a coordinated activity of muscles at the lowest levels possible. Most of the body segments behave as inverted pendulums in this motor task. The control systems have to generate commands that ensure a slow oscillation around a metastable position where body segments are aligned to the direction of gravity. Many sensors are integrated into this task: vestibular system, somatosensory systems, muscle spindles, Golgi tendon organs, joint receptors, etc. The task is to keep the direction between the centers of mass and pressure (point where the resultant ground reaction force acts at the sole) aligned with the vertical. The center of mass is called the center of gravity because the external forces are gravity forces. Therefore, the center of pressure belongs to the central zone of the support surface during stable standing. The small region where the position of the center of gravity is located, to guarantee the stable posture of the body, is called the stability zone.

Control of walking: Walking follows the voluntary decision to progress from one point to another in space as well as to maintain vertical posture. The first element in the planning of locomotion in able-bodied subjects is a visual cue. Walking is feasible without visual cues (e.g., walking in a dark room), but it is then based on the anticipation of no obstacles and no change in the contact surface. Good performance requires knowing the environment, which is rarely the case in normal life. A hallmark of successful and safe walking is the ability to adapt the basic gait patterns to meet environmental demands. The visual system allows a human to make an anticipatory adjustment to the walking pattern necessary for overcoming environmental constraints.

Bipedal walking is a cyclic activity. The prerequisite for bipedal walking is the ability to maintain posture. Walking occurs once the equilibrium required for stable posture ceases to exist owing to the changes in internal forces (muscle activities). The internal forces cause the center of gravity to shift outside the stability zone, in which the body then starts falling. The falling of the body is prevented by moving one leg in the direction of the fall, thereby providing new support and a new stability zone. After the moved leg has safely supported the body, the contralateral leg pushes the body up and forward and generates momentum, resulting in a progression of the center of gravity. The cyclic repetition of the above-described events is defined as walking. In short, the essentials for walking are: 1) provision of support to the body segments against gravity; 2) production of a locomotor rhythm, 3) production of muscle forces that will result in the friction force (between the foot and the ground) required for propelling it to the intended direction; 4) dynamic equilibrium of the moving body; and 5) adaptation of movements to meet the environmental demands and the tasks selected by the individual.

The model that is often used for describing locomotion is based on an assumption of the existence of the central pattern generator (CPG). A CPG is a neuronal network capable of generating a rhythmic pattern of motor activity in the absence of sensory input from peripheral receptors. The CPG has been identified and analyzed in many animals, and has been suggested, with great reservation, in humans.

Control of goal-directed movement: Goal-directed movement is a planned change of the body segments' positions, which ultimately leads to a task. The nervous system solves the following three tasks during goal-directed movements: 1) multimodal sensory integration or sensory intake; 2) transformations between different spatial and intrinsic coordinate systems; and 3) motor commands adequate to attain the objective. Goal-directed movement is reliant upon a balance of initial programming and subsequent correction. Initial

programming is based partly on the visual perception of objects and partly on proprioception (e.g., a visual cue is used to decide whether to pick up the object with one or two hands, and what type of grasp to use). The accuracy of visual perception determines the initial programming. The visual information is used to identify a target and its location in space, and also for corrections of ongoing movement. Goal-directed movement for a seen object benefits from visual feedback.^[4] Here, we will only concentrate on goal-directed movements of the upper extremities.

Biological control uses task dependent constraints to reduce the number of variables that have to be controlled voluntarily to the lowest amount possible by forcing other variables to follow the memorized schemes. This method was called synergistic control, and was first analyzed and described by Bernstein.^[5] Bernstein suggested that the problem of motor redundancy is solved using flexible relations (synergies) among the control variables that are directed at individual elements. Synergy can be found between individual joint movements, thus the dimensionality of the control is greatly reduced.^[6] Recent observations have indicated that humans' reaching movements are characterized by certain stereotypical kinematic features such as straight hand paths and bell-shaped velocity profiles, thus suggesting that the generated trajectories are not selected at random, but in a rather preferred way according to some general criteria or organizing principles.^[7] Humans can learn to make a virtually unlimited set of trajectories with widely varying levels of cocontraction. Thus, the nervous system must be able to control muscles almost individually. However, humans often do not use the full repertoire of possible trajectories, but produce movements that have certain invariant properties, suggesting a tendency to select one trajectory from the many available.

Goal-directed movement can be divided into reaching and grasping. The goal-directed movement control differs for the following tasks:

- *Pointing*—The target position is imprecisely designed, yet there is only the direction of the distal segment of the arm.
- *Point-to-point reaching without grasping*—Both the initial and the target positions are known; however, the orientation of the hand is irrelevant, as well as the trajectory of the hand between the end points.
- *Point-to-point movement with grasping*—Complex movement that requires the orientation of the hand that corresponds to the shape of the object to be grasped, in addition to having precision in reaching the target with the velocity being about the same as that of the object to minimize the impact.
- *Tracking*—Movement along a prescribed trajectory.

Grasping is a part of the prehension, which is a process of orienting the hand, opening it so that the object fits comfortably, coming in contact with the object, and then forming a firm grip. On the kinetic level, prehension entails applying forces during interaction with an object. Stable grasping requires that the forces are applied by hand surfaces in opposition to other hand surfaces or external objects to overcome perturbations. The human hand has a variety of ways to grasp objects firmly. The selection of the grasp depends on the function that has to be achieved and the physical constraints of the object and hand. A fundamental functional constraint is that once the object is grasped, it is not to be dropped. The posture used by the hand during the task must be capable of overcoming perturbations and include anticipated forces that may act at the object.

MAN-MADE CONTROL OF MOVEMENT

In terms of control engineering, the human body that is being controlled is referred to as the *plant*. The configuration of the system at any given time comprises the plant states. The system components that power the system are called actuators. The signals driving the actuators are called controls. The controller is the component that generates controls. The time histories of the plant states in response to the controls are referred to as the system trajectory.

The open-loop control operates based on a pre-programmed set of commands. The open loop control cannot change the command sequence even when the trajectories that are achieved are different from the ones desired. To correct disturbances and errors, a closed-loop controller needs to be utilized. Closed-loop controllers, or so-called error driven controllers, use feedback information based on sensors signaling about the actual plant states. The error based controllers require the following: 1) the complete knowledge of the system parameters; 2) desired trajectories of the system components; and 3) acceptable tracking errors. In parallel, control requires optimization because the systems are highly redundant. The optimization criterion can consider a single mechanical category (e.g., velocity, acceleration, energy, tracking error); yet, often it considers several categories.

Open-loop and closed-loop controllers are based on the simulation of the system performance. The simulation requires the modeling that has to be derived by way of using mechanics and mathematics.^[8] A mathematical model is a quantitative description that connects the states and controls. The models of the real world are never exactly correct. Errors in the models of physiological systems arise from the practical modeling necessity of omitting many factors that are either of

secondary importance to the problem studies or unknown. The second error arises because of the necessity of describing the spatially distributed systems by lumped systems. The first step is always to choose the scope of the model. Although it would be ideal to adopt one general model, it is not practical because the generality increases the mathematical complexity to an inadequately treatable level in real time. In parallel, the general model comprises too many states, controls, and parameters that cannot be determined with sufficient accuracy. The second step in the modeling process is the selection of the model form. One can choose between the black-box model, structurally based model, and reductionist model.^[9,10] In a structural model, the elements of the system are isolated on the basis of a known or assumed system structure. The models of the individual elements are combined into multielement systems to describe the overall behavior. The advantages of a structural model are that the knowledge of the internal structure and operation can be incorporated, and the internal states and parameters can be directly related to the physical properties and experimental estimations. A possible disadvantage of structural models is that the individual element models require knowledge of parameters that are impossible to estimate.

The reductionist models are in essence identical to the structural models. The reductionist models were introduced by engineers who design artificial control and assistive systems, but were accepted by kinesiologists for studying specific behaviors. The reductionist models consider only the isolated components that are chosen to be instrumental for the selected movement.

Fig. 2 shows one possible structural model of movement.

Typically, the structural models of movement place an emphasis only on the extremities. A body segment, when exposed to physiological loading, is modeled as a rigid body although it comprises soft tissues (e.g., muscles, tendons, ligaments, skin, etc). The inertial properties of a rigid body are its mass and the inertia tensor. The inertia tensor comprises information about the inertial properties of the body when rotating, and the mass is a measure of inertial properties when translating. In reality, it is impossible in vivo to determine the body segments' properties with the precision that is required from the instrumentation available today. The second problem is that the body segment parameters change during movement because of the redistribution of the soft tissues (muscle contraction).

An important issue in the modeling relates to the joint structures. The term in the theory of mechanisms for the connection of two rigid bodies is a kinematic pair. The position of the free rigid body is determined by way of six independent parameters (coordinates).

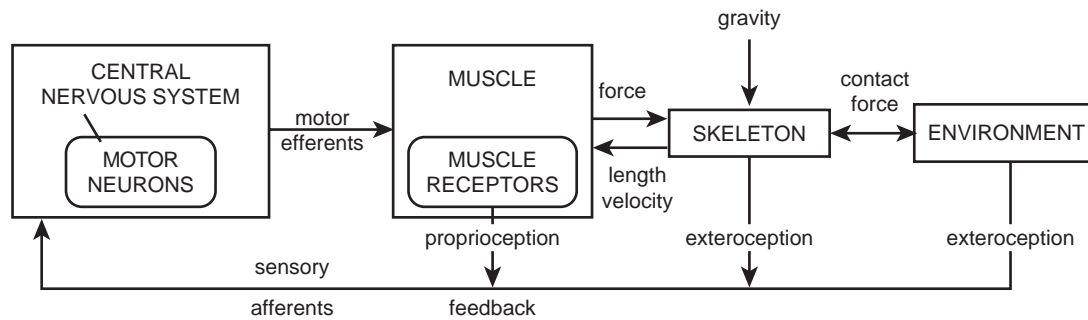

Fig. 2 The organization of sensory-motor systems leading to movement. The model corresponds to the general model shown in Fig. 1.

The independent parameter is termed degree of freedom (DoF). The theory of mechanisms defines the connection of segments (rigid bodies) as kinematic pairs having up to five DoFs. A typical human joint is a rotational kinematic pair having three DoFs (ball joint), or one DOF (pin joint). Many bodily joints cannot be reduced to a pin or ball joint. Some human joints are a structure that comprises two mechanical joints (e.g., the ankle joint consists of one joint for internal/external rotation and inversion/eversion, and the other for the flexion/extension that allows movements in the sagittal plane). In some cases the body segment motion results from complex structures such as two parallel bones connecting two joints (e.g., elbow and wrist). This structure provides a degree of freedom that cannot be associated with a joint (e.g., supination/pronation of the forearm).

The mathematical model allows the determination of the position of body parts in the absolute reference frame when the joint angles are known (direct kinematics), whereas the inverse kinematics compute the joint angles when a position of the body part is known. The direct kinematics analysis has a unique solution. An inverse kinematics solution depends on the redundancy of the structure, as well as the offsets and constraints, and in most cases the solution is not unique. Redundancy is an important feature in biological systems. An understanding of redundancy requires a distinction between a DoF and a permissible motion (e.g., rotation). The term DoF exclusively pertains to the permissible motion being independent from other motions. When analyzing the body as a whole, the total number of permissible rotations is termed system DoFs. It is difficult to determine which permissible rotations should be controlled, and which will be constrained by themselves owing to anatomical and physiological limitations.

Dynamic analysis deals with two problems: determination of forces and torques when desired laws of motion are known (forward dynamics), and determination of trajectories and laws of motion when torques and forces are prescribed (inverse dynamics).

A dynamic model is a set of equations that emulate the behavior of the physical system. Dynamic models specify how the current states of the system (e.g., body trajectories) depend on the past (e.g., the prior body trajectories and muscle forces). The inputs to a dynamic model of a human motor task are the muscle stimulation patterns, and the outputs are the computed body trajectories:

$$X' = f(X, U)$$

$$Y = g(X, U)$$

The differential equations can be written using the so-called Cauchy form. The vector X' comprises the first derivatives of the state vector X , vector Y comprises the outputs, nonlinear functions f and g describe the plant dynamics, and vector U consists of the controls.

There are twice more first-order differential equations compared with the number of DoFs. The first-order Cauchy form can also be represented in the following form:

$$\ddot{\theta} = A^{-1}(\theta)[M_a + M_{in}(\theta, \dot{\theta}) + M_g(\theta)]$$

where θ is the vector of joint angles, M_a , M_{in} , and M_g are the active, inertial, and gravity force based torques, respectively, and A^{-1} is the inverse matrix of the system. The muscle torque contribution is a vector of the torques produced by muscles spanning the joints. These torques are multiplied by A^{-1} , an inverse of the system matrix $A_{n \times n}$. A is the time variable, which depends on the inertial properties of the system, and also on the positions of the system components, which vary during the movement (e.g., trigonometric functions of joint angles). When A^{-1} has only diagonal elements, a muscle would only cause the angular acceleration of the joint it spans. A^{-1} is generally a full matrix with significant off-diagonal terms. Biarticular muscles (muscles crossing two joints) could accelerate a joint they span in a direction opposite to their torque at the corresponding joints.

Using the laws of mechanics in inverse dynamics works only for open chain structures such as an arm when reaching, or a leg during swinging, but it is not applicable for closed chain structures such as legs during the double support phase in walking, or the arm when contacting an immobile object, or in redundant systems. Every closed chained structure is dynamically undetermined, and the only possibility of determining forces and torques is to use the theory of elasticity. The theory of elasticity assumes that the elements of the structure are solid (not rigid), and this theory is inappropriate for control design because of its extreme complexity. The approximate solution of the dynamics of a closed chain mechanism assumes how forces and torques are distributed in the structure.

The complexity of a model depends on the number and types of body segments, the joints connecting the segments, and the interaction among the segments and the environment. The analysis of multijoint structures is always characterized by a reductionist approach, that is, the reduction of the number of DoFs to a manageable level (e.g., walking is often reduced only to the sagittal plane). Furthermore, there are three-dimensional models in the literature; yet, they typically add only a few joints that are out of the sagittal plane. Using a smaller number of links is essential for the simulation of movement. The dynamic analysis requires the decomposition of the system.^[11] The actuators in the body are muscles. The muscle produces a pair of forces of identical intensity but opposite direction, acting on two bodily segments that they connect. Some muscles connect non-neighboring segments, act over more than one joint, and are termed biarticular muscles or multiarticular muscles. When analyzing the body as a whole, the sum of forces generated by muscles is zero, and the muscle forces are called internal forces. The decomposition is virtual “dissection” of the body into segments. The result of decomposition is that now a muscle force acts as an external force to a specific bodily segment. The pair of agonist and antagonist muscles therefore results after decomposition as an external momentum with the net joint torque producing movement.

The modeling of muscles has received a great deal of attention. In, short muscle models can be grouped into three classes: 1) cross-bridge models including a sarcomere—microscopic, conventional cross-bridge, and unconventional cross-bridge models; 2) fiber models; and 3) whole-muscle—macroscopic models (viscoelastic and black box models).^[12] Here, we will introduce only macroscopic viscoelastic models of muscles.^[13] Winters generalized Hill’s model in a simple enhancement of the original, which makes no claim based on the microstructure.^[12,13]

Winters’ model deals with joint moments:

$$M = M_0 - B\dot{\Theta}, M_0 = AM_{0m}f(\Theta)$$

where M is the muscle moment exerted about the joint, M_0 is the isometric moment (active state) with a maximum possible value M_{0m} , Θ is the joint angle corresponding to the current contractile element length, A is a normalized activation variable ($A=0$ for relaxed muscle, $A=1$ for a tetanized muscle), $f(\Theta)$ is the normalized tetanic length–tension relation, and B is a variable damping coefficient. For shortening muscle (SM) and lengthening muscles (LM), the equations are:

$$B = M_0(1 + \alpha)/(\dot{\Theta} + \alpha\dot{\Theta}_0), \quad \dot{\Theta} < 0 \quad (\text{SM})$$

$$B = M_0(1 - \beta)/(\dot{\Theta} + \gamma\dot{\Theta}_0), \quad \dot{\Theta} > 0 \quad (\text{LM})$$

where α , β , and γ are constants.

The black-box model only considers a subset of states of interest and controls without assuming anything about how the system operates internally. The relation in the black-box model is often nonparametric, and nonparametric black-box models were also termed nonanalytical models. The system operation, not the plant, is modeled as a set of mappings between inputs and outputs. Nonanalytic control can be described as a replica of biological control.^[14,15] The basic mechanisms of nonanalytical control are rule-based controllers (RBC).^[16] An RBC is a system implementing “If-Then” rules, where the “If” part describes the sensory and motor states of the system while the “Then” part of a rule defines the corresponding motor activity to follow. The If-Then operation in nature is called reflex; hence, the man-made If-Then operation was termed “artificial reflex control.” Artificial reflex control belongs to discrete control systems, and in essence it decomposes the movement into time windows and defines synergies between the state space variables by the If-Then rules. The execution of the artificial reflex depends on how fine the tuning was, as determined by observing and analyzing biologically controlled movements. This control method comprises the following: 1) adaptivity; 2) modularity; and 3) ease of application and the possibility of integration into a man–machine system. The main problem is how to design the rules for artificial reflex control. Various machine learning techniques were shown to be suitable for acquiring the needed structure of rules for the RBC. Learning in general can be described as the capturing and memorizing of connectivities between facts. Machine learning is a computerized method for the capturing and memorizing of the processes.

HIERARCHICAL HYBRID CONTROL OF MOVEMENT

Hybrid means, in general, heterogenous in nature or composition. The term “hybrid systems” is understood to describe systems with behavior defined by entities or processes of distinct characteristics. The hybrid systems of interest here are dynamic systems where the behavior is determined by interacting continuous and discrete dynamics. These systems typically contain variables or signals that take values from a continuous set (e.g., the set of real numbers) and also variables that take values from a discrete and typically finite set (e.g., the set of symbols {a, b, c}). These continuous or discrete-valued variables or signals depend on independent variables such as time, which also may be continuous or discrete; some of the variables may also be a discrete event that is driven in an asynchronous manner.^[17,18]

There are many examples of hybrid systems. In the control area, a very well-known instance of a hybrid system is when a continuous-time linear time-invariant plant that can be described by linear differential equations (which involve continuous-valued variables that depend on continuous time) is controlled by a discrete-time linear time-invariant plant described by linear difference equations (which involve continuous-valued variables depending on discrete time). These types of systems are termed sampled data systems or digital control systems; digital control systems may of course include more general types of systems such as time-varying and nonlinear plants and controllers. If one were to also consider the quantization of the continuous-valued variables or signals, then the hybrid systems contain not only continuous valued variables that are driven by continuous and discrete times, but also discrete-valued signals. Another familiar example of a hybrid control system is a switching system where the dynamic behavior of interest can be adequately described by a finite (small) number of dynamical models, i.e., typically the sets of differential or difference equations together with a set of rules for switching among these models. These switching rules are described by logic expressions or a discrete event system with a finite automaton or a petri net representation.

There are several reasons for using hybrid models to represent movement. Reducing the complexity was and still is an important reason for dealing with hybrid systems. This is accomplished in hybrid systems by incorporating models of dynamic processes at different levels of abstraction. For another example, to avoid dealing directly with a set of nonlinear equations, one may choose to work with sets of simpler equations (e.g., linear) and switch among these simpler models.

This is a rather common approach in modeling physical phenomena. In control, switching among simple dynamical systems has been used successfully in practice for many decades.

The hybrid control systems typically arise from the interaction of discrete planning algorithms and continuous processes, and, as such, they provide the basic framework and methodology for the analysis and synthesis of autonomous and intelligent systems, i.e., planning to move the hand and grasp an object. The hybrid control systems contain two distinct types of components, subsystems with continuous dynamics and subsystems with discrete event dynamics, that interact with each other.

Another important way in which hybrid systems arise is from the hierarchical organization of complex control systems (Fig. 3). In these systems, a hierarchical organization helps manage the complexity, and higher levels in the hierarchy require less detailed models (discrete abstractions) of the functioning of the lower levels, necessitating the interaction of discrete and continuous components.

There are analogies between certain current approaches to hybrid control and digital control system methodologies. In digital control, one could carry the control design in the continuous-time domain, then approximate or emulate the controller by way of a discrete controller and implement it using an interface consisting of a sample and a hold device (analog to digital, A/D, and digital to analog, D/A, respectively). Alternatively, one could first obtain a discrete model of the plant taken together with the interface and then carry the controller design in the discrete domain. In hybrid systems, in a manner analogous to the latter case, one may obtain a discrete event model of the plant together with the interface using automata or petri nets.^[19]

Hybrid systems inherently combine logical and continuous processes, which are usually coupled with finite automata and differential equations. Thus, the continuous dynamics are modeled by a differential equation:

$$\dot{x}(t) = \xi(t), \quad t \geq 0$$

where $x(t)$ is the continuous component of the state taking values in some subset of a Euclidean space, and $\xi(t)$ is a controlled vector field that depends on $x(t)$ and the aforementioned logical or finite dynamics. Two categories of the switched systems are of interest: the autonomous switching where the vector field $\xi(\cdot)$ changes discontinuously when the state $x(\cdot)$ reaches certain boundaries, and the controlled switching where $\xi(\cdot)$ changes abruptly in response to a control command, and possibly with an associated cost.

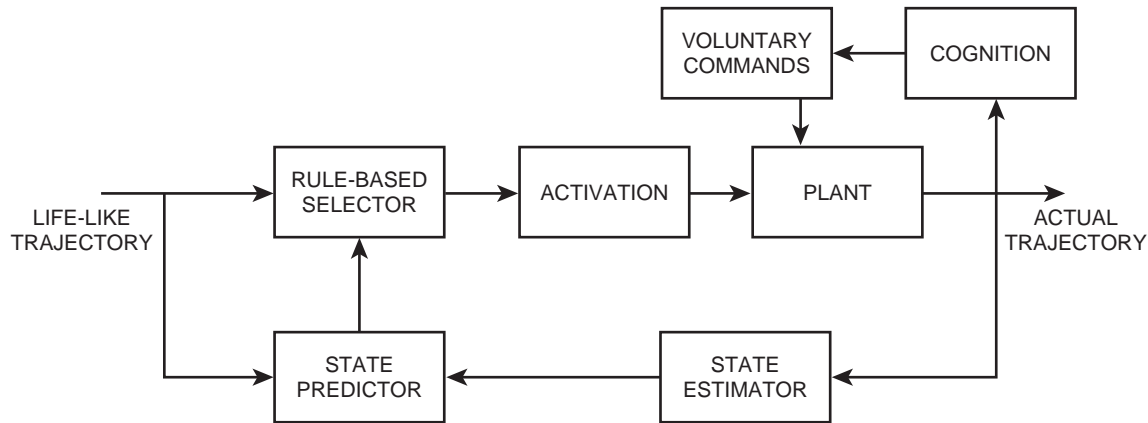

Fig. 3 The organization of a man-made hierarchical hybrid control system for restoring movement in humans.

A (continuous time) autonomous hybrid system may be defined as follows:

$$\begin{aligned}\dot{x}(t) &= f(x(t), q(t)) \\ q(t) &= v(x(t), q(t^-))\end{aligned}$$

where $x(t) \in R^n$, $q(t) \in Q \cong \{1, \dots, N\}$. Here, $f(\cdot, q): R^n \rightarrow R^n$, $q \in Q$, each globally Lipschitz continuous represents the continuous dynamics, and $v: R^n \times Q \rightarrow Q$ is the finite state dynamics. Here, the notation t^- indicates that the finite state is piecewise continuous. Thus, starting at $[x_0, i]$, the continuous-state trajectory $x(\cdot)$ evolves according to $\dot{x}(t) = f(x, i)$. If $x(\cdot)$ reaches $(v(\cdot, i))^{-1}(j)$ at time t_i , then the state becomes $[x(t_i), j]$, from which the process continues.^[20]

A continuous-time controlled hybrid system is:

$$\begin{aligned}\dot{x}(t) &= f(x(t), q(t), u(t)) \\ q(t) &= v(x(t), q(t^-), u(t))\end{aligned}$$

where everything is as above except that $u(t) \in R^m$, with f and v modified appropriately.

The schema of a hierarchical hybrid controller for movement incorporates three levels (Figs. 4 and 5). We have opted to describe the model of walking, but similar models can be easily envisioned for other movements.

The top artificial control structure is the interface between the user and the machine. This interface is the principal command channel, and it allows the user to trigger the operation of their choice volitionally.

The interface initiates the activity of a discrete, RBC. This RBC operates as a discrete, sample data feedback system, and its main role is to distribute the commands to the lowest actuator levels. The RBC implements the finite-state model of movement, and the rules have to be determined with sufficient generality to allow the application over many assistive systems to be applicable to the entire population with a

similar level of disability. The actuator level deals with specific muscle groups responsible for the flexion or the extension of a single joint, or in other cases, the action of several joints when a multiarticular muscle is externally stimulated. The actuator level implements the continuous feedback control and structural modeling.

The RBC system is applicable for the coordination level of control. This level deals with the following: 1) the strategy of how to employ the resources available and 2) the methodology of how to maximize the efficiency of the resources. The RBC in this multilevel control uses the simulation of movement as the pattern that has to be followed. This is to say that the RBC does not clone normal, able-bodied movement,

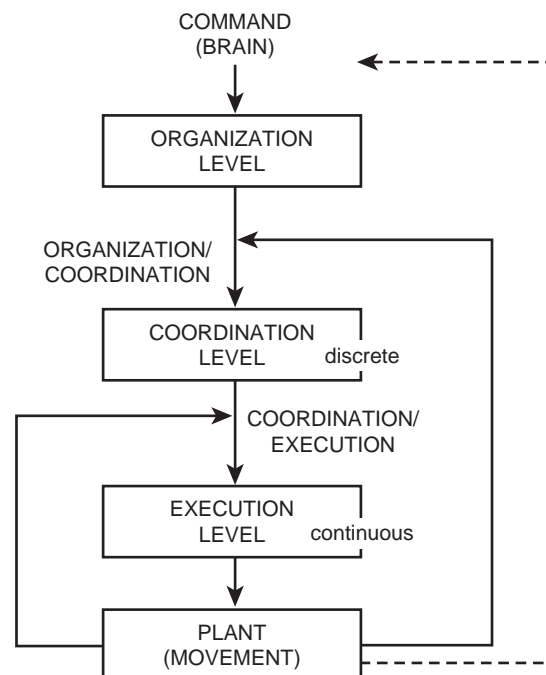

Fig. 4 The model of life-like movement controller based on a nonanalytical model of movement.

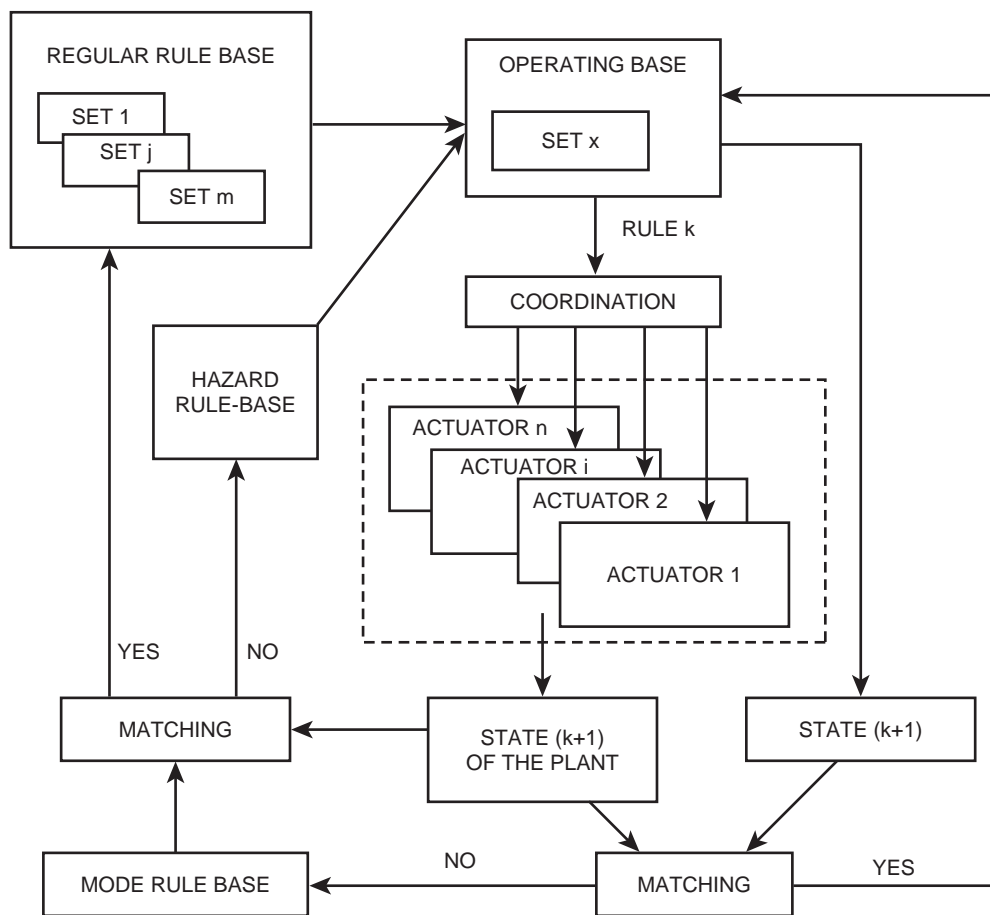

Fig. 5 The schema of a hierarchical hybrid controller for paralyzed extremities in humans with sensory-motor disability.

although the simulated movement along the desired trajectory is achievable. This means that the structural model is of great importance for this off-line analysis. The RBC comprises the following elements: the regular rules that sequentially switch from one to the expected action based on sensory input; mode recognition rules that are responsible for selecting the appropriate set of regular rules; and the hazard states that deal with conflict situations. The conflict situations occur as a result of the uncertainty of the available sensory information and/or hardware limitations, in addition to unexpected gait events. The hazard rules result in the safety “behavior,” which attempts to minimize the eventual catastrophic consequences of the hazard (e.g., falling, obstacles, nonphysiological loading).

The lower, actuator control level is responsible for executing decisions from the coordination level. Executing commands in the sense of artificial reflexes means that the electrical stimulation has to be delivered to a group of muscles that are controlling a joint. Single-joint control is achieved through a coordinated action of several muscles acting at the neighboring segments. Details on the various methods that are implemented for the control of movement by

means of neural prostheses of upper and lower extremities can be found in Chapter 5 of *Control of Movement for the Physically Disabled*, while the specifics on the hierarchical hybrid control regarding the rehabilitation of humans with disabilities can be found in Popović.^[1,21,22]

CONCLUSIONS

Compared with other classes of dynamical systems, the sensory and motor systems supporting the execution of functional motions in humans have three unique features: 1) they are highly redundant; 2) they are organized in a hierarchical structure, yet with many parallel channels; and 3) they are self-organized, relying, among other things, on an extremely complex connectionism. In spite of the above complexity, the movements resulting from the action of the sensory system, as a rule, are deterministic and they follow the preferred way of performing the intended motor task. In this entry some of the above phenomena are briefly discussed, taking a comprehensive approach, i.e., discussing general findings from motor physiology,

biomechanics, and automatic control. The entry offers a plausible explanation as to how the self-organized systems are able to force otherwise uncontrollable system components to perform the desired movement, essentially in a deterministic, nonstochastic way. In external control of movement the aim is typically to activate joints in a controlled way so as to restore as much motor function as possible in individuals with motor disabilities. The control strategies implemented in most of the assistive systems have so far been fairly simple, and have been developed largely in relation to the design of machines rather than to the design of nervous systems. Neural engineering is where the ultimate successes at this stage must come. The development of new implantable devices that interface directly the central and peripheral nervous system allowing wireless communication with the outside world opens the space for integrating the sophisticated artificial control. The nanotechnology is making a dramatic impact, and provides what has been difficult to imagine. This technology is ideal for implementing control that mimics natural regulation, and integration into the preserved sensory-motor systems of individuals with disabilities could be the method for improving the quality of life.

Controlled Release

Brent Vernon

Michael Wegner

The Harrington Department of Bioengineering, Arizona State University, Tempe, Arizona, U.S.A.

INTRODUCTION

Early drug delivery methods typically involved simple oral administration as liquid, powder, or tablets or topical delivery. As drugs were developed, such as proteins and peptide drugs, which cannot overcome the natural barriers present in oral and topical delivery, they began to be injected or delivered intravenously. Recently developed drugs with narrow therapeutic concentrations, systemic side effects, short half lives, or other barriers to efficient application require advanced methods of delivery. Delivery of these compounds to a specific location (spatial control) or with a specific pattern (temporal control), or both, is being pursued to overcome these barriers. “Controlled release” refers to this type of delivery.

Several system types have been or are under development to provide this spatial and temporal drug release. These different system types are classified as 1) mechanical/electrical systems, 2) polymeric systems, and 3) biological systems. Examples and history of these different types of controlled-release systems will be presented here. In these systems, modeling and analysis of the release profile is required because the rate of release is crucial. Furthermore, controlled-release technology often combines drug and device and sometimes biologics into one product. This combination of drug and device results in regulatory issues unique to these systems.

ADVANTAGES AND PURPOSES OF CONTROLLED RELEASE

Many drugs benefit from their controlled release to overcome a number of difficulties. Controlled release is often used to reduce toxicity associated with bolus oral or injected delivery by delivering the drug at steady lower therapeutic concentrations for an extended time instead of at high initial concentrations.^[1–3] These systems can replace multiple doses with a single dose or fewer doses. Controlled release can also reduce systemic toxicity by providing localized delivery, avoiding high concentrations of the drug throughout the body.

As an example, biodegradable polyanhydride wafers (GLIADEL) have been used to deliver toxic chemotherapy agents to malignant brain tumors in phase-three clinical trials.^[2] Many drugs also require precise timing in delivery; controlled-release technology can provide a solution for this need. For example, insulin delivery to diabetics needs to be correlated to high blood glucose levels,^[4,5] and other drugs require delivery timed with circadian cycles.^[6] In many other drug delivery devices, the goal is to obtain constant drug delivery rates. Controlled-release technology can also be used to bypass various barriers to drug delivery, such as cell membranes^[7] or aggressive digestive environments.^[8] Controlled-release systems provide protection from in-vivo metabolism to many drugs, especially proteins and peptides, allowing higher stability of the drugs and longer periods of efficacy.^[9] Controlled-release systems can also help to enhance delivery of poorly soluble drugs.^[10] Controlled-release systems often enhance the delivery of many cancer agents that are poorly soluble.^[10] Table 1 summarizes the advantages and purposes of controlled release.

MECHANICAL/ELECTRICAL SYSTEMS

There are several controlled-release systems developed or under development that are mechanical and/or electrical in nature. Early systems of this type were generally passive pumps that were intended to provide constant, sustained release over a long period of time using a constant pump rate. Common pump systems include infusion pumps, peristaltic pumps, and osmotic pumps.^[11] The first of these, the infusion pump, is commonly used for insulin release. First attempts at controlled release of insulin using infusion pumps began in the late 1970s.^[12] These systems improve diabetic treatment by providing a sustained continuous delivery of insulin.^[4] Future systems improved on this by adding programmable pumps to provide additional control over the timing of insulin delivery. More recent models combine insulin pumps with glucose sensors.^[5] However, the current unsolved issue is the development of a continuous and reliable sensor that provides

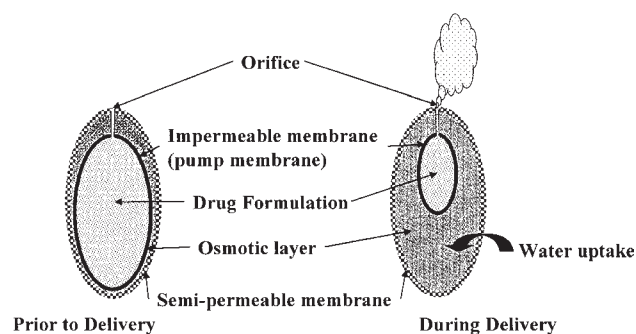

Table 1 Advantages and purposes of controlled-release technology

1. Reduce toxicity associated with bolus oral, injected, or intravenous delivery.
2. Reduce systemic toxicity by providing localized delivery.
3. Provide precise timing in delivery.
4. Bypass various barriers to drug delivery, such as cell membranes or aggressive digestive environments.
5. Protect drugs from in-vivo metabolism allowing higher stability of the drug and longer periods of efficacy.
6. Enhance delivery of poorly soluble drugs.

accurate and real-time glucose monitoring. The eventual development of such a “feedback-controlled” artificial pancreas will require a long-term stable glucose sensor; this would allow the controlled release of insulin in response to blood glucose levels.^[4] Although a preponderance of these systems have been investigated for the delivery of insulin, infusion pumps—external and implantable—have been pursued for delivery of numerous other drugs such as chemotherapy agents^[13] and neurological drugs.^[14] The use of an implantable infusion pump to treat cancer metastases in the liver provides a prime example of infusion pump technology used to localize the delivery of chemotherapy agents.^[13] Since the liver obtains a large portion of its blood supply from a single hepatic artery, slow infusion of drugs such as 5-fluorodeoxyuridine provides an increased concentration of the drug locally (in the liver) but avoids high systemic concentrations.^[13] In a 2000 review, Rise summarizes several implantable infusion drug delivery systems designed for delivery of neurological drugs and other chemical agents to the central nervous system (CNS).^[14] Medtronic offers an implantable and programmable drug infusion system called “Synchromed EL.”^[14] This system can be used to provide spatial and temporal control of drugs to the CNS. Such systems have been used to deliver neuro-modulating and pain-control agents.^[14]

Similar to the infusion pumps, peristaltic pumps have been developed for controlled delivery of insulin for diabetics. Early implantable peristaltic pumps for insulin release appeared in 1980.^[15] Early systems of this type showed the advantage of remote control using an external remote.^[15] So far, however, these systems have proven to be too expensive to be used practically.^[11]

The osmotic pump controlled-release system was first described by Theeuwes and Yum in 1976.^[16] Since then, the Alza Corporation has developed osmotic pump delivery systems for various drugs such as hydromorphone,^[3] verapamil hydrochloride,^[8] and pseudoephedrine.^[17] These osmotic pump drug-delivery systems work by surrounding a drug-filled impermeable

**Fig. 1** Representation of the mechanism used for osmotic pump controlled-release drug delivery systems. (Adapted from Ref. [18].)

membrane with a semipermeable membrane and an osmotic layer between the impermeable and semi-permeable membranes. Water is driven through the semipermeable membrane by osmotic pressure compressing the inner impermeable membrane, driving the drug formulation from the device. Figure 1 presents this mechanism for osmotic pumps.^[18] Various different configurations and designs have been developed using the same principle. Osmotic pumps are popular because they can provide zero-order release of the drug and avoid the “initial burst effect” seen with many other types of controlled-release systems. Figure 2 compares zero-order release to first-order release rates. As an example, one of Alza’s pumps released 262 ug/hour of the pain management agent, hydromorphone, over a two-week period while avoiding the burst effect seen in various degradable and nondegradable matrix systems.^[3] The Alza osmotic systems, ALZET osmotic pumps, are available for laboratory and veterinary use. More recently, osmotic pump systems have been shown to deliver pseudoephedrine with zero-order kinetics over 12 hours.^[17] In another osmotic pump device designed by G.D. Searle & Alza Corporation, a hydrophilic cellulosic membrane is used to delay the delivery of verapamil hydrochloride, a hypertension drug, for

**Fig. 2** Comparison between zero-order release and first-order release mass release rate with time showing constant release in zero-order systems compared with decreasing release rate in first-order systems.

4 to 5 hours after oral administration.^[6] Laser-drilled micropores allow release of the drug over 24 hours. This design is used to match delivery of the verapamil hydrochloride to circadian rhythm of hypertension.^[6]

Less common pump systems include positive displacement pumps and micropumps.^[11] Additionally, a pressure-induced permeation pump described by Uchiyama et al. in 2002 utilizes pressure-induced changes in insulin permeation through a permeable membrane to control release. With an applied pressure of 18 kPa, the release of insulin from this device increased 3.4-fold.^[19] Different mechanical and electrical technologies offer achievable devices that can control the release of numerous drugs. Many of these systems, when combined with computer or sensor control, can provide a sophisticated and useful delivery pattern.

POLYMERIC SYSTEMS

In examples of polymeric controlled-release systems, drugs combine with polymers and then release from the polymer. Early pioneer work was performed by Langer et al. to demonstrate the release of large macromolecule drugs such as proteins from polymeric devices.^[20] Since this early work, the use of polymeric materials for controlled release has expanded extensively.

These polymer systems can be either degradable or nondegradable. In both cases, there are two important classes: matrix and reservoir (see Fig. 3). In matrix systems, the drug is dispersed or dissolved within a solid or porous polymer matrix. The drug is generally delivered by one or more of three mechanisms from these polymer matrices: diffusion, degradation, and swelling-enhanced diffusion.^[21]

Degradation-controlled systems come in two classes: erodible systems and drug-polymer conjugates.^[22] In the first class, the drug is entrapped within a polymer matrix and is released as the matrix erodes. In the second class, the polymer is chemically attached to the matrix or polymer and is released as the drug-polymer bond is broken, usually hydrolytically or enzymatically. The degradable matrices in the erodible systems can undergo either bulk degradation or surface erosion. Bulk degradation occurs when water, or another agent that causes the degradation, can penetrate into the matrix and cause uniform degradation throughout the entire volume of the matrix. In bulk degradation systems, the drug is often released by a combination of diffusion and degradation mechanisms, referred to as heterogeneous degradation.^[22] In this case, the release rate of the drug is dependent on the permeability of the polymer matrix, which is changing with time due to bulk degradation of the matrix. For these systems, in a slab configuration, the rate of release is shown in Eq. 1,

$$\frac{dM_t}{dt} = \frac{A}{2} \left[\frac{2P_o e^{k_h t} C_o}{t} \right]^{1/2} \quad (1)$$

where dM_t/dt is the rate of release, A is the surface area, P_o is the permeability of the matrix, C_o is the original concentration of the drug, t is time, and k_h is the hydrolysis rate constant, a constant associated with the rate of change in the matrix permeability.^[22] Solutions are also available for other geometries.^[22] Surface erosion, on the other hand, occurs when the matrix is impermeable to water or other degradation agents and the degradation must occur on the surface. In surface erosion systems, the drug release rate is often equal to the polymer degradation rate, referred

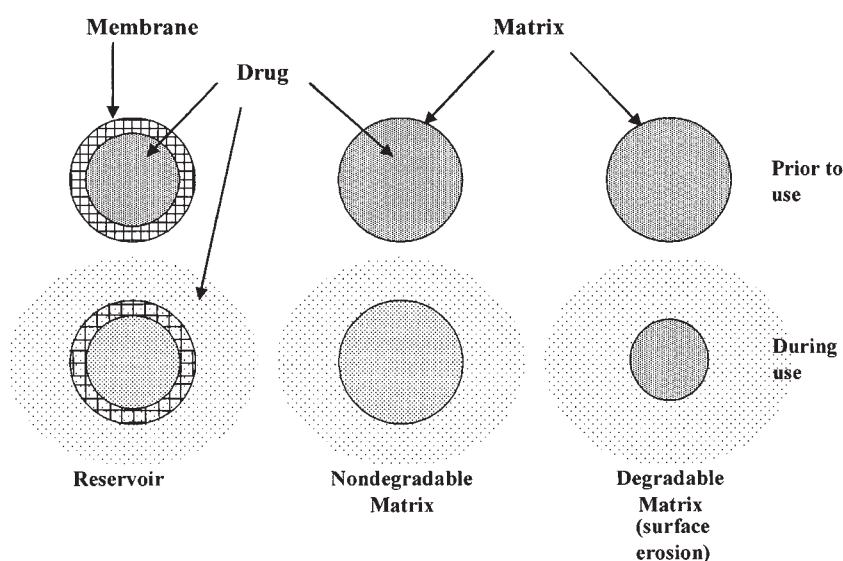

Fig. 3 Depiction of possible reservoir, nondegradable, and degradable matrix controlled-release systems designs.

to as homogeneous degradation.^[22] In this case, the release of the drug is dependent on the surface area of the system and the surface degradation rate. Device designs that provide constant surface area with time, as the material erodes, can provide constant zero-order release when release occurs by this mechanism. In systems with heterogeneous release, the release rate is dependent on the surface area of the system and the surface degradation rate as in Eq. 2,

$$\frac{dM_t}{dt} = k_{sd}C_oA \quad (2)$$

where dM_t/dt is the rate of release, C_o is the original drug concentration, k_{sd} is the surface erosion rate constant, and A is the surface area of the device.^[22] Many polymeric drug delivery devices show attributes of both surface and bulk erosion, to varying degrees.^[22] In these systems, the release profile can become more complicated.

As an example of bulk degradation, poly(lactide:glycolide/75:25) (PGLA) can be prepared as microspheres that degrade by bulk erosion.^[21] In controlled-release applications, these systems exhibit uniform degradation throughout the entire matrix. Generally, in these systems, the drug must diffuse out of the device as the device degrades to avoid drug dumping when the end-stage bulk erosion causes rapid mass loss in the matrix. In contrast, in surface-eroded devices, drug is released as the surface erodes; therefore, the release rate is dependent on the surface area of the drug delivery system.^[21] In an example of surface-erosion controlled delivery, Hanes et al. demonstrated drug delivery systems of polyether anhydrides for pulmonary delivery of drugs.^[23] The surface erosion properties of the ether anhydride provided a continuous drug-release profile over time spanning hours to days.

A current commercially available erodible system, Lupron Depot, is available from TAP Pharmaceuticals for prostate disease, endometriosis, and precocious puberty.^[24] The Lupron Depot system provides constant delivery of leuprolide at a rate of 120 ug/day for at least 12 months. As another example of eroding systems, injectable PGLA systems have been developed, made injectable by delivering in organic solvents, for drug delivery over periods of weeks to months.^[25] In these injectable PGLA systems, the polymer is dissolved in Food and Drug Administration (FDA)-approved water-miscible organic solvents such as dimethyl sulfoxide (DMSO) and then drug is added to form a homogeneous solution or suspension. When this solution or suspension is injected, the polymer precipitates due to insolubility in water as the organic solvent is replaced by water. The drug is then slowly released from the system. A major challenge in these systems is an initial burst of drug released at injection.^[25]

In the drug-polymer conjugate systems, the polymer-drug conjugate is often referred to as a prodrug. The polymer can be the polymer matrix of a drug delivery device, or the polymer may be a water-soluble polymer chain making the prodrug water soluble.^[26] This can be an important method for improving the solubility and delivery of poorly soluble drugs. In these systems, especially if the drug is inactive when attached to the polymer, the drug is released after the attachment between the polymer and the drug is broken. A number of factors can influence the drug delivery rate of polymer-bound drugs from matrix systems. These factors include.^[22]

1. The mode of degradation of the matrix (i.e., surface versus bulk, homogeneous versus heterogeneous).
2. The permeability of the matrix to water.
3. The diffusion coefficient of the released drug or prodrug in the matrix.
4. The solubility of the drug in water and in the matrix.
5. The rate of hydrolytic or enzymatic cleavage of the drug from the polymer.

In reservoir-type systems, different than in the matrix-type systems, the drug is enclosed within the lumen of a permeable membrane.^[27] The thickness and the permeability properties of this membrane control the rate of drug release from these types of devices. Zero-order release can be obtained from reservoir-type devices if the reservoir concentration is constant. This can occur when the drug is loaded within the reservoir above the saturation concentration and the diffusion through the permeable membrane is sufficiently slow to allow equilibrium of the concentration within the reservoir, particularly at the inner surface of the permeable membrane. A disadvantage to the reservoir systems is that the permeable membrane is generally constructed from nondegradable materials. If removal is required for safety or reapplication purposes, surgery would be required. These systems can also “dump” toxic quantities of the drug if the membrane is compromised. An example of a current reservoir system is Norplant, a silicone membrane-encapsulated hormone system for long-term contraception. The Norplant system was first seen in clinical trials in the early 1980s.^[27] Since then, Norplant has become an important controlled-release system available in the clinic.

More advanced systems are also under development using environmentally sensitive polymers to provide additional control mechanisms beyond diffusion and degradation for the delivery of drugs.^[21] Polymers that are sensitive to temperature, pH, electric field, ultrasound, magnetic field, and ionic strength have been used in development of controlled-release systems.^[28] In these systems, this environmental trigger can control the release of the drug. As an example, pH-sensitive

systems for oral delivery of insulin have been investigated to protect the insulin in the stomach but allow release in the intestine.^[8]

RELEASE PROFILES AND MODELS

In the polymeric systems, important release models have been developed to assist in understanding and designing these systems. For many drug delivery systems, zero-order delivery is ideal, while most polymeric systems provide first-order release. A truly zero-order delivery system would be time-independent with respect to release. This can occur when the concentration at the diffusion boundary is constant. On the other hand, in first-order delivery, the rate of release is dependent on the concentration of the drug in the device as it decreases by diffusion. Typically, controlled-release data are reported as mass released and as percent mass released or fraction mass released. In the reservoir and matrix system, diffusion becomes an important mechanism to control the rate of release. Because of this importance, a number of models and analytic methods have been developed to understand and predict the release. Insight into the release mechanism can often be gained by determining the dependence of the release profile on time. The profiles can be analyzed using Eq. 3, where M_t/M_∞ is the fraction of drug released at time t , t is the release time, k is a kinetic constant dependent on the system geometry and diffusion coefficients, and n is the diffusional release exponent.^[29]

$$\frac{M_t}{M_\infty} = k \cdot t^n \quad (3)$$

The diffusional release exponent found in Eq. 1 can provide indications regarding the drug-release mechanism. An exponent, n , of 0.5 suggests normal concentration-controlled Fickian diffusion, while n of 1.0 indicates zero-order (time-independent) release.^[29] Values between 0.5 and 1.0 indicate that there is some anomalous or non-Fickian diffusion occurring in the system.^[29] Exponent values greater than 1 indicate a super-release mechanism such as swelling-or degradation-enhanced release.^[29] For systems with Fickian diffusion, solutions have been derived for Fick's second law (conservation of mass) for a variety of different controlled-release system configurations including spherical, cylindrical, and flat sheet. Many of these solutions have been outlined by Saltzman.^[30]

BIOLOGICAL SYSTEMS

The final system type is biological. Biological systems provide controlled release of a drug by using living

cells or tissue. The primary difference between biological systems and the polymeric systems is the use of the living cells or tissues for the in-situ production of the delivered drug. Typically, the living cells or tissue are encapsulated in a semipermeable membrane (polymer), physically isolating the cells from the host immune system. Several polymers have been used to immunoisolate the cells including poly(hydroxyethyl methacrylate-co-methyl methacrylate)^[31] and alginate/poly-L-lysine.^[32] With this immune protection, different cell sources can be used: autologous, allogenic, xenogenic or genetically engineered. Autologous cells are cells derived from the organism to be implanted, allogenic cells are derived from the same species, and xenogenic cells are derived from another species.

Although not the only examples, two important drugs, for which this type of system is being developed, are L-dopa for the treatment of Parkinson's disease^[31] and insulin for the treatment of diabetes.^[32] These types of systems are often referred to as tissue-engineered or biohybrid systems. In the first example, Sefton et al. have demonstrated the microencapsulation of PC-12 cells in a copolymer of hydroxyethyl methacrylate-methyl methacrylate (HEMA-MMA) for the prolonged delivery of L-dopa.^[31] However, they also address the difficulty of maintaining the PC-12 cells in vivo after implantation and the difficulty of implanting microencapsulated cells. They describe that the biocompatibility and long-term viability of the system is contingent on the method and site of implantation.^[31] In the treatment of diabetes, several clinical trials have been conducted using alginate-polylysine-encapsulated islets of Langerhans, a subset of cells in the pancreas that provide insulin production and secretion.^[32] Clinical trials have been conducted using human and porcine islets.^[32] Some of the challenges faced in the islet encapsulation clinical trials are scarcity of the human tissue for implantation and the need for immunosuppression. However, approval for human trials in the United States was obtained, and VivoRx planned to start trials in the United States in 1998 for nonimmunosuppressed diabetics.^[32]

There are two main advantages to biological systems. First, biological systems provide physiological delivery of the drug. The drug is synthesized and released by the entrapped cells in response to physiological stimuli or in some physiological rate or pattern. As an example, encapsulated islets respond to glucose concentration with modified insulin production and release.^[33] Figure 4 presents rat islets of Langerhans that are immobilized within a 5-wt% poly(N-isopropylacrylamide-co-acrylic acid) hydrogel with 2-mol% acrylic acid as part of work^[33] toward the development of a refillable biohybrid artificial pancreas. Secondly, biological systems also provide in situ drug production. Therefore, these systems do not require

Fig. 4 Rat islets of Langerhans entrapped in 5-wt% hydrogels of poly(N-isopropylacrylamide-co-acrylic acid) with 2-mol% acrylic acid. Encapsulated islets are envisioned as a potential controlled-release system for insulin.

application of toxic quantities of the drug, guaranteeing that even device failure will not result in a bolus drug release. This provides extra protection against potentially dangerous drug overdoses. The in situ drug generation also allows continuous, potentially permanent, delivery of the drug over longer periods with low initial drug load.

Despite these advantages, there are a number of disadvantages that must be overcome prior to widespread clinical use of these systems. The main disadvantage to the biological systems is the need for immune protection. Unless the cells are autologous, these systems require either immune suppression or immune barriers. Although device failure would not result in bolus drug release, it would result in an immune response due to the immunogenicity of the entrapped cells. Also, the implanted cells have a finite lifespan, generally due to immune components or diffusion restrictions, requiring device replacement after a certain time.

REGULATORY ISSUES

Prior to marketing any of these controlled-release systems in the United States, approval must be obtained from the Food and Drug Administration of the U.S. federal government. However, the FDA considers many of these controlled-release systems as combination products. In 1991, the FDA defined [combination products] as (definition from 21 CFR Part 3, Subpart A, Section 3.2 (e)).^[34]

1. A product comprised of two or more regulated components, i.e., drug/device, biologic/device,

drug/biologic, or drug/device/biologic, that are physically, chemically, or otherwise combined or mixed and produced as a single entity;

2. Two or more separate products packaged together in a single package or as a unit and comprised of drug and device products, device and biological products, or biological and drug products;
3. A drug, device, or biological product packaged separately that according to its investigational plan or proposed labeling is intended for use only with an approved individually specified drug, device, or biological product where both are required to achieve the intended use, indication, or effect and where upon approval of the proposed product the labeling of the approved product would need to be changed, e.g., to reflect a change in intended use, dosage form, strength, route of administration, or significant change in dose; or
4. Any investigational drug, device, or biological product packaged separately that according to its proposed labeling is for use only with another individually specified investigational drug, device, or biological product where both are required to achieve the intended use, indication, or effect.

From the preceding definition, it is apparent that most controlled-release systems fit this classification, involving both device and drug and in some cases adding biologics. The combined nature of these devices complicates the regulatory environment, adding challenges to the premarket review, approval, and post-market surveillance processes. The three classes—devices, drugs, and biologics—are reviewed, approved, and monitored by different divisions or centers of the FDA. Device products are under the jurisdiction of the Center for Devices and Radiological Health (CDRH); drug products fall under the jurisdiction of the Center for Drug Evaluation and Research (CDER), while biologic products are controlled by the Center for Biologics Evaluation and Research (CBER). For products with combinations of drugs, devices, and biologics, it is not immediately clear which center should have jurisdiction, and it is necessary that multiple centers participate in the review, approval, and monitoring processes. Therefore, in 1991, the three centers entered into multiple intercenter agreements regarding the handling of combination products; these agreements can be found online at www.fda.gov/oc/combination/intercenter.html. For many controlled-release products, the intercenter agreement between CDRH and CDER is important.^[35] This agreement outlines the primary jurisdiction for many combination device/drug products.

In 2002, the Medical Device User Fee and Modernization Act of 2002^[36] helped to centralize the combination product review, approval, and postmarket

surveillance responsibilities of the FDA. This act amended the Food and Drug Act requiring the establishment of an Office of Combination Products within the FDA. In December of 2002, this office was established with the responsibilities to determine the center with primary jurisdiction and to coordinate multicenter input in the review, approval, and monitoring processes. This office is required to assign responsibility for these products to the appropriate center based on the products' "primary mode of action." Although multicenter participation can occur during the review, the center assigned primary jurisdiction defines what requirements must be met. As an example, systems found to have the drug as the primary mode of action are required to submit an Investigational New Drug (IND) application, while systems found to have the device as the primary mode of action are required to submit an Investigational Device Exemption (IDE) application to perform clinical trials. Additional information regarding regulatory issues for drug/device combination products, especially those where the primary function is "drug," can be found in a review by P. Marroun.^[37]

CONCLUSION

The primary goal of controlled-release technology is to improve the efficacy and safety of drug delivery by controlling the release rate and/or location. Numerous design approaches have been pursued in the development of controlled-release systems. Mechanical/electrical systems of insulin pumps combined with glucose sensors are the hope for improved delivery of insulin for type I and type II diabetics. Osmotic pumps are being used to deliver a variety of different drugs. Polymeric systems often rely on diffusion, swelling, and degradation to control the release of a compound. More advanced polymeric systems add potential environmental control by using materials that are sensitive to pH, temperature, or other stimuli. Biological systems combine living cells with devices to provide physiologically relevant delivery of important biological molecules. These systems have the potential to deliver their compound in response to physiologically specific signals or conditions and provide long-term delivery with low drug load. In all of these systems, the rate and timing of the release are extremely important and must be fully considered during development. Also, these systems have special requirements in the regulatory arena because of their characteristic combination of drug, biologics, and devices. Finally, controlled release provides spatial and/or temporal control that can be used to reduce toxicity, improve efficacy, bypass barriers, enhance solubility, and prolong activity for the delivery of many different drugs.

INTRODUCTION

Over the last 30 years, many surgical procedures have been devised to modify the refractive power of the eye in order to improve vision.^[1] Being the most accessible layer of the ocular system and providing about 70% of the total dioptric power of the human eye, the cornea is a preferred candidate for these procedures. Refractive change can be achieved by increasing the cornea's refractive power either by altering, in part, its refractive index by means of an insert or changing the radius of curvature of its anterior surface where, at the air-tissue interface, most of the refraction of light occurs. This can be done either by means of an insert, surface sculpting, or precisely locating cuts in the cornea. These surgical procedures are included under the umbrella term of refractive corneal surgery or refractive keratoplasty.^[2] Many refractive procedures require implantation of inserts in which human donor corneal tissue and collagen have been used, but this has been associated with problems such as immune response, proteolytic degradation, and, in the case of donor tissue, limited supply. With the advent of synthetic polymers, artificial inserts became an established alternative. Surgery on the cornea may be also performed when the cornea becomes opaque due to disease or trauma causing poor vision or blindness such that its central part must be excised and replaced. This procedure is known as penetrating keratoplasty (PK) when the replacement is donor tissue. Interest has been also directed at developing synthetic alternatives to donor tissue for the replacement of the cornea. Historical roots of this procedure, known as prosthokeratoplasty, can be traced back to the 18th century.^[3]

This article focuses on the use of polymeric biomaterials as corneal implants for refractive purposes or full-thickness corneal replacement as an artificial cornea. Since the 1960s, numerous research groups have examined the responses of corneal tissue to implanted biomaterials in terms of inflammation, opacification, tissue melting, and refractive changes. Important issues that soon became apparent to researchers were the thickness, diameter, edge profile, refractive index, water content, and porosity of the materials. Much of

the early research involved implantation of biomaterial samples at approximately midstromal depth within animal corneas and assessing clinical and histological outcomes. Pioneers in this work included Krwawicz, Knowles, Choyce, and Dohlman. By the end of the 1970s, it was well established that certain materials could be retained in the medium- to long-term and that both clarity and refractive changes could be achieved. This work led to the development of artificial refractive devices and further progression in the development of artificial corneas (keratoprotheses).

GLOSSARY

Bowman's layer: an acellular layer in the cornea that is located between the epithelium and stroma.

Descemet's membrane: a basement membrane in the cornea that is located between the stroma and endothelium.

Endothelium: a single, ordered layer of hexagonal cells on the posterior surface of the cornea.

Epithelium: the external layer of the cornea consisting of specific cells organized into five to seven layers.

Hyperopia/hypermotropia: the refractive status of the eye that is either too short or in which its focusing apparatus (cornea, lens) is too weak so that light rays come into focus behind the retina, and additional converging power is required through surgical alteration or optical aids.

Intraocular lens (IOL): a synthetic replacement for the natural crystalline lens that may be removed due to cataract, trauma, or refractive reasons.

Keratoprosthesis (KPro): a synthetic, or artificial, cornea, i.e. a full-thickness replacement for a diseased cornea that is intended to maintain ocular integrity and allow transmission and refraction of light.

Melting: a loss of corneal stromal tissue through pathologically induced enzymatic degradation.

Myopia: the refractive status of the eye that is either too long or its focusing apparatus (cornea, lens) is too strong so that light rays come into focus in front of the

retina, and diverging power is required through surgical alteration or optical aids.

Penetrating keratoplasty (PK): a replacement of a diseased cornea with a human donor corneal graft.

Prosthokeratoplasty: a surgical procedure for insertion of a keratoprosthesis.

Pseudophakia: a removal and replacement of the natural crystalline lens with a synthetic IOL. An eye with its natural crystalline lens removed and not replaced is called aphakic.

Stroma: the main layer of the cornea comprising about 90% of the total corneal thickness and consisting of collagen fibrils, proteoglycan ground substance, water, and a small number of specialized fibroblasts (keratocytes).

IMPLANTS FOR REFRACTIVE KERATOPLASTY

Lamellar refractive keratoplasty constitutes the main group of procedures within refractive keratoplasty^[2] and includes all procedures involving addition of material by placing a lenticule or a ring on or within the cornea. Three of these procedures (keratophakia, epikeratoplasty, and intracorneal ring insertion) may make use of synthetic polymers (Fig. 1) and will be further discussed.

Implants for Keratophakia

Keratophakia involves placement of a lens within the cornea (Fig. 1) to alter its refractive power either by altering its anterior radius of curvature or incorporating a lens of higher refractive index. Such lenses, usually termed lenticules or inlays, can be made of donor tissue (homoplastic) or, as will be discussed here, a synthetic material (alloplastic). The technique has been felt most suitable for aphakic patients who are unsuited for intraocular surgery or contact lens wear. Usually, a lamellar disc of cornea is excised, the

lenticule is placed in the lamellar bed, and the disc is sutured into its original position. Early proof-of-principle for the ability of polymer inserts to be retained and cause permanent refractive alterations was provided by experiments with silicone rubber and poly(methyl methacrylate) (PMMA), which caused little tissue response.^[4] Other researchers felt that silicone rubber was more suited to use as a barrier implant, which causes a desirable degree of anterior dehydration in edematous corneas.^[5]

Hydrogels are hydrophilic polymers that are able to swell in water without dissolution due to the existence of water-attracting functional groups in the polymer chains. Attached water molecules act to hold the polymer strands apart, which results in an inherent structural microporosity. The best known representative of this class is poly(2-hydroxyethyl methacrylate) (HEMA), which is used in a large range of biomaterial applications and attracted interest as a material for keratophakia in early stages.^[6] McCarey and co-workers used copolymers of HEMA to improve the solute permeability and aimed for an ideal implant material that was described as transparent, chemically inactive, permeable, nonabsorbable, dimensionally stable, soft, and pliable.^[7] These researchers established^[8] that lenticules made of copolymers of HEMA with methacrylic acid (MAA) and/or 1-vinyl-2-pyrrolidinone (VP) permitted bulk flow of water and nutrients, a refractive change could be achieved, and the endothelium and epithelium remained essentially normal. But the researchers also established that the refractive change could be unpredictable when placed in middepth pockets. It was appreciated that, to achieve a significant alteration in curvature of the anterior corneal surface, the surgical technique must breach the strong Bowman's layer, which lies just deep to the corneal epithelium, and through most of its circumference to allow the tissue to deform. The earliest experiments used convex implants to steepen the cornea and correct aphakia or hyperopia in which greater refractive power was required. But, researchers then found that doughnut-shaped hydrogel implants could cause corneal flattening and correct myopia.^[9] A commercial lens became available, the Keratogel[®] intracorneal lens (Allergan Medical Optics, United States of America), manufactured from Lidofilcon[®] A (an MMA/VP copolymer), which was evaluated in human clinical trials. This insert provided significant refractive corrections—initially in aphakic patients—although best-corrected visual acuity took several months to return to its preoperative level. The outcomes were often disappointing when large hydrogel implants (made from Lidofilcon[®] A or Perfilcon[®] A, a HEMA/VP/MAA terpolymer) were implanted since poor predictability and astigmatism were common features. Successful implantation of these hydrogel lenses depends

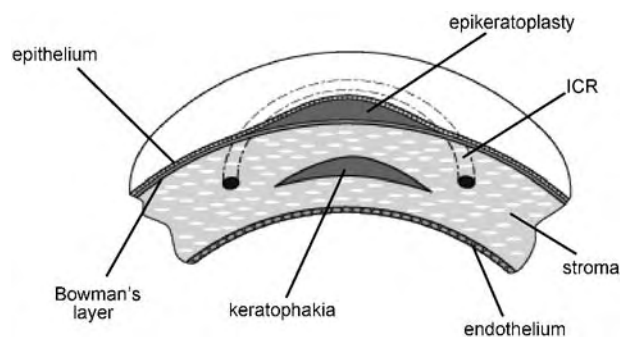

Fig. 1 Diagram of the cornea showing the major structural layers and position of refractive implants.

upon skillful manipulation of microkeratomes and is, thus, a more complex procedure than implantation of a high refractive index lens using freehand stromal dissection.

An alternative approach to implanting hydrogels and relying upon creating a predictable change in anterior surface curvature was proposed by Choyce.^[10] Namely, this approach was to implant intrastromally a lens that was sufficiently thin enough not to affect corneal curvature but with a significantly higher refractive index so that it would provide an additional refractive interface when implanted deeply within the cornea. The ideal diameter of a lenticule implant was proposed to lie within 4–5 millimeters to ensure that the size of the impermeable device does not affect anterior nutrition while the optical aberrations and decentration effects were minimized. A polysulfone produced from Bisphenol A and 4,4'-dichlorophenylsulfone was proposed and assessed for this purpose. Adverse events including cloudiness, which may have been related to instability to UV light, were reported^[11] along with lipid deposits and inflammatory reactions in some cases. Fenestration of the material to improve permeability and tolerance was proposed but, in turn, caused optical problems.

Recent work to address the limitations of hydrogel intracorneal implants for keratophakia has been conducted at Anamed, Inc. (United States of America). Their PermaVision[®] lenticule, which was made from a proprietary hydrogel (Nutrapore), was evaluated in animals^[12] with generally acceptable results in the short- to medium term. Although, it appears that safety problems are likely in the long term and may limit the use of this device. Synthetic intracorneal lenses are yet to have a proven place in refractive surgery.

Implants for Epikeratoplasty

Epikeratoplasty, a technique first suggested by Werblin and Kaufman in 1979,^[13] involves the placement of a lenticule superficially, just beneath the corneal epithelium, by suturing it to a groove in the de-epithelialized surface of the cornea and allowing re-epithelialization over it (Fig. 1). It has an advantage over keratophakia by avoiding incisions through the optical zone. Progress in this field was reviewed by Thompson and coworkers.^[14] The positioning of the lenticule anterior to Bowman's membrane, an important structural layer of the cornea, makes the procedure theoretically completely reversible and avoids adverse reaction to stromal healing. But, it does depend upon achieving adhesion of the lenticule and a stable overlying epithelialization. This has been achieved for donor tissue inserts but not to date for

synthetic inserts in such a position. The lenticule is concave when the procedure is performed for correction of myopia and convex when it is performed in an aphakic or hyperopic eye.

The use of synthetic lenticules for this application was explored during the 1980s and, due to their location just deep to the epithelium, a high degree of permeability was essential. Hydrogels developed for contact lenses (e.g., Lidofilcon[®] A) were assessed for this purpose, and it was further realized that surface modification with fibronectin, epidermal growth factor, or other biological adhesion promoters would be desirable to enhance epithelialization. Collagen-hydrogel combinations were also proposed, but disadvantages include a susceptibility to collagenolytic degradation. Other researchers achieved the epithelialization of poly(vinyl alcohol) (PVA) copolymers after coating them with basement membrane components, but no lenticules for clinical use were produced. Synthetic lenticules can be made with great accuracy, avoid disease transmission, compensate for the lack of donor availability, and are not subject to scarring or remodelling. Additionally, it was realized that the option of postoperative excimer laser ablation of the lenticule could provide for fine-tuning of the refractive outcome.^[15] However, there are significant biomaterial-associated challenges when a synthetic lenticule is used since the polymer needs not only to remain inert but must actively promote recovery and maintenance of the epithelium. Fixation methods attempted included mechanical, i.e., surgical dissection of a cut ring, laser welding, biological nontoxic glues, and suturing. However, suturing is difficult due to the delicacy of the thin layer. In practice, reversibility is often limited by residual scarring. Since the refractive outcomes from pre-lathed donor tissue implants were not as good as had been expected, they are no longer supplied. Clinical interest in the technique, whether with donor tissue or synthetic lenticules, has abated. Research interest continues in developing a synthetic onlay, which is sometimes inappropriately referred to as an artificial cornea.^[16] Some of the current research is focused on polymers that will allow re-epithelialization of the onlay. Promising results in animal experiments have been reported with perfluoropolyether-based polymers produced by the photo-oxidative polymerization of perfluoroalkylenes and surface-modified by covalent bonding of components of extracellular matrix.^[16,17]

Intracorneal Ring

An intracorneal ring, known also as intrastromal corneal ring (ICR), in the mid-peripheral cornea (Fig. 1) could either steepen the central corneal radius of

curvature and increase its power if the ring is tightened in situ or would flatten the central cornea and provide a myopic correction if the ring maintains its position or tends to stretch peripherally. Important variables include the diameter and thickness of the ring, the width of the channels dissected for it to lie within, and the material itself. Generally, the channel is cut at about two-thirds of the stromal depth by using a special circular cutter that makes only a small entry incision. So far, the preferred material for ICRs was exclusively PMMA. Proof-of-principle was first demonstrated in the rabbit model and then in eye bank human corneas.^[18] The bulk of the device itself was found to contribute to central corneal flattening. Results of ICR in humans with low myopia were good with reversibility and lack of significant complications.^[19] Higher degrees of myopia were treated less reliably, and the procedure is not without risks, including infection or perforation of the anterior chamber. Commercially known as Intacs[®] (KeraVision, United States of America), the devices are approved for use in low- to moderate myopia and myopic astigmatism. By the same principle, injection of a synthetic gel has a similar effect.^[20] In this procedure, known as gel injection adjustable keratoplasty (GIAK), crosslinked polymer gels, such as polysiloxanes^[20] or poly(ethylene oxide),^[21] have been used so far in eye bank corneas or animals.

KERATOPROSTHESIS

A true artificial (synthetic) cornea, or keratoprosthesis (KPro), is meant to totally replace the central part of an opaque cornea. Figure 2 shows three basic conceptual forms of KPros and their placement within the cornea. An artificial cornea is not merely a refractive device since its purpose is to restore vision lost due to corneal opacification in cases in which the transplantation of donor corneal tissue has little chance of success. Research on KPro has a long history, which includes substantial progress along with many failures, as shown in some major reviews.^[22-25] The most serious complication of prosthokeratoplasty is the loss, or extrusion, of the KPro, which is usually preceded by tissue melting around the prosthetic rim. Other complications include the formation of retroprosthetic membranes, inflammation, infection, retinal detachment, and cataract. Despite its complications, prosthokeratoplasty is the only hope for the visual recovery of those patients in which the transplantation of donor cornea is impracticable.

Due to a high incidence of extrusion, the early KPros made of glass or quartz were abandoned at the end of the 19th century, and, for an ensuing long period of time, no significant research was reported on KPro. The introduction in the late 1940s of synthetic

Fig. 2 Basic types of keratoprosthesis. A: full thickness; B: core-and-skirt; C: nut-and-bolt.

polymers as materials marked the beginning of a modern era in the development of KPro. PMMA was the first polymer to be used for developing a variety of one- or two-piece KPros,^[26] and it is still used in some models.^[27] The introduction of lateral-supporting perforated or meshwork plates (flanges) around the PMMA optical cylinder led to the so-called core-and-skirt KPros, which were aimed at promoting integration of the host cornea with the periphery of the KPro (Fig. 2B). However, these devices led to only slightly better clinical outcomes when compared with nonperforated devices. Fixation of the implants on both external and internal aspects of the host cornea, as exemplified in the nut-and-bolt KPro designs (Fig. 2C), led to some improvement in the clinical outcome. But, the presence of a retrocorneal nut remained a source of complications. PMMA is still preferred by many researchers as a material for artificial cornea, and models comprising various fixation means of increasing complexity are still a frequent feature of contemporary KPro research.

The research on KPro was generally conducted along two directions. The first trend was aimed at finding a suitable synthetic polymer with the underlying criterion being ocular biocompatibility. As many materials more or less fulfill this prerequisite, the range of synthetic polymers proposed or used for optical core and prosthetic skirts was rather extensive,^[24] including polysiloxanes, PHEMA, polytetrafluoroethylene (PTFE), poly(ethylene terephthalate) (usually Dacron[®]), polyurethanes, polyalkylenes, poly(vinyl alcohol), polycarbonates, poly(glyceryl monomethacrylate), poly(ethylene oxide), carbon fibers, and carbon fiber composites. A second

research trend was triggered by the perceived need for biointegration at the polymer-tissue interface. As an unavoidable consequence, KPros of high level of complexity have been developed, which in some cases were indeed retained for a long time in the host cornea. However, the sophistication involved in their design rendered these KPros unavailable off-the-shelf to surgeons and patients. A revealing example is perhaps one of the Cardona's through-and-through KPro. It consisted of a central PMMA cylinder (peripherally pigmented to prevent glare) surrounded by a perforated PTFE plate, which was reinforced with both a mesh of Dacron[®] and a layer of autologous tissue (usually periosteum excised from the same patient). As this KPro had to pass through the eyelid, extensive surgery was needed, including the total removal of the crystalline lens and iris, the partial removal of the vitreous, the excision of eyelid muscles and, finally, the permanent closure of the eyelid skin. In other KPro models, the central PMMA cylinder was surrounded by autologous tissue, such as bone and tooth (osteodontokeratoprosthesis), and covered with mucous membrane, which requires multistage surgery on patients. Although providing some chance for visual improvement in the long term, such KPros are acceptable only for the most severe bilaterally blind cases due to their complexity, complicated and lengthy surgery, aesthetically disfiguring result, and visual fields lower than 30 degrees.

By the end of 1980s, it became clear that acceptable integration of the host corneal tissue into the prosthetic peripheral region could not be assured by large holes in the skirts or through autologous tissue. KPro researchers began to understand that this integration should occur through growth within voids of a width in the micron range, which is not much larger than the size required to accommodate the stromal fibroblasts, and these voids should be of unlimited length through the material, i.e., contiguous. In addition, it was realized that the simplest conceptual form of KPro (Fig. 2A) could be employed without any need for mechanical fixation means. The attempts to achieve this goal led to the development of core-and-skirt KPros with a porous skirt.

Keratoprotheses with Porous Skirts

A relatively small number of research groups pioneered independently KPros comprising skirts with a true porous structure. From a tissue-engineering standpoint, the skirts can be regarded as nonbiodegradable scaffolds. These developments were extensively reviewed elsewhere.^[24,28] One of the first KPro models with a porous skirt comprised a polysiloxane core surrounded by carbon fibers,^[29] which was eventually abandoned despite partial success in animal

experiments. Other researchers chose a melt-blown fibrous web of polybutylene/polypropylene blend for the skirt and pol(vinyl alcohol-co-vinyl acetate) copolymers as core materials.^[30] This model was also abandoned after little success in animal trials. Legeais' group in France developed KPros with skirts of porous PTFE. Their latest model, in which the core was made from polysiloxane coated with PVP,^[31] has been approved for distribution and clinical use in Europe as BioKP[®] Sil (FCI, France). The KPro developed by Caldwell in the United States of America, in which the skirt was also made from porous PTFE and the core from transparent polyurethane, had only partial success in human patients.^[32] The concept of using hydrophilic polymers in a KPro has been applied in the development of a model in which the core and the porous skirt were both made from PHEMA.^[33,34] The main features of this KPro include a PHEMA sponge as a skirt, which was created by phase-separation polymerization, and interpenetrating polymer networks as an attachment between core and skirt. In clinical human trials,^[35,36] this model (Fig. 3) led to a lower risk of some of the complications traditionally associated with prosthokeratoplasty. The device has obtained widespread regulatory approval for distribution and use in human patients, including the U.S. FDA approval, and is currently marketed as AlphaCor[™] (Argus Biomedical, Australia). In order to promote better fixation of the device within the host tissue, some researchers included not only a porous skirt but also elements for additional anchoring to the sclera. For instance, the Seoul-type KPro consists of a PMMA optical cylinder, a skirt form porous polyurethane or fibrous polypropylene, and loops made of monofilament polypropylene. This KPro has only been evaluated in a small number of human patients.^[37]

Fig. 3 The AlphaCor[™] keratoprosthesis.

CONCLUSION

Corneal refractive devices for visual correction and artificial corneas for visual restoration are becoming major fields for the application of polymeric biomaterials. However, the implantation of polymers into the cornea remains significantly associated with clinical complications. To solve such problems, researchers have adopted multidisciplinary approaches that enabled them to optimize polymer selection and their structural modification. The range of synthetic polymers proposed and evaluated as refractive devices (corneal onlays, corneal inlays, intracorneal rings) is rather limited and requires more work and diversification. The development of artificial corneas has involved a much greater number of polymers, but devices produced to date are justifiable for implantation only in high-risk cases. An artificial cornea of sufficiently low risk to replace donor grafts in all cases is still some years away.

Corrosion

Rachel L. Williams

Department of Clinical Engineering, University of Liverpool, Liverpool, United Kingdom

INTRODUCTION

Corrosion of metallic biomaterials occurs as an electrochemical reaction at the surface of the metal with the biological fluids acting as the electrolyte.^[1-3] The consequences of corrosion are changes in the surface chemistry of the metal and the accumulation of metal ions in the electrolyte. Both are important in terms of the behavior of an implanted device. These, along with measurement of the electrochemical reactions, form the basis for evaluation of the corrosion phenomena that occur. The important consequences of corrosion for implanted medical devices are not only degradation of the material properties but also, and often more importantly, the biological response to the degradation products. This article will consider the corrosion of metallic biomaterials under the following three headings:

1. The electrochemical reactions
2. Surface analysis of the metal
3. Chemical analysis of the electrolyte

THE ELECTROCHEMICAL REACTIONS

The electrochemical reactions relevant to implantable medical devices take place on a metal surface in an aqueous electrolyte. There are always two reactions that occur: the anodic or oxidation reaction, which yields metallic ions resulting from the oxidation of the metal to its salt,

and the cathodic or reduction reaction, in which the electrons generated are consumed. The precise cathodic reaction will depend on the nature of the electrolyte, but two of the most important in aqueous environments are the reduction of hydrogen,

and the reduction of dissolved oxygen,

in acidic solutions or

in neutral or basic solutions.

In all corrosion processes, the rate of the anodic or oxidation reaction must equal the rate of the cathodic or reduction reaction. This is a basic principle of electrochemically based metallic corrosion. It also explains how variations in the local environment can affect the overall rate of corrosion by influencing either the anodic or cathodic reactions. The whole corrosion process can be controlled by altering either of these reactions.

When a metal is placed in an electrolyte, the electrochemical reactions will occur until an equilibrium is set up across the interface such that the rate of the anodic reaction equals the rate of the cathodic reaction. At this point, the potential across the interface is related to the corrosion current density by the Nernst equation:

$$E = E_0 + (RT/nF) \ln(a_{\text{anod}}/a_{\text{cath}}) \quad (5)$$

where E_0 is the standard electrode potential, RT/F is a constant, n is the number of electrons transferred, and a is the activity of the anodic and cathodic reactants. E_0 is defined as the electrode potential measured against a standard hydrogen electrode in a 1 N solution of its salt at 25°C. At low concentrations, the activity can be approximated to the concentration. In this situation, there is a net dissolution of the metal and a current will flow. At equilibrium, the rate of the metal dissolution is equal to the rate of the cathodic reaction, and the rate of the reaction is directly proportional to the current density by Faraday's law; therefore

$$i_{\text{anodic}} = i_{\text{cathodic}} = i_{\text{corrosion}} \quad (6)$$

and the Nernst equation can be rewritten

$$E - E_0 = \pm \beta \ln(i_{\text{corr}}/i_0) \quad (7)$$

where β is a constant and i_0 is the exchange current density, which is defined as the anodic (or cathodic) current density at the standard electrode potential.

The relationship between electrode potential and the corrosion current can be measured experimentally. The

data are useful in evaluation of the corrosion behavior of a particular metal/electrolyte system.

For an actively corroding metal, if the potential difference relative to a reference electrode is driven by some external process, then the current density will increase exponentially and a plot of the potential against the \ln current is a straight line. Most implantable structural metals and alloys will form a passivating oxide layer on their surface rapidly on exposure to the atmosphere such that when placed in an aqueous environment, active corrosion is inhibited. These materials result in a typical S-shaped polarization curve as shown in Fig. 1. Important information about the corrosion behavior of a metal or alloy can be obtained from these curves. The position of the equilibrium or corrosion potential (E_c) will lie within the passive region of this curve. It is important to notice that in this region there is still a finite current density and therefore a release of metal ions into the environment. As the potential is raised, the breakdown potential (E_b) will be reached, at which point the passive layer will begin to break down allowing active corrosion to occur and thus the current density begins to increase. If the potential is cycled, a potential will be reached at which repassivation occurs. The differences between the equilibrium potential, the breakdown potential, and the repassivation potential provide useful information to characterize the corrosion behavior of a particular metal/electrolyte system.

When a metallic device is implanted, there are also various practical considerations that can modify the basic corrosion of the metal in the electrolyte. These include geometrical considerations (crevice corrosion), relative movement of components (fretting corrosion), incidences where metal types are combined (galvanic corrosion), or situations where the implant is stressed (stress corrosion cracking).

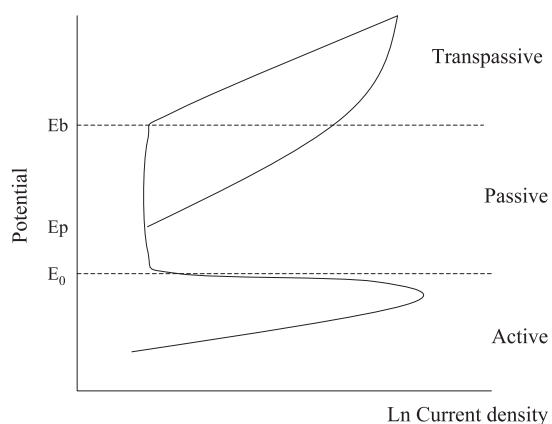

Fig. 1 Typical S-shaped polarization curve of a passivating metal or alloy.

Crevice Corrosion

Crevice corrosion can occur due to the geometry of the device. The area between the head of a bone screw and countersink on the fracture fixation plate can be influenced by the crevice conditions that the geometry creates.^[4] Porous coated implants may also demonstrate crevice corrosion.^[5] The crevice geometry restricts diffusion of oxygen into the crevice. Initially, the anodic and cathodic reactions occur uniformly over the surface, including within the crevice. As the crevice becomes depleted of oxygen, the reaction is limited to metal oxidation balanced by the cathodic reaction on the remainder of the surface, resulting in a small actively corroding area which will not repassivate. In an aqueous sodium chloride solution, the buildup of metal ions within the crevice causes the influx of chloride ions to balance the charge by forming the metal chloride. In the presence of water, the chloride will dissociate to its insoluble hydroxide and acid. This is a rapidly accelerating process since the decrease in pH causes further metal oxidation within the crevice.

Fretting Corrosion

Fretting corrosion results from the removal of the passive layer by a mechanical process.^[6,7] This can be a scratch that does not repassivate, resulting in the formation of a pit, or a continuous cyclic process in which any reformed passive layer is removed. It is suggested that this can contribute to the corrosion observed between a fracture fixation plate and the bone screws attaching the plate to the bone. Fretting can also affect the corrosion rate due to plastic deformation of the contact area; this can subject the area to high strain fatigue and may cause fatigue corrosion. Furthermore, stirring of the electrolyte can increase the limited current density of the cathodic reaction by upsetting the charge equilibrium that is established at the metal/electrolyte interface.

Galvanic Corrosion

If two metals are independently placed within the same solution, each will establish its own electrode potential with respect to the solution. If these two metals are placed in electrical contact, then a potential difference will be established between them, and electrons will pass from the more anodic to the more cathodic metal. Thus equilibrium is upset and a continuous process of dissolution from the more anodic metal will take place. This accelerated corrosion process is galvanic corrosion. It is important if two different alloys are used in an implantable device when the more reactive may corrode freely.

Whenever stainless steel is joined to another implant alloy, it will suffer from galvanic corrosion. If both alloys remain within their passive region when coupled in this way, the additional corrosion may be minimal. Some modular orthopedic systems are made of titanium alloys and cobalt-based alloys on the basis that both should remain passive, but evidence of corrosion has been reported.^[8] Galvanic corrosion may also take place on a microscopic scale in multiphase alloys where phases are of considerably different electronegativity. In dentistry, some amalgams may show extensive corrosion because of this mechanism.

Crevice, fretting, and galvanic corrosion could all occur on modular hip prostheses,^[9] where fretting initiates the breakdown of the passive layer, and once initiated, the crevice conditions cause continued corrosion without mechanical loads. This was shown to occur on both Co-Cr-Mo head/Co-Cr-Mo neck and Co-Cr-Mo head/Ti-6Al-4V neck prostheses.

Stress Corrosion Cracking

Stress corrosion cracking is a form of corrosion where an applied stress and a corrosive environment work together and cause complete failure of a component, when neither the stress nor the environment would be a problem on their own. The stress level may be very low, possibly only residual stress, and the corrosion may be initiated at a microscopic crack tip that does not repassivate rapidly. Incremental crack growth may then occur, resulting in fracture of the implant. Industrial uses of stainless steels in saline environments have shown susceptibility to stress corrosion cracking, and therefore it is a potential source of failure for implanted devices.

Electrochemical techniques can be used to build up an understanding of the corrosion behavior of a metal/electrolyte system. Measurement of the equilibrium corrosion potential, relative to a standard electrode, is used to assess the corrosion behavior. If the equilibrium electrode potential reaches a stable value rapidly, it is concluded that the metal forms a stable and protective passive layer. In some incidences, the equilibrium electrode potential fluctuates with time, leading to the conclusion that the passive layer is continually breaking down and reforming. Conditions that result in a lowering of the equilibrium electrode potential suggest reduced likelihood of device corrosion. Changes in the electrolyte composition—for example, the addition of H₂O₂ to PBS to mimic the in-vivo inflammatory response—caused the equilibrium electrode potential of Ti to increase, suggesting a reduction in the corrosion resistance, although when the H₂O₂ was replaced with PBS alone, the equilibrium electrode potential returned to a value similar to that in PBS

alone.^[10] Changes in the surface properties of the metal—for example, surface treatment of 316L and Nitinol stents, causing the formation of an amorphous oxide—resulted in a lower and more stable equilibrium potential.^[11] In bacterial cultures, the equilibrium electrode potentials of Ni-Cr and precious metal alloys were shown to drop in response to the formation of a biofilm on the surface, thus influencing the electrolyte interaction with the surface.^[12]

Small polarization of the electrode on either side of the equilibrium electrode potential (e.g., ± 20 mV) gives rise to the polarization resistance. This is a measure of the corrosion rate of the material under the defined conditions. This is a nondestructive technique and can be used to compare different materials under similar conditions, demonstrating the greater corrosion resistance of certain metals or the enhanced corrosion resistance of a particular surface modification or environment.^[12,13]

Anodic polarization, in which the metal is polarized over a wide potential range ($\pm 1-2$ V), is often used to compare materials. In particular, the position of the breakdown potential and the magnitude of the passive current are used to compare the corrosion resistance of different alloys, different surface modifications, or the influence of different electrolyte compositions. Three different titanium alloys—Ti6Al7Nb, Ti13Nb13Zr, and Ti15Zr4Nb—were studied using measurement of corrosion current density versus time and anodic polarization, and both studies concluded that the Ti6Al7Nb was the most corrosion resistant and that all three alloys had a high pitting corrosion resistance.^[14,15] Electrochemical processes have been used to evaluate the effect of casting conditions and subsequent sandblasting or polishing processes on titanium and titanium alloys^[13] and demonstrated that all the titanium materials tested were highly corrosion resistant and that the surface treatments had more effect than the casting processes. Surface treatment to form an amorphous oxide on 316L stainless steel and NiTi stents was analyzed using anodic polarization. The original polycrystalline oxide on the 316L had a high susceptibility to pitting corrosion as demonstrated by a relatively low breakdown potential and a large hysteresis loop before repassivation. The treated surfaces were highly pitting corrosion resistant as demonstrated by a high breakdown potential and insignificant hysteresis.^[11] Various surface treatments of NiTi^[16] have also demonstrated an effect on corrosion resistance by evaluation of a reduction in passive current density and an increase in the breakdown potential for all treated surface compared to an untreated control.

The characteristics of the passive layer can also be evaluated using AC impedance measurements. This technique evaluates the resistance of the electrolyte at

the metal/solution interface and therefore can be used to follow the interaction of the components of the electrolyte—for example, proteins, cells, and bacteria—with the surface of the metal and their influence on the corrosion behavior. Using impedance spectroscopy,^[17] it was concluded that the addition of H₂O₂ caused a decrease in the corrosion resistance of Ti owing to its influence on the structure of the oxide. It was suggested that the H₂O₂ thickened the oxide and increased its porosity. Thermal oxidation of Ti6Al4V caused a change in the electrochemical impedance spectroscopy results but did not impair the osteoblast cell response to the material.^[18] AC impedance measurements for commercial pure Ti in culture medium with and without L929 murine fibroblasts demonstrated that a layer of biomolecules formed on the surface and acted as a capacitor, reducing the diffusion of molecules and therefore increasing corrosion resistance.^[19]

Fretting corrosion can be assessed by measuring the corrosion current and anodic polarization behavior.^[7] Comparison of different Ti alloys demonstrated the poor fretting behavior of the conventional Ti alloy Ti-6Al-4V and the much improved behavior of Ti-15Zr-4Nb-4Ta.

There are many studies in the literature that evaluate the electrochemical behavior of implant alloys using a range of electrolytes to model the in-vivo environment. It is important to consider the properties of the environment so that these studies are useful predictors of the in-vivo corrosion. The biological environment to which biomaterials are exposed during prolonged use (i.e., the internal milieu of the body) can be described as an aqueous medium containing various anions, cations, organic substances, and dissolved oxygen. The anions are mainly chloride, phosphate, and bicarbonate ions. The principal cations are Na⁺, K⁺, Ca²⁺, and Mg²⁺, but there are smaller amounts of many others. This represents an environment with a chloride concentration of approximately a third of that of sea water.^[20] The concentration of dissolved oxygen also influences the aggressive nature of the environment and in venous blood is approximately a quarter of that in air. The organic substances include low-molecular-weight species as well as relatively high-molecular-weight proteins and lipids. The protein content of the environment is known to have a significant influence on the corrosive nature of body fluids.^[21,22] The pH in this well-buffered system is around 7.4, although it may change for short periods following surgery due to inflammation to as low as 4 or 5.^[2] The temperature remains constant around 37°C. When metals are placed in this environment, the electrochemical reactions result in the dissolution of metal ions into the electrolyte. Once in solution, the metal ions can interact with components

of the electrolyte, and this can influence the corrosion process and the biological response to the corrosion products.

There is sufficient evidence to support the premise that the presence of proteins, cells, and bacteria can influence the rate of corrosion of some metals.^[6,12,20–23] The stability of the oxide layer depends on the electrode potential and the pH of the solution. Proteins and cells can be electrically active and interact with the charges formed at the interface and thus affect the electrode potential.^[2] Bacteria^[12] and inflammatory cells^[10,20] can alter the pH of the local environment through the generation of acidic metabolic products which can shift the equilibrium. The stability of the oxide layer is also dependent on the availability of oxygen. The adsorption of proteins and cells onto the surface of materials could limit the diffusion of oxygen to certain regions of the surface. This could cause preferential corrosion of the oxygen-deficient regions and lead to the breakdown of the passive layer. Alternatively, the biomolecule adsorption layer could act as a capacitor preventing the diffusion of molecules from the surface.^[19]

The biological molecules could upset the equilibrium of the corrosion reactions by consuming one or more of the products of the anodic or cathodic reaction. For example, proteins can bind to metal ions and transport them away from the implant surface. This will upset the equilibrium across the charged double layer and allow further dissolution of the metal. Clearly if either the accumulating positive metal ions in the surrounding media or the accumulating electrons in the metal are removed, the balance between the dissolution and the replacement of the ions will be disturbed. This will occur in the biological environment surrounding implanted alloys due to the interaction of the proteins with the metal ions. Metal ions can form complexes with proteins,^[3,24,25] and these complexes can be transported away from the immediate vicinity. This removes the metal ions from the charged double layer at the interface allowing further release of metal ions to reestablish the equilibrium. Similarly, relative movement between the implant and the tissue—for example, at a bearing surface or on a cyclically loaded implant—will cause mixing at the interface and will modify the composition of the electrolyte and may modify the surface of the alloy.^[6] The equilibrium is established precisely because of the imbalance of charge, so that if the charge balance is disturbed, further corrosion will occur to attempt to reestablish the balance. The result will be continued dissolution as the system attempts to achieve this equilibrium. An environment that allows the removal of electrons in contact with the metal or stirring of the electrolyte will achieve this.

SURFACE ANALYSIS OF THE METAL

The effect of corrosion on the metal occurs at the surface. It is possible to investigate the corrosion behavior of a metal/electrolyte system by evaluating changes to the surface properties of the metal. This includes changes in the composition of the surface both in terms of a depth profile and as a function of time. Many of the commonly used surgical alloys contain highly reactive metals such as titanium, aluminium, and chromium. Because of this high reactivity, they will react with oxygen upon initial exposure to the atmosphere. This initial oxidation leaves an impervious oxide layer firmly adherent to the metal surface; thus all other forms of corrosion may be significantly reduced because the oxide layer acts as a protective barrier. The manufacturing process for implant alloys may include a passivating step to enhance the oxide layer prior to implantation, for example, nitric acid treatment of 316L stainless steel.^[26]

Of the three elements that are strongly passivated (i.e., aluminium, chromium, and titanium), only Ti is used on its own. Chromium is widely used in alloys, especially in stainless steels and in the cobalt-chromium-based alloys, where it is normally considered that a level of above 12% gives good corrosion resistance and about 18% provides excellent resistance. Aluminium has an important role in several Ti alloys, whereas titanium is used as a pure metal or as the major constituent of alloys.^[27] In alloys, the passivating layer promoting the corrosion resistance is predominantly composed of one of these metal oxides. For example, chromium oxide passivates 316L stainless steel and Co-Cr-based alloys and Ti oxide in Ti alloys. The other alloying elements may be present in the surface oxide, and this can influence the passivity of the layer.^[28] Careful pretreatment of the alloys can be used to control the passivity of these alloys by controlling the structure and chemistry of the oxide layer.^[11,16] In particular, production procedures need to be controlled due to their influence on the surface oxides, for example, the cleaning^[29] and sterilization^[30] procedures.

The stainless steels used in implantable devices are passivated by the chromium oxide that forms on the surface. It has been shown, however, that in a physiological saline environment, the driving force for repassivation of the surface is not high.^[5] Thus, if the passive layer is broken down, it may not repassivate and active corrosion can occur.

Localized corrosion can occur as a result of imperfections in the oxide layer, producing small areas in which the protective surface is removed.^[31] These localized spots will actively corrode and pits will form in the surface of the material. This can result in a large degree of localized damage because the small areas of

active corrosion become the anode and the entire remaining surface becomes the cathode. Since the rate of the anodic and cathodic reactions must be equal, it follows that a relatively large amount of metal dissolution will be initiated by a small area of the surface, and large pits may form.

If some areas of the alloy become depleted in chromium, as can happen if carbides are formed at the grain boundaries, the regions adjacent to the grain boundaries become depleted in chromium. The passivity of the surface in these regions is therefore affected and preferential corrosion can occur. Although this problem can easily be overcome by heat-treating the alloys,^[32] it has been observed on retrieved implants^[33] and can cause severe problems since, once initiated, it will proceed rapidly and may cause fracture of the implant and the release of large quantities of corrosion products into the tissue.

Characterization of the oxide can provide useful information about the corrosion processes that have occurred. As seen in Fig. 2, components of the electrolyte will interact with the surface of the oxide. Metal ions can diffuse through the oxide and be released into the environment, and dissolution of the oxide can occur, also releasing metal ions.^[34] Oxygen can diffuse through the oxide and react with the bulk metal, increasing the thickness of the oxide. Hydroxides can interact with the surface oxide, producing a metal hydroxide surface layer.^[35] Calcium and phosphate ions can become incorporated into the surface oxide. In in-vitro electrolytes containing Ca and phosphate ions, it has been shown that repassivation results in the incorporation of titanium phosphate into and the adsorption of calcium phosphate or calcium titanium phosphate onto the surface of Ti.^[23,36] Macromolecules (for example, proteins and lipoproteins) can adsorb onto the surface.

Fig. 2 Schematic representation of the metal/oxide/biological environment interface.

Superimposed on these reactions are the particular conditions under which the metal is being used—for example, the mechanical environment, the geometry of the device, any relative movement between components, and any compositional variations. There is a dynamic process occurring at this interface, and therefore changes in the surface oxide can have longer-term implications in terms of the performance of a device.

The principal techniques available to study the surface chemical composition are X-ray photoelectron spectroscopy (XPS)^[14,36] and auger electron spectroscopy (AES).^[36–38] They provide information on the elements present in the surface and how the composition changes with depth into the oxide. XPS can analyze the bonding environment of the elements present, and AES can give spatial resolution of the elements.

There have been many studies that have investigated the surface properties of implant alloys and how these change on implantation.^[34] It is well known that the composition of the oxide is not representative of the bulk chemistry of the alloy. For commercially pure Ti, the natural occurring oxide was found to be composed of TiO₂, Ti₂O₃, and TiO.^[28] Ti alloys were shown to have additional alloy component oxides (for example, Al₂O₃, Nb₂O₅, and V-oxides), and the concentration of these oxides in the surface layers was dependent on the pretreatment of the materials. Spontaneously formed oxides on Ti-7Nb-6Al were shown to have large surface enrichment of Al oxide, and Ti-13Nb-13Zr and Ti-15Zr-4Nb were found to have significant surface enrichment of Zr oxide and some Nb oxide but to a lesser extent.^[14] Surface treatments of Ni-Ti stents were shown to influence the oxide composition and thickness,^[16] and this in turn influenced the corrosion resistance. It was concluded that a thin uniform oxide provided the most corrosion-resistant surface. The composition of the oxide and its solubility can be particularly important if there is concern about the biological toxicity of some of the alloy components, for example, Ni in Ni-Ti alloys or Al and V in Ti-6Al-4V.

These analyses can also be used to evaluate the relationship of the corrosion of the metal with time. This can be performed on model in-vitro experiments as well as on retrieval studies, either in animal studies or following clinical implantation.^[34]

CHEMICAL ANALYSIS OF THE ELECTROLYTE

Corrosion results in the release of metal ions into the environment. It is important^[3] to investigate the amount of metal ion released, the chemical form of the metal ion, where and how much is transported away

from the local site, and thus the pathological consequences of the corrosion process.

In an in-vitro closed environment, the quantification of the metal ion concentration in the electrolyte is a measure of the amount of corrosion that has occurred. This can be measured using atomic absorption spectroscopy (AAS) or inductively coupled plasma mass spectroscopy (ICP-MS).^[2] Another important consideration is the valence of the metal ions that have been released; neither AAS or ICPMS will provide this information, but polarography can be used to gain insight into this problem.

In vivo, however, the metal ions can bind to proteins and be transported away from the immediate vicinity of the implant. This has various implications. Since the metal ions are removed from the electrolyte surrounding the metal, the equilibrium will be disrupted and thus allow continual replacement of the metal ions from the surface, i.e., continual corrosion. There is a large body of literature on the release and distribution of metal ions from orthopedic devices as reviewed by Jacobs et al.^[3]

In in-vitro studies, metal ion release can be measured under controlled conditions, and therefore the effect of changing the conditions can be followed closely. For example, the influence of fretting,^[20] the composition of the electrolyte,^[2,39] and the surface treatment of the alloy^[40] can be investigated. These studies also demonstrate how comparison of changes in the surface properties of the oxide layer and ion release into the electrolyte can help to characterize the corrosion behavior of a particular implant alloy/environment system.

In in-vivo studies, total metal ion release is more difficult to obtain, but the distribution of metal ions systemically can be assessed by collecting tissue and organs from around the body (either in animal studies^[41] or at autopsy^[3]) and analyzing for metal ion content using AAS or ICPMS. In-vivo release of metal ions can also be correlated with the local or systemic tissue response using histological methods.^[2,3]

The collection of samples of body fluids (for example, serum and urine from patients following joint replacement surgery) and the analysis of metal ions in these samples have demonstrated significant increases in the concentration of various metal ions, and in some studies the increase correlates with implant loosening.^[3] Different implant systems and the influence of different mechanical environments, for example, can be investigated and compared with clinical outcome.

Studies on the systemic reaction to implant corrosion have concentrated on hypersensitivity reactions, although potential carcinogenicity has also been considered.^[2,3] In these studies, the valence of the metal ion is important. A number of studies have investigated the valence state of chromium released from

implants because the biological activity of Cr^{3+} and Cr^{6+} differ. To study this, polarographic techniques are used and have shown that in Ringer's solution and in blood in-vitro 316L stainless steel releases Cr^{6+} rather than Cr^{3+} .

CONCLUDING REMARKS

One of the important criteria to be taken into account when choosing structural implant alloys is their corrosion resistance. The corrosion resistance of most of these materials is due to a naturally occurring passive oxide layer. Even under these conditions, metal ions are released into the surrounding environment on implantation. Any process that modifies, either intentionally or not, the surface oxide may influence the corrosion resistance of the material. The amount of metal ion release may be so low that it is inconsequential to the structural integrity of the material; however, the biological response to the metal ions may lead to severe adverse biological responses either locally or systemically.

INTRODUCTION

Biological metabolism in living cells dramatically diminishes and eventually stops at low temperatures, a fact that permits the long-term cryopreservation (i.e., low-temperature preservation) of the living cells and tissues. With recent and rapid advances made in the clinical diagnosis and treatment of diseases, there is an increasing requirement for using cell and organ transplantation to cure acquired diseases and to correct genetic defects. Coupled with this, more and more types of living cells, tissues, organs, and engineered tissues are urgently required to be cryopreserved and banked at low temperatures. Cryopreservation is not only important for modern medicine/healthcare but also for many other areas, because it is indispensable for: 1) the banking of a large quantity of living cells/tissues for HLA typing and matching between the recipients and donors to meet the greatly increased clinical needs and, sometimes, the urgent needs (e.g., in a war or in events such as the “9-11” terrorist attack, natural disasters, or other accidents); 2) facilitating the transport of cells/tissues between different medical centers; and 3) allowing sufficient time for the screening of transmissible diseases (e.g., HIV) in donated cells/tissues before transplantation. In addition, 4) any engineered tissues (from tissue engineering research) need to be successfully cryopreserved before their practical use in any applications and commercialization; and 5) the cryopreservation of sperm and oocytes/eggs of endangered or transgenic species is urgently needed.

However, there is an apparent contradiction between the concept of cryopreservation and experimental findings that cells/tissues can be killed by the cryopreservation process itself. In fact, the first successful cryopreservation of living mammalian cells became reality in 1949 when Polge et al.^[1] found glycerol as a cryoprotective agent (CPA), reducing cell's injury during cryopreservation. Since then, a number of glycerol-like CPAs have been discovered and used in cryopreservation. The major steps in the cryopreservation process include: 1) adding cryoprotective

agents (CPAs) to cells/tissues before cooling, 2) cooling the cells/tissues to a low temperature (e.g., -196°C , liquid nitrogen temperature at pressure of 1 atm) at which the cells/tissues are stored, 3) warming the cells/tissues, and 4) removing the CPAs from the cells/tissues after thawing. Injury to cells has been shown to be caused by each or a combination of the above steps. Cryobiology is a multidisciplinary science to study the physical and biological behaviors of cells and tissues (including their interactions with environment) at low temperatures (especially at temperatures below the freezing point of water, 0°C). A very important part of the research in fundamental cryobiology is to reveal the underlying physical and biological mechanisms related to the injury of cells at low temperatures (so-called cryoinjury), especially associated with the phase change of water in both extra- and intracellular environments. With the understanding of the mechanisms of cell cryoinjury, one may establish biophysical/mathematical models describing cell responses to environmental change during the cryopreservation process and use these models to develop the optimal procedures/devices for the long-term cryopreservation of living cells, preventing cryoinjury.

CRYOINJURY MECHANISMS DURING FREEZING PROCESSES

Contrary to popular belief, the challenge to cells during cryopreservation is not their ability to endure storage at low temperature; rather, it is the lethality of an intermediate zone of temperature (-15 to -60°C) that cells must traverse twice: once during cooling and once during warming.^[2] As cells are cooled to about -5°C , both the cells and surrounding medium remain unfrozen and supercooled. Between -5 and about -15°C , ice forms (either spontaneously or as a result of artificially introducing ice crystals to the solution) in the external medium but the cells' contents remain unfrozen and supercooled, presumably because the plasma membrane blocks the growth of ice crystals into the cytoplasm. The supercooled water in the cells

Fig. 1 Schematic of physical events in cells during freezing.

has, by definition, a higher chemical potential than that of water in the partially frozen extracellular solution, and thus water flows out of the cells osmotically and freezes externally (Fig. 1). The subsequent physical events in the cells depend on the cooling rate as shown in Fig. 1. If cells are cooled too rapidly, water is not lost fast enough to maintain equilibrium; the cells become increasingly supercooled, eventually attaining equilibrium by freezing intracellularly.^[3,4] Muldrew and McGann invoked an osmotic rupture hypothesis and model of intracellular freezing injury based on solid experimental data and theoretical derivations,^[4] indicating that the water flux across the cell membrane during the freezing/thawing can induce intracellular ice formation causing injury. Diller and Cravalho developed novel microscopy to observe the cell behavior as well as intracellular ice formation (IIF) temperatures and IIF dynamics during the freezing processes.^[5,6] Recently, based on heterogeneous nucleation theory and thermodynamics, as well as experimental results, Toner et al. developed an IIF model and equations describing the probability of IIF as a function of cooling rate, temperature, and cryobiological characteristics of a specific cell type.^[7,8] The freezing behavior of the cells can be modified by the addition of cryoprotective agents (CPAs), which affect the rates of water transport, nucleation, and crystal growth. Karlsson and Toner further developed a model of diffusion-limited ice growth inside cells in the presence of CPAs.^[9] They successfully predicted the IIF phenomena as a function of cooling rate, temperature, and CPA concentration, and also predicted optimum cooling protocols preventing IIF. In most cases, cells undergoing intracellular ice formation (IIF) are killed.^[4,7,8,10–19]

If cooling is sufficiently slow, the cells will lose water rapidly enough to concentrate the intracellular solutes sufficiently to eliminate supercooling. As a result, the cells dehydrate and do not freeze intracellularly. However, if the cells are cooled too slowly, they will experience a severe volume shrinkage and long-time exposure to high solute (mainly electrolyte)

concentrations before eutectic temperature (the temperature at which all components in a solution are solidified) is achieved, both of which may cause cell injury (Fig. 1). Lovelock proposed that the increased concentration of solutes and cell dehydration have deleterious effects on the lipid-protein complexes of cell membranes, weakening them and increasing lipid and phospholipid losses.^[20] The cell is rendered permeable to electrolytes and swells, eventually rupturing. Levitt proposed that loss of water from the protoplasm brings protein molecules into apposition, presenting the opportunity for the formation of new chemical bonds previously too distant and rigidly structured in hydrated form to permit combination.^[21] Thawing would have a disruptive force on the new combination, permitting unfolding and denaturation. Karow and Webb explained slow freezing injury as a consequence of the extraction of bound water from cellular structures for incorporation into ice crystals, denuding proteins of lattice-arranged bound water essential to cell integrity.^[22] The possible effects that may cause cell injury as a result of concentration of solutes have been characterized collectively by Mazur et al. as “solution effects.”^[23] Mazur et al. suggested that solution effects on cells are greatly enhanced in a slow cooling process during which the time of the exposure of cells to a highly concentrated solution is prolonged. They also indicated that hyperosmotic stress may cause a net leak/influx of nonpermeating solutes (mainly, electrolytes); when cells are returned to isotonic conditions, they swell beyond their normal isotonic volume and lyse. Meryman proposed that the slow freezing results in the decrease in intracellular volume beyond a critical volume.^[24] As the cell reduces in size in response to increasing extracellular osmolarity, the compression of contents enhances the resistance to further shrinking. This results in a hydrostatic pressure difference across the cell membrane, incurring cell membrane damage. Steponkus and Wiest proposed a maximum cell surface area hypothesis: Cell shrinkage induces irreversible membrane fusion, and hence the effective area of cell membrane is reduced; when returned to isotonic

condition, the cells lyse before their normal volume is recovered.^[17] Some cells could be shown to exhibit a reversible inhibition of shrinkage at some point during a progressive increase in extracellular solute concentration, implying the development of membrane stress.^[25] Alternative theories have embraced such mechanisms of slow-freezing injury as macromolecule denaturation from dehydration or phase transition of membrane lipids.^[26] Pegg et al. proposed a packing effect, which is an inverse dependence of cell survival upon the proportion of the initial sample volume that is occupied by the cells.^[27] Mazur and colleagues, however, have proposed that a considerable portion of the damage, at least in human erythrocytes, is due to the reduction in the size of the unfrozen channels, which results in increased cell-ice or cell-cell contacts or interactions.^[28]

In general, either too high or too low a cooling rate can kill cells, although the mechanisms underlying cell damage are different. These cell responses to freezing were first expressed quantitatively by Mazur^[2] and directly linked with cell cryoinjury by Mazur's two factor hypothesis:^[23] 1) at slow cooling rates, the cryoinjury occurs due to the solution effects (i.e., the solute/electrolyte concentration, severe cell dehydration, and the reduction of unfrozen fraction in the extracellular space), and 2) at high cooling rates, cryoinjury occurs due to the lethal intracellular ice formation (IIF). The optimum cooling rate for cell survival should be low enough to avoid IIF but high enough to minimize the solution effects. Based upon this, an optimal cooling rate for cell cryosurvival should exist between the high and the low rates, as shown in Fig. 1. This has been confirmed experimentally. As shown in Fig. 2, cell survival plotted as a function of cooling rate produces a characteristic inverted U-shaped curve. There is an optimal cooling rate for a specific cell type. For a given cell type, low cooling rate (relative to the optimal cooling rate) results in

Fig. 2 Relationship (inverted U shape) between percent survival and cooling rate in three types of cells. Stem cells refer to mouse bone marrow stem cells, and hamster cells refer to hamster oocytes. (Redrawn from Ref. [13].)

solution-effects cryoinjury while high cooling rate (relative to the optimal cooling rate) results in lethal IIF.

It is clear from the above cryobiology theory that whether a given cooling rate is too high or too low for a given cell type depends on the ability of water to move across the cell membrane, i.e., water permeability of cell membrane, which is cell-type dependent. Differences in water permeability account largely for the magnitude of difference in optimal cooling rates for different cell types (Fig. 2). Diller et al.,^[6] Levin et al.,^[29] McGrath et al.,^[30,31] and Gao et al.^[32,33] developed devices/modeling to determine cell membrane permeabilities. Devireddy and Bischof et al. developed a novel differential scanning calorimeter (DSC) method to determine cell permeabilities during the freezing processes.^[34] The rate of water transport across cell membrane during the freezing process with different cooling rates can be described by four simultaneous equations.^[35] The first relates the loss of cytoplasmic water to the chemical potential gradient between intracellular supercooled water and external ice, expressed as a vapor pressure ratio,

$$\frac{dV}{dt} = \frac{L_p A R T}{v} \ln \frac{P_e}{P_i} \quad (1)$$

where V is the volume of cell water, t is time, L_p is the permeability coefficient for water (hydraulic conductivity), A is the cell surface area, R is the universal gas constant, T is temperature, v is the molar volume of water, and P_e and P_i are the vapor pressures of extracellular and intracellular water, respectively. The change in this vapor pressure ratio with temperature can be calculated from the Clausius-Clapeyron equation and Raoult's law:

$$\frac{d \ln(P_e/P_i)}{dT} = \frac{L_f}{RT^2} - \frac{N_v}{(V + N_v)V} \frac{dV}{dT} \quad (2)$$

Here, N is osmoles of intracellular solute and L_f is the latent heat of fusion of ice. Time and temperature are related by the cooling rate (B), which, if linear, is given by

$$\frac{dT}{dt} = B \quad (3)$$

Finally, L_p is related to temperature by the Arrhenius relation,

$$L_p = L_{p0} \exp \left[-\frac{E_a}{R} \left(\frac{1}{T} - \frac{1}{T_0} \right) \right] \quad (4)$$

where L_{p0} is the permeability coefficient of water at a known temperature, T_0 ; E_a is the activation energy of L_p ; and R is the universal gas constant.

To avoid intracellular freezing, the water content of the cell given by the above four equations must, before reaching the intracellular ice-nucleation temperature (usually between -5 and -40°C), have approached the equilibrium water content given by

$$V = \frac{vM_i}{\exp\left(\frac{L_f}{RT} - \frac{L_f}{273R}\right) - 1} \quad (5)$$

where M_i is the initial osmolality of the extracellular solution. The above quantitative expressions permit one to calculate the extent of supercooling in cells as a function of the cooling rate provided one knows or can estimate the permeability of the cell to water (L_p), its temperature coefficient or activation energy (E_a), the osmoles of solute initially in the cell, and the ratio of the cell surface area to volume. The results of such calculations are commonly expressed as plots of the water content of a cell as a function of temperature relative to the normal or isotonic water volume. Figure 3, for example, shows computed water loss curves for mouse ova. The calculated extent to which a cell becomes supercooled is the number of degrees that any given curve is displaced to the right of the equilibrium curve at a given subzero temperature. In the example shown, mouse ova cooled at $4^{\circ}\text{C}/\text{min}$ will be supercooled by 15°C as the temperature passes through -20°C . Three biological parameters have special influence on the position and shape of these curves, namely water permeability coefficient (L_p), its activation energy (E_a), and the size of the cell, or more properly, its surface-to-volume ratio (A/V). An increase in L_p produces the same effect as a comparable decrease in cooling rate. The effect of cell size is the opposite. An increase in size reduces the cooling rate required to produce a given probability of intracellular freezing. Changes in these two parameters shift the positions of the curves. Changes in the activation energy, E_a , have a major effect on the shape of the curves. For instance, the dashed line in Fig. 3 shows the effect of changing E_a from 14 to 17 kcal/mol. All the parameters needed to compute the curves can be estimated from permeability measurements. Once computed, these curves can be used to estimate the probability of intracellular freezing as a function of cooling rate. Cells that have dehydrated close to equilibrium, prior to reaching their ice-nucleation temperature, will have a zero probability of undergoing intracellular freezing. Cells that are still extensively supercooled when cooled to their nucleation temperature, and therefore still hydrated, will have a high probability of undergoing intracellular freezing.

It should be mentioned that in the preceding text, Mazur's theory and method have been introduced as an example to show how to predict an optimal cooling

Fig. 3 Computed kinetics of water loss from mouse ova cooled at 2 to $8^{\circ}\text{C}/\text{min}$ in 1 M DMSO. The curve labeled EQ shows the water content that ova have to maintain to remain in equilibrium with extracellular ice. The other solid curves, labeled 2 to $8^{\circ}\text{C}/\text{min}$, were computed assuming the activation energy E of L_p to be 14 kcal/mol. The dashed curve shows the effect of changing E to 17 kcal/mol. (Redrawn from Ref. [15].)

rate to prevent IIF. Different parameters and cryobiological properties of cells will be needed to predict optimal cooling conditions to prevent IIF if different physical models are used, as described by Toner et al.,^[7,8] and Muldrew and McGann.^[4]

PREVENTING CRYOINJURY DURING SLOW FREEZING

It could be inferred from the preceding text that a slow cooling process should be used to avoid IIF. While the avoidance of numerous and large intracellular ice crystals is necessary for cell survival, it is not sufficient. Most cells also require the presence of cryoprotective agents (CPAs). The role of glycerol as an effective CPA for sperm and human erythrocytes was discovered nearly 50 years ago by a research group in Mill Hill, England.^[1,35] Glycerol remains one of the most effective and commonly used CPAs to date, although others have since emerged and are, in some cases, more effective, namely dimethylsulfoxide, ethylene glycol, methanol, propylene glycol, and dimethylacetamide. The most important characteristic of all these solutes is that they are, for the most part, readily able to permeate cells and they are relatively nontoxic to cells in concentrations approaching 1 M or more. The primary basis for their protective action is that they lower the concentration of electrolytes during freezing and decrease the extent of osmotic shrinkage at a given low temperature.^[15,36] The extent of protection depends primarily on the molar ratio of the CPA to endogenous solutes inside and outside the cells, and the general protective mechanism of action is thus

colligative. The effectiveness of a given CPA for a given cell type usually depends on the permeability of that cell to that CPA and that CPA's toxicity. While this class of CPAs must permeate to protect, their permeation before freezing and their removal after thawing generates osmotic volume changes, which themselves can be damaging,^[37-39] a topic that will be further discussed in the following text.

The second class of CPAs is composed of non-permeating solutes. This includes sugars and higher molecular weight compounds such as polyvinylpyrrolidone (PVP), hydroxyethyl starch (HES), polyethylene glycols (PEG), and dextrans. In most cases, these solutes will not protect in the absence of a permeating CPA, but will often substantially augment the effectiveness of a permeating CPA or permit the use of a lower concentration of permeating CPA. These non-permeating CPAs may contribute to enhance vitrification of the solutions, stabilize proteins and membranes, and prevent progressive ice formation.^[40-42]

PREVENTING CRYOINJURY BY VITRIFICATION

All preceding discussions refer to the role of CPAs during slow equilibrium freezing at low enough cooling rates to prevent intracellular ice formation (IIF). A diametrically different approach to cryopreservation is to use either high concentrations of certain CPAs or ultrarapid cooling rates ($>10^6$ °C/min) to induce the cell cytoplasm to form a glass (i.e., to vitrify cells/tissues) rather than to crystallize. However, ultrarapid cooling rates are technically difficult to achieve. Several of the CPAs that are effective in ameliorating slow freeze injury also act to promote glass formation, but the required concentrations are so high, e.g., 4–8 M,^[41] that they can be very toxic to the cells/tissues.^[41,42] Recently, Jackson et al.^[43] demonstrated the significant effect of interaction between the microwave and CPA concentration on vitrification of aqueous solutions and is developing a novel single-mode microwave cavity to enhance the vitrification with relatively low CPA concentrations and relatively low cooling rates.

CRYOINJURY DURING THE STORAGE PERIOD

Usually, the cryopreserved samples are stored at or below -70 °C. The question is often asked as to the length of time that cells can be kept in the frozen state without damage. The question is probably moot if the storage temperature is below -120 °C and is certainly moot at -196 °C (liquid nitrogen). Below -120 °C, chemical reactions cannot occur in human-relevant times. At -196 °C, no thermally driven reactions can

occur in less than geologically relevant times. The reactions that can occur are the slow accumulation of direct damage from ionizing radiation, but this becomes significant only after centuries of storage.^[15]

CRYOINJURY ASSOCIATED WITH WARMING PROCESS

A cell that has survived cooling to low subzero temperatures still faces challenges during warming and thawing that can exert effects on survival comparable to those of cooling.^[15] These effects depend on whether the prior rate of cooling has induced intracellular freezing or cell dehydration. In the former case, rapid thawing can rescue many cells, possibly because it can prevent the growth of small intracellular ice crystals into harmful large ice crystals (i.e., so-called recrystallization). Even when cells are cooled slowly enough to preclude intracellular freezing, the response to warming rate is often highly dependent on the freezing conditions and cell type and is difficult to produce a priori. For human sperm, previous reports used a wide variety of imprecise methods yielding a wide variety of warming rates. These include thawing in ambient air, in water baths with temperatures ranging between 5 and 37°C, in coat pockets, and thawing the samples in the investigator's hands. A more comprehensive study was conducted by Mahadevan in which warming rates between 9.2°C/min and 2140°C/min utilizing coat pocket, hands, air (5, 20, or 37°C), or water baths (5, 20, 37, 55, or 75°C) were examined in combination with a standard freezing rate of 10.0°C/min from +5 to -80 °C.^[43] The results of that study indicated that slower warming in 20 or 35°C air resulted in more optimal cryosurvival of human sperm in terms of both motility and supravital staining, although there were significant differences in post-thaw motilities only between the two fastest rates (1837 and 2140°C/min) and the other 12 rates. Additionally, Mahadevan examined the interaction between cooling and warming rates.^[43] Slow warming was reported optimal for samples frozen slowly; however, there was little effect of warming rate when a fast cooling rate was employed probably because the cells had been killed by the IIF during the fast cooling process before the warming process started.

OSMOTIC AND POTENTIAL TOXIC EFFECTS OF CRYOPROTECTIVE AGENTS (CPAs) ON CELL INJURY

Survival of cells subjected to cryopreservation depends not only on the presence of CPAs but also on the concentration of the CPAs. For example, the

percentage of mouse bone marrow stem cells that survive freezing after cooling at the optimal rate increases dramatically as the concentration of glycerol increases from 0.4 to 1.25 M.^[44] The results are similar for other cells.^[15] Two important procedures related to the use of permeating cryoprotective agents (CPAs) in the cryopreservation of cells are: 1) the addition of a CPA to the cells before freezing and 2) the removal of the CPA from the cells after thawing. Cells transiently shrink upon addition of a CPA and then return to near-normal volume as the CPA permeates. They undergo transient volume expansion during the removal of the CPA, the magnitude of which depends on how the removal is effected and on the inherent permeability of the cell to water and CPA. In several cell types, for example, oocytes, the addition of cryoprotectants (DMSO and 1,2-propanediol) has been shown to cause disruption of the cytoskeleton chemically.^[45,46] Sperm of many species (e.g., bull, boar, and human) are damaged by exposure to glycerol.^[47] Sherman^[48] reported that glycerol exposure caused a reduction in human sperm motility. Critser et al.^[49] have demonstrated that exposure of human sperm to 7.5% glycerol for as little as 15 min causes a dramatic reduction in sperm motility, accounting for approximately 50% of the motility loss observed after 24 h post-thaw. Historically, bull spermatozoa were exposed to medium containing glycerol for an extended period of time, which was referred to as equilibration time. However, Bemdtson and Foote reported that glycerol was able to permeate bull sperm at either 25 or 5°C within 3 to 4 min, and found further that maximum post-thaw motility occurred when the sperm were exposed to glycerol for the shortest time measured (10 sec).^[50,51] These data suggest that bull spermatozoa are either highly permeable to glycerol or, unlike other cells, permeation is not required for protection. What then is the role of equilibration time? Is it, as some have proposed, a matter of allowing for protective membrane alterations?^[47] It is important to note that human sperm differs from the sperm of most domestic species and does not show enhanced cryosurvival with increasing delay between addition of CPA and freezing.^[48,52] Karow et al. found that the survival of human sperm in vitro at 3°C was significantly enhanced by 20 mM potassium (K⁺) in Tyrode's solution relative to Tyrode's solution with less K⁺.^[53] A metabolizable sugar such as glucose was essential to maintain sperm viability in K⁺-free media. The addition of raffinose to media containing glucose improved motility of sperm stored at 3°C for 6 h. The detrimental effect of glycerol to sperm can be alleviated to a certain extent by reducing the temperature at which the cryoprotectant is added in both bull and human sperm cells.^[49,52,54] To what extent the sensitivity of sperm to glycerol reflects the osmotic

consequence of its addition and removal, or to what extent it reflects chemical toxicity, is a current subject of investigation. Recently, it has been shown that for human sperm, the adverse effect of glycerol is mainly attributable to the osmotic volume changes induced during addition and removal of glycerol rather than specific chemical action.^[37] In this study, a systematic investigation was also conducted to determine the human sperm volume excursion (shrinkage or expansion) tolerance limits beyond which the cells will be irreversibly injured. The tolerance limits determined for human sperm in combination with the permeability data of cell membrane to water and CPA have been used to develop the optimal multistep procedures for addition and removal of glycerol in sperm to prevent cell osmotic injury.^[37]

COLD SHOCK INJURY AT LOW TEMPERATURES ABOVE THE WATER FREEZING POINT

Currently, most procedures for cryopreservation of sperm, across species, utilize an initial slow cooling rate between body temperature or the temperature at which the sample is collected (often ambient temperature) and +5°C.^[47,52,55,56] In general, this is due to the fact that some species of mammalian spermatozoa are sensitive to temperature changes in this range, with abrupt cooling (a high cooling rate) causing a high frequency of the cells to become irreversibly damaged. This phenomenon has been termed cold shock or chilling injury.^[47,57] The sensitivity of sperm to cold shock varies among species; bull, ram, boar, and stallion sperm are highly sensitive, dog and cat sperm are moderately sensitive, and rabbit and human sperm are relatively resistant.^[47,49,54,57] The resistance of human sperm to cold shock is of particular importance in the context of developing new approaches to human sperm freezing. It is also an important example of the differences in fundamental cryobiology of cell types among species, highlighting the fact that simple modifications of procedures developed for freezing of domestic animal sperm are unlikely to yield optimal results in other species. Currently, the mechanism of cold shock is unclear.

OTHER POTENTIAL MECHANISMS OF CRYOINJURY

In most previous studies to date, cells have generally been considered simple compartments of cytoplasmic solution enclosed by a semipermeable plasma membrane. The emphasis has been on how cell survival is related to the physical responses of the whole cell to

the physical-chemical events involved in the cryopreservation process. Survival has generally been defined in terms of its viability (e.g., the intactness of cell membrane, etc.) and/or the ability of the cells to undergo subsequent growth and development (e.g., hematopoietic stem cells or embryos). Intactness of the plasma membrane is obviously necessary for functional cell survival. However, in many cases (e.g., granulocytes; Armitage and Mazur^[58]), intactness of the plasma membrane is not sufficient. Findings like the latter emphasized that cells are not simply bags of cytoplasm bound by a plasma membrane. Rather, within the bounds of the plasma membrane are other membrane-bound structures and organelles essential to cell functions. Little is known about how these intracellular structures and organelles respond to freezing, partly because it is difficult to assay their state and function *in situ* in an unambiguous fashion.^[59]

The spermatozoon has been used as an especially good model for investigating the cryobiological role of both intracellular structures and the plasma membrane, because sperm possess two clearly defined and measurable characteristics, motility and the acrosome reaction phenomenon, both of which depend on both functional integrity of organelles and the plasma membrane. An especially attractive feature of the acrosome reaction endpoint in cryobiology is that it involves membrane fusional events.^[60] Investigation of the effects of freezing on such a reaction may provide an experimental model for the growing view that membrane fusion plays a major role in cryobiological injury.^[28,61] To be fully functional, sperm must reach the site of fertilization and the oocyte, capacitate, undergo the acrosome reaction, penetrate the zona pellucida, and fuse with the plasma membrane of the oocyte. Freezing could interfere with or ablate the capacity of the sperm to undergo one or more of these steps.^[62-64] While a motile spermatozoon is not necessarily a fully functional cell, a nonmotile sperm or one exhibiting a damaged plasma membrane is almost certainly nonfunctional (in the context of unassisted fertilization). Consequently, multiple levels of biological function must be considered in assessing the role of the biophysical parameters that have been shown to be critical to cell survival.

SUMMARY

Although there is great diversity in the cryobiological response of different cell types or given cells among different mammalian species, cryosurvival requires that cell freezing and thawing be carried out within certain biophysical and biological limits defined by cryobiology principles. Namely: 1) Cells must be

frozen in such a way that little or none of their water freezes intracellularly. In addition, they must be warmed in such a way that any unfrozen intracellular water remains unfrozen during warming, or that small ice crystals that form during cooling remain small during warming.^[15] 2) Even when these conditions are met, most cells will not survive unless substantial concentrations of CPAs are present. These CPAs must be introduced before freezing and removed after thawing in ways that do not exceed osmotically tolerable limits. Their concentrations also must not be toxic. Although these general limits are necessary, they may not be sufficient, for a number of possible reasons. One is that cells may be injured by factors such as cold shock that have nothing to do with ice formation or CPA damage. Another reason is that cell viability limits are defined primarily in terms of an intact plasma membrane that retains normal, semipermeable properties. It is possible that conditions that allow the plasma membrane to survive may not allow the survival of critical organelles inside cells.

As reviewed in the preceding text, with the progress in understanding mechanisms of injury to cells during cryopreservation, various physical modeling and mathematical formulations have been developed in cryobiology research to simulate a cell's response to environmental change during the cryopreservation process and to predict optimal cryopreservation conditions.^[2-4,7,65] The ability of these predictive models has been confirmed using data collected on cell types ranging from plant protoplasts to mammalian embryos.^[4,7,15,37,38,65] Application of these models to a given cell type requires the determination of a series of cell cryobiological characteristics, including 1) osmotic behavior of the cells, cell volume and surface area, as well as osmotically inactive intracellular water fraction; 2) temperature dependence of cell membrane permeability coefficients to water and the CPA as well as reflection coefficient of cell membrane to the CPA; 3) temperature dependence of safe volume excursion limits of cells; 4) intracellular ice formation temperatures, 5) kinetic and thermodynamic heterogeneous nucleation parameters, etc. These characteristics of many cell types have not been investigated until recently. Determination of these cryobiological characteristics as well as further understanding of the mechanisms of cryoinjury and cryoprotection of CPAs are ongoing research in fundamental cryobiology. Other important on-going research areas in fundamental cryobiology include the investigations of 1) mechanisms and modeling of cryoinjury and cryoprotection to multicellular systems, i.e., tissues and organs^[66,67] and 2) mechanisms of new potential CPAs, such as antifreeze proteins^[68] and inhibitors of cell apoptosis.^[69]

Defibrillators

Paul Wang

Stanford University Medical Center, Stanford, California, U.S.A.

INTRODUCTION

Defibrillators are devices that deliver electrical shocks to the heart in order to convert rapid irregular rhythms of the upper and lower heart chambers to normal rhythm. External defibrillators deliver energy to the chest externally, creating a high energy field in the heart. Automatic external defibrillators (AEDs) have automated features that permit their use by nonmedical personnel and lay people. Implantable defibrillators are fully implantable devices that deliver electric energy internally to the heart.

DEFIBRILLATION

Ventricular Fibrillation and Ventricular Tachycardia

Basic definitions

Normal Conduction System and Sinus Rhythm. The normal impulse originates in the sinus node, which lies within the right atrium, one of the two upper chambers of the heart. The impulse from the sinus node spreads through the two atria and activates the auricular-ventricular (A-V) node and His-Purkinje system, which spreads the electrical activation through the ventricles (Fig. 1). The left ventricle is the primary chamber of the heart responsible for pumping blood to the body. This pattern of activation is responsible for the normal rhythm, called sinus rhythm. With activity there is an increase in heart rhythm; the increased heart rate provides an increased amount of blood flow to the body required by exertion.

Ventricular Tachycardia. In some cases, particularly in the setting of severe abnormalities of function of the ventricles, the electrical impulse in the heart originates in the ventricles rather than in the atria. These rhythms, when rapid, are termed ventricular tachycardia or ventricular fibrillation. Ventricular tachycardia is a rapid heart rhythm originating in the ventricles, usually from one location at a time, at a rate over 100 beats per minute and usually between 150 and 250 beats per minute. Ventricular tachycardia most commonly originates from a relatively constant position

within the ventricles. Each beat of such ventricular tachycardias on the surface electrocardiogram (ECG) is nearly identical. These ventricular tachycardias are considered monomorphic. In contrast, ventricular tachycardias may be less commonly polymorphic, meaning that they originate from shifting locations in the ventricles, and each beat's shape changes over time. Ventricular tachycardias frequently occur in individuals who have had prior heart attacks, called myocardial infarctions. The rapid activation of the ventricles during ventricular tachycardia is inappropriate to the metabolic demands of the heart and body and causes low blood pressure and poor output of the heart. The decreased blood flow through the heart, called cardiac output, may manifest as the absence of a pulse.

Ventricular Fibrillation. Ventricular fibrillation is an extremely rapid rhythm originating in the ventricles but without a discrete point of origin. Multiple regions of the ventricles are activated simultaneously by moving wavefronts that are changing over time (Fig. 2). The ventricular rate is difficult to count and exceeds 300 beats per minute. Activation of many regions of the left ventricle results in no significant contraction of the ventricles. Ventricular fibrillation uniformly results in immediate death unless defibrillation is performed.

Atrial Fibrillation. Atrial fibrillation is an extremely rapid rhythm originating in the atria without a discrete point of origin (Fig. 2). There are multiple wavefronts of electrical activation throughout the atria. Atrial fibrillation results in no significant contraction in the atria. However, passive blood flow from the atria fills the left ventricle. Therefore, patients are usually able to function fairly normally during atrial fibrillation, and the ventricles continue to contract. Patients may be asymptomatic or may experience symptoms such as shortness of breath, fatigue, or rapid heart sensation.

Mechanisms of ventricular fibrillation

Ventricular fibrillation is characterized by multiple waves of cardiac excitation that travel from one region to the next adjacent one. The activation pattern changes from beat to beat. Each beat is called a cycle.

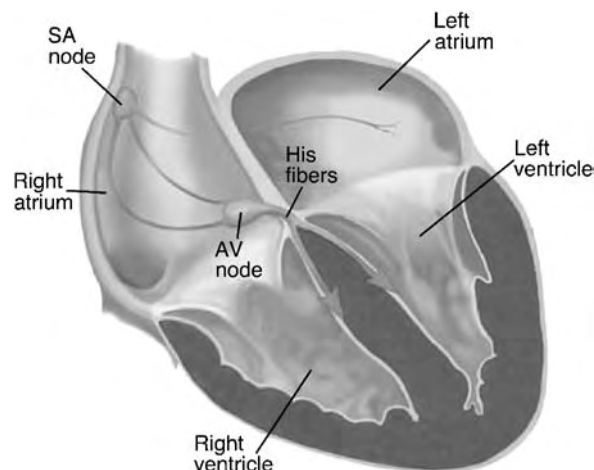

Fig. 1 Normal conduction system of the heart. The normal impulse originates in the sinus node of the heart within the upper chamber called the right atrium. The impulse travels through the right and left atria and reaches the A-V node. The impulse then travels through the His-bundle and Purkinje fibers to the ventricles.

The period of time between cycles is approximately 210 milliseconds (ms).^[1] Activation occurs so rapidly that each region of tissue has just recovered the ability to be electrically activated, a state called excitability. There may be brief periods during which the ventricular tissue is excitable prior the arrival of the next wavefront, consistent with a so-called excitable gap.^[2] However, existence of an excitable gap during human ventricular fibrillation has not been clearly demonstrated.^[1] Ventricular fibrillation is often described as proceeding through four stages.^[3] In the first two stages, comprising the first one to two minutes, activation occurs rapidly at a cycle length of 90 to 120 ms. In the last two stages, activation slows significantly.

Biophysics of Defibrillation

Mechanism of defibrillation

Defibrillation is based on the termination of the multiple activation wavefronts that are responsible for sustaining ventricular fibrillation.^[4] An electrical field is created, altering the membrane potential of the heart muscle cells called myocytes, and disrupting the activation wavefronts present in ventricular fibrillation.^[4,5] Electrical activation of cardiac tissue, referred to as depolarization, must occur over a sufficiently large region or mass of myocardial tissue to terminate the preexisting wavefronts. Depolarization of up to 90% of the myocardial mass may be necessary for successful defibrillation.^[6]

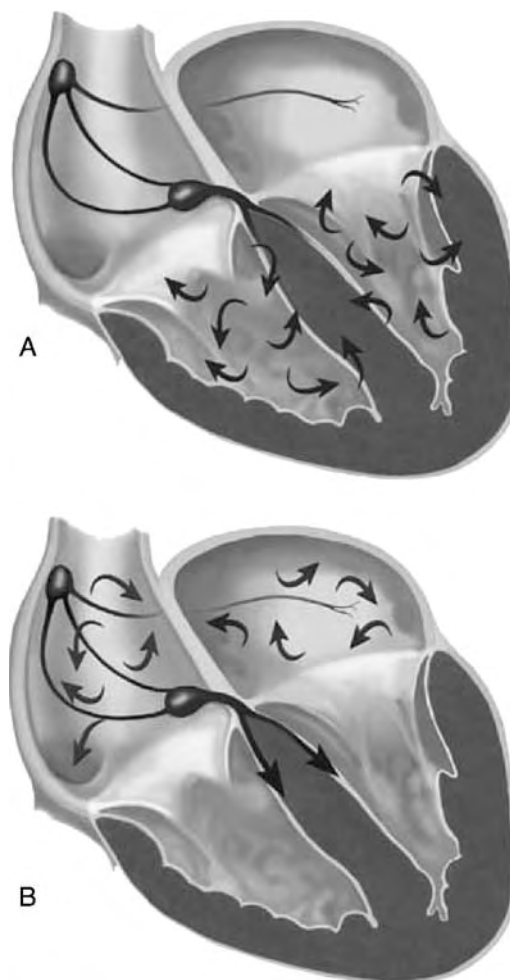

Fig. 2 Schematic diagrams of ventricular fibrillation and atrial fibrillation. (A) Ventricular fibrillation is an extremely rapid rhythm created by multiple wavefronts of electrical activation that are constantly changing. The rate is over 300 beats per minute and results in no significant contraction of the ventricles. Death occurs unless defibrillation is rapidly performed. (B) Atrial fibrillation is an extremely rapid rhythm in the atrium resulting from multiple wavefronts of electrical activation without a discrete point of origin.

Waveforms

The two commonly used clinical waveforms for defibrillation are monophasic and biphasic shocks. In monophasic shock waveforms, the polarity does not change during the shock. In contrast, in biphasic shocks, the polarity of the shock reverses during the shock delivery (Fig. 3). In general, biphasic shocks are more successful in defibrillating the heart than monophasic shocks.^[7]

Implantable defibrillators most commonly use biphasic shock waveforms. Their shocks use a truncated exponential waveform. External defibrillators more recently have begun using biphasic shock waveforms with a damped sinusoidal shape.

Fig. 3 Monophasic and biphasic waveforms. During monophasic waveforms, the polarity of the energy delivered is constant throughout the duration of the shock. During biphasic waveforms, the polarity reverses during the shock.

EXTERNAL DEFIBRILLATORS

Clinical Use

External defibrillators used by medical personnel

External defibrillators are nonimplantable devices used primarily to convert ventricular fibrillation by delivering a shock to the chest. External defibrillators may also be used to convert ventricular tachycardia and atrial fibrillation. External defibrillators are used by hospital and emergency medical personnel.

Clinical use of AEDs

The survival of patients with cardiac arrest depends critically on the time that elapses before defibrillation is performed. To decrease the time to defibrillation, automatic external defibrillators have been introduced for use by first responders, including lay people and nonmedical personnel such as police and firefighters. Automatic external defibrillators (AEDs) recognize the presence of ventricular fibrillation automatically and prompt a lay person or nonmedical personnel to initiate shock delivery.^[8-12] This strategy of defibrillation using AEDs has been called public access defibrillation (PAD). Studies have demonstrated that the time to defibrillation is decreased by Automatic external defibrillator use by police or firefighter personnel. Automatic external defibrillator use by security personnel in casinos and on airplanes has also been shown to decrease the time to defibrillation.

Design

Electrode system

In external defibrillators, the shock is delivered to the chest using one or two types of electrode systems:

1) a pair of hand-held devices called paddles that have metal plates serving as electrodes, or 2) adhesive electrode pads. A conductive gel or paste is used with the defibrillator paddles to improve conductivity through the skin and minimize skin burns. Increased pressure on the paddles or adhesive electrode pads decreases the impedance through the skin and improves defibrillation success.

Defibrillators

Standard External Defibrillator. A standard external defibrillator consists of a power supply, an electrocardiographic monitor, and a connector to the electrode system. The defibrillator has a battery power supply and an AC power supply. The defibrillator uses a step-up transformer and a capacitor to store the charge. External defibrillators typically deliver from 200 to 360 Joules biphasic energy and up to 360 Joules monophasic energy. For pediatric patients, the size of the paddles or adhesive patches is reduced and the amount of energy may be reduced and adjusted to a target Joule/kg of energy delivered. Most manual external defibrillators are capable of synchronizing the shock to the ECG signal to achieve synchronized cardioversion. Some external defibrillators have the additional ability to stimulate the chest wall via the adhesive patches to pace the heart at, for example, 60 beats per minute as a therapy for slow heart rates.

Automatic External Defibrillator (AED). Significant advances in AED technology have reduced the size, weight, and cost of AEDs, and have improved the accuracy of the ability of AEDs to recognize rhythms automatically. These advances have led to the explosion in the use of AEDs in public settings.

AEDs use self-adhesive electrode pads with diagrams indicating the method of applying them. An automatic algorithm interprets the rhythm. The AEDs provide voice and text prompts to guide the user through the steps of use.

AEDs use biphasic waveforms and large electrode pads to convert the rhythm with a high frequency of success. AEDs use nickel cadmium or nonrechargeable lithium batteries that provide a long shelf life. AEDs test themselves automatically in regular intervals.

IMPLANTABLE CARDIOVERTER-DEFIBRILLATORS (ICDS)

History

Implantable cardioverter-defibrillators (ICDs) are fully implantable devices capable of cardioversion (conversion

of atrial fibrillation and ventricular tachycardia) and defibrillation (conversion of ventricular fibrillation). These devices were first implanted in patients in 1980 and were approved by the Food and Drug Administration in 1985. The implantation of the first ICDs required placing an epicardial patch on the surface of the heart, necessitating open-chest surgery. However, the introduction of transvenous ICD lead systems obviated the need for open-chest surgery.

Design

Implantable defibrillator design elements

Implantable cardioverter-defibrillator (ICD) systems consist of two main components: the ICD itself, called the generator, and the lead(s).

ICD generator

The ICD generator has several critical components: microprocessor, memory units, high-voltage system, pacing circuitry, and sensing amplifiers. Each device is hermetically sealed within a titanium case and is fully implantable (Fig. 4).

Microprocessor and Memory Units. The microprocessor units are responsible for timing and function control in the ICDs. The ICD receives electrical signals from the sensing amplifier system and classifies the rhythm, using a series of recognition algorithms. Once the ICD determines the therapy should be given, charging of the ICD capacitors occurs.

The ICD is capable of digitally storing the electrical signals from the heart during arrhythmia episodes. These stored signals are called electrograms. The ICD

Fig. 4 ICD generator. The ICD generator has a hermetically sealed titanium casing—called a can—that contains all of the components required for defibrillation and pacing other than the lead(s). The ICD lead is inserted into the top (header) portion of the ICD generator.

may now store several minutes of these electrograms. Physicians can retrieve these stored electrograms in order to reconstruct the arrhythmic events leading to device therapy.

High-Energy System. The high-energy system consists of a battery, DC-to-DC converters, and high-energy output switches.^[13] The batteries used in the ICD industry are predominantly based on vanadium oxide. These batteries have a low internal impedance. High current pulsing of the batteries and reforming of the electrolytic capacitors are automatically performed periodically for optimal high-energy system function. Aluminum oxide may accumulate on the anodal plate of the capacitor in aluminum electrolytic capacitors that are used in most ICDs.

The battery of the beginning of device life of an ICD has a voltage output of approximately 3.2 V. However, defibrillation requires delivery of voltages in the range of 600–800 V. DC-to-DC or step-up converters are used to achieve the high voltage needed for ICDs. These converters consist of a low-voltage high-current switch, a fly-back transformer, a rectifying diode, and a capacitor element. The low-voltage switch closes, permitting current flow to the fly-back transformer. The switch opens and the energy stored in the fly-back transformer is transferred to the secondary circuit, resulting in charge storage on the capacitors. This process is repeated in small steps until the required voltage is stored.

Pacing System. The ICD functions not only by shocking the heart but by pacing it, using small-amplitude electrical stimuli. These electrical stimuli, approximately 3 to 5 volts with a 0.4- to 0.6-ms pulse width, are used to depolarize the heart from leads in the atrium and ventricle in dual-chamber ICDs or from the ventricle alone in single-chamber ICDs.

Sensing Amplifiers. Sensing amplifiers are responsible for sensing the cardiac signal. The cardiac signal amplitude typically varies between fractions of a millivolt during ventricular fibrillation to up to 20 millivolts in normal rhythm. The ICD sensing amplifiers must detect signals with this range of amplitudes even when the amplitude is rapidly changing over time. Because the cardiac signal is used mainly to detect the heart rate, it is important that each heart beat be detected only once per cycle. Because repolarization creates an electrical signal in addition to depolarization, sensing amplifiers must distinguish between the primary depolarization signal and the subsequent repolarization signal.

The electrical signal from the sensing lead typically undergoes amplification and band-pass filtering. There are two basic methods of sensing the rapid

signals of varying amplitude that are present in ventricular fibrillation. An automatic gain control system is one sensing method. Using a decay constant, there is a limit to the rate at which the amplifier may respond to variations in amplitude. Each beat reaching a threshold is counted toward the heart rate. In one modification of this system, the threshold is dynamic and varies based on the amplitude of the prior signals.

ICD leads

The primary functions of ICD leads are to provide a path for the high-voltage energy from the ICD generator to the heart and to carry electrical signals from the heart to the ICD generator for rhythm determination. In addition, the ICD leads serve as pacing leads to prevent slow heart rates.

Implantable cardioverter-defibrillators leads use a coil structure to create the high-current density within large regions of the myocardium required for defibrillation (Fig. 5).

Clinical Function and Use

Implantation of ICDs

Implantation of ICDs involves a number of steps: 1) making an incision for insertion of the ICD and leads; 2) accessing the venous system; 3) advancing

Fig. 5 ICD defibrillation lead. An ICD lead typically has two long defibrillation coils along its length. Energy travels from the ICD generator through the length of the ICD lead to the defibrillation coils. The energy delivered from the ICD defibrillation lead coils creates sufficient current density within a large percentage of the ventricular mass of the heart to convert the rhythm to normal. At the tip of the lead is an electrode used for sensing the cardiac signal and for transmitting electrical stimuli from the ICD generator to the heart to maintain an adequate heart rate.

and positioning the ICD leads within the heart; 4) connecting the leads to the ICD generator; 5) placing the ICD generator under the subcutaneous tissue; 6) testing the ICD function; and 7) surgically closing the skin. Implantable cardioverter-defibrillators implantation is performed in a sterile surgical environment in order to minimize the risk of ICD device infection. Implantation of the ICD system requires expertise gained from specific training in this area. The ICD is fully implantable, meaning that there are no external wires or devices required for its function.

Radiofrequency programming

A device called a programmer is used to communicate and send commands to the ICD. Most current programmers are modified portable computers that use radiofrequency energy to communicate with the implanted ICD. Hundreds of parameters or settings in ICD function may be reversibly altered by commands sent from the programmer. The programmer is used to record and measure the electrical signals from the ICD in order to confirm appropriate sensing and proper connections. Device and lead abnormalities are typically detected using this system. Stored electrograms of the arrhythmia episodes necessitating therapy are transferred by radiofrequency energy from the device to the programmer and may be downloaded to a floppy disk for archiving.

Clinical indications and clinical trials

Implantable cardioverter-defibrillators detect and treat life-threatening ventricular arrhythmias. They are primarily indicated in several groups of patients: 1) patients who have survived life-threatening ventricular tachycardia or ventricular fibrillation, requiring resuscitation; 2) patients with short runs of ventricular tachycardia, prior heart attack, and ventricular tachycardia produced during a special test called an electrophysiologic study; and 3) patients with a prior heart attack and severely reduced heart function. Randomized clinical trials have demonstrated improved survival of patients with ICDs in these three patient groups. Implantable cardioverter-defibrillators are also indicated in patients with episodes of loss of consciousness and ventricular tachycardia produced during electrophysiologic study.

Clinical functions

In addition to terminating ventricular arrhythmias using shock therapy, ICDs in some cases may terminate

ventricular tachycardia using rapid pacing, called antitachycardia pacing. By interrupting the activation pathways resulting in ventricular tachycardia, antitachycardia pacing may terminate the rhythm without the need for shock therapy.

Most defibrillators may pace the heart in response to patient activity, a feature called rate-adaptive or rate-responsive pacing. In addition, a new generation of ICDs is capable of pacing not only the atrium and the right ventricle but also the left ventricle, via a lead placed in a vein on the outside of the left ventricle. This vein is accessed via the vein called the coronary sinus, which drains into the right atrium. The activation of both ventricles is called biventricular pacing or resynchronization therapy and has been shown to increase exercise tolerance in patients with severely impaired heart function.

CONCLUSION

External defibrillators deliver energy to the heart via the chest wall. Automatic external defibrillators are being used by nonmedical personnel and lay people in numerous settings. Implantable defibrillators are implantable devices, capable of automatically recognizing life-threatening ventricular arrhythmias and delivering shock therapy directly to the heart. Defibrillators have become critical to improving survival of patients with life-threatening rhythm problems of the heart. Significant technological advances have made these devices more accurate and more successful in converting these rhythms.

Degradable Polymer Composites

Debra D. Wright

Department of Biomedical Engineering, Michigan Technological University, Houghton, Michigan, U.S.A.

INTRODUCTION

Degradable polymers have found a number of uses in biomedical engineering. Drug delivery and tissue engineering are but two examples gaining widespread use. In drug delivery, degradable polymers hold the promise of zero order release, or continuous release of a drug that is independent of time. Current devices have not achieved this gold standard, but they still aid in delivering appropriate amounts of drugs with less reliance on patient compliance.^[1] In tissue engineering, a significant amount of research has investigated the use of scaffolds seeded with cells to replace or augment human tissues. Scaffolds have been shown to mediate cell growth in critically sized bone defects^[2] and mediate nerve cell regeneration.^[3] However, degradable polymers by themselves lack the mechanical properties necessary to sustain fixation of many load-bearing bones while they are healing. Therefore, composite materials are being investigated as new options to traditional materials.

OVERVIEW

Current methods of internal fracture fixation include plates, pins, and screws that are fabricated primarily from metallic materials. There are several limitations with metallic implants. Metallic implants lead to stress shielding, i.e., local weakening of the bone, in the area of the implant due to the high mismatch in stiffness between metals and bone. Metallic plates also prevent the natural healing of bone. Natural healing of bone promotes a large callus formation at the fracture site that supports the fracture as it heals and the bone remodels. This was shown by Sarmiento et al.^[4] when he imposed simple transverse fractures of the radius and ulna on two sets of adult dogs. One group had fixation by a metallic plate while the other group had no fixation method. The group with a metallic plate had significantly less bone remodeling activity and no callus formation. This was also seen by Claes^[5] when comparing metallic plates of different stiffnesses and carbon fiber-reinforced polymer plates. Clinically, this is seen after plate removal as the weakened bone is more susceptible to breakage in up to 30% of

patients,^[6-8] which recreated the original problem. Furthermore, approximately 66% of patients require a second surgery to remove the implant.^[9] For these reasons, alternative devices are desired for internal fracture fixation.

Degradable materials have the potential to solve the current limitations with metallic materials. The challenge is to create materials that are strong enough to support the loads seen in bone while degrading at a rate that matches the remodeling of bone. With a degrading material, a second surgery to remove the plate is avoided, which reduces the cost of the procedure and recuperation time for the patient.^[10] Since degradable polymers by themselves do not have sufficient strength to support bone while it heals, composite materials are the next progression.

This article presents an overview of the materials used in degradable composites, the properties and manufacturing of composite materials, clinical uses of these materials, and current limitations of these devices.

DEGRADABLE POLYMERS

Polymer Structure and Properties

Polymers are long chain molecules derived from many repeating units. Typically, a carbon backbone comprised of covalent bonds is along the chain while weak secondary bonds exist between the molecules. When the carbon backbone is made from groups that are hydrolytically unstable, these long chain molecules will degrade when placed in water. Initially, these polymers were thought to be unsuitable for any application, but the need for biomedical devices that degrade over time has led to a variety of applications for these materials.^[11] There are many degradable polymers clinically used in devices today. The most commonly used materials are the class of materials known as poly(α -hydroxy acids), such as poly(lactide) (PLA) and poly(glycolide) (PGA).^[12] These contain an ester linkage that is hydrolytically unstable. Other bonds that are unstable in an aqueous environment include anhydrides, orthoesters, and amides.^[11] PLA and PGA both have U.S. Food and Drug Administration (FDA)

approval and are currently in clinical use for a variety of applications. An excellent review on the properties of many degradable polymers has been written by Middleton and Tipton.^[11] This article focuses on the poly(α -hydroxy acids) and how the structure and properties of these materials affect their mechanical behavior, degradation behavior, and use in polymer composites because they are the most common polymers found in clinical use today. The most important structural characterizations are percent crystallinity and molecular weight.

The percent crystallinity plays an important role in determining the properties of a polymer. With all other factors remaining constant, a polymer with more crystalline regions will be stronger and degrade at a slower rate. Crystalline regions in the polymer have stronger secondary bonds between the polymer chains that make them less susceptible to degradation. PGA is a highly crystalline material (45–55%), and can be made into stiff, high-strength fibers. The crystallinity leads to a reduction of strength of 50% at two weeks, and it completely loses its structural integrity at four weeks.^[11] It can take anywhere from four to six months to degrade completely.

In contrast, PLA can be found as one of two isomers, *D* (PDLA) and *L* (PLLA). These isomers can also be blended into a copolymer poly(DL-lactide) (PDLLA). PDLLA is completely amorphous, degrades too rapidly to be used in orthopedic applications, and has a low tensile strength. The naturally occurring form, poly(L-lactide) (PLLA) is approximately 37% crystalline and requires over two years to be completely resorbed. However, copolymers of PLLA and PGA can speed the degradation time by reducing the crystallinity of the resultant polymer.^[11]

The second factor that has a major impact on the degradation of these polymers is the molecular weight. As the molecular weight of a polymer increases, the polymer is strengthened by the covalent bonds along the chain and the increasing number of entanglements in the structure. The degradation process also slows because more covalent bonds must be broken per chain before the polymer chains can be metabolized. The molecular weight degrades before the strength or mass of the polymer so this can be a method to track the degradation and predict the degradation rate of a new material.^[11]

Degradation Mechanisms

In general, polymers may degrade by a variety of mechanisms, including oxidation, heat, radiation, or chemical exposure. The focus of this article is polymers that degrade in a biological system. When a biodegradable polymer is placed in water, the

hydrolytically weak functional group is susceptible to degradation from the aqueous environment. As the polymer chains become shorter, they become water soluble and can be metabolized. Degradation methods have been well studied for drug delivery applications, and there are two main mechanisms:

- Surface erosion.
- Bulk erosion.

Surface erosion occurs on the surface of the implant and when water is unable to penetrate the device in large concentrations. The device will shrink in size as the water degrades the polymer on the surface. This type of erosion will occur in all devices and particularly devices with a low porosity. It is also more common with the polyanhydrides and polyorthoesters because of their high hydrophobicity.

In bulk erosion, water penetrates the bulk of the device and breaks bonds from within the polymer device. This type of erosion is more common in devices with porosity. Bulk erosion is also more common for polymers based on poly(α -hydroxy acids). As these polymers degrade, lactic or glycolic acid are formed that can then be converted into natural metabolites. If the production of these degradation products is greater than the metabolism of them, the pH of the surrounding area increases. As the local acidic concentration is raised, the degradation process is further accelerated. Clinically, this can result in pain, discomfort, or swelling.^[13] In a porous implant, nutrients and fluid flow may be quite small in a low-porosity implant, which leads to even more acid buildup and more rapidly accelerates the degradation of the polymer.

Biocompatibility

Perhaps the biggest challenge in any biomaterial's application is the design of materials that will integrate with the human body and cause no adverse reactions. The biocompatibility of a material refers to how well the material is accepted in the body.^[1] When a foreign material is implanted in the body, the surrounding tissues are compromised, and the inflammatory response is activated to heal the damage. During this process, proteins and cells adsorb to the surface of the implanted material. The overall response of the body to the material is a complicated reaction to a combination of factors such as material properties, surface topography, and surface chemistry. The vascularity of the implant site also affects the biocompatibility. Well-vascularized sites can transport degradation products more easily than poorly vascularized tissues, which leads to an improved cellular response.^[14] Clinical

responses to degradable implants include irritation at the implant site, a sterile sinus, or osteolysis.^[14] Examples of the biocompatibility of specific devices will be presented subsequently.

COMPOSITE MATERIALS

Materials are generally classified into three categories: polymer, metal, and ceramic. A composite material is a combination of two or more categories or two or more distinct materials from one of the categories. Composite materials are particularly useful in engineering because they typically take advantage of the best properties of each of the individual materials used to create the composite.

The common element in any composite material is the existence of a reinforcing phase surrounded by a matrix. The reinforcing phase could be particulate or fibrous. Fibers possess a high strength and high modulus due to the orientation of the polymer molecules. The matrix can be ductile or brittle and has several primary functions. It acts to transfer the applied load between the fibers, bonds the fibers together, and deflects cracks during fracture. A critical component to the success of a composite material is the bond between the reinforcing phase and the matrix.

This bonding is even more critical in the corrosive environment of the human body. If water can leach into the composite and degrade the bond between fiber and matrix, the results can be disastrous. The first polymer composites intended for orthopedic fracture fixation failed because of this very reason. A partial list of materials under consideration for these plates included carbon fiber-reinforced epoxy resin, polyetheretherketone (PEEK), polysulphone (PS), polybutylene terephthalate (PBT) reinforced with polyacrylonitrile (PAN), carbon fiber-reinforced PS, and chopped carbon fiber-reinforced PEEK.^[5,15–19] The benefits of these materials include less stress shielding in the bone, a modulus that can be tailored from about 1.5 to five times that of bone,^[18] and the elimination of corrosion effects from metallic plates. Despite these improvements, however, a loss of strength and stiffness was noted after in-vitro conditioning or in-vivo use in animal models. Delamination of the fibers from the matrix was noted and a foreign body response to the carbon fibers eliminated these composite materials from in-vivo applications.

Another desirable aspect of composite materials is the ability to tailor the properties of the material more precisely. By adjusting the percentage of reinforcing material, the properties can be varied dramatically. Often, there is an optimum concentration of reinforcing material and deviating from this optimum will yield an inferior material.

Self-Reinforced Composite Materials

A subcategory of composite materials are self-reinforced composites (SRC). These composites consist of a reinforcing fiber and matrix material that are fabricated from the same polymer—hence the term self-reinforced. They are processed by a hot compaction mechanism. They were developed at least in part because of the stringent requirements of the FDA. A common problem in the biomaterials field is the development of new materials to meet new device requirements and determining their biocompatibility. New materials are often developed from existing materials having proven biocompatibility, which eliminates some of the toxicity testing that surrounds a new material.

A schematic of the process commonly used to fabricate SRCs is shown in Fig. 1. Fibers are laid in a metal mold and heated under pressure so that the outer surfaces of the fiber soften and meld together to form the matrix. There is no addition of a matrix material or other bonding agent. Two main events occur during processing:

1. The reinforcing fibers lose their orientation (and strength).
2. The bonding between the fibers, or development of the matrix, increases.

The matrix must be developed so that it is strong enough to bond the fibers together while still maintaining the orientation and integrity of the original fibers. The fiber orientation gives the composite its strength. The optimum balance between the loss of orientation and the development of the matrix yields the best mechanical properties.

Although the focus of this article is on degradable polymer composites, SRCs have been developed for a variety of materials and applications. Ward et al. have used this method with great success with polyethylene (PE),^[20–28] poly(ethylene terephthalate),^[29] and polypropylene fibers.^[30] Wright et al. have used these

Fig. 1 Schematic of the standard self-reinforced composite processing method. At left, a constant mass of the fibers is placed in a mold. The middle picture illustrates the composite being heated under pressure. At right, the fibers are now joined to each other and considered a composite material.

methods to fabricate SRCs from poly(methyl methacrylate) in an effort to improve the bone cement in total hip replacements.^[31,32] Törmälä and colleagues have performed the most extensive studies with self-reinforced degradable composites,^[10,33–54] and this work will be discussed in detail subsequently.

POLYMER FIBER COMPOSITES

Self-Reinforced Composites

Self-reinforced composites fabricated from PLLA and PGA materials are currently in clinical use and marketed by Linvatec Corporation. They can be fabricated into screws, pins, rods, tacks, wires, and membranes, and can be used for a variety of fractures, especially in the humerus, radius, and craniofacial applications. The manufacturers of these implants have written a number of review articles on the subject of their manufacturing, use, and clinical successes.^[34,35,47,48,52] Table 1 shows a summary of representative mechanical properties for self-reinforced rods and injection-molded controls for PLLA and PGA materials. The self-reinforced composites show a two to three times increase for most mechanical properties when compared to the injection-molded unreinforced material.^[52]

Early work presented the development of the materials and initial in-vitro biocompatibility results.^[40–42,44,46,49,51,54,55] Animal studies have examined their viability in a variety of applications^[41,42,44,49,51] and have shown some success in load-bearing applications for femoral osteotomies in rabbits.^[41] Amorphous composites based on PGA tend to absorb more quickly—about eight weeks—whereas crystalline composites based on PLLA absorb in about 36 weeks.^[52]

Clinical Uses and Experiences

Clinically, these materials have been in use since 1984, and over 300,000 devices have been implanted.^[48] The originators of this device have performed more than 3,200 operations with these devices^[48] so the clinical

results of these devices are well documented in studies by the originators of the device^[36,37,39,45,53,56] and others.^[57,58] Complications have been minimal, but they include the formation of a sterile sinus at the site of the implant. McVicar et al.^[57] reported no adverse effects due to the degradation of a self-reinforced PGA membrane, which may be due to the small quantity of material present in the material. For larger implants, where these effects will be magnified, it is recommended that the smallest implant necessary be used in areas that are well vascularized.^[52] These problems also become more pronounced when particulate debris from the device is present and is more prevalent for PGA implants.^[48,13] Ashammakhi et al.^[35] note that PLA particulate debris is found for 0.1% of orthopedic patients. Since self-reinforced PGA implants degrade more rapidly than self-reinforced PLA implants, Ashammakhi et al.^[35] recommend that these implants be reserved for children because of their increased metabolism in bone tissue.

Limitations and Challenges

Self-reinforced composites have revolutionized the degradable composites available for fracture fixation. Their mechanical properties are improved over unreinforced materials, and their clinical use has shown good biocompatibility with few serious complications. However, these materials are mainly processed using a trial-and-error method. Although optimization is mentioned in some articles, no known attempt has been made to link the properties of the starting fibers with the processing method of the composite. Improving the processing techniques to a greater extent could further improve the strength of these materials. Additionally, in some cases, the formation of a sterile sinus can lead to a second operation to remove the implant, which would negate the benefits of a degradable device. Finally, although these implants are biocompatible in the traditional sense, they are surrounded by a fibrous capsule and do not provide good surfaces to guide bone growth and bone bonding to the implant. Further improvements to the manufacturing, reductions in inflammatory responses, and increased

Table 1 Representative mechanical properties for self-reinforced and injection-molded PLLA and PGA

Polymer	Processing	Bending modulus (GPa)	Bending strength (MPa)	Shear strength (MPa)
PGA	Self-reinforced	13	320	240
PGA	Injection-molded	7	218	95
PLLA	Self-reinforced	10	300	220
PLLA	Injection-molded	3	119	68

From Ref. [52].

bone bonding would further improve degradable self-reinforced composites for future applications.

DEGRADABLE POLYMER-CERAMIC COMPOSITES

A recent advance in the area of degradable polymer composites is the incorporation of ceramic particles into the polymer matrix. This can be achieved for porous scaffolds,^[59–65] nonporous materials,^[66–74] membranes,^[75] and injectable materials.^[76,77] The form that the material takes indicates its intended application. Foams and injectable materials are generally targeted toward bone graft substitutes while solid materials can be fabricated into plates, pins, or screws. Membranes are used to guide tissue growth in maxillofacial applications. Table 2 summarizes the polymers and ceramics used in these studies. Although there is a great variety in the polymers and ceramics chosen, the majority of studies focus on derivatives of poly(α -hydroxy acids).

Ceramic particles yield several benefits for degradable polymer composites. First, they add a considerable amount of strength and stiffness to the polymer matrix. Secondly, degradable ceramics such as hydroxyapatite (HA) and α -tricalcium phosphate (α -TCP) have been shown to be extremely biocompatible with bone. Transmission electron microscopy studies have well documented the interface between ceramic particles and natural bone. In these studies, HA is seen to directly bond to bone whereas TCP bonds to bone through an intermediate apatite layer. In both cases, the new bone formed is indistinguishable from new natural bone.^[78–80] Glass ceramics have also demonstrated these bone bonding properties. Dissolution of the calcium and phosphorus from the glass ceramic mediates the formation of an apatite layer on the material and subsequent bone bonding can occur.^[81,82] Despite these excellent properties, ceramics are too brittle to be used in orthopedic applications. However, polymers lack the necessary strength for these same applications, and the build up

Table 2 Polymers and ceramics used for composite applications

Polymer	Ceramic	Use	Authors
PLA	45S5 bioactive glass	Microspheres	Qui et al. ^[77]

of acidic by-products is still a limitation to their use in some applications. The combination of these materials may yield composite materials with properties that match the given need more closely.

Work in this area is relatively new and centers on material development and in-vitro characterization of the resultant materials and apatite formation or cell viability in vitro. Only a few studies have examined the behavior of these materials in an animal model,^[62,69,71–74] and none are in clinical use. However, these materials represent the future of degradable polymer composites, and their development is important to consider in this context.

Polymer-Ceramic Scaffolds

The addition of ceramic particles is highly desirable in three-dimensional scaffold applications. In these applications, the polymer is highly porous, and cell growth is mediated through the interconnected pores. However, these materials lack structural integrity, and, if the degradation products from the polymers cannot be transported out of the scaffold, cell growth will be limited because of the increased acidic environment in the interior of the scaffold. By adding ceramic particles that are also degradable, the strength of the scaffold can be increased, and bone growth can be accelerated or enhanced.

Ignatius et al. has reported use of porous poly(L, DL-lactide) scaffolds with ceramic or glass ceramics in an animal model^[62] as a bone graft substitute. Implants containing either α -TCP or a glass ceramic were implanted in the tibia of sheep, and the bone growth in them was studied at 6, 12, or 24 months. No significant differences were seen between the two ceramic materials, and adverse effects were not reported until 24 months. At 24 months, a significant amount of PLA had degraded, and histological examination found that the bone had osteolytic characteristics. These materials were found to be unsuitable for clinical use primarily because the degradation time of the polymer component did not adequately match the bone healing and ceramic degradation.^[62] The ceramics were completely absorbed at six months whereas the polymer component did not have significant degradation at two years. Their future solutions will seek to better match the degradation time of each component to the healing time of bone.

In another study, Murphy et al. reported the use of a copolymer of PLA and PGA in a 85:15 ratio.^[64] They point to the challenges of bony reconstruction using only a single material. Because the problem is so complex, they have elected to investigate a composite consisting of 85:15 poly(lactide-co-glycolide) with a carbonated apatite layer incorporated in the scaffold. Their hypothesis is that the addition of the apatite

layer prior to cell seeding will enhance bone growth and mineralization within the scaffold. The processing method consisted of one-step solvent casting and particulate leaching. Their work centered on an in-vitro study that characterized the apatite formation in the scaffold and subsequent mechanical properties. Their work showed a continuous apatite formation within the scaffold and a fivefold increase in compressive modulus after 16 days compared to the control samples.^[64] These studies were not verified in an animal model but instead points to the positive early results seen with these scaffolds.

Marra et al.^[63] has approached this challenge with new materials. Blends of two degradable polymers, poly(caprolactone) and poly(D,L-lactic-co-glycolic acid), have been combined with hydroxyapatite (HA). HA has a higher strength than the TCP ceramics considered earlier, but it also has a slower degradation rate. In their work, mechanical studies and in-vitro degradation was studied. Cells were cultured and incubated in physiological conditions. One challenge with all porous scaffolds is promoting growth of cells deep within the scaffold. Their work showed cellular activity and collagen formation 500 μ m within the scaffold, which is an improvement over results seen by others.^[83]

Another novel approach is to fabricate calcium phosphate-PLAGA microspheres—each an individual composite—and sinter the microspheres to obtain a porous disc as done by Ambrosio et al.^[59] Fabrication of the calcium phosphate occurred within the microsphere to promote noncrystalline formation of calcium phosphate that more closely resembles the low crystallinity of natural bone tissue. The size and concentration of the microspheres can be varied to modify the resultant pore size. Composites were fabricated that have a minimum pore size of 100 μ m, and 75% porosity. It is hypothesized that these scaffolds will be able to support cellular growth for bone repair applications.

Nonporous Polymer-Ceramic Materials

Nonporous polymer-ceramic composites are used in applications such as orthopedic pins, screws, or plates. The earliest work in this area was performed by Andriano et al.^[70,71] and examined copolymers of poly(ϵ -caprolactone/L-lactide) and poly(ortho ester) reinforced with three proprietary glass fibers. Two fibers were shown to be nontoxic in preliminary tests, but composites with the sodium-calcium-aluminum-polyphosphate glass fiber caused necrosis when implanted intracutaneously in a rabbit.^[71] This may have been due to the radiation sterilization method employed for these materials.

Positive results have also been seen with PLLA/HA^[72] and PDLA/TCP^[69] composites. Furukawa et al.^[72] compared two composites fabricated with a matrix of PLLA and a reinforcing particle of either calcined or uncalcined HA. These materials were implanted in the tibia of a rabbit, and bone bonding was studied at a period of 8, 16, and 25 weeks after implantation. Bone bonding as measured by a detaching mechanical test was improved by at least an order of magnitude for all composites when compared to controls of PLLA at all time periods. No difference was seen between the experimental composites during the experiment. Direct bone bonding was noted for the PLLA/HA composites while a layer of connective tissue surrounded the PLLA implant. Similar bone bonding results were seen by Lin et al.,^[69] but mechanical tests were not performed on the implants after retrieval. In Lin's study, a two to threefold increase in compressive strength is seen with the addition of TCP, which indicated the mechanical benefit of incorporating ceramic particles in a polymer matrix.

Recent research is also investigating new, starch-based polymers as matrices for HA particles.^[73] Initial biocompatibility assays show good results in intracortical and intramuscular implantation in Dutch milk goats at 12 weeks. Bone contact was seen for both implants, although a fibrous layer was noted in areas where bone was remodeling. No strength data was presented for these materials. New materials may yield an improved match between bone healing rates and polymer degradation rates.

NANOCOMPOSITES

Cutting-edge research is investigating the incorporation of nanometer-sized particles in polymer matrices to control material properties on a much smaller size scale. The primary benefit of these materials is the ability to mimic living tissues in engineered materials in structure and assembly.^[84] Du et al. fabricated a collagen-nanohydroxyapatite that bears resemblance to the organic-inorganic structure of living bone.^[85,86] Their work found that bone remodeling occurred in a similar manner to natural bone in intimate contact with the nanocomposite. Although work is just beginning in this area, the ability to design materials with structures at the nano-scale represents an exciting future for new devices.

CONCLUSION

In 1995, the market for biodegradable medical devices was \$300 billion in the United States alone. Only 5%

of this market was for orthopedic devices whereas 95% was for degradable sutures.^[11] However, the market for orthopedic devices is growing at approximately 6% per year. If new materials, methods, and devices are developed for orthopedic applications utilizing degradable polymers, the potential for market growth in this area is limitless. Degradable polymer composites have the potential to drastically reduce the medical costs associated with these procedures because the need for a second operation to remove the device is eliminated. For example, one British study calculated the cost savings associated with degradable implants to be £608–1011 (approximately US\$ 1000–1700) per patient when compared to metallic implants due to decreased time in the hospital.^[10] The market growth and savings in health care costs are limited by the properties of the polymeric materials and the current technologies used to process them.

It is clear that novel new approaches need to be considered to solve the complex problem of fracture fixation and bone healing. Traditional devices fabricated from metals do not have mechanical properties that match natural bone and require more recuperation time and a higher medical expense. Degradable polymer devices do not have the necessary strength for many applications and are plagued with problems of acidic by-product buildup, which leads to an inflammatory response and loss of bone.

Composite materials, such as the ones presented here, represent the future for these devices. Self-reinforced degradable devices reduce the stress shielding seen in metallic implants and eliminate the need for removal, but they are still not strong enough as fracture fixation plates for load-bearing bones, such as the femur and tibia. These implants also have the complication of a foreign body reaction due to the reaction of the degradation products with the human body and a limited ability to bond directly to bone. Polymer materials reinforced with ceramic particles hold the promise of better mechanical properties and bone bonding ability, but only clinical studies will verify whether these promises become reality.

INTRODUCTION

Dendrimers are a unique class of macromolecules, having a highly branched, three-dimensional architecture with very low polydispersity and high functionality (Fig. 1). A typical dendrimer molecule has an initiator core, several interior layers composed of repeating units, and multiple active terminal groups (Fig. 2). The diameter of a polyamidoamine (PAMAM) dendrimer ranges from 1.5 to 14.5 nm. Dendrimers such as PAMAM dendrimers have attracted growing attention in engineering, materials science, chemistry, and biological science, because they have unparalleled properties over traditional polymers and because a variety of commercialized dendrimers allow researchers to easily construct nanoscale devices. Dendrimers are recognized as the most versatile, compositionally, and structurally controlled nanoscale building blocks. Thus, dendrimers provide critically needed nanoscale starting building blocks for the development of high specialty materials such as light-harvesting agents,^[1] chemical sensors,^[2] catalysts,^[3] and cross-link agents.^[4] Dendrimers have also been investigated in the biomedical field for drug delivery,^[5,6] gene therapy,^[7] and imaging contrast agent delivery.^[8] Several products using dendrimer as platform have been developed and commercialized upon the approval of the FDA. Among them, VivaGelTM (Starpharma, Melbourne, Australia) is a topical microbicide to prevent the transmission of HIV and other sexually transmitted diseases. SuperFect[®] (Qiagen, Valencia, CA) is used for gene transfection of a broad range of cell lines. Alert TicketTM (US Army Research Laboratory, Adelphi, MD) is an anthrax-detection agent. Stratus[®] CS (Dade Behring, Deerfield, IL) is used for cardiac marker diagnostic.

The pharmaceutical and biomedical applications of dendrimers, with an emphasis on polymeric drug delivery, are mainly reviewed. Polymeric drug delivery technologies help improve the efficiency of drug delivery and the biopharmaceutic and pharmacokinetic property of drugs. In a polymeric drug delivery system,

drugs of interest can be either attached to the polymer backbone via a permanent/cleavable bond or physically encased inside the core of a polymeric micelle. According to Langer, polymeric drug delivery systems are expected to continuously maintain drug levels in a therapeutically desirable range, reduce harmful side effects, decrease amount of drug needed, decrease number of dosages and possibly less invasive dosing, improve patient compliance with the prescribed drug regimen, and facilitate drug administration for pharmaceuticals with short in vivo half-lives (e.g., proteins and peptides).^[9] If a polymer backbone has additional sites, these additional sites will be able to accommodate targeting moieties to direct the drug carrier to a desired biological site and allow the modification of the polymer backbone with other functional groups to change the solubility of the system. For example, polar groups can be incorporated to increase the solubility in aqueous phase, or nonpolar groups can be incorporated to enhance the solubility in lipid regions. The unique structure makes dendrimers an ideal building block to create a polymeric drug delivery system with multiple functionalities, which is difficult to be achieved with linear polymers (Fig. 3).

DENDRIMER SYNTHESIS

Dendrimers were introduced by Tomalia^[10] and Newkome^[11] in the early 1980s. The synthesis of early dendrimers was based on the divergent method.^[10,11] In each generation-adding step, the molecular weight and the diameter of the dendrimer were nearly doubled. For the synthesis of an ammonia core dendrimer, a two-step process, exhaustive Michael addition to a suitable amine initiator core with methyl acrylate and extensive amidation of the resulting esters with a large excess of ethylenediamine, is required. The so-called de Gennes dense packing effect is such that the end groups on the surface of the globule become more densely packed as a dendritic molecule grows larger, and eventually the dendrimer reaches its upper

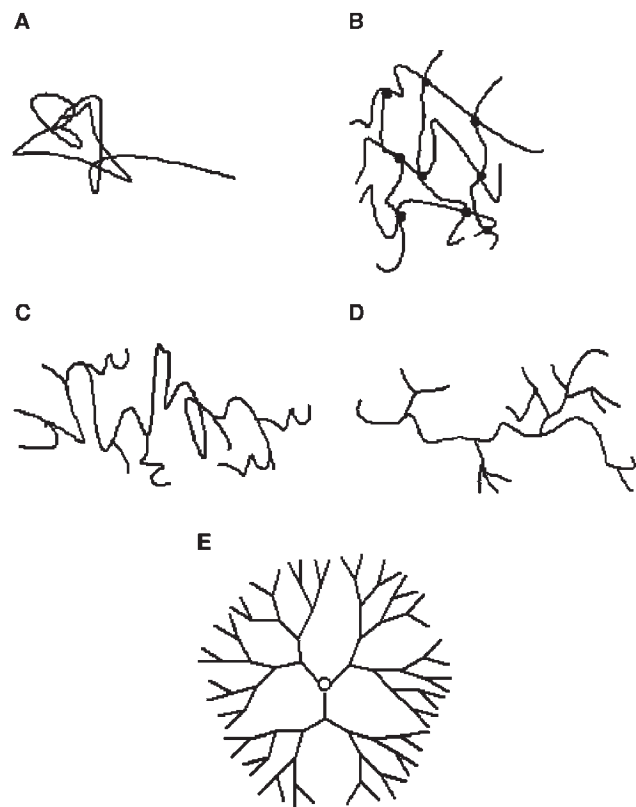

Fig. 1 Simplified architecture of four major classes of polymers: (A), linear; (B), cross-linked; (C), branched; (D), hyperbranched; and (E), dendritic.

generation limit.^[12] Ethylene diamine (EDA)-cored PAMAM dendrimers can only reach up to generation 10 owing to the de Gennes dense packing effect. The divergent method requires tens and even hundreds of simultaneous reactions and produces imperfect samples because of incomplete growth steps and side reactions. In addition, currently available technologies are not advanced enough to isolate pure divergently grown dendrimers from side products of similar structures. Frechet and coworkers^[13] developed the convergent method as a good alternative to the divergent method. Opposite to the divergent method, the reaction begins at the surface of a future dendrimer molecule and proceeds to the core, only requiring two simultaneous reactions to produce next generation of the dendrimer. This method allows intermediate purification, and results in the production of a nearly perfect dendrimer structure. In addition to the divergent and convergent methods, double-stage convergent growth approach,^[14,15] hypercore or branched monomer approach,^[16] double-exponential dendrimer growth approach,^[17] orthogonal coupling,^[18] and self-assembly strategy^[19] have also been developed for reducing synthesis and purification steps and to increase yield. A variety of dendrimers such as poly(propyleneimine) (PPI) dendrimers,^[20] polyesters,^[21]

polyamides,^[22] phosphorus dendrimers,^[23] thiophosphate dendrimers,^[24] melamine dendrimer,^[25] siloxane dendrimers,^[26] and peptide dendrimers^[27] can be obtained by using different initiator cores, repeat units, and surface groups.

DENDRIMER-BASED DRUG DELIVERY SYSTEMS

The delivery of drugs relies on physical or chemical bonding of drugs to the carrier. The dendrimer-based drug delivery systems are discussed in the following sections.

Physical Encapsulation and Bonding

Dendritic box

Meijer and coworkers were the first to entrap guest molecules in a dendritic molecule by using tert-butyloxycarbonyl (t-BOC) groups to produce bulky, sterically crowded amino acid derivatives on the PPI dendrimer surface (Fig. 4). Owing to a densely packed shell on the dendrimer surface, several Rose Bengal dye molecules were stably entrapped inside the dendrimer core, and the guest molecules did not diffuse out of the box^[28] even after prolonged heating or sonication. The Rose Bengal molecules can be liberated by acid hydrolyzing the outer shell to yield the original flexible dendrimer.

Unimolecular dendritic micelles

Polymeric micelles, made of amphiphilic block copolymers, are investigated for drug encapsulation and delivery, because the inner core created by the aggregation of hydrophobic segments can accommodate hydrophobic drugs. The critical micelle concentration (CMC) of polymeric micelles is much lower than that of conventional low-molecular-weight micelles; however, the polymeric micelles are still temperature and concentration dependent. Dendritic unimolecular micelle is another delivery system that can entrap drugs inside. Unimolecular micelles have amphiphilic characteristics, and one single micelle molecule behaves similarly to an assembly of amphiphilic molecules in an aqueous environment. Different from conventional micelles, unimolecular micelles are independent of concentration and temperature.

Dendritic unimolecular micelles can be built through PEGylation on the dendrimer surface (Fig. 5).^[11,29–32] The hydrophobic core of a dendrimer can hold guest molecules and increase the water solubility of hydrophobic drugs.^[33] When polyethylene glycol (PEG) is conjugated to the dendrimer, it helps stabilize

Fig. 2 Schematic structure of a G2.5 PAMAM dendrimer molecule (generally, commercial carboxylate dendrimer is in the carboxylate sodium salt form which is stored in methanol).

entrapped drugs and provide additional sites to retain more drugs. Low generation PAMAM dendrimers have desired biological properties such as nontoxicity and nonimmunogenicity for *in vivo* applications.^[34] However, they are more flexible than higher generations (generation 5 or higher), which may allow some of the surface sites to fold inward, thus reducing their accessibility for reaction and the volume of the inner space.^[35,36] Therefore, low generation dendrimers do not entrap the same amount of guest molecules as high generation dendrimers.^[33] Dendrimer generation and PEG's arm length and arm number at the surface impact the encapsulation of drugs. In the case of the encapsulation of anticancer drugs within PEGylated PAMAM dendrimers done by Kojima et al.,^[37] dendritic micelles with a higher generation dendrimer core

(G4.0 as opposed to G3.0) and longer PEG arms (average molecular weight 2000 Da as opposed to 550 Da) achieved high drug encapsulation. Polyethylene glycol arms help not only the stability of the entrapped molecules but also the solubility of hydrophobic molecules within the PEG layers.^[37,38] Yang, Morris, and Lopina^[39] found that low generation such as G3.0 PAMAM-based dendritic micelles can still enhance the water solubility of hydrophobic compounds, and PEG arm length can be varied to control the extent of the solubility. The scaffold size and flexibility are important factors considering their drug delivery applications. The number of PEG arms and their molecular weight on the surface should be controlled to avoid a decrease in the flexibility of the system. In addition, too many PEG arms would result

Fig. 3 Schematic drawing of an ideal dendrimer-based multifunctionalized drug delivery system.

in steric hindrance, which reduces further coupling other small molecules of interest to the dendrimer surface. Therefore, for practical *in vivo* applications, the use of high generation or densely PEGylated dendrimers was deliberately avoided.

Dendritic hydrogels

Multiple surface-ending groups make dendritic macromolecules ideal cross-linking agents to obtain dendritic cross-linked hydrogels. The number of the junctions can be controlled by varying the generation of the dendrimer. Gitsov and Zhu^[40] synthesized amphiphilic hydrogels with highly shape persistent cross-linking junctions composed of linear blocks such as PEG and perfectly branched dendritic macromolecules and found that the relative PEG content, the polarity of the medium, and the temperature affected the swelling of the gels. The incorporation of PAMAM dendrimers into poly(vinyl alcohol) (PVA) can lead to the formation of physically cross-linked PVA/

Fig. 4 A dendritic box.

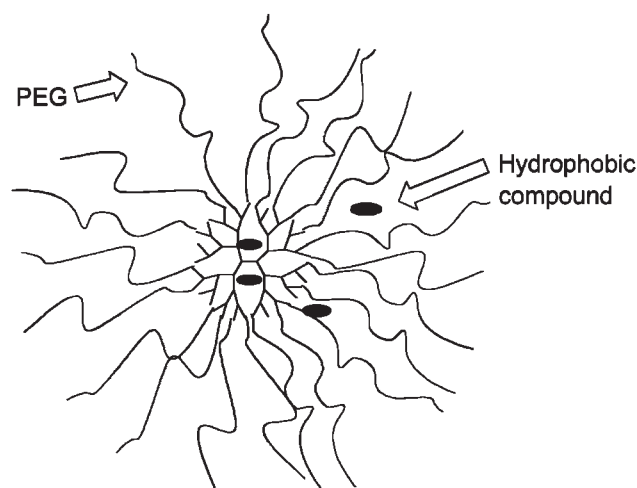

Fig. 5 A unimolecular dendritic micelle.

PAMAM dendrimer hydrogels, and such a hydrogel obtained higher swelling ratios and faster reswelling rate because of the high hydrophilicity of PAMAM dendrimers.^[41] Hydrogels and macroscopic fibers can also form through salt-induced self-assembly of water-soluble, polycationic, phosphorus dendrimers.^[42] Such hydrogels are thermoreversible and their sol-gel transition temperature can be tuned over a wide range of temperatures. Dendrimers may provide hydrogels with inner structures different from conventional cross-linking agents. Dendritic cross-linked hydrogels hold promise for drug delivery and controlled release and need further investigation to obtain thorough understandings of the relationships between hydrogel structure and hydrogel properties.

Dendrimer/DNA complexes

Dendrimers as gene carriers have shown efficiency regarding gene transfection and targeting efficacy *in vitro*. Cationic dendrimers have multiple cationic groups on the surface. Therefore, cationic dendrimers can form complexes with negatively charged DNA. The overall positive charge of the complex allows interaction with negatively charged cell-surface groups (Fig. 6), and can maintain the structural stability of DNA/dendrimer complex.^[43] There are several formulations of the dendrimer/DNA complex that have been investigated, such as PAMAM/DNA,^[43] PEG-PAMAM/DNA,^[44] PAMAM-PEG-PAMAM/DNA,^[45] PPI/DNA.^[46] Gene transfection efficiency depends on the size and amount of dendrimer in the DNA-dendrimer complex. The release of intracellular DNA, stability of DNA in the cytoplasm, unpacking of the DNA-vector complex, and the targeting ability of DNA to the nucleus also affect gene transfection

Fig. 6 DNA/cationic dendrimer complex.

efficiency. Endosomal release, nuclear localization, and transcription may be the rate-limiting steps rather than cellular uptake. The compaction of DNA by dendrimers can protect the DNA from nuclease degradation; however, it also inhibits transcriptional activity for DNA/dendrimer complexes.^[47] Therefore, it is more appropriate to consider the structural effects of DNA/dendrimer complexes on the individual events during the gene delivery process.

Chemical Bonding

Dendrimer–drug conjugates

Drug molecules can be either chemically conjugated to the dendrimer surface or physically encased inside a dendrimer core. For chemical conjugations, a good coupling efficiency may be achieved if functional groups are activated prior to coupling. Hydroxyl (OH), carboxyl (COOH), primary amine (NH₂), thiol (SH), and guanidino are commonly found functional groups in drug molecules and polymers. The strategies for the activation of such functional groups are reviewed and discussed by Veronese and Morpurgo.^[48] There are many drug molecules of interest such as anticancer drugs that can be directly conjugated to the dendrimer surface. Baker and coworkers^[49] conjugated folic acid to the dendrimer surface to obtain a targeting agent to deliver effective doses of the anticancer drug methotrexate to malignant cells. Contrast agents and fluorophores can be also conjugated to the dendrimer surface to detect the alterations of tumor vessel permeability^[50] and to amplify signals in immunoassays.^[51] Polyethylene glycol is widely used in drug delivery

owing to excellent solubility in both aqueous and most organic solutions and nontoxic and nonimmunogenic properties. Attachment of PEG to the dendrimer surface can modify the unfavorable properties of dendrimers and minimize dendrimers' toxicity and immunogenicity. In addition, each PEG strand can provide one additional ending group for coupling reaction(s). Yang and Lopina^[52] have developed synthetic approaches to synthesize penicillin-conjugated PEG-PAMAM star polymers, in which penicillin was conjugated to the outmost ending site of PEG based on full generation and half generation PAMAM dendrimers.

Glycodendrimers

Glycodendrimers are built with carbohydrates as building blocks. A typical building block is saccharide residues such as mannose, D-galactose, and lactose that make up the dendrimer's outer surface groups, the central core, or the branching units. Attachment of saccharide residues to the dendrimer surface produces cluster effect to amplify carbohydrate–protein interactions.^[53] Glycodendrimer's structure advantages generate unique properties. Saccharide-functionalized dendrimers are large enough to span multiple lectin-binding sites.^[54] Immunomodulatory and antiangiogenic properties can be obtained by conjugating D(+)-glucosamine and D(+)-glucosamine 6-sulfate to the dendrimer surface. Dendrimer glucosamine and dendrimer glucosamine 6-sulfate can be used together to prevent scar tissue formation.^[55]

Peptide dendrimers

Peptide dendrimers consist of amino acid building blocks.^[56–58] Dendrimer-mediated oligonucleotide delivery successfully inhibited the *in vitro* vascular endothelial growth factor expression and choroidal neovascularization.^[59] PPI dendrimers significantly enhanced the uptake of oligonucleotides by breast, prostate, and ovarian cancer cells.^[60] Dendrimers were reported to prolong the corneal residence time and increase the bioavailability of pilocarpine nitrate and tropicamide in eye drops.^[61] Recently, Baker and coworkers^[62] proposed a novel DNA-assembled PAMAM dendrimer drug delivery model for targeting cancer cells in which dendrimers conjugated with fluorescein and folic acid separately were linked with complementary DNA oligonucleotides.

DNA dendrimers

Using DNA building blocks to construct polymeric materials has attracted much attention, because DNA

Fig. 7 A DNA dendrimer molecule.

has desirable physiochemical properties. Luo and coworkers^[63] designed and prepared dendrimer-like DNA nanostructures from Y-shaped DNA building blocks for the first time. There are two strategies for the synthesis of the Y-DNA: stepwise synthesis and all-in-one (one-pot) synthesis. In the stepwise synthesis of DNA dendrimers, one arm of a Y-DNA is assembled by two oligonucleotides with partial complementary sequences, and the other two arms of the Y-DNA are assembled by the third oligonucleotide that is complementary to the first two unmatched portions of oligonucleotides. In the onepot approach, a Y-DNA is assembled by mixing equal moles of all three oligonucleotides together and the resulting DNA is stable and almost monodisperse (Fig. 7). Potential applications of such DNA dendrimers may be based on the fact that the multivalent DNA dendrimers can be either isotropic or anisotropic and thus can provide great potential to link other entities.

PROPERTIES OF DENDRIMERS

Starburst™ PAMAM dendrimers are most investigated owing to their early and successful commercialization. The PAMAM dendrimers are water soluble and are called *artificial proteins*, because their size and contour are similar to many important natural globular proteins.^[64] For example, the size of G3.0 PAMAM dendrimer is close to insulin that has a 30 Å diameter,

and G5.0 has an equivalent diameter to hemoglobin of 55 Å. Natural proteins are easily denatured upon the change of pH, temperature, and light. In contrast, dendrimers are much more stable. Their unique properties make them good replacements of natural proteins for drug delivery and gene therapy. The PAMAM dendrimers behave similarly to liposomes. Small lipid vesicles known as liposomes have gained regulatory approval for passive targeted drug delivery,^[65] and are being widely explored for active targeting.^[65–67] Liposomes, however, must be stabilized against leakage, releasing drug before reaching the targeted site. Researchers have exploited the ability to control vesicle parameters including cholesterol content, surface charge, and vesicle size to optimize liposome-based drug delivery. The stability of dendrimers makes them good substitutes of liposome for drug delivery. Dendrimers have shown promise as drug carriers. In order to fully understand the biocompatibility, cytotoxicity, and biodistribution of dendrimers and dendrimer-based delivery systems, *in vitro* and *in vivo* evaluations are necessary. Particularly, good cell viability and morphology, no hemolysis, and other satisfying cellular parameters warrant further studies of dendrimers as carriers for drug delivery.

Roberts, Bhalgat, and Zera^[34] used V79 cells (Chinese hamster lung fibroblasts) and male Swiss-Webster mice to study PAMAM G3.0, G5.0, and G7.0 dendrimers. They found that PAMAM toxicity is dose and generation dependent *in vitro*. There was not apparent evidence of immunogenicity for any tested generation (G3.0, G5.0, or G7.0) in Roberts's study. According to Malik et al.,^[68] cationic dendrimers (with amine end groups) caused hemolysis and cytotoxicity. In contrast, 8-branched and 32-branched anionic carboxylate dendrimers were neither hemolytic nor cytotoxic up to a concentration of 2 mg/ml. Such unsuitable dendrimers as cationic PAMAM dendrimers may be accepted for biological application if the surface is attached to anionic or neutral groups. Twelve branched and thirty-six branched poly(ethylene oxide)-grafted carbosilane (Csi-PEO) dendrimer^[68] at concentrations up to 2 mg/ml did not induce hemolysis or exhibit toxicity to CCRF and HepG2 cells. However, for B16F10 cells, viability was decreased at higher concentrations (over 0.1 mg/ml) of 12-branched or 36-branched Csi-PEO dendrimers. Thirty-six branched dendrimers still allowed higher cell viability than the 12-branched dendrimers. Low generation PAMAM dendrimers (G5.0 or below) appear to have relatively fewer problems for *in vitro* applications than higher generations. The very high polycationic nature of high-generation PAMAM dendrimers (G6.0 or higher) may be responsible for some or all of their toxicity and unusual

biodistribution.^[34] Cationic PAMAM dendrimers may be biologically acceptable if the surface is modified with anionic or neutral group to reduce the toxicity of the “naked” dendrimers.^[68] Other types of dendrimers such as melamine dendrimers have been analyzed in a similar way to PAMAM dendrimers.^[69]

Therapeutics can cross cell membranes or biological barriers with the aid of dendrimers. Anionic PAMAM dendrimers G2.5 and 3.5 showed rapid serosal transfer rates in crossing adult rat intestine *in vitro* and had low tissue deposition.^[70] The transport of G3.0 PAMAM and surface-modified (with lauroyl chains) G3.0 PAMAM across Caco-2 cell monolayers followed endocytosis-mediated cellular internalization.^[71] Based on a study of the dynamics of cellular entry of dendritic polymers into human lung epithelial carcinoma cells, it was found that the cellular entry of dendritic polymers was dependent on the functional end groups and molecular mass.^[72] The electrostatic interaction with negatively charged epithelial cells, probably via the fluid phase pinocytotic route, contributed to a faster cellular entry of cationic G3.0 and G4.0 PAMAM dendrimers. A slow entry of neutral G3.0-PEG and polyol polymers may depend on nonspecific adsorption to the cell membrane and subsequent ingestion by endocytosis.^[72] Thomas et al.^[73] synthesized dendrimer-antibody (60bca, and J591) conjugates and studied their *in vitro* biological properties. These conjugated antibodies bound to the antigen-expressing cells in a time- and dose-dependent fashion, with affinity similar to that of the free antibody. The dendrimer-antibody conjugates were partly internalized. Florence, Sakthivel, and Toth^[74] synthesized lipidic peptide (polylysine) dendrimers based on lysine with 16 surface alkyl (C12) chains and investigated the absorption of a fourth generation dendrimer after oral administration to female Sprague-Dawley rats. They found that the levels of uptake and translocation are lower than those exhibited by polystyrene particles in the range from 50 to 3000 nm.

CONCLUSIONS

The application of dendrimers for drug delivery is promising owing to their unique dendritic architecture. Dendrimers also provide a unique platform to study the mechanism of cellular biology and to develop novel enabling technologies.

INTRODUCTION

The biomechanical analysis in dental area represents a relevant task in biomedical research. Universities, research centers, and industrial laboratories show a growing interest in investigating different aspects such as dental biomaterials performances, soft and hard tissue mechanics, dental implants, and orthodontics devices reliability, by means of experimental and numerical approaches.

In this article, according to the necessity of limiting the arguments to be treated, the attention is addressed to the periodontal ligament (PDL), tooth and dental implant mechanics. These topics allow for a preliminary discussion about the response of the soft and hard tissues that characterize the mechanics in dental area and for a direct investigation about the functional behavior of main structural components during masticatory action.

Particular attention is paid to the numerical approach to dental biomechanics, showing the offered potentialities and discussing the refined and reliable results. Data from experimental analysis are also reported as a basis for a reciprocal reliability evaluation. This article is not only aimed at offering an introduction to the investigation of mechanical problems in dental area but it also gives an appropriate description of specific relevant tasks and can represent the starting point for further developments.

BIOMECHANICS OF THE PDL

The PDL

The PDL is a thin layer of soft connective tissue that surrounds the root of a tooth and provides a connection with the alveolar bone. The transmission of loads, as occlusal and masticatory or orthodontics loads, from tooth to alveolar bone is regulated by the PDL according to its structural configuration, composed of ground material and collagen fibers.^[1] The PDL overall stiffness is much lesser than surrounding bone and tooth materials. As a consequence, the PDL

deformation mostly determines tooth instantaneous and short-term mobility.^[2] Furthermore PDL strain state regulates the activity of cells involved in alveolar bone remodeling process and consequently influences tooth long-term mobility.^[3] It follows that biomechanical characterization of PDL is a fundamental task to analyze tooth response to loads. The biomechanical response of PDL is investigated by means of both experimental and numerical analysis.

Structural Arrangement and Mechanical Behavior of PDL

Alveolar bone, cementum, lamina propria of gingiva, and PDL form the boundary structure of tooth, usually named periodontium. Near the alveolar crest, PDL joins with gingiva, while in the lower portion of its apical region PDL is in direct contact with dental pulp. In crestal, central, and upper apical regions, PDL is directly linked to alveolar bone on one side and cementum on the other side (Fig. 1A). The thickness of human PDL ranges from 0.15 to 0.25 mm, depending on the specific tooth and position around the root and varies with age and healthy condition of the subject.^[1,4]

The PDL is a well-vascularized soft connective tissue consisting of a fibrous stroma, with collagen (varying in the range from 53% to 74% in volume) and elastin fibers embedded in a gel of ground substance. Collagen fibers mainly withstand tensile stresses as most soft connective tissues, while ground substance withstands compressive stresses.

The ground substance is a viscous gel that contains proteoglycans, hyaluronan, glycoproteins, and water. The high liquid content of the ground substance and electrostatic phenomena, mainly involving proteoglycans, determines the volumetric behavior and the consequent compressive stiffness of the PDL. Tissue viscoelastic behavior is mainly dependent on the liquid substance fluxes inside the fibrous network.

Collagen fibers develop through PDL from cementum to alveolar bone. In Fig. 1B, the distribution of the collagen fibers and fibrils, as the principal sub-component of collagen fibers, is reported. Their orientation is influenced by the loads acting on the

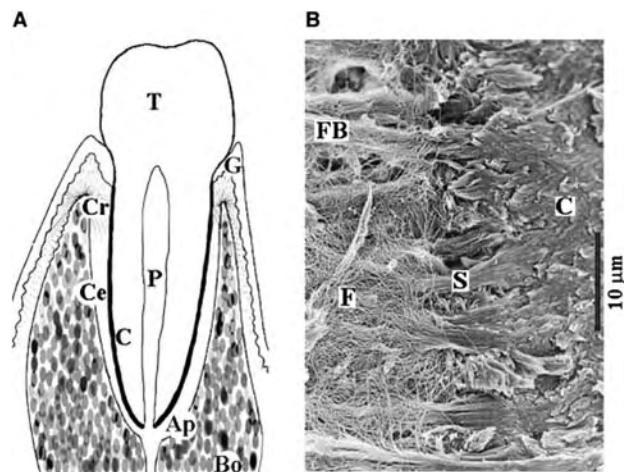

Fig. 1 (A) Schematic representation of tooth (T), alveolar bone (B), gingiva (G), dental pulp (P), cementum (C), crestal region of PDL (Cr), central region of PDL (Ce), apical region (Ap) and (B) configuration of collagen fibrils bundles (F) and fibers (FB) within a human PDL sample; Sharpey fibers (S) connect soft tissue with cementum (C).

tooth. In the unloaded state, they are characterized by a typical crimped conformation, while tensile loading determines uncrimping phenomena. The waviness change under tensile loading contributes to the typical nonlinear stress–strain behavior of the PDL, showing a low stiffness at moderately large strains and much higher stiffness at large strains. By increasing the load, failure phenomena can take place and tissue stiffness decreases, showing a typical softening behavior.

Experimental Analysis of PDL

Experimental investigation of the PDL biomechanical properties is mainly developed following two complementary strategies. To characterize the PDL as a material, it is necessary to develop experimental tests on simple geometry specimens, while the characterization of the PDL as a structure entails experimental testing of the entire tooth unit (tooth, alveolar bone, and PDL).

The former strategy usually requires cutting the tooth unit into slices perpendicular to the tooth longitudinal axis (Fig. 2A).^[5] Subsequently the testing samples are prepared starting from the slices (as indicated in Fig. 2B by white rectangles) to obtain specimens that contain a part of bone, a part of root, and a part of the PDL between them, as reported in Fig. 2C. Samples' cutting is usually developed by rotating metal saws, providing for a continuous perfusion by water or water solutions to reduce tissues alterations. The geometric dimensions of the specimen, with particular regard to the PDL layer, must be carefully evaluated by means of optical microscopes. Experimental tests are developed maintaining the soft tissue inside a physiologic solution, to avoid drying out phenomena. Mechanical tests are usually developed by standard material testing machines, but because of the peculiar properties of biological samples surfaces, it is necessary to develop special clamping fixtures, to avoid slipping or damage of the sample.^[6] Before testing the PDL specimens, preconditioning procedures of the tissue should be developed to stabilize the material response.^[7] Standard

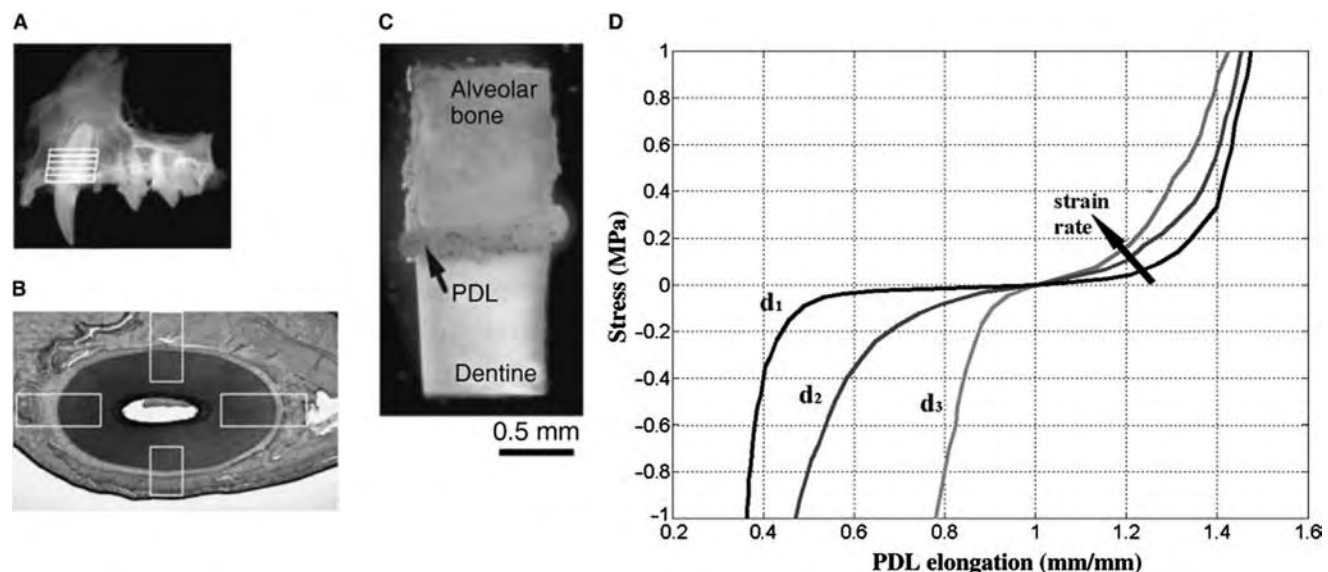

Fig. 2 (A) Experimental tests on tensile and compressive response of cat PDL sample: maxillary canine of cat (white rectangles indicate the transverse sections that are cut out); (B) transverse slice from the maxillary canine (white rectangles indicate the specimens taken for experimental testing); (C) sample including alveolar bone, dentine, and PDL between them; and (D) stress–elongation curves for tensile and compressive tests at different strain rates as d_1 , d_2 , and d_3 .

elongation tests make it possible to obtain information about tissue stiffness and strength.^[8]

Fig. 2D reports data from tensile and compression loading tests, by considering different strain rates, on cat PDL specimens.^[5] Results emphasize the time dependence of PDL mechanical behavior by showing the influence of strain rate on the stress–elongation curve. The different responses of the tissue in tension and compression must be pointed out. A strong dependence on the strain rate is found in compression, while tensile tests are less affected by the strain rate. This behavior is mostly determined by the different fluxes of liquid phases inside the fibers network. Elongation tests at different strain rates are performed also for investigating hysteresis, stress relaxation, and creep response to determine the PDL viscoelastic properties.

Fig. 3 represents data from a tensile loading test on pig PDL specimen.^[6,9] The tensile stress–elongation curve is characterized by strongly nonlinear behavior in the first branch that is correlated with the collagen fibers uncrimping, followed by an almost linear region. During the uncrimping process, mechanical stiffness gradually increases and keeps a nearly constant value in an almost linear range. Afterwards, as previously mentioned, damage phenomena take place and tissue stiffness decreases.

The characterization of PDL as a structure entails the “in vivo” testing of the tooth and the measurement of the corresponding displacements.^[10] To obtain meaningful data about PDL response, the tooth under testing must not have any contact with adjacent teeth.^[11] The procedure requires accurate systems for load application and evaluation of the tooth displacements and rotations. Several methods have been adopted both for load application and for displacements measurement. For example, loads can be applied

by direct contact between tooth and mechanical devices or by pulling a thread that is enveloped around the tooth,^[12] while displacements can be measured by using optical systems^[13] or electric devices.^[12] These techniques make it possible to directly characterize the tooth mobility when physiological loads are applied.

Formulation of Constitutive Models and Numerical Analysis of PDL

Mechanical testing shows that PDL is characterized by nonlinear and time-dependent mechanical response, while histological analysis, with particular regard to the collagen fibers distribution, suggests considering PDL as an anisotropic material. A first approach to constitutive modeling of the PDL has been developed in the framework of linear elasticity.^[14] This approach entails heavy limitations in evaluating the appropriate biomechanical behavior. A more accurate representation of the nonlinear characteristic and almost-incompressible response of the PDL can be performed by using isotropic and anisotropic hyperelastic constitutive models.^[15,16] These models entail the definition of a strain energy function capable to interpret the nonlinear response of the tissue accounting for the almost-incompressible and anisotropic behavior. To define PDL mechanical behavior along the whole stress–elongation curve (Fig. 3E) up to a failure region, elastodamage constitutive models have been formulated.^[17] These models are defined starting from hyperelastic formulation by introducing a specific damage function. In this way it is possible to account for damage phenomena such as collagen fibers rupture. This approach is particularly useful for the analysis of tooth mobility in the case of degeneration owing to ageing or pathologies.

The analysis of the PDL biomechanical behavior must evaluate the time-dependent response, assuming viscoelastic constitutive models in the framework of the hyperelastic or elastodamage formulations.^[18] Another approach to the analysis of PDL mechanics and in particular to the time-dependent behavior is the adoption of the porous media formulation, which accounts for the contribution of the fibrous network and fluid components considering the flux of the liquid phase within the fibrous network.^[19] This approach can describe the interaction between liquid and solid phases of the soft tissue and provides a better micro-mechanical consistency of the model.

Constitutive parameters must be defined within the numerical model formulated. This is usually performed by comparing the experimental data from tests on simple geometry specimens with the results obtained by analytical solutions that interpret the tests themselves,

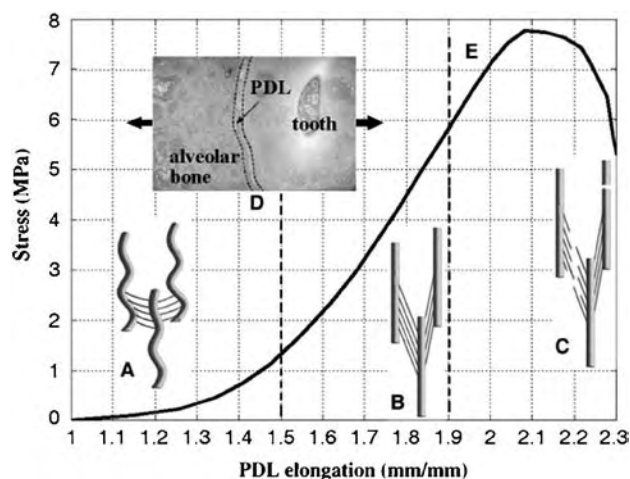

Fig. 3 Configuration of fibrils and interfibrillar bonds (A, B, and C) within a stress–elongation curve (E) for pig PDL sample test in tension (D).

leading to operational procedures that often determine remarkable difficulties.

As constitutive models are defined, the investigation of the biomechanical response of the PDL and the tooth mobility requires the development of solid and numerical models, to perform a finite element analysis (FEA) of the problem. Solid models are usually obtained starting from radiographic or tomographic data of the tooth unit. Fig. 4 reports the result of the FEA of tooth short-term mobility, when load is applied along buccolingual direction (Fig. 4A) and a comparison between experimental and numerical results.^[19,20] The load is kept constant for a short term (2.5 sec) and then relaxed (Fig. 4B). The analysis is performed by a numerical model of the tooth unit (Fig. 4C) and assuming a poroelastic constitutive model for PDL. The evolution of tooth displacement on time is reported in Fig. 4D. It must be confirmed the necessity to compare numerical results with experimental data from “in vivo” tests to provide a reciprocal validation of the procedures.

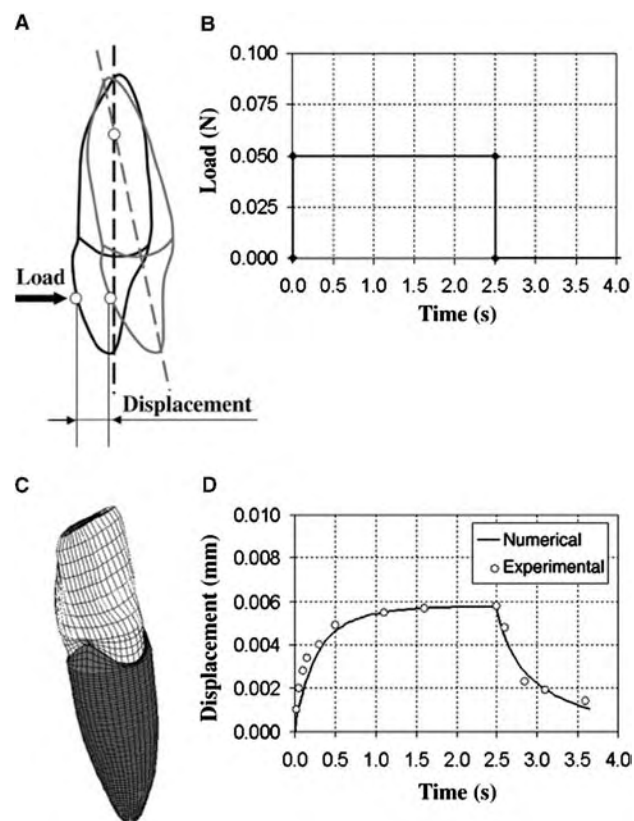

Fig. 4 Porous media analysis of tooth mobility as loading-unloading response of a central incisor: (A) schematic representation of the tooth loading conditions; (B) load history; (C) numerical model of tooth and PDL; and (D) tooth displacement in loading and unloading conditions as comparison between experimental and numerical results.

This formulation of constitutive models for PDL makes it possible to analyze tooth short-term mobility, while the analysis of long-term mobility requires also the introduction of a remodeling law for the adjacent alveolar bone. Several authors have proposed the existence of correlations between PDL strain state and the activity of alveolar bone osteoblasts and osteoclasts,^[3,21] leading to the possibility to investigate orthodontic treatments.

BIOMECHANICS OF DENTAL IMPLANTS

Introduction to Dental Implants Mechanics

Implantology is probably the most efficient procedure for the treatment of partial and total edentulous patients.^[22] This technique is becoming more and more available among dentists and is receiving major attention by researchers investigating the clinical, biochemical, and biomechanical aspects that represent the basis of treatment success.

A single implant can be fixed in bone (mandible or maxilla) to directly support an artificial tooth, while other surgical plans make use of two or more implants inserted in the bone and connected by bridgework that becomes the support for a set of artificial teeth. This prosthetic configuration, mostly adopted in the case of total edentulous patients, is more complex also from a biomechanical point of view, and must be evaluated also with regard to the passive connection (fit) between implants and framework.^[23]

Many aspects that are at the basis of success or failure of a fixed prosthesis are closely related to mechanical issues. The implant system must be capable to guarantee a normal functionality to the patient by the capability to remain fixed and to bear the occlusal loads. These requirements entail a correct design of the implants, of all the secondary components, of the bridgework in multi-implant configurations, and, especially, the evaluation of the way in which the implants get and maintain their fixity in bone tissue. The last aspect is particular important, because success or failure of fixed prostheses also depends on the capability to transmit occlusal loads to the bone in which the implants are placed, inducing appropriate mechanical stress. In fact, an excessive mechanical stress could induce bone resorption. The consequence is usually very heavy for the patient and the risk of bone overloading should be very carefully evaluated. Therefore, the correct clinical treatment should entail also a structural design of the prosthesis in the true sense of the word, and this task can be achieved by using traditional engineering methods, both experimental and numerical.

Configuration of Dental Implants

Dental implants usually have a cylindrical threaded shape offering, whether self-tapping or not, a good mechanical performance with regard to the interaction phenomena occurring between implant and surrounding bone tissue. Other shapes, conical for example, are also present but are not frequently used. Surgical procedures adopted can also be different depending on “one-stage” or “two-stage” technique. With the first technique, the implant is placed in bone with one only surgical intervention and the shape of the implants designed to protrude through the gingival tissues. In the “two-stage” technique, a fixture is placed in bone and is totally covered by soft tissues until it reaches a sufficient fixity in bone. By a second surgical intervention, an abutment is connected to the fixture by using different connection procedures and the whole system finally protrudes through the gingival tissues. The material of dental implants is mostly titanium (for example grade-2, or -4), which offers an optimum biocompatibility and an excellent resistance to corrosion in physiological environment.^[24]

The prosthetic bridgework is designed according to the specific anatomical configuration of every patient and is obtained by using different materials and manufacturing procedures.

Dental Implants Integration

The biomechanical functionality of dental implants is related to their capability of being a fixed support. An essential requirement is the fixity of the implant in bone tissue that is correlated with the osseointegration, which is defined as “a direct structural and functional connection between ordered living bone and the surface of a load carrying implant.”^[25] During the healing phase after the insertion of an implant, the tissue growing is favored by the presence of small ridges and asperities. This configuration can be provided by adopting a proper treatment of the implant surface.^[26]

Plasma-spray techniques or chemical deposition make it possible to obtain a surface roughness on fine scale that promotes such a growth of bone. A proper roughness of the surface can be obtained also with other procedures such as sandblasting, electroerosion, or deposition. Hydroxyapatite coating has been used to offer a surface with a similar chemical composition of bone tissue for its growth. Recent developments in surface treatments have considered the use of specific peptides that favor the adhesion of osteoblasts and the following growth of bone tissue. This technique should improve the tendency of the osseointegration, especially in the very initial phase of healing.

The shape, the choice of appropriate diameter, and length of the endosseous portion of the implants have obviously relevant effects on the mechanical action induced by occlusal loads on the peri-implant bone tissue. This is directly correlated to the maintenance of osseointegration in time and, therefore, on the long-term fixity and success of the implant. The details in the geometrical configuration are also important for their influence on mechanical performances. The use of threaded implants can offer a primary fixity and is nowadays widely used in clinical practice.

Mechanical Testing on Dental Implants

Mechanical testing on dental implants is necessary to reach reliability requirements, mostly with reference to the capability of getting the fixity in mandible and bearing the occlusal loads. It is also necessary to estimate the magnitude and the type of occlusal loads. This estimation is really hard, because the loads depend on several factors such as the patient anatomy and the prosthetic configuration. The type of occlusal forces related to masticatory activity has been studied in different “in vivo” tests^[27,28] and attention has been also paid to correlate the magnitude of these forces to the strength in the components making up the implant, or the loss of marginal bone caused by an excessive stress-strain state of the peri-implant region that can reduce the mechanical function of the implant.^[29-31]

Concerning the mechanical performance of the implant, experimental tests to evaluate the ultimate load and the postelastic behavior of the implant are performed with the aim of estimating the ductility level, i.e., the ability to experience plastic (large) deformations without failure. Generally speaking, implant systems with a good level of ductility should be preferred, while the choice implants showing a brittle failure, i.e., a failure that immediately follows the elastic limit of the structure, should be avoided. These mechanical tests are also capable of giving information about the strength hierarchy of the different components within an implant system.

The loading related to occlusal activity induces cyclical stresses on the different components of the prosthetic systems, leading to failure. It is extremely interesting to evaluate the cycle-dependent strength of the different components of the implant system for an estimation of the long-term reliability of dental implants. It is obviously very difficult to perform “in vivo” fatigue tests, because the total number of loading cycles should be in the order of some millions and also because of the problem to control “in vivo” combination and amplitude of the forces acting at the level of an implant. Fatigue tests “in vitro”^[32] can be performed, by adopting a specific test machine that is

capable of applying cyclical loading on an implant fixed in a synthetic support, usually made up of an acrylic resin or aluminum. A typical failure correlated to cyclical loads can occur in the small connecting screw of those prosthetic systems that are characterized by the join of endosseous fixture and abutment.

The direct application of occlusal loads is not the only reason of the stress induced in bone and in the different components of the prosthetic systems. In fact, in multi-implant prosthetic configurations relevant stress states can be caused by a misfit in the join between the different implants and the connecting bar. The level of stress is directly related to the magnitude and type of misfit and also to the stiffness of the connecting bar. The misfit depends on several factors, mainly concerning the accuracy in manufacturing process adopted. Several experiences have been made to estimate bar-implant misfit, both making use of “in vivo” and “in vitro” techniques. The latter are more suitable for obtaining information about the mechanical state of the prosthetic components. Some “in vivo” tests have been performed to verify the risk of mobility of an implant correlated to excessive stress of peri-implant tissue induced by misfit.^[33] This type of tests including the action of occlusal loads are not performed. This is a limit of the investigation, as it is clear that the effective mechanical state of the prosthetic system and peri-implant regions is the combination of occlusal forces and coaction owing to a possible misfit.

Numerical Analysis of Dental Implants Mechanics

As mentioned in the previous section, experimental testing represents heavy and complex task. In addition, experimental tests performed on animals give rise to ethical problems. In an experimental activity, many

Fig. 5 (A) Three-dimensional virtual solid model and (B) finite element model of a threaded implant inserted in a mandible.

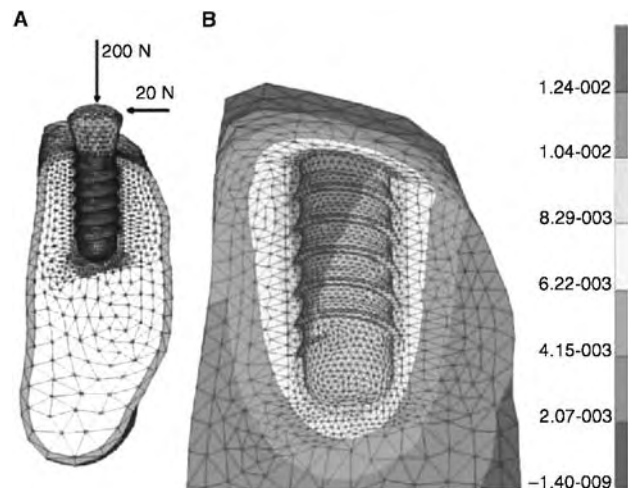

Fig. 6 (A) Finite element model of a single implant inserted in a mandible with indication of typical occlusal forces and (B) magnitude displacement field induced in the mandible by the indicated loading configuration.

parameters such as stress or strain in the peri-implant bone region remain unknown, while only a partial number of data is reasonably achievable. These reasons, together with time and costs requested, favor the use of numerical analysis to investigate the mechanical behavior of implant systems and the functional response of anatomical districts that interact with implant themselves. In the last decade in particular, the use of finite element method has reached wide diffusion because of its capability to provide extended and reliable data on the biomechanical behavior of dental implant systems that can be correlated with data taken from experimental activity for a reciprocal validation. This method makes it possible to simulate the mechanical response of the bone-implant compound, because effective geometry, mechanical properties of the

different materials, and loading conditions can be accurately defined in the finite element model.^[34]

Concerning the mechanical response of a single implant fixed in the mandible bone, a FEA can be oriented to investigate several factors such as the variability of implants (length, diameter, etc.) and their placement within the jaw, the effects of the type of loading (intrusive, transversal, etc.), and the influence of the mechanical properties of the bone tissue that interacts with the implant. All these terms affect the biomechanical reliability of the implant. If the analysis is properly performed, the results obtained can lead to reliable evaluation, as it can be analyzed under several configurations that interpret the real working conditions. As a way of example, a three-dimensional geometric model and the corresponding finite element model of a threaded implant with the surrounding region of the mandible are shown in Fig. 5. The displacement induced for a typical combination of occlusal forces acting on another type of implant (Fig 6A) inserted in a mandible is proposed in Fig. 6B.

The large potentiality of the numerical analysis is also evident when the investigation is extended to more complex systems made up of more implants connected by bridgework. Such a case is reported in Fig. 7, which shows virtual solid model and the corresponding finite element model of two implants inserted in a premolar region of a mandible and connected by a bar with a cantilever in the mesial side. The magnitude displacement fields in the mandible bone induced by occlusal loads acting on the bridgework are depicted in Fig. 8. The main interest of this analysis is to evaluate the mechanical function of the bone-implant system, depending on the type of loading. It is interesting to estimate the worst loading condition, usually represented by intrusive or transversal forces acting on the end of the cantilever and inducing large stress on the mesial side of the nearest implant to the cantilever. This can be correlated to the risk of a partial crestal bone loss that is sometimes remarked during clinical follow-up.^[29,35] The

same estimation can be made for the case of an induced misfit between implants and bar. It is noteworthy to remark that the effects of stress induced by misfit and those correlated to occlusal loads can be coupled, thus analyzing the behavior for a very general condition. It is evident that this capability is just an example of the larger opportunities offered by numerical analysis with respect to the experimental testing.

It is essential that the model must be accurately defined in terms of geometric configuration, material properties, and loading conditions. For instance, an important task concerns the definition of the mechanical properties of the peri-implant bone tissue, which changes its morphology during the healing time after the surgical insertion.^[36,37] Experimental data are necessary to define the elastic and strength properties of the bone tissue, including anisotropy characteristics.^[38] In this way, numerical investigation allows for a reliable and detailed definition of the mechanical behavior of the bone implant interface, to characterize the interaction phenomena between bone tissue and the surface of the implant.^[39,40] Moreover, numerical analysis can represent also the basis for a new advanced approach to the design of dental implant to have a better understanding of the biomechanical response.

CONCLUSIONS

The relevance of mechanical aspects in dental area is confirmed by the interest of international research community. It is essential to have a strong cooperation between researchers acting in different areas to be able to reach a better understanding of problems that appears to be very complicated, offering solutions that must be directly transposed to clinical practice. It is necessary to perform experimental and numerical analyses, to consider the results for a reciprocal validation procedure, and to combine medical and

mechanical competences to perform both basic and applied research. This cooperation will determine a consistent improvement of the general knowledge in dental area and it will provide, in particular, better reliability of biomedical devices as far as biomechanical aspects are concerned, also with the aim of addressing the results to industrial activity.

Dental Implants

Nirit Tagger-Green

Eli E. Machtei

Unit of Periodontology, Department of Oral and Maxillofacial Surgery, Rambam Medical Center and The Faculty of Medicine, Haifa, Israel

INTRODUCTION

Dental implants are one of the most important revolutions introduced to the field of dentistry in the past 50 years. The concept of implants replacing removable dentures was more readily accepted by patients than by their dentists. Dentists received the new mode of therapy only after long-term clinical data based on research and scientific data were presented.

Today, after 50 years of experience, almost every dental practice—even general practitioners—use dental implants on a daily basis. Treatment that was once preserved for highly selective cases is now being widely used. The costs of dental implants have decreased substantially, and new treatment modalities are now often introduced.

HISTORY OF DENTAL IMPLANTS

Dental implants mimicking natural tooth roots were invented thousands of years ago by the ancient Chinese, Egyptians, and Incas.^[1] The modern era of root form implants began only in the 19th century. Two types of implants from the past are still functional and rarely used, the blade form implant and the subperiosteal implant. The blade-vent implants have become less popular due to low survival rate and the formation of connective tissue around the implant.^[2] The subperiosteal implants may have a long-term survival rate but exhibit soft tissue problems and fractures of the metal framework.^[3]

Use of root form implants began after the pioneering research of Branemark and his coworkers. They inserted submerged titanium implants with a machined surface in the jawbone of dogs. In 1969, they published the first evidence of direct bone anchorage named osseointegration.^[4] A few years later, they published results of 10–15 years of clinical experience with the osseointegrated implants.^[5,6] Branemark's team was the first to suggest the idea of osseointegration between implants and bone, but they could not show histologic evidence because there were no methods available to section intact, undecalcified bone together with the metallic

implant. Histologic sections of the implant area could be prepared only after the implant was removed—probably with some of the tissues surrounding the implant and then only could the bone be inspected.^[7] Schroeder, who was working in Switzerland independently from Branemark, used new techniques to cut through undecalcified bone and implant without separating them first. He demonstrated very clearly direct bone-to-implant contact and called this connection functional ankylosis.^[8] Nevertheless, it is very important to emphasize the great contribution of Branemark and his team, who are considered the pioneers of the field of implantology.

Development of the Surgical Technique

The earliest modern investigations on dental implants were carried out on implants placed according to the method published by Branemark in 1977—the two-stage technique. The two-stage surgical protocol uses a two-piece implant pillar. The main reasons to this approach are to minimize the risk of infection, prevent apical downgrowth of mucosal epithelium, and minimize the risk of premature loading. In addition, a stress-free period of three to six months is recommended before piercing the mucosa with the abutments. Such a stress-free period was considered to be an absolute prerequisite for successful osseointegration.^[9]

Over the years, Branemark's original protocol was reevaluated. Schroeder et al. were the first to show the possibility to achieve osseointegration without submerging the implant. During the last decade, reports have demonstrated a successful clinical treatment outcome using the one-stage surgical approach. The ITI group proposed the use of one-stage surgical technique for oral implantology (Waldenburg, Switzerland). This technique involves nonsubmerged implants and loading, which usually starts earlier than in the submerged technique. Recent developments have brought implants into the next step, immediate loading. This technique not only inserts the implants transgingivally, but it also loads them at the same time. Immediate loading raises the problem of micromovement that, in excess of 100 μm , can induce fibrous tissue formation at the bone-to-implant interface instead of the desired bone

formation.^[10] In order to prevent micromovement during the initial phase of healing, new designs of implants and modification of the surface are being invented. The common aim of the new designs is to try and achieve the best initial stability possible. The results from recent studies indicate predictable results for treating partial or total edentulism with dental implants using the one-stage, immediate-loading technique. According to some studies, the results can be comparable with the success rate of implants placed according to the original protocol. Patient selection is probably the most important factor in achieving high success rates. Adequate dimensions of the alveolar process are mandatory, and patient cooperation should be at the highest level. Multicenter studies are necessary before this treatment modality can be recommended for general use^[11] (Figs. 1 and 2).

OSSEOINTEGRATION

Osseointegration represents a direct connection between bone and the implant without interposed soft tissue layers. A 100% bone-to-implant contact does not occur, and there is neither agreement as to the extent of bone-to-implant contact required for acceptance of the connection as osseointegration nor even on the criteria for definition of the term. Histologically, osseointegration is defined as bone in direct contact with an implant seen at the magnification of the light microscope.^[12] Another definition is based on clinical stability rather than on histologic criteria: "... a process whereby clinically asymptomatic rigid fixation of alloplastic materials is achieved in bone and maintained during functional loading."^[13]

Fig. 1 Clinical picture of dental implants inserted in the traditional method, with cover screws, 4 months after the insertion of the implants. (Courtesy of MIS (Medical Implant System), Shlomi, Israel.)

Fig. 2 A panoramic X-ray demonstrating implants of different methods in both jaws. (Courtesy of MIS (Medical Implant System), Shlomi, Israel.)

In 1981, Albrektsson et al. presented a series of factors that need to be controlled to achieve osseointegration:

1. Biocompatibility.
2. Design.
3. Surface condition of the implant.
4. Status of the host bed.
5. Surgical technique.
6. Loading conditions applied afterwards.^[14]

Osseointegration shares many prerequisites with primary bone fracture healing, such as precise alignment, primary stability, and adequate loading during the healing period. Osseointegration requires a bioinert or bioactive material and a surface configuration that are osteophilic, i.e., attractive for bone deposition. Surface properties of implants influence the elaboration of bone-to-implant contact. The assumption is that a rough surface improves adhesive strength compared with a smooth one. A smooth surface transmits only compressive forces with minor resistance against shear. Mild roughness ($<10\ \mu\text{m}$) augments the resistance against shear. In order to obtain adhesion, there is a need for a chemical bond or microporosity.^[15] Macroporosity ($100\text{--}500\ \mu\text{m}$) favors bony ingrowth and is used in porous coating.

Stages of Osseointegration

Several phases can be distinguished in the process of osseointegration:

- (a) Direct bone healing. This phase is activated by lesion of the pre-existing bone matrix. When the matrix is exposed to extracellular fluid,

noncollagenous proteins and growth factors are set free and activate bone repair.

- (b) Incorporation by woven bone formation. The first type of bone that is formed is woven bone. It is considered a primitive type of bone and is the major type that is formed during the first four to six weeks after surgery.
- (c) Adaptation of bone mass to load. This phase starts at the second month. The microscopic structure of bone changes towards lamellar or parallel-fibered bone. Bone remodeling characterizes the last stage of osseointegration. It starts around the third month and continues for the rest of life. Remodeling is the last stage of osseointegration, and it improves bone quality by replacing necrotic bone and the primitive woven bone. Remodeling also leads to functional adaptation of the bone structure to load by changing the dimensions and orientation of the supporting elements.

IMPLANT DESIGN

Implant design refers to the three-dimensional structure of the implant, including the shape, form, configuration, surface macrostructure, and macroirregularities. The objective of all the designs is to create an implant with a long-term survival and high success. The huge variety of implants available today can be classified in a number of different ways. One possibility is classification based on the interface between the implant and the abutment. Another is based on the shape of the body of the implant and the implant-to-bone surface.^[16]

The Interface Between Implant and Abutment

This interface is described as an internal or external connection. The most common external connection is the hexagonal connection or external hex. The aim of that design is to have an antirotational effect on the prosthetic restoration. There are variations in the height and width of the hex. Other forms of external connection are the octagonal top or octa and the spline interface. The internal connection includes the Morse taper interface and the internal hexagonal and internal octagon.

The connection can be further characterized as a slip-fit joint, in which there is a slight space between the mating parts and the connection is passive, or as a friction-fit joint, in which there is no space between the components. They are actually forced together. Reviewing the prosthetic possibilities and various connections available is beyond the scope of this introduction.^[17]

The Shape of the Implant

The geometry of the body of the endosteal implant can be classified into three basic shapes, a threaded screw (ad modum Branemark), a press-fit cylinder (ad modum IMZ), and a hollow basket cylinder (ad modum ITI). Implants are further categorized as being threaded or nonthreaded and as solid or hollow cylinder.

Changing the geometry of an implant can induce dramatic changes in the functional surface area. The functional surface area is defined as the amount of thread that participates in compressive and tensile load transmission under the action of an axial occlusal load. As the bone density decreases, increasing the surface area can offset the potential increase in stress. Anatomical landmarks, machining limitations, and engineering constraints must be considered when choosing a design. For example, the height and width of the implant must fit the anatomical landmarks of the maxilla and mandible. On the other hand, the minor diameter must be large enough to prevent fatigue fracture.

Implant's threads

Threads are used to maximize initial contact, improve initial stability, enlarge implant surface area, and improve the distribution of forces. The depth, thickness, pitch, face angle, and the helix angle of the threads are all parameters that define the functional thread surface and affect the biomechanical load distribution of the implant. Thread pitch is the distance between two adjacent threads. Decreasing the pitch increases the number of threads on the implant; thus, this increases the surface area of the implant's body. Changes in pitch are not constrained by the anatomy of the jaws, and they create a big increase in the surface of the implant without noticeably modifying the dimensions of the implant.

Thread shape is another important factor in the design of the implant. There are three common shapes of threads, a v-thread, a square thread, and a buttress thread. The v-thread results in a tenfold increase in the in-shear resistance at the implant-to-bone interface compared with the square thread design. Thread depth can also be altered along the implant so that the surface of the implant will be increased or decreased in high- and low-load areas. This design increases the functional surface area in the crestal region. The load transfer is reduced and transferred throughout the length of the implant. Thread shape and functional surface area are becoming more important with increasing numbers of practitioners using the immediate-loading procedure. These are particularly important when anatomical considerations dictate the placement of short implants^[18] (Fig. 3).

The crest module

The crest module of the implant is the transosteal region of the implant and is characterized as a region of highly concentrated mechanical stress. Bone loss due to the design of the area is a common finding if it is not well designed for load bearing. Bone loss is so common that the manufacturers prepare this area to a very smooth finish so that, when bone loss occurs, plaque accumulation will be reduced.

The crest module should be slightly larger than the outer thread diameter. Thus, the crest module seats completely over the osteotomy. The seal created by the larger crest module also helps to achieve greater initial stability of the implant. A larger diameter also increases the surface area, which, in turn, contributes to decreases in stress at the crestal region. A polished collar of minimum height should be designed on the upper (occlusal) part of the crest module—just under the prosthetic part. In implants with a longer polished collar, bone is subjected to excessive shear loading. This overload is manifested by significant bone loss in the crestal region attributed to the lack of effective mechanical interlocking between the smooth coronal region and the bone.

A common clinical finding is bone loss down to the first thread. This bone loss cannot be attributed to any anatomic feature because the distance to the first thread varies from 1.2 to 3.0 mm, according to the brand of implant. An improved design or surface condition of the crest module can reduce the risk for crestal bone loss (Fig. 4).

Implant length

As the length of the implant increases, the overall surface increases as well. A common axiom was to insert as long an implant as possible, but this is being

reevaluated. Quite often, the bone that requires more stabilization and a larger surface area is of bone type D3 or D4. This bone exists mainly in posterior areas of the jaws in which the height of the bone is not sufficient for longer implants. There is a minimum implant length for each bone density, depending on the width and design. As a rule, the softer the bone, the longer should the implant be. Usually, the bone in the posterior areas of the maxillae is softer, and, if necessary, in the mandible repositioning of the inferior alveolar nerve is possible while in the maxilla augmentation of the floor of the maxillary sinus may be needed.

Apical design considerations

Most root form implants are circular in cross section. The problem with the round cross section is that it does not resist torsion or shear forces, and a single round implant does not resist rotational force. As a result, an antirotational feature in the form of a vent or a hole is incorporated, which is usually in the apical region of the implant body. A hole in the apical area increases the surface area, but, when inserting implants simultaneously with sinus elevation, the hole may be filled with fibrous tissue or with mucosa and thus become a source of retrograde contamination. Another way to resist rotation is to create flat sides or grooves along the implant or at its apical part only. Bone that grows against these features prevents rotation of the implant.

A few implants have an active apical part, which means that the implant itself helps while inserting it. This is especially helpful in dense bone (types D1–D2) (Fig. 5).

Implant Design and Distribution of Forces

Finite element analysis (FEA) has been used to show that stresses in cortical bone decrease are in inverse

Fig. 5 $\times 20$ magnification of the apical part of the implant. (Courtesy of MIS (Medical Implant System), Shlomi, Israel.)

proportion to an increase in implant diameter with both vertical and lateral load. Using the widest implant is not necessarily the best choice when considering stress distribution to surrounding bone. Occlusal forces are distributed primarily to the crestal bone rather than evenly throughout the entire surface of the implant. In summary, the optimum length and diameter necessary for long-term success depends on the bone support condition. If the bone is in normal condition, the length and width of the implant are not significant factors. But, if the bone is of poor quality, large diameter implants are recommended.

Polished necks of implants do not osseointegrate. This characteristic was investigated by FEA when comparing the bonding created to a smooth neck to that found on implants with retentive elements. Retention elements at the implants neck dramatically decrease the peak interfacial shear stress. The retention elements may counteract marginal bone resorption in accordance with Wolff's law on bone remodeling (Fig. 6A–C).

Surface Characteristics

The study of biomedical implant surfaces and the effect of surface modification have become popular in recent years because of the notion that surface characteristics directly influence the interaction between the bio-material and the tissue. Direct apposition of bone to commercially pure titanium (cpTi) surface results in cellular attachment and implant stability. These characteristics are attributed to the oxide layer that is formed spontaneously on the implant's surface. Many studies attempted to define the nature of the interaction between the oxide layer and the surrounding tissue. Studies were also dedicated to investigating the biologic effects of modifying the surface. The effect of surface roughness on the formation of the oxide layer and cellular adhesion has also been studied.

The oxide layer can exhibit microscopically smooth or rough topographies, depending on the cleaning and passivating process. Surface macroscopic roughness is

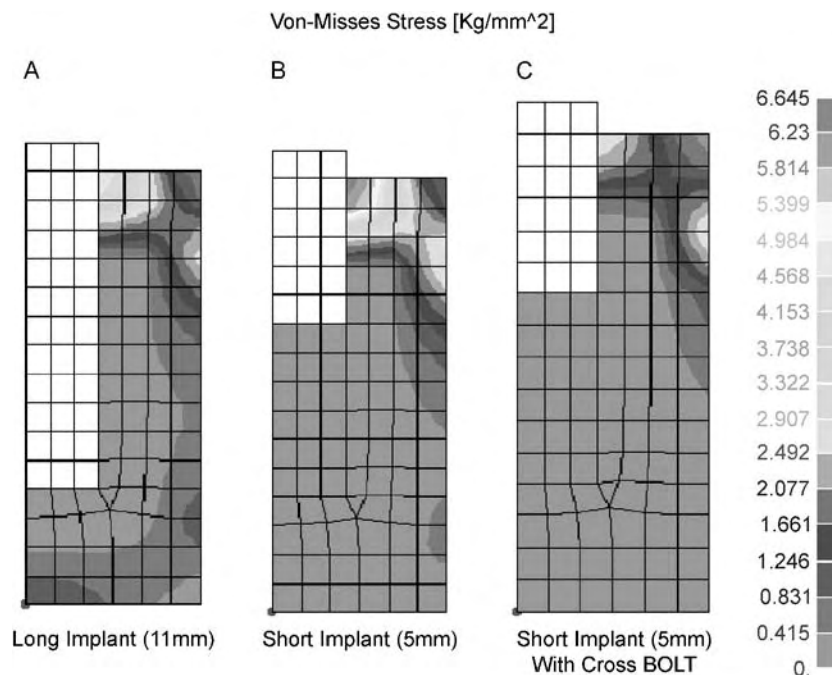

Fig. 6 (A) FEA of a long implant (11 mm). (B) FEA of a short implant (5 mm). (C) FEA of a short tri-cortical implant (5 mm). (Courtesy of MIS (Medical Implant System), Shlomi, Israel.)

normally introduced into the substrate beneath the oxide by mechanical grinding, resorbing by particulate blasting, or a chemical procedure (acid etching). The thickness of the oxide layer remains rather constant since the moment that it is first exposed to air.

Oxide modification may occur during in-vivo exposure. The highest oxide thickness is observed in close relation to bone marrow while the lowest growth appears in contact with cortical bone. Increased quantities of calcium and phosphorous are found in the oxide layer and are the result of ion exchange at the interface.

Microstructure of the implant's surface is important because variations in the surface microstructure influence the stress distribution, retention of the implant in bone, and cell response in the implant. Several authors have discussed the ideal roughness that would provide increased retention and an improved bone response. Roughness could be considered on different levels, macrostructural, microstructural, and ultrastructural. Roughness on these different levels has different effects on living tissues. In order to gain complete growth of bone into a material's irregularities, they have to be at least 100 μm in size. Growth of bone into cavities or pores of this size will give a mechanical interlocking of the material with bone. Bobyn et al. investigated the optimal pore size to get bone ingrowth. They have tested alloys with a pore size of 50–400 μm and found that optimal results are achieved with a pore size of 100 μm .^[19]

The optimal pore size to obtain bone ingrowth depends also on the material. Titanium alloy implants have an optimal pore size of 100 μm . Increased removal torques were found when using titanium-coated screws of stainless steel with a pore size of 10–40 μm . These small pores do not allow maximum ingrowth of bone but provides increased retention based on mechanical interlocking. There are a few mechanisms, besides mechanical interlocking that determine the reaction between bony tissues and biomaterials. Studies in vitro show that surface topography influences the function of cells, matrix deposition, and bone mineralization. Cells are sensitive to microtopography and may use the morphology of the material for orientation and migration. Microtopography also influences the differentiation of mesenchymal cells into fibroblasts, chondroblasts, or osteoblasts.

MATERIALS USED FOR DENTAL IMPLANTS

The choice of metals for dental implants is based on a several factors, including biomechanical properties, previous experience with working and handling the material, and the possibility to sterilize the final product. The implant is a foreign body and does not

behave like a living tissue. Indeed, some metals and metal alloys provoked adverse tissue reaction, and their long-term survival was short. Corrosion is the visible destruction of metals. The corrosion of new metals used in surgery is very small, and very sensitive techniques are needed to detect it. Noble metals like gold and silver have an acceptable resistance to corrosion in air, i.e., about in the middle of a practical scale, but, in physiologic solution, their resistance to corrosion is much lower.

Titanium is a reactive metal. When it is exposed to air or to physiologic solutions, a dense oxide film forms immediately at its surface. The oxide is primarily titanium dioxide with small quantities of Ti_2O_3 and TiO .

This film has a thickness of 4 nm. Its mode of growth is specific in that the oxygen ions migrate towards the metal and react with the titanium at the base of the oxide. This mechanism is unique to titanium, silicon, and zirconium. All are bases with a valence of IV. The advantage of that mode of oxidation is unique in that it does not release metal ions into the electrolyte. This surface feature creates a potent barrier against dissolution of the metal. The oxide on surgical implants is primarily amorphous if it is formed at normal temperature. If cpTi is processed at elevated temperatures or anodized at high voltage, the oxide forms a crystalline atomic structure and can be much thicker.

In serum, the concentration of titanium is about 0.1 μm and, in human skeletal muscle, it gets up to 5 μm . The concentration of titanium in the tissue around implants is about 100 times higher than that of muscle tissue. In spite of this high concentration, no case of systemic or local reaction to titanium has been documented.

Titanium and titanium alloys are the material of choice for dental implants, but the prosthetic parts are usually made of gold alloys, stainless steel, nickel-chromium, and cobalt-chromium alloys. Consequently, there is a chance to have a galvanic action between the dissimilar metals with possible effects on the electrochemical corrosion, oxidation, and even triggering pain.

The stoichiometric composition of commercially pure titanium (cpTi) allows its classification into four grades that vary in the oxide content. Grade 4 has the highest oxide content (0.4%), and grade 1 has the lowest content (0.18%). The properties of the oxide layer are not altered, but there are mechanical differences between the grades. The differences are attributed to the contaminants that are present in very small quantities. Other elements that are found are nitrogen, carbon, hydrogen, and iron. All improve the stability and mechanical or physicochemical properties of the implant. Iron improves the resistance to corrosion, and aluminum increases the strength and decreases the density.

Properties of the Material and Finite Element Analysis (FEA)

Properties of the material greatly influence the stress and strain distribution in a structure. These properties can be modeled in Finite Element Analysis (FEA) as isotropic, transversely isotropic, orthotropic, and anisotropic. In an isotropic material, the properties are the same in all directions. An anisotropic material has different properties in different directions. The assumption is that most of the materials are homogeneous and linear plus they have elastic material behavior characterized by two material constants of Young's modulus and Poisson's ratio. One of the difficulties in calculating FEA is that the surrounding bone is neither homogeneous nor isotropic. These characteristics of the bone present difficulties in assessing the values for ultimate strain and modulus of elasticity during stress or strain.

Surface of the Implant

Hydroxyapatite coating

There is significant controversy concerning the benefit of hydroxyapatite (HA) coating of titanium implants. Some of the reports show the benefit of the HA coating while others claim that the coating compromises the long-term survival of the implant. In-vivo and in-vitro studies have shown that HA is osteoconductive and promotes bone healing at gaps between the implant and the bone.^[20] A retrieval analysis of HA-coated implants revealed that the HA was biocompatible and bonded the surrounding bone without dissolution of the coating. Others clinicians observed that the coating dissolved and separated from the metal core of failing implants. Advocates of HA claim that the coating is stable in a physiologic pH. Some claim that the coating does not provide any benefit over the conventional uncoated implants. It even worsens the survival of implants since microorganisms may adhere to the coating and cause the implant to fail. The results of a metaanalytic review revealed that many of the studies concerning HA-coated implants are anecdotal. Studies were conducted that examined in detail and evaluated the survival by overall percentage or life tables. The survival rates of the coated implants were in the range of survival as the titanium implants. If degradation of the coating results in implant failure, the yearly interval survival rates should decrease with successive follow-ups. Yet, progressive decrease of the yearly interval survival rate was not observed in any study.^[21]

Machined surface

Machined implants exhibit an irregular surface with grooves ridges and pits. Proponents of that system

claim that this is the most conductive surface for cell attachment. Most of the literature reports are based on the average surface roughness (Sa). Sa smaller or equal to 1 μm is considered smooth, and those with surface roughness greater than 1 micrometer is described as rough.

Machined (turned) cpTi is a smooth surface with an Sa value of 0.53–0.96 μm , depending on the manufacturer's protocol, grade of the material, and shape and sharpness of the cutting material. Circumferential parallel lines of 0.1 μm depth and width perpendicular to the long axis of the implant are a common finding in the machined surface.

Plasma-spray coating

Plasma-spray coating (TPS) is one of the most common methods for surface modification. Plasma-spraying may be used on titanium or over HA surface. Porous or rough titanium surface has been produced by plasma-spraying a powder form of molten drops at high temperatures. At temperatures around 15,000 degrees, argon plasma provides high velocity partially molten particles of titanium powder. After fusion, the plasma sprayed layer gets the thickness of 0.04–0.05 mm. Microscopically, the coating shows round or irregular pores that can be connected to each other.

Microtextured titanium (MTX)

A new surface of dental implant is being used by Centerpulse. The MTX surface is grit-blasted with a soluble, biocompatible medium. The implant is then cleansed with a mild acid wash that removes any residual microblast powder. The MTX process produces a uniform 1–2 μm surface roughness that exhibits 44% more surface area than machined titanium. The roughened surface is proven to enhance bone attachment. The MTX process does not weaken the titanium implant body and ensures that the strength of the implant is maintained. Implant threads are not rounded by the MTX process, and cutting grooves remain intact for efficient self-tapping.

Other surface modification

Blasting with particles of varying diameters is another method for surface alteration. In this approach, the implant is bombarded with particles of aluminum oxide (Al_2O_3) or titanium oxide and by abrasion. Among the titanium surfaces, both blasted and TPS surfaces showed a slight increase in bone contact over machined surface. Etching with hydrochloric or sulfuric acid after particle blasting resulted in a more

Fig. 7 $\times 1000$ magnification of a dual-etched surface. (Courtesy of MIS (Medical Implant System), Shlomi, Israel.)

dramatic increase in the bone contact level. The dual-etched surface treatment resulted in a 3.5 increase in mechanical pull-out force compared to the original machined surface. Studies *in vivo* showed that bone growth into chambers maintained contact with the titanium surface. In contrast, the machined surface exhibited lifting of the clot from the wall, which resulted in less bone contact (Fig. 7).

Lazzara et al., in a split implant study, evaluated the difference between machined titanium and dual-etched surfaces. They demonstrated that the dual-etched surfaces showed increased bone contact six months after insertion of the implant.^[22] In a study conducted by London et al., histologic comparison was carried out between dual-etched implants to machined TPS and HA surfaces. They compared the bone contact *in vivo* in rabbits. They found that the bone to implant contact varied from 3% after one week for the TPS and up to 60% after four weeks for the dual-etched. DE surfaces showed the highest bone-to-implant contact over the eight weeks. The machined and the TPS implants showed the least bone-to-implant contact. Each of the implant surfaces showed an increase in bone contact percentage over time. After eight weeks, the machined TPS and DE surfaces showed similar bone contact levels.^[23]

An interesting recent innovation in surface technology is the combination of two or more surfaces on the same implant body. The rationale is to achieve improved soft tissue response, stability, and attachment in cortical bone with a machined or etched coronal implant surface and better mechanical locking in medullar bone with a roughened TPS or HA surface in the middle to apical portion of the implant. One design even includes four different surfaces on the same implant body.

Evaluation of the Interface

There are two methods to assess the quality of the osseointegrated interface, biomechanical test and histomorphometric analysis. There are usually three types of biomechanical tests, pull-out, push-out, and torque (Figs. 8 and 9).

Pull-out measurement. The stress values are estimated by dividing the failure load by the total implant surface area. Wong et al. tested the shear strength as a function of various implant surfaces. The shear strength was tested by push-out and pull-out measurements. They showed a nearly linear relationship between the push-out load to failure and surface roughness in microns.^[24]

Push-out test. When performing this test, both the coronal and the apical parts of the implant must be free

Fig. 8 Graph illustrating axial implant load. (Courtesy of MIS (Medical Implant System), Shlomi, Israel.)

Fig. 9 Graph illustrating 30° implant load. (Courtesy of MIS (Medical Implant System), Shlomi, Israel.)

of bone contacts. If not cleared, high forces are necessary to resist the bone structure between the threads at the apical end of the implant. The coronal portion accepts the applied push-out force, but the apical end must be exposed to allow smooth and free extrusion of the implant. Push-out and pull-out tests are indicated when measuring cylindrical and press-fit implants. Threaded implants are tested more effectively by the torque test.

Torque. The moment of a force about a point tends to produce rotation or bending about that point. This moment refers to as torque or torsional load. This force is the most destructive for the implant system. Torque may be imposed on implants as a result of long cantilevers. A few authors compared various implant systems and surface treatments and found that the removal torque values increase with time.

Histomorphometry

These analyses of the bone-to-implant interface can be carried out in different ways. Investigators often present bone-to-implant contact as a percentage of the total implant length and as a percentage of the three consecutive best threads length. Implant design and material, surface treatment, healing time, and loading conditions are some of the parameters that affect the analytic approach. Thread volume fill and the number of cells in contact with the implant surface are two other important variables.

Difficulties in assessing the bone-to-implant interface by FEA

Most FEA analyses assume a state of optimal osseointegration and perfect bonding between bone and implant. In clinical situations, this doesn't usually

occur. Bone is a porous material with complex microstructure. Part of it is dense cortical bone, and the middle is a softer trabecular bone. The proportion between the two types of bone is dependent on the location of the implant in the jaw. Therefore, the model for FEA of osseointegration is a rather complex algorithm.

Survival of Dental Implants

Since the introduction of endosseous implants, many design modifications have been made. Each element in of implant design may theoretically present certain advantages and disadvantages to the clinician. The status of bone-to-implant contact is also important because it is the basis for the successful long-term osseointegration. All these parameters and many others may influence the success of the implant, but there are rather few objective-independent investigations concerning short- and long-term survival of implants.

No precise definitions of implant success or failure are available. Cases, which qualified as success in one clinical situation, may not be considered successful in a different situation. The American Academy of Periodontology determined in 1996 a list of criteria for assessing implant success. This list is compiled from various studies.^[25]

Common criteria used to determine success of implants:

1. Less than 1 mm mobility in any direction.
2. No radiolucency.
3. Bone loss not greater than 1/3 of implant.
4. Provide functional service for five years in 75% of cases.
5. Absence of persistent and/or irreversible signs and symptoms such as pain, infection, neuropathies, paresthesia, and violation of mandibular canal.
6. Clinically immobile.
7. No peri-implant radiolucency.
8. Bone loss less than 0.2 mm annually after first year of service.
9. 85% success after five years; 80% success after 10 years.
10. Implant design allows satisfactory restoration to patient and dentist.
11. Implant still in mouth.
12. Absence of continuous marginal bone loss.
13. Minimal marginal bone loss.
14. Absence of persistent soft tissue complications.
15. Surgical retrievability.
16. Probing depth less than 4-5 mm; bone loss less than 4 mm.
17. No mechanical failure.

18. Bone loss does not reach apical 1/3 of implant.
19. Nonstandardized radiographs demonstrate less than 50% of implant has bone loss.

In 2000, the American Academy of Periodontology published the report of the three-year results from the Veteran Administration's (VA) multicenter prospective implant study.^[26] This report, known as the Dental Implant Clinical Research Group (DICRG), is considered to be the consensus for dental implants. The DICRG findings can be applied to most endosseous implant systems, dentists of all skills, and most patients.

The first part of the report deals with the survival and stability of six implant designs from placement to 36 months. The study was performed in 30 VA medical centers and two dental schools. More than 2900 implants were placed and restored. Survival was determined for each of the three phases of implant treatment. Phase 1 is from the time of implant placement to uncovering of the submerged device. The second stage is from uncovering to placement and loading of the prosthesis. Phase 3 is from initial loading of the prosthesis to 36 months. The stability of the implant was checked using the periotest[®]. The periotest scale ranges from -8 (clinically firm) to +50 (very loose) so that the more negative a reading, the more stable the implant. There were two approaches to determine survival of the implant. A common approach was to consider as failures only implants that failed after loading. The DICRG considered as failure every implant that had to be taken out, regardless of whether it had been loaded or not. The results show that the largest difference in survival, which includes implants that failed before loading, was for the cpTi implants (21.7%). According to the DICRG criteria, the HA cylinder implants had the highest survival rate (97.5%). When the postloading approach was used, the titanium alloy screw had the highest survival rate (99.4%). The HA cylinder was next (98.6%). The conclusions were that the HA-coated implants had the highest survival rate. Non-HA implants showed increased stability following loading while HA-coated implants showed a slight decrease or no change in stability.

The next investigation was to see if the length and diameter of the implant was related to survival. Various implant lengths were investigated—7 mm, 8 mm, 10 mm, 13 mm, and 16 mm. The diameters investigated were 3–4 mm and 4 + mm. The results were that the stability of the 3–4 mm implants was significantly smaller than that of the group less than 4 mm. The survival was significantly larger for the 16 mm implants (96.4%) than for the 7 mm implants (66.7%) ($p=0.001$).

The next step in the investigation was to assess the survival of implants that were mobile at placement. Orenstein et al. showed that out of 2641 implants that were included in the DICRG survey, 81 (3.1%) were

mobile at the time of placement and that 76 (93.8%) of these were osseointegrated at uncovering, which was compared with 97.5% of the implants that were immobile at placement. The difference was not significant. The conclusion is that implant stability at the time of placement is clearly desirable, but it may not be a prerequisite to osseointegration or to the long-term survival of the implant. HA-coating significantly improved the performance of mobile and immobile implants at placement up to three years after placement.

Truhlar et al. documented changes in stability, as reflected in the PVT values, correlated with various implant surfaces, designs, and bone density. The findings were that bone quality and surface coating of the implant did influence the implant's stability. For bone quality type I and II, the stability improved over time. But, for bone qualities type III and IV, all implants showed a slight decrease in stability over the five years following insertion. Anyway, the PTV at the time of uncovering was the best predictor to the clinical acceptance at the bone-to-implant interface. When comparing the stability of HA coated implants to noncoated implants, HA implants became slightly less stable over time while the noncoated showed an improvement in stability.

Biomechanical Aspects of Dental Implants

All structures and combinations of structures that are exposed to functional loading can be exposed to overload that can lead to mechanical complications and failures. In implant dentistry, such failures can occur in the implant itself or in the prosthetic parts.

Implant versus tooth mobility

The biomechanical situation of an osseointegrated implant is fundamentally different from that of a natural tooth. The initial deflection of an implant is linear and elastic whereas the natural tooth has an initial phase of periodontal compliance followed by a more rigid appearance at the engagement of the alveolar bone. Axial and horizontal mobility of a natural tooth has been estimated to be larger than that of an osseointegrated implant by a factor of 12–100.

The existence of such great differences between the mobility of the tooth and the implant have generated recommendations not to use rigid prosthetic connections between the tooth and the implant, and, if possible, avoid combinations of natural teeth and implants as abutments for a single prosthetic appliances. Recently presented in-vivo data have shown that the biomechanical significance of controlled superstructure misfit has indicated higher compliance for vital alveolar bone.

Force generation

Patients treated with dental implants can be exposed to a range of traumatic situations; yet, the prosthetic and surgical planning of implant placement generally considers only the physiologic loading of implants and implants superstructure. A wide range of loading variations must be taken into account. For example, Bruxism must be considered as a condition that requires special attention. It causes not only increased loading levels but also prolonged loading times and an increased number of loading cycles (Figs. 10 and 11).

In the natural dentition without implants, the mean maximal vertical bite force is of a magnitude of 469 ± 85 N at the region of the canines, 583 ± 99 N at the second premolar region, and 723 ± 138 N at the second molar. Average values of the maximal voluntary bite force are 545 N in men and 383.6 N in women. The angle between the bite force and a plane that is perpendicular to the occlusal plane is typically 3.9 degrees.^[27]

Bite forces after implant treatment

For implants used to replace a single tooth, in-vivo forces ought to duplicate the forces exerted on natural teeth. This is expected because, in both cases, biting would occur on a single, stand-alone crown. Factors such as the width of the crown's occlusal table, the height of the abutment above the bone level, and the angulation of the implant with respect to the occlusal plane affect the value of the lever moment on the implant. When dealing with a prosthesis borne by several implants linked together, leverage effects can be expected because of geometric factors relating to the

Fig. 10 Machine designed to test mechanical configuration. (Courtesy of MIS (Medical Implant System), Shlomi, Israel.)

Fig. 11 Artificial bone used for mechanical testing. (Courtesy of MIS (Medical Implant System), Shlomi, Israel.)

restorations. Such factors cause the implant to be subjected to increased bending moments as well as to axial forces that can be tensile and compressive. For fixed prostheses the maximal occlusal force ranged from 35 to 330 N with the largest values at the area of the second premolar.^[28]

Dental implants are subjected to occlusal load when placed in function, and the load may change dramatically according to the patient, location of the implant, and parafunctional habits. Even before loading, the implant is subjected to passive mechanical load from the mucosa and the cover screw. The implants are also subjected to horizontal forces from the tongue and the perioral mucosa. Application of nonpassive prostheses may also generate mechanical forces from the abutments, even without occlusal load.

A force applied to a dental implant usually results in three-dimensional loading that is not necessarily exclusively along the long axis of the implant. Vertical and transverse loads from mastication include axial forces and bending moments and results in stress gradients in the implant and bone. A key factor for the success of the implant is the manner in which stresses are transferred to the surrounding bone. Load transfer depends on the bone-implant interface, the length and diameter of the implant, the shape and characteristics of the implant surface, the prosthesis type, and the quality and quantity of the surrounding bone. Finite Element Analysis (FEA)^a helps researchers to

^aFEA is a technique for obtaining a solution to a complex mechanical problem by dividing the problem domain into a collection of smaller and simpler domains (elements). In other words, FEA is a method where instead of seeking a solution to the entire domain, one formulates the solution functions to each finite element and then combines them to obtain the solution to the entire body.

predict the stress distribution in the contact area of the implant with cortical bone and around the apex of the implant in trabecular bone. It is known that there is some adaptive remodeling of the surrounding bone, but the precise mechanism is not fully understood.

THE FUTURE OF DENTAL IMPLANTS

Dental implants (DI) will become a more common mode for treating edentulism. In order to offer the use of DI to every patient, the surgical procedure will be simplified.

One way to simplify the surgical procedure is by what is called flapless surgery, i.e., inserting the implant without the need to raise a flap. There are many advantages in this procedure for the patient as well as for the surgeon. The procedure is less time consuming, bleeding is minimal, implant placement is expedited, and there is no need to place or remove sutures.^[29] This approach also minimizes proximal alveolar bone loss associated with sectioning of collagen fibers while elevating a surgical flap.^[30] This approach may be aided by using navigation techniques. This technique uses three-dimensional CT-based models for preoperative planning. The models are transferred into the surgical environment by mechanical devices that are being fixed to the bone or teeth. Thus, precise intraoperative verification of operation planning is more feasible by using CT data for the intraoperative navigation of the implantation tools. This technique enables intraoperative control in the deep bone without surgical exploration. A drilling tool can be controlled three-dimensionally by watching its manipulation on a screen that shows three-dimensional reconstruction of the CT scan. With this technique, precise placement of implants without injury to critical anatomic structures should be possible, even in severely atrophic jaws.^[31] These procedures already exist, but their use is rather limited. These techniques and others will enable the general practitioner as well to insert DI more easily and safely. Another field for progress is to expand the possibilities of augmentation of the residual ridge and thus enable the insertion of the DI in extremely resorbed ridges.

Patients are seeking an esthetic, quick, and easy solution. The one-stage immediate loading technique provides a better solution from the patient's point of view. Companies will try to provide implants that are inserted more easily and have a better chance to achieve primary stability.

There are two possibilities in improving primary stability—by modifying the surface of the implant or by a more radical approach such as changing the

Fig. 12 Illustration of new tri-cortical implant. (Courtesy of MIS (Medical Implant System), Shlomi, Israel.)

form of the implant. For example, the MIS company is developing an implant that gets its primary stability from a screw that is inserted at the apical part of the implant through the cortical plate.

These innovations—or at least part of them—will be seen more and more in the future. In turn, this will enable more patients to restore their dentition with dental implants (Figs. 12 and 13).

CONCLUSION

Dental implants have changed enormously since they were first introduced. The composition of the alloy has changed although titanium has remained the major component. The surface of the implants and the mode of modification of the surface are being constantly changed. The time required to achieve osseointegration has been shortened and the more adventurous treatments are being implemented.

The revolution was successfully carried out, but the evolution of dental implants has not said its last word. The fruitful cooperation between clinicians, researchers, and bioengineers will continue to bring new technology for the benefit of all patients.

Diamond and Diamond-Like Carbons

James H. Arps
Geoff Dearnaley

Southwest Research Institute, San Antonio, Texas, U.S.A.

INTRODUCTION

The number of biocompatible materials available for use *in vivo* is severely limited, and carbon in its various forms is one of them. Over the past decade or so, it has become possible to coat materials with adherent films of diamond or diamond-like carbon (DLC) to provide many potential applications in orthopedics, cardiovascular components, guidewires, etc. We shall review the various methods of deposition, their advantages and disadvantages, and the properties of the resulting coatings.

It will be seen that, of these properties, one of particular value is that of smoothness, resulting in much lower wear of a softer counterface. It is here that DLC emerges as a superior coating. On a well-prepared substrate it can be atomically smooth, with roughness (R_a) lower than 1 nm.

The volume of publications on the biomedical applications of DLC, in particular, has grown steadily over the past decade as an outcome of successful demonstrations *in vitro* of its wear resistance, low friction, and biocompatibility. At the same time, increasingly more applications are being found for this versatile form of carbon. It has now reached an exciting stage of development as a biomaterial.

DIAMOND COATINGS

Because of its extreme hardness and generally low coefficient of friction, crystalline diamond may be considered the ideal wear-resistant coating, for example, for orthopedic implants. We shall see, however, that the requirement of smoothness makes this difficult to realize.

There are numerous ways to deposit diamond coatings, but the most widely and successfully used is by microwave plasma-activated chemical vapor deposition (CVD) from a mixture consisting mostly of hydrogen with minor admixtures of a carbonaceous precursor, such as methane.

However, before deposition of diamond onto metal surfaces, it is necessary to carry out a pretreatment in order to improve the nucleation and adherence of the diamond. This is necessary for several reasons, two of which are: 1) the interatomic bonding in diamond is

wholly covalent and distinct from that in a metal; and 2) there is generally a mismatch in the coefficients of thermal expansion (CTE). Thus, the CTE of titanium alloy is about 2.6 times that of diamond, and since deposition temperatures in CVD are typically 700°–800°C, the coating develops a high compressive stress on cooling that may lead to peeling. Mechanical treatments such as scratching and diamond polishing and application of interlayer or bond coats such as titanium nitride or diamond-like carbon have been described by Fu et al.^[1] These interlayers were much less effective than a process of plasma nitriding followed by plasma carbonitriding of the titanium substrates. Scratching of the surface with diamond powder substantially increased the nucleation density and adherence of the coatings.

Rats et al.^[2] describe the coating of Ti-6Al-4V disks with diamond in a tubular reactor crossed by a waveguide connected to a 6-kW microwave generator operating at 2.45 GHz. In some cases, a 1% CH₄/H₂ mixture at 700°C was used, whereas other coatings were made in the presence of 8% CO/H₂ at the somewhat lower temperature of 600°C. The pressure was set at 10 Torr. Raman spectrometry and friction and wear tests showed that the CO/H₂ mixture gave more pure diamond with lower friction. The residual growth stress in the 600°C coatings was lower, –5.2 GPa, compared with –6.2 GPa for those grown at 700°C.

For most tribological applications, however, these coatings all had the drawback of excessive roughness due to the individual diamond crystallites. Although the R_a values were 70 to 80 nm, the peak-to-valley ratio was in the range of 0.5 to 0.5 micron, some of which was due to the prior scratching. This hard abrasive surface produces very rapid wear of all uncoated metallic counterfaces. In view of this, the same research group attempted to produce finer-grained and smoother diamond coatings on Ti-6Al-4V alloy at 600°C.

The preliminary polishing was carried out to an R_a of about 5 nm, and nucleation and growth step procedures were varied in order to achieve coatings about 2 microns thick, with submicron crystalline size. The final roughness values varied from 5 to 140 nm, the lowest figure being obtained by polishing for 6 hours against a diamond-coated flat. Friction coefficients of diamond

against diamond of 0.05 to 0.07 were reported for the finer-grained coatings. The wear of uncoated titanium alloy pins against these diamond-coated disks was very strongly dependent on their surface roughness. Thus, the wear rate increased from $2 \cdot 10^{-9} \text{ mm}^3/\text{Nm}$ to $5 \cdot 10^{-7} \text{ mm}^3/\text{Nm}$ as the roughness increased from 5 nm to 140 nm. When a diamond-coated titanium alloy pin with a 3.5-micron coating was worn against a diamond-coated disk, it was observed that, after only 200 m of sliding an alloy of 13 N, the alloy substrate became exposed. Subsequent wear remained low as the Hertzian contact pressure on the pin surface diminished due to flattening, and the wear of the coated disk was unmeasurably small. The Hertzian pressure is defined as the maximum pressure induced by the applied load beneath the spherical contour of the pin. The authors conclude that these may be the same engineering applications for which adherent diamond coatings on titanium alloys will be useful.

Thus, polycrystalline diamond coatings on titanium are extremely hard, have low friction coefficients, and can be highly adherent, but nevertheless are not ideal for tribological purposes because of their roughness and the considerable difficulty of polishing them smooth. A second problem lies in the high growth stress due to the mismatch in coefficients of thermal expansion, producing a tendency toward decohesion. Attempts have been made to polish CVD diamond coatings using molten rare earth metals, liquid iron at 1250°C , and hyperthermal oxygen ions, but all these methods have their drawbacks and would not be easily applied in a production process. In conclusion, polycrystalline diamond has not emerged as a viable material for coating of orthopedic implants or other wear-resistant biomedical components.

Turning next to the feasibility of applying diamond coatings to cobalt–chromium orthopaedic alloys, we encounter another problem that was first revealed when diamond was deposited onto cobalt-cemented tungsten carbide tools. Cobalt has a catalytic influence that causes the initial layer to consist of graphite, which is weak and results in poor adhesion. It is therefore necessary to remove the cobalt binder from the surface by acid etching, laser ablation, or other procedures before diamond deposition. These methods are obviously not applicable to cobalt alloys, but there is an alternative that so far has not been explored. If silicon is deposited at an elevated temperature around 500°C by ion beam-assisted deposition (IBAD), surface cobalt may be converted completely to cobalt disilicide, CoSi_2 , which is no longer catalytically active. This procedure has been successful in the case of cobalt-cemented tungsten carbide.^[3] However, the problems associated with the roughness of polycrystalline coatings, described earlier, would also pertain to their use as cobalt–chrome or other substrate systems.

In conclusion, the applications of crystalline diamond coatings in the medical field appear to be limited, and it is significant that in his survey of CVD diamond applications and projects for the future, Michael Seal did not include a single biomedical application.^[4]

DLC COATINGS

An alternative way to overcome the problems due to roughness in crystalline diamond coatings, while retaining some of their merits of hardness, low friction, and chemical inertness, is by the use of deposited amorphous DLC. With care, exceptional degrees of smoothness can be achieved, together with good coating adherence under stress because growth stresses in DLC films can be better controlled than in diamond.

As mentioned earlier, DLCs comprise a broad family of compositions and microstructures and all have some degree of hardness arising from the presence of a strong matrix containing three-dimensional carbon–carbon bonds (sp^3 bonding), with a dispersion of nanocrystalline graphite islands (sp^2 bonding). The presence of the sp^3 bonding justifies use of the term “diamond-like.” Figure 1 shows a typical transmission electron microscope cross-section of a DLC film.

There are numerous methods available for the deposition of DLC coatings; these will be considered in turn.

DEPOSITION OF DLC COATINGS

It is now more than thirty years since Aisenberg and Chabot reported in 1971 the results of a direct ion

Fig. 1 TEM micrograph of DLC coating.

beam deposition of DLC. Since then, the methods developed include:

- Direct ion beam deposition.
- Dual ion beam sputtering.
- Pulsed laser ablation.
- Filtered cathodic arc deposition.
- Ion beam conversion of condensed precursor.
- Magnetron sputtering.
- Radio-frequency (RF) plasma-activated CVD.
- Plasma source ion implantation and deposition.

Each of these requires the choice of a carbonaceous precursor, such as methane, acetylene, or butane, and some make use of elemental carbon. In other cases, the precursor may be a much more complex molecule chosen to possess the low vapor pressure for a condensate film. Alternatively, the material may contain silicon and oxygen, in the form of a siloxane, or metallic constituents, as in ferrocene or metal-containing phthalocyanines. Some of the methods are versatile enough to produce a wide range of modified DLCs with varying but controllable electrical conductivities, hydrophobic properties, and catalytic behaviors. By comparison with polycrystalline diamond films, the potential exists in DLC to tailor the microstructure and the composition and to grade these where necessary to achieve the required functionality.

We now consider the advantages and limitations of each process in turn before addressing the applications of DLCs in the biomedical field.

Direct Ion Beam Deposition

The principle of this method is to bombard a surface, in vacuum, with energetic ions usually of methane so that, upon impact, the molecule dissociates and most of the hydrogen is liberated. Ion energies of 100 to 750 eV have been used, e.g., by Liu et al.,^[5] the current density of about 2.5 A/cm² corresponds to an arrival rate of approximately $1.5 \cdot 10^{16}$ carbon atoms/cm²/sec, most of which are retained.

With a uniform atom-by-atom arrival, the coatings are very smooth and have a Knoop microhardness of 6000 kg/mm² according to Liu et al.^[5] Although the residual hydrogen content is not stated, this hardness value suggests that it is relatively low. Against a zirconia pin, the wear rates were below 10^{-7} mm³/Nm, and friction coefficients for dry sliding were 0.02 to 0.10, increasing with relative humidity for reasons discussed later.

Dual Ion Beam Sputtering

This is the method developed by Weissmantel in early work, and it makes use of one ion beam, usually of

argon, to sputter carbon onto the substrate while it is simultaneously irradiated with 100–300 eV ions by a second gun. This IBAD process increases considerably the adherence of the sputtered carbon deposit. However, the forward momentum transferred by the ion-assist beam compacts the coating and, if used excessively, will lead to a high compressive stress that can result in coating decohesion. For this reason, some workers have preferred to use higher ion energies and lower fluxes to achieve good coatings with some degree of ion beam mixing at the coating-substrate interface. The process is slow due to the low sputtering coefficient of carbon, but the method is capable of producing relatively pure coatings, although typically with a small percentage of argon.

Pulsed Laser Ablation

Voevodin et al. described a process for the deposition of DLC coatings using KrF excimer laser to vaporize material, in vacuum, from either a graphite target or one consisting of polycarbonate. The latter results in hydrogenated DLC films sometimes designated as α -C:H. Steel substrates were either negatively biased or unbiased with regard to the target. Those coatings deposited under bias, from –100 to –800 V, have somewhat lower friction coefficients. The wear rates of the carbon films against sapphire pins were remarkably low, at about 10^{-9} mm³/Nm, whereas for the softer α -C:H films, the wear rate was around 10^{-6} mm³/Nm at a contact pressure of 0.8 GPa.

A potential drawback to pulsed laser ablation (PLD) is that occasionally droplets or chunks of the target material are ablated and cause a surface roughness that is not easily removed. The internal stress can also be very high, but Wei et al.^[6] have described a functionally-graded DLC coating with reduced compressive stress and improved adhesion.

Ion Beam Conversion Coatings

One of the more versatile methods for depositing DLCs is by the simultaneous ion bombardment and condensation of a low-vapor-pressure compound. The rupture of C–H bonds releases hydrogen into the vacuum leaving a largely carbonaceous coating. Deposition rates are high, up to 10 μ m/hour, and the compressive stress in such coatings is low (1 GPa or less), perhaps due to the progressive removal of hydrogen from within. The precursor materials may be either diffusion pump fluids or solids such as adamantane or coronene. Arps has shown that if ferrocene is used, the coating may contain up to 24 wt.% of iron. Siloxane precursors such as pentaphenyld trimethyl siloxane produce films with a small percentage of

silicon and oxygen, with advantageous properties, such as reduced dependence of friction coefficient or relative humidity. The ion energies used may range from 100 eV to 100 keV. Accounts of the process have been published by Fountzoulas et al.^[7]

It is also possible to incorporate elements such as sulfur, fluorine, or nitrogen by choice of the precursor, and some of these assist in providing a low friction coefficient. The coatings produced by these methods are smooth, but due to the residual hydrogen content, typically 15 wt. %, they are not as hard as amorphous carbon coatings. However, they can still be comparable with hard tool coatings such as titanium nitride or alumina.

Filtered Cathodic Arc Deposition

This is a method for producing very hard, virtually hydrogen-free DLC coatings. An arc is drawn in vacuum between a graphite cathode and an anode, typically at 50–60 A. As illustrated in Fig. 2, adapted from Xu et al.,^[8] a radial magnetic field steers and filters carbon ions and rejects macroparticles. A bias voltage of 100 to 300 V is applied to the substrate.

Fig. 2 A filter cathodic arc apparatus for DLC deposition.

That the filtering is effective is shown by the high degree of smoothness of the films. Xu et al.^[8] report an R_a value of about 0.4 nm. Stresses in the coatings are high, -7 to -10 GPa, and this contributes to coating hardness that may reach superhard values of 40 to 50 GPa.

Such hardness is advantageous in resisting abrasive wear, but the high compressive stress means that there will be a tendency toward decohesion unless adhesion is strong. Most of the reports refer to substrates of silicon or quartz, to which carbon adheres strongly.

Plasma Source Ion Implantation and Deposition

In this method, described by Anders et al.,^[9] a plasma is created in the work chamber and the workpieces are immersed in it. Periodic pulsing to around 2 kV accelerates carbon ions from the expanding plasma sheath during the pulse of duration 1 microsecond. The carbon plasma may be formed by a pulsed cathodic arc, with a magnetic filter (as described earlier) to remove macroparticulates. The films are virtually free of hydrogen and are hard. Anders et al. report values up to 45 GPa, with low friction coefficients.^[9]

The compressive stress in such coatings is high, but Anders et al.^[9] described a method for varying the substrate bias during deposition to produce alternating hard and softer layers with a net reduction in stress. Some of these coatings have been the subject of orthopedic testing (to be discussed later), with outstanding results.

Magnetron Sputter Coating

Magnetron sputtering is a widely used process for physical vapor deposition and it can be employed for carbon, but deposition rates are relatively low due to the low sputtering coefficient. Peng et al.^[10] used DC magnetron sputtering as one of the four methods of deposition in a study of the smoothness of DLC coatings. Nonhydrogenated films up to 1 micron thick were prepared by sputtering from a pure graphite target in an argon plasma. A bias voltage was applied to the substrate and could be varied from 200 to 300 V. The argon pressure was around 1 Pa. A literature survey indicates that magnetron sputtering is not widely used for DLC deposition, by comparison with CVD methods or the filtered cathodic arc method.

RF Plasma-Activated CVD

Chemical vapor deposition, involving the thermal dissociation of a selected precursor, is extensively used for coating tools and semiconductor devices. The addition of an electrical plasma lowers process temperatures. It is easy to apply the method for DLC, and Erdemir et al.^[11] described a careful study of the results of using four different source gases; namely, methane, ethane, acetylene, and ethylene, at pressures of 10 to 13 mTorr. The substrate bias was 1600 V, and the substrates were of steel. The lowest friction and wear, against steel balls, were obtained for methane, and the poorest for acetylene. The authors attribute the difference to the hydrogen:carbon ratio, the role of hydrogen possibly being to promote a higher sp^3 content, or else to decorate the coating surface and reduce friction. Methane/hydrogen mixtures in the plasma (1:1) gave even lower friction, the coefficient against steel falling to 0.01. It is a pity that these results were not correlated with determinations of the residual hydrogen present in the coatings, which can be done by an elastic-recoil ion beam technique.

The wear resistance corresponded to a friction behavior of about $9 \dots 10^{-9} \text{ mm}^3/\text{Nm}$ for methane-grown films and two orders of magnitude greater for the acetylene-grown film. In conclusion, methane/hydrogen mixtures are shown to be best for tribological applications of DLC.

THE TRIBOLOGICAL PROPERTIES OF DLC

For a number of biomedical applications, it is desirable to have coatings that provide low friction and low wear under load-bearing conditions. For reasons discussed by Liu and Meletis,^[12] DLC can meet such requirements and provide corrosion resistance as well.

Both experimental and molecular dynamics modeling studies show that, during sliding wear, the outer molecular layers of DLC undergo transformation to graphite, with its basal planes parallel to the surface. This enables shearing to take place at load-bearing asperities, and provides friction coefficients in dry nitrogen as low as 0.01.

It has long been known that the friction and wear behavior of diamond is controlled by a macromolecular film of adsorbate at the surface, and Field et al. have shown the same to be true of DLC. Hydrogen atoms play a key role, as does the formation of a transfer film of DLC on the counterface. Under steady-state conditions, at contact pressures up to 1 GPa, both mating surfaces are decorated by hydrogen atoms that slide over one another with no tendency for adhesion. A very smooth surface then also minimizes the likelihood of plowing and abrasive wear.

In humid air, the friction coefficient of DLC inverses and may rise above 0.3. Gardos et al. attribute this to the possibility of hydrogen being removed due to the relative strength of hydrogen bonding to water molecules. Additions of silicon to DLC substantially reduce the influence of humidity or friction. However, there is evidence that the reduced rate of surface graphitization of DLC in water, or presumably body fluids, will reduce its already low wear rate, according to Jiang et al.^[13]

THE SMOOTHNESS OF DLC COATINGS

The surface roughness of hard coatings has a strong influence on the wear of the counterface, especially when this is a soft material such as ultrahigh-molecular-weight polyethylene (UHMWPE). A careful study has been made by Peng et al.^[10] of the roughness of DLC coatings prepared by three different techniques, and of the effects of postdeposition treatments.

The methods chosen were RF plasma-activated CVD in methane, DC magnetron sputtering in argon, and a carbon ion beam extracted from a cathodic arc discharge. In each case the bias voltage applied to the substrate could be varied up to about 350 V. After deposition, some specimens were subjected to argon plasma sputtering, hydrogen etching in a plasma, or heat treatment at 500°C in vacuum. The substrates were of silicon, were argon-sputter cleaned, and had a roughness of only 0.046 nm.

The coating roughness was similar for all three deposition methods, but depended markedly on the bias voltage, as ion impingement energy, with the lowest values of about 0.04 nm being obtained at a bias of 250–300 V. Heating at 500°C increased roughness, as did argon sputtering and hydrogen etching, which perhaps remove graphitic clusters from certain regions of the surface.

Thus, under preferred conditions, DLC coatings up to 700 nm thick could be as smooth as a carefully prepared silicon crystal substrate.

ORTHOPEDIC APPLICATIONS OF DLC

The load-bearing surfaces of total hip and knee arthroplasties are subject to wear, and it is well recognized that the most serious consequences are those due to the formation of polyethylene (PE) debris at a rate of perhaps 10^{10} particulates per year. These particles are phagocytosed, resulting in granulomatous lesions, osteolysis, and bone resorption, causing pain and aseptic loosening of the prosthesis.

Diamond-like carbon coatings have been explored over the past 10 years as a means for eliminating this problem, with some highly encouraging results. The goal is to demonstrate lower PE wear than occurs against metals and ceramics such as alumina or zirconia. Fractures have occurred in ceramic femoral heads, and so a hard, low-friction coating on metal would potentially be the best solution. Figure 3 shows a DLC-coated example prepared using IBAD.

Some early investigations of DLC by Davidson and Mishra were beset by problems of high compressive stress and decohesion, but the work referred to earlier has done much to reduce the likelihood of coating

Fig. 3 DLC coated and uncoated alumina femoral heads.

delamination, either by bond coats or control of coating stress.

Results over the past five years have indicated the excellent potential for DLC in total joint replacements—but the findings, although all good, have been variable, and it is interesting to arrive at an explanation for this in terms of coating roughness and test procedure.

Saikko et al.^[14] compared femoral heads of CoCr, alumina, and CoCr coated with DLC prepared by an RF plasma discharge in acetylene. Tests were done in bovine serum, with no additives, in an anatomical hip wear simulator operating at 1 Hz. The wear of UHMWPE over 3 million cycles was similar for each type of head.

Sheeja et al.^[15] tested Co–Cr alloy disks coated with DLC by the filtered cathodic arc method and compared them with uncoated Co–Cr against UHMWPE pins in a simulated body fluid. The wear rates were similar, but it was found that the corrosion rate for the coated alloy was reduced by a factor of about 10,000.

In an NSF-funded study, Xu and Pruitt^[16] examined DLC coatings on Ti-6Al-4V alloy against UHMWPE in pin-on-disk tests in water. The DLC was prepared by the plasma source method described earlier. The rate of PE wear was reduced by a factor of 3–4, compared with uncoated alloy.

Oñate et al.^[17] used a knee wear simulation machine to compare Co–Cr, alumina, and Co–Cr coated with DLC from acetylene (as provided by Saikko et al.^[14]). In this case there was a substantial improvement over the uncoated alloy, by a factor of 4, and 40% less wear than against alumina.

A hip joint simulator was used by Lappalainen et al.^[18] to compare DLC coatings on stainless steel, Ti-6Al-4V, and CoCrMo alloy, by the filtered cathodic arc method, with a chromium bond coat. With ultra-smooth coatings with a roughness of 7 nm, the wear rate of UHMWPE was reduced 30- to 600-fold compared with that of the uncoated metal. Corrosion rates in 10% HCl were decreased over 10,000-fold.

Affatato et al.^[19] made use of a hip joint simulator to compare DLC-coated titanium alloy with CoCr and alumina over 5 million cycles in bovine serum with addition of EDTA (ethylene diamine tetraacetic acid) to minimize precipitation of calcium phosphate, which they state can strongly affect friction and wear properties. The DLC, made by PACVD from methane, was comparable to alumina in terms of PE wear.

The variability of these findings suggests that care must be taken in regard to:

- DLC deposition procedure: Methane is superior to acetylene as a source gas.
- Smoothness of the substrate and coating.
- Additive to serum to inhibit calcification.

When conditions are favorable, tests indicate that DLC coatings have the potential to provide the lowest wear rates of UHMWPE—perhaps half those against alumina—without the risks associated with fracture of ceramic components. Corrosion and leaching of metal in body fluids has been shown to be very markedly reduced by DLC coatings.

BIOCOMPATIBILITY OF DLC COATINGS

It would hardly be possible to use DLC as a coating for items *in vivo* unless it had been shown to be biocompatible, and all studies to date agree that this is the case. We will here summarize the evidence.

In an early study, Thomson et al.^[20] used mouse peritoneal macrophages and fibroblasts on DLC prepared by the dual ion beam method, monitoring levels of lactate dehydrogenase (LDH) as a measure of cell viability. There was no indication of cytotoxicity. Similar results were obtained by Allen et al.^[21] using the murine macrophage cell line, IC-21, in a growth medium supplemented with calf serum, on DLC made by plasma-activated CVD. Cell growth studies were made using human synovial fibroblasts and a human osteoblast-like cell line, SaOS-2. Cell growth kinetics were determined by counting after each 24-h incubation period, following disaggregation and staining. Cells grew well on DLC-coated glass and polystyrene with no evidence of abnormal morphology. Cells generally grew faster on DLC, adhered well, and produced extensive filopodia.

Other *in vitro* studies made use of human ML-1 hematopoietic myeloblasts, which are immature and can differentiate into monocytes as macrophages as a result of environmental conditions. There was no difference in cell growth or morphology on DLC coatings (Lu et al.^[22]) made by the direct ion beam method.

Butter and Lettington^[23] reported preliminary *in vivo* studies involving the implantation of DLC-coated pins into soft tissue and femurs of sheep. Much better bonding was observed at DLC rather than metal–tissue interfaces, indicating a lower risk of infection. They also described work done by Mitura on the coating of orthopedic screws with DLC by the RF plasma method. Over a period of 52 weeks, implanted DLC-coated metal showed no evidence of corrosion products or chronic inflammatory reaction.

Blood compatibility tests have been carried out by Dion et al. on DLC-coated Ti6Al4V alloy showing that more albumin adheres to DLC than to medical grade silicone elastomer, by a factor of about 2.2, and this is known to have positive consequences for platelet adhesion. The higher the albumin:fibrinogen ratio, it is believed, the lower will be platelet adhesion and at 1.24 the value for DLC is superior to the 0.76 for silicone.

Ex vivo experiments with whole blood have shown that DLC-coated stainless steel and titanium compare well with LTI carbon and are superior to glass. There is a need, however, for *in vivo* trials, justified by the fact that all biocompatibility tests of DLC-coated surfaces have been successful, with no contrary indications.

In an extension of the biocompatibility of DLC, Steffen et al.^[24] used it as a substrate for heparin following treatment in an ammonia plasma to form amino reaction sites for attachment. The optimum plasma exposure time at a pressure of 3.10^{-3} mbar was around 45 seconds. This treatment with heparin increased blood coagulation times from 25 to over 250 seconds.

Successful *in vivo* tests of the biocompatibility of DLC have been reported by Allen et al.^[25] who implanted DLC-coated CoCr cylinders into intramuscular locations in rats and transcortical sites in sheep. After 3 months, histologic analysis showed that the specimens were well tolerated. Based on this excellent biocompatibility, the authors have initiated a long-term animal study of a DLC-coated knee arthroplasty.

Finally, for some applications, it can be reported that DLC adheres very strongly to silicone elastomers, probably due to the formation of strong Si–C bonds at the interface.

CARDIOVASCULAR APPLICATIONS OF DLC

Heart valves are conventionally made from LTI carbon and, despite great care in manufacture, there remains a very small but finite risk of failure due to fracture initiated at an undetected surface or sub-surface flaw. Therefore, there has been interest in replacing this brittle material with a metal coated with hard carbon that is nonthrombogenic.

Butter and Lettington^[23] suggested the use of NiCr18 stainless steel coated with carbon by a non-line-of-sight method. The plasma conversion method would be a suitable choice. It has been reported that a silicon-containing DLC may be a better coating for cardiovascular purposes, but Butter and Lettington^[23] commented that in tests it showed no difference from the controls. The published studies all show DLC to be a promising biomaterial for heart valve applications, and proprietary work is in progress on this topic.

Arterial stents can induce platelet activation and may initiate thrombosis by shear forces on the flow and by platelet adhesion to the metal. Gutensohn et al.^[26] evaluated *in vitro* the performance of stents coated with DLC. Growth arrays using smooth muscle cells and endothelial cells showed that DLC did not affect proliferation rates, and no cytotoxic effects were

observed. Flow cytometric analyses showed no significant changes in mean channel fluorescence intensity for the structural antigens CD41a and CD42b, whereas by contrast, expression of the activation-dependent antigens CD62p and CD63 increased significantly in uncoated compared with DLC-coated stents.

Release of metal ions into the bloodstream is a matter of concern, and Gutensohn et al.^[26] used atomic adsorption spectrometry to detect a significant release of nickel and chromium ions from noncoated stents into human plasma over a 96-hour period. However, only minimal concentrations of released ions could be detected in the case of DLC-coated stents. Similar results were obtained by inductively-coupled plasma mass spectrometry analysis, and in this case the release of metal ions from DLC-coated stents was virtually undetectable. The authors concluded that the coating of intracoronary stents with DLC may contribute to a reduction in thrombogenicity and consecutively a reduction in the incidence of acute occlusion and in-stent restenosis *in vivo*.

Radioactive coatings have been applied successfully on stents in order to reduce restenosis as a result of the growth of scar tissue. Rhenium isotopes are beta-emitters with a conveniently short half-life, but the soluble perrhenate anion, ReO_4^- , tends to leach out. Evans et al.^[27] described the use of DLC coatings deposited from an RF plasma to form a barrier layer over the rhenium. After one month in 0.9% saline solution, the amount of released radioactivity was determined. The DLC coating reduced the release of activity by an average of a factor of 3, with greater effectiveness obtained at higher bias voltages of 500 V. It was inferred that the greater energy of ion bombardment served to densify the DLC coating and so reduce the leach rate. It was also shown in this study that there was no cytotoxicity for cells in contact with the DLC coating.

Diamond-like carbon coatings on segmented polyurethane were tested for blood compatibility by Alanazi et al.^[28] they showed that the coated polyurethane was superior to an excellent nonthrombogenic polymer, 2-hydroxyethyl methacrylate (HEMA), in tests carried out in a parallel flow chamber. The authors concluded that greater attention should be paid to DLC for use in the medical field.

OTHER BIOMEDICAL APPLICATIONS OF DLC

Four examples will serve to demonstrate the versatility and usefulness of DLC coatings in other biomedical applications. There seems no doubt that others will follow.

Elinson et al.^[29] applied thin coatings of DLC (20–200 nm) to soft contact lenses and contact lens

cases to reduce the problems of biofilm formation. The authors regard microbial contamination of contact lens cases to be as major a problem as that of the lenses themselves, and showed that lenses stored in DLC-coated cases were free from any contamination.

McLaughlin et al.^[30] investigated RF plasma-deposited DLC on stainless steel medical guidewires and found good adherence with a coefficient of friction superior to that of PTFE. Furthermore, the thin DLC coating did not alter the overall stiffness of the guidewires, in contrast to PTFE or silicon coatings that were up to 300 microns thick.

In ophthalmic surgery, the surgeon may need to suture the corneal region while causing the least distortion of the eyeball. Butter and Lettington^[23] referred to experiments that have shown that a DLC coating on the needle reduces the force required to penetrate the corneas of pigs' eyes by about 30%. There may be more such applications in microsurgery, and the authors point out that the dark color of DLC would have the further benefit of reducing reflections from the lights of operation microscopes.

Finally, Schwank et al.^[31] made use of the high electrical resistance of hydrogen-containing DLC, made by the plasma-activated CVD method, to insulate the tip of a new design of Pt/Ir needle for intracellular potential measurement. In order to render the tip of the needle conductive, exposure to localized oxygen plasma at a pressure of 10 bar was used. This may remove the carbon by reactive ion etching, but in addition may transform the film into a more graphitic (sp^2) state.

CONCLUSION

Whereas diamond coatings may have some applications in biomedicine, it is DLC that has emerged over the past decade as a most versatile and useful biomaterial. Harder than most ceramics, bioinert, and with a low friction coefficient, DLC is one of the best materials for orthopedic applications. If deposited with the preferred composition on a very smooth substrate, it offers the lowest wear rate of a UHMWPE counterface, below that observed against polished alumina or zirconia, and without risks associated with fracture of a brittle ceramic.

All studies of the biocompatibility of DLC are in agreement that there is no cytotoxicity, and cell growth is normal on a DLC-coated surface. Its blood compatibility is as good as that of the well-established LTI carbon used in heart valves. Diamond-like carbon coatings on stainless steel have performed very well in *in vitro* studies of hemocompatibility.

Undoubtedly there is more work in progress than has been reported in the open literature, and the stage

has been reached at which in vivo testing of DLC is warranted. With cautious optimism, we look forward to the application of well-bonded DLC coatings in a variety of orthopedic and cardiovascular applications. All of these procedures involving total joint replacements, heart valves, and stenting, for that DLC may provide greater efficacy and an extended service life, are ones that give patients a much higher quality of life.

Dielectric Properties of Tissues

Kenneth R. Foster

Department of Bioengineering, University of Pennsylvania, Philadelphia, Pennsylvania, U.S.A.

INTRODUCTION

This entry presents a nontechnical review of the dielectric properties of tissues, at frequencies ranging from DC to the microwave range. These properties (dielectric permittivity and conductivity) are needed for purposes such as the development of telemetry applications or diagnostic applications based on electrical measurements. They also can provide useful information about the structure and function of tissues. Special attention is paid to the historical development of this field.

HISTORY

The bulk electrical (or dielectric) properties of tissues and cell suspensions have been of interest to many investigators for more than a century, for both technological and scientific reasons.

Spurred both by the usefulness of dielectric studies in examining the physical properties of biological material, and advances in instrumentation, numerous scientists studied the dielectric properties of biological materials intensively during the early years of the 20th century. In the first decade of the century, Rudolf Höber (1886–1961) demonstrated by means of electrical measurements that cells had a thin insulating layer—which was one of the first convincing proofs of the existence of the cell membrane and a scientific discovery of the first order (for an interesting biographical sketch of Höber see Ref. [1]). Following this lead, a number of other distinguished scientists began to study the dielectric properties of tissues and cell suspensions. For example, in the early 1920s Hugo Fricke (1892–1972), the famous Danish biophysicist (and eventual head of Cold Spring Harbor Laboratory in New York, U.S.A.), published an influential series of papers on the electrical conductivity of cell suspensions.

These studies, which involved painstaking measurements of the physical properties of cells and biological materials and the interpretation of the results in terms of quantitative models, might be considered to be early contributions to the modern field of biophysics. Because the information that such measurements can

provide about the electrical characteristics of cell membranes is limited, other investigators began to explore the use of more refined electrical measurements. A major breakthrough was introduced by K.S. (known universally to cell biologists as “Kacy”) Cole (1900–1984), who pioneered the use of impedance techniques to study cellular membranes from the giant squid axon using electrodes placed inside the cells. His simultaneous recording of the action potential and impedance change in a squid axon (published in 1939) was a major development in electrophysiology.

Other important dielectric studies in the first part of the 20th century were conducted by physical chemists who wished to learn about the shape and motion characteristics of proteins. Famous work along those lines was conducted starting in the early 1930s by the American chemist J. L. Oncley (1910–2004) and R. H. Cole (1914–1990) (brother of K. S. Cole).

After the middle of the 20th century, dielectric measurements on bulk samples were largely supplanted by advanced electrophysiological techniques that allowed investigators to study directly the electrophysiology of cell membranes. Other spectroscopic techniques appeared, such as magnetic resonance, which provided more specific information about molecular properties. Dielectric spectroscopy remains an important scientific tool in polymer and colloidal chemistry and other fields.

Apart from their scientific interest, the development of applications of electromagnetic fields in medicine has led to a growing need for accurate data on the dielectric properties of tissues and biological materials. Already in the mid-1930s, groups at Siemens (Erlangen, Germany) and General Electric (Schenectady, New York, U.S.A.) and elsewhere were developing therapeutic applications of radiofrequency energy, including diathermy for treatment of pain and radiofrequency therapy for cancer. This work has continued, with many investigators around the world developing radiofrequency methods for hyperthermia. Developing treatment devices, and modeling the thermal consequences of treatment, requires knowledge of the bulk electrical properties of tissues. Studies on health and safety of radiofrequency energy, which began in earnest in the United States and other countries shortly after the end of World War II, created a need for dielectric

properties of tissues for purposes of dosimetry. Finally, numerous techniques have appeared that depend on measurements of the electrical properties of the body to detect disease and monitor physiological processes.

Herman P. Schwan (1915–2005), a German-born scientist who spent most of his career at the University of Pennsylvania, is undoubtedly the best-known investigator in the dielectric properties of tissues during the mid to the late 20th century.^[2] Schwan developed measurement techniques that remain unsurpassed in accuracy and precision today, and he wrote definitive review articles on the dielectric properties of tissues and their measurement techniques.^[3,4] The present entry is based on a longer review written jointly with Schwan.^[1]

CONDUCTIVITY AND PERMITTIVITY

Electrical conductivity σ and permittivity $\epsilon'\epsilon_0$ are measures, respectively, of the current flow or polarization induced by an electric field in matter. (Analogous properties can be defined for magnetic fields, but will not be considered here.) These properties are usefully defined over distance scales exceeding the size of individual molecules. In complex materials such as tissue, the distance scale of interest depends on the needs of a particular investigation. For example, when studying the absorption of microwave energy for purposes of dosimetry in health studies, the required spatial resolution is usually in millimeters or greater. In that case, the dielectric properties of a tissue can be measured using bulk samples of millimeter or centimeter dimension. For studies of the distribution of an externally imposed field within cells and across cell membranes, information is needed about the dielectric properties over much smaller distances.

The following discussion assumes that the response is linear (i.e., the induced current is proportional to the applied field). This is usually the case when the applied field is small (a few volts per meter or less), in which case the dielectric properties typically reflect physical mechanisms of charge transport in the material as opposed to biological responses. A variety of nonlinear effects are well known, both biological (such as membrane excitation) and nonbiological (e.g., electrical breakdown of cell membranes), which are separate from dielectric effects as considered in this entry. These nonlinear responses generally require quite strong fields, hundreds of volts per meter or more. For technological applications, which typically involve fields that are insufficient to produce nonlinear responses, the linear dielectric properties are usually sufficient.

The conductivity σ and permittivity $\epsilon'\epsilon_0$ are measured by applying an alternating electric field to the sample, and measuring the current that flows in phase

(conductive current) and 90° out of phase (reactive current) with the applied field. The relative permittivity ϵ' (no units) is the permittivity of a medium divided by ϵ_0 , the permittivity of free space (8.85×10^{-12} F/m). The conductivity σ has dimensions siemens per meter (S/m).

These properties are illustrated in terms of an idealized capacitor consisting of two electrodes of area A and separation d (Fig. 1). The region between the plates is filled with material of permittivity ϵ' relative to free space and conductivity σ . A voltage V is impressed between the plates. The electric field between the plates is assumed to be uniform. The capacitance C and the conductance G of this system are:

$$\begin{aligned} C &= \epsilon'\epsilon_0 A/d \\ G &= \sigma A/d \end{aligned} \quad (1)$$

For tissues and other biological materials that contain water and ions, the major contribution to the conductivity is the motion of mobile ions. By contrast, the permittivity reflects the polarization of bound charges in the tissue and other effects. Because the electrical transport mechanisms are time dependent, the current and polarization will both change with time after a field is suddenly imposed. In that case, the capacitance and conductance in Eq. (1) would be values measured after the system has reached a steady state after the imposition of a field.

An alternative approach to characterizing the dielectric properties of a material is to apply sinusoidal fields, in which case ϵ' and σ would be functions of frequency.

It is useful to consider the dielectric properties as parts of a single complex quantity. This can be seen by noting that the capacitance and conductance in Eq. (1) can be combined into a complex admittance Y^*

$$\begin{aligned} Y^* &= G + j\omega C \\ &= \frac{A}{d}(\sigma + j\omega\epsilon'\epsilon_0) \end{aligned}$$

Fig. 1 Equivalent circuit of an idealized parallel plate capacitor filled with material of relative permittivity ϵ' and conductivity σ . The plate area is A and the distance between plates is d . In a real circuit, a small additional shunt capacitance would occur from the stray fields in the air outside the material. (From Ref. [5].)

where

$$\omega = 2\pi f \quad \text{and} \quad j = \sqrt{-1} \quad (2)$$

We can define a complex conductivity σ^* as:

$$\begin{aligned} \sigma^* &= \sigma + j\omega\epsilon'\epsilon_0 \\ &\equiv \sigma' + j\sigma'' \end{aligned} \quad (3)$$

and a complex permittivity ϵ^* as:

$$\begin{aligned} \epsilon^* &= \epsilon' - j\sigma/\omega\epsilon_0 \\ &\equiv \epsilon' - j\epsilon'' \end{aligned} \quad (4)$$

where the asterisks denote complex quantities. Defined in this way, the imaginary part of the complex permittivity (known as the loss factor ϵ'') is proportional to the measured conductivity of the material. An important theoretical result, called the Kramers–Kronig relations, is that the real and imaginary parts of ϵ^* cannot vary independently with frequency.^[5]

The ratio ϵ'/ϵ'' is a measure of the relative contributions of the capacitive to conductive nature of current flow in the material. When this ratio is less than 1, the material is primarily conductive, i.e., the current is nearly in phase with the applied field. This is typically the case with tissues at frequencies below about 1 MHz. In the other limit, when ϵ'/ϵ'' is much less than 1 (which is sometimes the case at high frequencies) the tissue is electrically similar to a dielectric material.

Arrangements similar to that shown in Fig. 1 can be used to measure the dielectric properties of biomaterials, with due consideration of a variety of real-world effects such as electrode artifacts, stray fields, and wave propagation effects at high frequencies. An extensive, and still valuable, review of dielectric measurement techniques was done by Schwan.^[2] Fig. 2 shows a sample cell that was used by Schwan and his colleagues for many years to study the dielectric properties of protein and cell suspensions, in which the capacitor “plates” are small platinum-coated electrodes that are surrounded by the material being measured.^[6] The cell would be calibrated using known dielectric fluids such as alcohol and aqueous electrolyte solutions; the electrodes are coated with electrolytically deposited platinum (called platinum black) to reduce electrode artifacts. Depending on the sample being measured, such a cell would be useful between a few megahertz and several hundred megahertz. At lower frequencies, electrode artifacts would become severe, while at higher frequencies wave propagation effects would become troublesome.

Fig. 2 Schematic of measuring cell used by Schwan for many years in studies of dielectric properties of tissues, cell suspensions, and biopolymer and protein solutions. The electrodes at the bottom of the cell are platinum, covered with a layer of electrolytically deposited platinum black to reduce electrode artifacts. A water jacket for thermal control surrounds the measurement volume. The cell would be used with an impedance bridge, and was usable over the frequency range from about 1 to several hundred MHz. (From Ref. [4].)

DIELECTRIC RELAXATION

The permittivity and conductivity are typically functions of frequency, and studying these properties over a wide frequency range yields a kind of spectroscopic information about the material. At different frequencies, different mechanisms of charge transfer contribute differently to the conduction and polarization.

As a simple example, consider a material whose polarization, in response to a step change in field, relaxes to its final value as a single exponential process with time constant τ . In response to an applied field that oscillates sinusoidally at frequency ω radians per second (or $\omega/2\pi$ Hz), the complex permittivity can be written as follows:^[5]

$$\epsilon^* = \epsilon_\infty + \frac{\epsilon_s - \epsilon_\infty}{1 + j\omega\tau} \quad (5)$$

or, separating into real and imaginary parts,

$$\begin{aligned}\varepsilon' &= \varepsilon_\infty + \frac{\varepsilon_s - \varepsilon_\infty}{1 + (\omega\tau)^2} \\ \varepsilon'' &= \frac{(\varepsilon_s - \varepsilon_\infty)}{1 + (\omega\tau)^2} \omega\tau\end{aligned}\quad (6)$$

In the above expression, ε_s is the value of the permittivity in the limit of low frequencies, while ε_∞ is the limiting value at high frequencies.

Fig. 3 shows the variation in permittivity ε' , loss, and conductivity with frequency for this dispersion. The center frequency of the dispersion is called the relaxation or characteristic frequency f_c , and is equal to $1/(2\pi\tau)$ Hz. In this example, with single time constant relaxation, most of the change in permittivity occurs over a decade of frequency centered about f_c . The conductivity σ increases by an amount

equal to $(\varepsilon_s - \varepsilon_\infty)/(\varepsilon_0\tau)$ over this relaxation. The broad frequency dependence of this relaxation stands in contrast to much narrower resonance peaks that are measured by various spectroscopic techniques including MRI.

Characteristically, the dielectric properties of biological materials are far more complex than the single time constant relaxation given by Eqs. (5) and (6). Various reasons include the presence of multiple relaxation mechanisms and the structural complexity of the material. There are also dielectric relaxation processes with nonexponential relaxation characteristics. As a result, the dielectric properties of these materials, when plotted vs. frequency, exhibit far broader dispersions than would be expected for single time constant relaxation. If the relaxations are widely separated in frequency, multiple dispersion regions might be apparent in the data. More commonly,

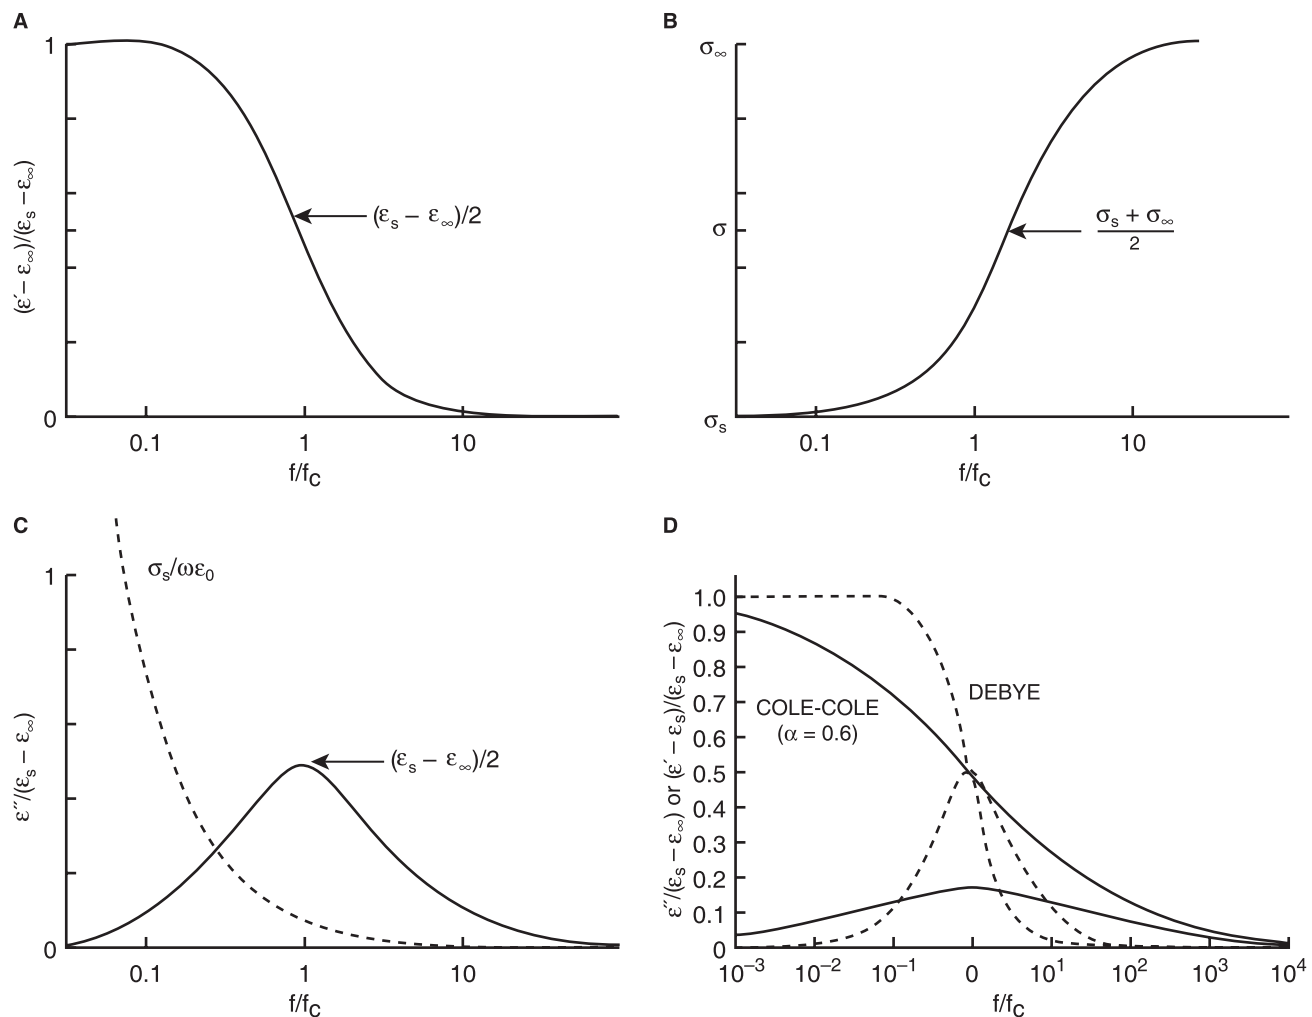

Fig. 3 Single time constant relaxation. (A) Relative permittivity vs. frequency; (B) conductivity vs. frequency; (C) loss vs. frequency showing (broken line) a contribution from a DC conductivity; and (D) comparison of single time constant relaxation with broadened relaxation described by the Cole-Cole equation, representing the effects of a distribution of relaxation times. (From Ref. [5].)

however, the dispersions overlap considerably, which complicates the interpretation of the data.

A particular mathematical form, the Cole–Cole expression, is often successful in empirically describing the dielectric properties of biological materials over a broad frequency range. This equation, named after K. S. Cole and R. H. Cole, who first introduced it in 1941, can be written as:^[7]

$$\varepsilon^* = \varepsilon_\infty + \frac{\varepsilon_s - \varepsilon_\infty}{1 + (j\omega\tau)^{1-\alpha}} \quad (7)$$

In Eq. (7), α is a parameter that characterizes the breadth of the dispersion. In the limit where α approaches zero, this approaches Eq. (5) for single time constant behavior. Fig. 3 compares a single time constant relaxation with that described by the Cole–Cole equation.

The Cole–Cole equation is frequently successful in describing dielectric data from many materials over broad frequency ranges, and experimentalists routinely fit their data to it. Unfortunately, the equation is empirical only, and yields no particular insights into the underlying mechanisms involved.

DIELECTRIC RELAXATION MECHANISMS IN BIOLOGICAL MATERIALS

Several major, and a number of minor, mechanisms contribute to the dielectric properties of tissues and other biological materials. Depending on the material and frequency range of interest, one or another might predominate in its influence.

Dipolar Relaxation

Many molecules and biological structures possess electric dipole moments owing to their distribution of charges. An externally imposed electric field will exert a torque on the dipoles, causing them to partially align, contributing to the polarization in the material. This effect is an important source of polarization in dipolar liquids such as water, and in solutions of dipolar molecules including proteins. A theory, originally attributed to the Dutch chemist Peter Debye (who won the Nobel Prize in chemistry in 1936 for his work on dipole molecules) provides a simple quantitative model for the phenomena.^[8]

The Debye theory considers an ensemble of independent dipoles, each with dipole moment μ . An externally imposed electric field of intensity F will exert a torque on each dipole given by $\mu F \sin(\theta)$, where θ is the angle between the dipole moment and the field. This torque will act to orient the dipole, but it will be

opposed by random thermal agitation. Debye calculated the mean orientation of a molecule in the ensemble to be:

$$\langle \cos(\theta) \rangle \approx \frac{\mu F}{3kT} \quad (8)$$

where k is Boltzmann's constant (1.38×10^{-23} J/K) and T is the absolute temperature (K). Eq. (8) refers to a mean orientation, averaged over many dipoles. At any realistic field strength, this mean orientation is very small; the effects of the torque to align the molecules are far overwhelmed by random thermal agitation.

When a field is suddenly imposed on the ensemble of dipoles, the polarization will develop gradually as the dipoles diffuse in the viscous medium in which they are located. For a spherical molecule of radius a , the mean relaxation time τ can be obtained by considering the diffusion of the sphere in a viscous medium. Application of Stokes' law gives:

$$\tau = \frac{4\pi\eta a^3}{kT} \quad (9)$$

where η is the viscosity (Poise).

The relaxation time τ ranges from picoseconds for small dipolar molecules such as water, to microseconds for large globular proteins in aqueous solution. The corresponding dielectric dispersion, measured with alternating fields, will have a center frequency that ranges from megahertz frequencies (for protein molecules) to 20 GHz (for water). If the molecule is not spherical, as is typically the case with proteins, additional dielectric dispersions will appear that correspond to rotational diffusion along each principal axis of the molecule. Table 1 summarizes the dielectric properties of various proteins, from Oncley.^[9]

Water, the major component by volume of soft tissues, shows a strong dipolar relaxation that is very close to single time constant in nature, with a low-frequency permittivity of 78 and center frequency of about 20 GHz at room temperature. This is well above the frequency range of most other relaxation processes that occur in tissue. Consequently, at frequencies above about 1 GHz, the dielectric properties of tissue are dominated by those of water. This fact underlies the frequent use of dielectric techniques to measure the water content of agricultural and other materials.

Counterion Polarization

Both biological and nonbiological materials characteristically show huge dielectric dispersions at low frequencies. Tissues, for example, show astonishingly large permittivity values at low frequencies, in the range of tens of millions for soft tissues at frequencies

Table 1 Dielectric properties of various proteins at 25°C

Protein	Mol wt ($\times 10^{-3}$) (Da)	$\Delta\epsilon'/\text{g/L}$	μ (D)	$\tau \times 10^8$ (sec)	a/b
Ovalbumin	44	0.10	250	18; 4.7	5
Horse serum albumin	70	0.17	380	36; 7.5	6
Horse carboxyhemoglobin	67	0.33	480	8.4	1.6
Horse serum pseudoglobulin	142	1.08	1100	250; 28	9
β -Lactoglobulin (in 0.25 M glycine)	40	1.51	730	IS; 5.1	4
Myoglobin	17	0.15	170	2.9	

Mol wt, molecular weight (daltons); μ , dipole moment (debye units); τ , rotational relaxation times; a/b , axial ratio; $\Delta\epsilon'/\text{g/L}$, total increase in permittivity per gram of protein per gram of solution, measured at low frequencies above the permittivity of pure water.

of 1 Hz or below. Similar effects are found in colloidal and other nonbiological suspensions, indicating that the phenomenon is essentially nonbiological in origin. The effect is associated with displacements of clouds of mobile charges in the material, and not the orientation of permanent dipoles.

This phenomenon has been subjected to extensive theoretical and experimental work, and the effect is understood in principal even though a detailed analysis of the effect in most biomaterials remains beyond reach. The first important theory for the effect was proposed by the Swiss theoretical chemist G. Schwarz in 1962, who postulated that counterions diffuse along the surfaces of the particles under the influence of the applied field, inducing a dipole moment in the particle when charges of opposite sign accumulate at each end.^[10]

Schwarz's theory is simple and intuitively appealing, and has been cited in hundreds of papers over the years. But scientists now accept a very different explanation of the effect, involving diffusion of ions in the bulk electrolyte surrounding the particle (not, as in Schwarz's model, counterions on the surface of the particle). This diffusion leads to regions in the electrolyte near the surface of the particle where the electrolyte concentration is higher or lower than in the surrounding bulk electrolyte solution.

Because of its importance in understanding colloidal systems, a great many theoretical and experimental studies have been conducted on the effect over the years, typically with reference to nonbiological systems including colloidal suspensions or suspensions of polystyrene microparticles. Important contributions to the problem were published in a 1974 book by Ukrainian investigators Stanislav Dukhin and Vladimir Shilov; however, perhaps because of a flawed translation the work received little attention in the West.^[11] The problem subsequently, attracted the attention of numerous scientists in Argentina, Australia, the Netherlands, Spain, Ukraine, as well as the United States, and other countries. Important contributions to the problem have been recently made by A. Dukhin, the son of S. Dukhin and a distinguished physical

chemist in his own right. An excellent (now dated) review of this modern theory is by Mandel and Odijk.^[12]

While the modern theory is surely more correct than the simple model for "counterion polarization" developed by Schwarz, it is not necessarily more useful to the experimentalist. The theory, which has to take into account both electrical and hydrodynamic forces on the ions, is mathematically very complex. Presently, it can be applied rigorously only to the simplest systems, such as dilute suspensions of polystyrene microspheres. This is a serious impediment to trying to interpret the low-frequency dielectric dispersion that is found in most biomaterials, which are neither structurally simple nor dilute in nature.

Interfacial Polarization (Maxwell-Wagner Effect)

If a material is electrically heterogeneous, a dispersion occurs in the bulk properties from the charging of the interfaces within the material. This phenomenon does not arise from dielectric relaxation in the bulk phases of the material or movement of counterions (which might also be present), but is purely a macroscopic effect arising from the heterogeneity of the material leading to changes in the distribution of electric fields within the material at different frequencies. This effect is named after K. W. Wagner, who published an influential paper on the effect in 1914, extending an earlier result by the famous physicist James Clerk Maxwell. The theory is straightforward but mathematically cumbersome, and is described in more detail in^[5] and many other places.

One example of biological significance is a suspension of membrane-covered spheres that are filled with and surrounded by electrolyte solution, which is a simple model of a cell suspension.^[5] Because the membranes are thin, they have a large capacitance whose impedance decreases inversely with frequency. The membranes are considered to be nonconductive, but (because they are thin) they have a capacitance similar to that of cell membranes.

Fig. 4 Finite element calculation, showing paths of currents around and through a membrane covered sphere (approximating a cell) at different frequencies. The sphere was chosen to have properties reminiscent of those of a cell: radius $10\ \mu\text{m}$, conductivity of inner and outer media $1\ \text{S/m}$, membrane capacitance $0.01\ \text{F/m}^2$. The figures show one-quarter of each cell; because of symmetry the patterns of current flow would be repeated in the other three quadrants that are not shown.

Fig. 4 shows a numerical solution for the current flow around a single sphere, obtained using a finite element program. At low frequencies, the current flows around the spheres because of their high impedance. As the frequency is increased, progressively more current flows through the cells. At very high frequencies, the membranes are short-circuited owing to their capacitance, and no longer impede current flow. At low frequencies, the conductivity of the suspension will be low (owing to the presence of the nonconducting sphere) and the permittivity will be high (owing to the collection of charge against the membrane); at very high frequencies the permittivity and conductivity of the suspension will be close to those of the media that are contained by and surround the spheres.

This model can also be solved analytically, but the mathematics involved is cumbersome.^[5] For dilute

suspensions of spheres with properties similar to those of cells, approximate results can be written in the simple form:

$$\epsilon_s \simeq \frac{9pRC_m}{4\epsilon_0} \quad (10)$$

(relative permittivity of the suspension at low frequencies),

$$\sigma_s \simeq \sigma_a(1 - 3p/2) \quad (11)$$

(conductivity at low frequencies), and

$$\tau \simeq RC_m \left(\frac{1}{2\sigma_a} + \frac{1}{\sigma_i} \right) \quad (12)$$

(relaxation time).

In the above expressions, p is the volume fraction of the spheres (assumed to be small), R is the radius of the spheres (m), C_m is the capacitance of the membrane (F/m^2), and σ_a , σ_i are the conductivities of the outer and inner media (S/m).

To give a numerical example, for a suspension with electrical parameters typical of those of cells ($R = 10 \mu m$, $p = 0.1$, $\sigma_a = \sigma_i = 1 S/m$), the static permittivity is about 1000 and the center relaxation frequency is about 1 MHz. Suspensions of cells such as erythrocytes show quite similar properties.

This simple theory is remarkably successful in predicting the dielectric properties of cell suspensions. The theory can be extended to more concentrated suspensions, and to suspensions of nonspherical cells.^[5]

This simple theory has important implications for the dielectric properties of tissues and cell suspensions. The dielectric properties of the suspension depend very little on the conductance of the membrane but depend quite strongly on the membrane capacitance and size of the cells. (The membrane conductance, which usually is of greater interest to cell biologists than the membrane capacitance, is very difficult to measure by straightforward dielectric techniques). Also, the conductivity of the suspension at low frequencies depends strongly on the volume fraction of extracellular liquid, which is the chief pathway for the current through the suspension.

This example has important implications concerning the possible biological effects of electromagnetic fields.^[5] When low-frequency currents are passed through the cell suspension, potentially substantial fields are imposed across the cell membrane, equal (for spherical cells) to the $1.5R$ times the field strength in the surrounding medium. At frequencies substantially above the relaxation frequency, the potential differences that result across the cell membranes are very much smaller. Indeed, at radio-frequencies and above, very little of the applied field is imposed across cell membranes, because they are short-circuited by virtue of their capacitance.

Dielectric Properties of Tissues

Now, after nearly a century of study, a vast literature exists on the dielectric properties of tissues and biological materials have accumulated. Fig. 5 indicates the dielectric permittivity of a typical soft tissue, from an early (1957) review by Schwan.^[3] The terminology invented by Schwan for the major dispersion regions, alpha, beta, and gamma, remains in use. Table 2 summarizes these major dispersion regions and the mechanisms that give rise to them.

Figs. 6–8 show more recent data, from excised sheep tissues at body temperature.^[13]

Fig. 5 A schematic illustration of three major dispersion regions found in typical tissues, with permittivity and conductivity values typical of soft tissues.

Several points are worth noting from these figures:

- The tissues all show broad and rather featureless dielectric relaxations that extend over a wide frequency range, which are not clearly separated in frequency. This complicates the interpretation of the data.
- Over most of the frequency range covered by the data, the tissues are primarily resistive ($\epsilon'' > \epsilon'$), i.e., the current and field are in phase. Thus, for many practical applications, the permittivity is not an important factor in determining current flow.
- The tissues show a pronounced dispersion above 1 GHz, which is due to dipolar relaxation of the tissue water content.
- The dielectric properties of all four tissues summarized in Figs. 6–8 show dispersions in the megahertz region which arise, at least in part, from the charging of cellular membranes.
- The dielectric properties of two of the tissues (brain and skeletal muscle) show large, low-frequency

Table 2 Major dispersion regions observed in the dielectric properties of tissues and their origin

Type	Frequency range	Mechanism
α	^a mHz– ^b kHz	Counterion effects; long-range structures in tissue
β	0.1–100 MHz ^c	Maxwell–Wagner effects; charging of cellular membranes
γ	0.1–100 GHz ^d	Dipolar reorientation of water

(From Ref. [3].)

^a1mHz = 10^{-3} Hz

^b1kHz = 10^3 Hz

^c1MHz = 10^6 Hz

^d1GHz = 10^9 Hz

Fig. 6 Permittivity of four representative ovine tissues (skeletal muscle, grey matter of brain, blood, and cortical bone).

dispersions, which arise, at least in part, from counterion effects.

We consider these properties separately in different frequency ranges. The discussion will attempt to relate the theoretical discussion in the preceding section, with the data obtained from tissues.

Fig. 7 Conductivity of four representative ovine tissues (skeletal muscle, grey matter of brain, blood, and cortical bone).

Fig. 8 Ratio of ϵ'/ϵ'' of four representative ovine tissues (skeletal muscle, grey matter of brain, blood, and cortical bone).

Low Frequencies (<0.1 MHz)

At frequencies below the beta dispersion frequency, current is largely excluded from the interior of cells by virtue of the high impedance of their membranes; the current flows primarily through the extracellular space. Indeed, in 1924 Hugo Fricke successfully modeled the electrical conductivity of blood using electrolyte-soaked sand. The conductivity of tissues, which is nearly independent of frequency, at low frequencies (Fig. 7) reflects conduction in the electrolyte in the extracellular space. At low frequencies, this conductivity depends on both the volume of extracellular space and the geometry of the cells [cf. Eq. (11)], but not the electrical characteristics of the cells themselves.

The permittivity of two of the soft tissues (muscle and brain) increases to very high values at low frequencies, far higher than that of blood. These reflect counterion effects, although other effects related to tissue structure (polarization in the sarcotubular system in muscle, for example) might be important also.

All of the tissues show relaxation behavior that is far broader than would be attributed to a single time constant process. Either multiple dielectric relaxation processes are occurring over this frequency range, or the dominant relaxation process cannot be described by single time constant behavior. Several authors have suggested that this broad relaxation arises from structural factors in the tissue, which give rise to a fractal-like behavior of the relaxation.^[14]

Frequencies Between 1 and 100 MHz

In this frequency range, the cell membranes are largely short-circuited owing to their capacitance and do not offer significant barrier to current flow. Thus, the tissues can be considered to be electrically equivalent to suspensions of nonconducting protein (and other solids) in electrolyte. The conductivity of most soft high water content tissues levels off noticeably around 10–100 MHz and comes to approach that of the electrolyte that constitutes 70–80% of soft tissues (Fig. 7). The conductivity of cortical bone in the same figure does not show this behavior because other conduction mechanisms dominate.

Other smaller effects have been identified between 100 MHz and 1 GHz. This includes dipolar relaxation of “bound water” near protein surfaces, and a Maxwell–Wagner effect that contributes a small dispersion at several hundreds of megahertz owing to the dissimilar electrical properties of tissue protein and electrolyte.^[5]

Microwave Frequencies (>1 GHz)

Above 1 GHz, the electrical conductivity of tissues increases dramatically with frequency owing to dipolar relaxation in the tissue water. For typical soft tissues, the conductivity at 3–5 GHz is due in roughly equal proportions to ionic conductivity and to dipolar loss of water. The permittivity is slightly lower than that of pure water owing to the displacement of water by solid content. At frequencies above about 10 GHz, the permittivity starts to decline noticeably, owing to the dipolar relaxation of the tissue water.

DIELECTRIC PROPERTIES—SOURCES OF DATA

Numerous dielectric data from tissues are available in the literature, over widely varying frequency ranges, and of varying reliability (for one extensive table see Ref. [5]). The data in the literature show considerable variability, even in samples of the same tissue type from animals of the same species. The dielectric properties vary with the condition of the samples being measured (e.g., freshly excised tissues vs. autopsy specimens vs. tissues *in vivo*), orientation of the sample being measured (skeletal muscle in particular is highly anisotropic in its properties), age and physical condition of the animal donating the tissues, volume of blood in the tissue, distribution of tissue fluids between intracellular and extracellular space, and other factors. These variations may be significant or not, depending on the needs of an investigator who uses them. While

there have been many attempts to use impedance techniques to monitor physiological events and detect pathology in humans, the lack of specificity of the dielectric properties with respect to biologically important endpoints has been an enduring problem in this field.

For technological applications, a particularly useful set of data have been provided by Gabriel and Gabriel.^[13] These data were taken from similar animals (in most cases, sheep) under similar conditions, over a broad frequency range. The investigators also provided empirical functions, based on the Cole–Cole equation Eq. (7) to enable the user to obtain representative values of the dielectric properties of numerous tissue types over the broad frequency range from 10 Hz to 20 GHz. These data are available on several websites (e.g., <http://www.brooks.af.mil/AFRL/HED/hedr/reports/dielectric/Report/Report.html> and <http://niremf.ifac.cnr.it/tisprop/>), and spreadsheets and other programs can be found on the Internet to facilitate the use of this data set. While not the last word on the subject, this standardized and widely accepted set of data greatly aids in the development and testing of many biomedical applications.

CONCLUSIONS

The dielectric properties of tissues have been of interest to scientists and engineers for many years, from the insights that they provide about the structure and properties of biological materials, for practical applications of electromagnetic fields in medicine, and for studies of possible health and safety problems from exposure to electromagnetic fields. A good theoretical understanding exists of the underlying mechanisms even though the theories may be difficult to apply in detail to specific biomaterials. Extensive collections of data, including one standardized set of data from many tissues that is widely available on the Internet, are of great benefit for the development of applications of electricity in medicine.

Digital Biomedical Signal Acquisition and Processing: Basic Topics

D

Martin Oswaldo Mendez Garcia

Luca T. Mainardi

Department of Biomedical Engineering, Polytechnic University, Milan, Italy

INTRODUCTION

Biological signals carry useful information for probing, exploring, and understanding the behavior of biological systems under investigation. Often, such information cannot be readily accessed, being masked by noise or buried by other vital signals simultaneously recorded. In these cases, the raw signal has to be processed to yield useful results.

Biomedical signal processing (BSP) deals with representation, transformation, and manipulation of biomedical signals and their informative content. The objectives of BSP may be various, ranging from the enhancement of features (waveforms) of interest, the quantitative analysis of physiological systems (from cells to organs to the whole human organism), to the definition of reliable indexes to be used in clinical practice for diagnostic, therapeutic, and rehabilitation purposes.

In this article, the basic tools in the BSP field are presented. Far from being exhaustive, the article is intended as a review of the fundamental concepts of digital filtering, synchronous averaging, and spectral analysis in the special context of biomedical signals. The processing of biomedical signals is an intriguing, unique challenge in which the need to investigate complex biological systems is often associated with the availability of indirect, noninvasive observations of the phenomena. The article is organized as follows: in section “Acquisition,” a brief introduction to the acquisition of biomedical signals is presented, while classical techniques for filtering and signal averaging are described in section “Signal Enhancement.” Section “Spectral Analysis” is dedicated to fundamental concepts of spectral analysis while the problem of extracting relevant signatures from vital signals is presented in section Event Detection. In each section, a few examples will be used to illustrate the problems related to the analysis of biomedical signals and possible solutions. Only basic approaches will be presented. More advanced methods will be described in a latter article of this encyclopedia.

ACQUISITION

Acquisition deals with the problem of converting physical magnitudes (biological signals) into digital data. Basics steps for signal acquisition are: signal sensing, signal conditioning, and Analog-to-Digital (A/D) conversion. “Sensors” (or transducers) serve as interface between biological and electrical system: They pick up signals representing biological variables and convert them into electric signals, which may be easily handled, processed, and transmitted. Several books on biomedical instrumentation provide detailed descriptions of the various transducers and hardware employed in the acquisition of biomedical signals.^[1,2]

After sensing, the signal must be conditioned to satisfy the requirements of the following hardware. A conditioner stage is used to “amplify” the signal [biomedical signals are quite small in amplitude: 1–10 mV for the electrocardiogram (ECG) in the adults—around 10 μ V in the fetus—from 2 to 100 μ V for the electroencephalogram (EEG)], to “compensate” for some nonlinearity in the sensor characteristics, to adapt impedances, or to reduce the amount of undesired noise. In addition, the signal is limited in band (antialiasing filter) to satisfy the requirement of the sampling theorem (see section “The Sampling Process”). The conditioner stage must preserve the information contained in the original biological signal, whose waveforms are analyzed by the physician to detect signs of pathologies (i.e., displacement of ST-segment in the ECG, peak-and-wave patterns in EEG, and so on). Any distortion introduced by the acquisition procedure may lead to misleading interpretation of the data and may prevent in correct diagnoses. For this reason, requirements on the design of the conditioner stage are usually restrictive: The block must be designed with a “linear-phase” and “constant-modulus” frequency response at least in the band of interest. A linear phase introduces a purely time delay, thus avoiding phase distortion in the signals. Finally, the analog signal is A/D converted into a digital one. The A/D conversion can be conceptually divided into two

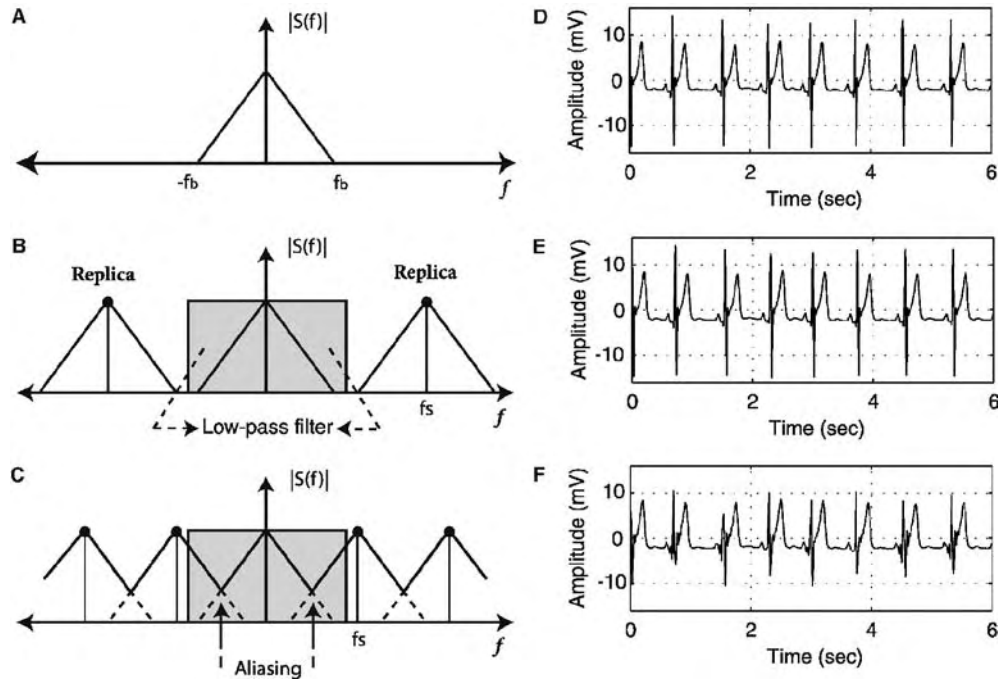

Fig. 1 (A) Fourier transform of a continuous-time band-limited signal; (B) FT of the sampled version of (A) when the sampling theorem is satisfied ($f_s > 2f_b$): the original signal may be recovered with a low-pass filter (rectangle); (C) aliasing effect produced when $f_s < 2f_b$. The replicas overlap with the original spectrum generating a corrupted signal; and (D) original ECG signal (band limited at 250 Hz), and its discrete-time versions sampled at 500 Hz (E) and 50 Hz (F), respectively. Note the alterations in the QRS shape induced by inappropriate sampling rate.

different processes: sampling and quantization. These processes will be briefly discussed from a signal processing point of view.

The Sampling Process

The “Sampling Theorem” (or Shannon Theorem) states that a continuous-time, band-limited signal is entirely represented by its discrete-time (sampled) version, if and only if, the sampling rate is greater than twice the signal bandwidth. When this hypothesis is satisfied, the sampled signal can be processed instead of the original waveform, without losing or destroying any information.

Let us consider a continuous waveform $s(t)$ and its band-limited (between $-f_b$ and f_b) Fourier transform (FT), $S(f)$ (Fig. 1A). The sampled signal $s_s(t)$ is obtained by multiplying the continuous waveform $s(t)$ with an impulse train $i(t)$:

$$\begin{aligned} s_s(t) &= s(t) \cdot i(t) = s(t) \cdot \sum_{k=-\infty}^{\infty} \delta(t - kT_s) \\ &= \sum_{k=-\infty}^{\infty} s(t) \cdot \delta(t - kT_s) \end{aligned} \quad (1)$$

where the $\delta(t)$ is the Dirac delta function, T_s is the sampling interval, and k is an arbitrary integer. In the

frequency domain we obtain

$$\begin{aligned} S_s(f) &= S(f) * I(f) = S(f) * \frac{1}{T_s} \\ &\times \sum_{k=-\infty}^{\infty} \delta(f - kf_s) \\ &= \frac{1}{T_s} \sum_{k=-\infty}^{\infty} S(f - kf_s) \end{aligned} \quad (2)$$

In Eq. (2), $*$ denotes the operation of convolution, and $f_s = 1/T_s$ corresponds to the sampling frequency. It can be appreciated from Eq. (2) that the FT of $s_s(t)$ is an infinite and periodic replication of the FT of $s(t)$. Each replica of $S(f)$ is centered around multiples of f_s . Let us consider the two situations depicted in Fig. 1B and C. In Fig. 1B ($f_s > 2f_b$, i.e., the sampling theorem is satisfied), there are no overlaps among the replicas and the original signal may be easily recovered by low-pass filtering the sampled signal. Conversely, when $f_s < 2f_b$, adjacent replicas overlap and higher frequencies are summed up to lower components: the phenomenon is known as “aliasing.” In the presence of aliasing, the spectral content of the original signal is irreversibly corrupted, and there is no way of recovering it.^[3–5] Fig. 1D depicts a band-limited ECG signal ($f_b = 250$ Hz), while Fig. 1E and F show the same ECG sampled at

500 Hz and 50 Hz, respectively. In Fig. 1E, the signal maintains all the waveform characteristics of the original one, because it was correctly sampled. Conversely, in Fig. 1F, the QRS complexes are altered because the adopted sampling frequency is lower than the maximum frequency contained in the signal. It is worth noting that the appropriate sampling frequency depends either on the frequency content of the signal or on the purpose of the analysis. For example, the recommended ECG sampling rate for diagnostic electrocardiography is 500 Hz (American Heart Association recommendations). The sampling rate can be lowered for long-term acquisition (ambulatory ECG) or increased (>1 kHz) for high-resolution ECG [i.e., for the analysis of ventricular late potential (VLP) or pacemaker functions].^[6]

Quantization

So far, we are supposing that the amplitude of each discrete-time sample is set within a continuous range of values. In practice, this amplitude must be selected among a finite, predefined set of values, depending on the characteristics of the A/D converter (ADC). When a uniform quantizer is used, the ADC voltage range is uniformly divided into equally spaced intervals (the quantization interval Δ is constant: $\Delta = 2^{-b}$, where b is the number of bits used for coding), and the signal amplitude is assigned to the nearest binary level (rounding) or to the closest lower level (truncation). Obviously, this procedure introduces some errors in the description of the signal.

Even if quantization is a highly nonlinear procedure, some of its effects can be modeled statistically. Let us assume that the sampled and quantized signal $s_q(n)$ can be described by the following model

$$s_q(n) = s_s(n) + e(n) \quad (3)$$

Here the effect of quantization is seen as an additive noise term, $e(n)$, superimposed onto the sampled signal. The $e(n)$ is known as “quantization error” and, to deal with a simplified mathematical problem, is usually supposed to satisfy the following hypothesis:

1. $e(n)$ is a white noise with uniform distribution.
2. $e(n)$ is uncorrelated with $s(n)$.

Depending on the adopted coding procedure, the probability density function (PDF) of $e(n)$ is different: in the case of rounding, the PDF is uniform in the range $-\Delta/2 < e(n) < \Delta/2$, with zero mean and the variance (σ_e^2) equal to $\Delta^2/12$; in case of truncation, the PDF is still uniform but within the interval $-\Delta < e(n) < 0$, the mean is $-\Delta/2$ and the variance is unchanged. As

$\Delta = 2^{-b}$, the variance of the error is reduced when the number of bits is increased.^[4]

Because $e(n)$ is seen as an additive noise corrupting the signal, one can estimate the signal-to-noise ratio (SNR) of the quantization process. Defining σ_s^2 as the variance of the signal, we have

$$\begin{aligned} \text{SNR}_{\text{dB}} &= 10 \log_{10} \left(\frac{\sigma_s^2}{\sigma_e^2} \right) \\ &= 6.02b + 10.79 + 10 \log_{10}(\sigma_s^2) \end{aligned} \quad (4)$$

It is interesting to note that SNR increases by 6 dB for each added bit of coding.

In biomedical applications, several quantization procedures can be adopted, including uniform quantization (described above), nonuniform quantization (as logarithmic, exponential, look up table), and semiuniform quantization.^[3-5,7]

SIGNAL ENHANCEMENT

The relevant information contained in the acquired biomedical signal may be not immediately available. It may be masked by “endogenous” and “exogenous” noise sources. Endogenous effects include disturbances related to other biomedical signals simultaneously recorded such as influences of maternal ECG in fetal ECG recordings, muscle artifacts in ECG leads, ECG disturbances in EEG signals, or the case of evoked potentials (EP) hidden by the normal brain activity. Exogenous effects are related to the interaction between the recording instrumentation, the patient, and the environment (disturbances from electrode motions, power line interference, and so on).

The recovery of a signal from background noise is known as “signal enhancement.” For this purpose, several signal-processing techniques have been developed. Two of them will be described in the sections “Digital Filters” and “Signal Averaging.” The former is appropriate when the frequency contents of signal and noise do not overlap; the latter is useful when a deterministic signal is buried in stochastic noise.

Digital Filter

A digital filter is a discrete-time system that transforms an input signal $x[n]$ into an output sequence $y[n]$ in which some desired properties of $x[n]$ are enhanced and emphasized. We may write $y[n] = T[x[n]]$, indicating that a particular transformation $T[\]$ is applied to $x[n]$ to produce $y[n]$. When $T[\]$ is time invariant and satisfies the linear superposition principle, the class of linear, time-invariant (LTI) filters is obtained. The LTI

filters have been widely studied and have important applications in BSP.^[3-5,7-11]

When the properties of a system have to be analyzed, we may observe the system output when known functions are at the input. To define the properties of LTI filters, two input functions are of particular interest: 1) the δ -Dirac function ($\delta[n]$) and 2) complex sinusoids.

The filter output, obtained when an impulse is at input, is known as the “impulse response” (IR). The filter outputs when sinusoids are the input define the “frequency response” of the filter.

The knowledge of the IR makes possible to compute the filter response to any input. To prove that, let us express a generic signal as the sum of weighted and delayed impulses

$$x[n] = \sum_{k=-\infty}^{\infty} x[k] \cdot \delta(n-k) \quad (5)$$

Each $\delta[n-k]$ will generate the same IR $h[n-k]$ (filter is time invariant), even if delayed. The responses can be summed up at the output, so that we obtain

$$y[n] = \sum_{k=-\infty}^{\infty} x[k] \cdot h(n-k) \quad (6)$$

or in the z -domain

$$Y(z) = H(z)X(z) \quad (7)$$

where $H(z)$ is the “transfer function” of the filter. Thus, in a LTI system, the output is computed by convolving the input with the IR. Two important filter properties can be deduced by the IR: stability (any bounded input will produce a bounded output) and causality (the filter will not generate any output before the input is applied). In fact, it can be demonstrated that a filter is stable only if

$$\sum_{k=-\infty}^{\infty} |h(k)| < \infty \quad (8)$$

and causal if and only if

$$h(k) = 0 \quad \text{for } k < 0 \quad (9)$$

Now, let us assume a complex sinusoid, $x[n] = e^{jwn}$, as the input, so that the filter output becomes

$$\begin{aligned} y[n] &= \sum_{k=-\infty}^{\infty} h[k] e^{jw(n-k)} \\ &= e^{jwn} \sum_{k=-\infty}^{\infty} h[k] e^{-jwk} = e^{jwn} H(w) \end{aligned} \quad (10)$$

Thus, the sinusoid in input is still the same at the output, but multiplied by a complex quantity, $H(w)$.

This quantity is known as the “frequency response” of the filter, and it is usually defined in terms of its modulus $|H(w)|$ and phase. Eq. (10) tells us that, according to its pulse frequency, a sinusoid as an input may be amplified [when $|H(w)| > 1$] or attenuated [when $|H(w)| < 1$] by the filter. Therefore, if the signal and noise are separated in the frequency domain, we may design a linear filter to enhance the signal contribution. The ideal filter should have $|H(w)|$ equal to 1 in the signal band and equal to 0 in the noise band.

A LTI filter can be expressed by the following difference equation

$$y[n] = \sum_{m=0}^M b_m x[n-m] - \sum_{k=1}^N a_k y[n-k] \quad (11)$$

where the a_k and b_m are the filter coefficients. If at least one a_k is different from zero, previous output values contribute to the current output. The filter is said to be “recursive.” Conversely, when the a_k values are all zeros, the filter is “non-recursive.”

Applying the z -transform at Eq. (11), after a few rearrangements, the “transfer function” becomes

$$\begin{aligned} H(z) &= \frac{Y(z)}{X(z)} = \frac{\sum_{m=0}^M b_m z^{-m}}{1 + \sum_{k=1}^N a_k z^{-k}} \\ &= b_0 z^{N-M} \frac{\prod_{m=1}^M (z - z_m)}{\prod_{k=1}^N (z - p_k)} \end{aligned} \quad (12)$$

where the z_m and the p_k are, respectively, the zeros and the poles of the transfer function. In terms of modulus and phase, we have

$$|H(e^{jw})| = |b_0| \frac{\prod_{m=1}^M |e^{jw} - z_m|}{\prod_{k=1}^N |e^{jw} - p_k|} \quad (13)$$

$$\angle H(e^{jw}) = \angle b_0 + \sum_{m=1}^M \angle (e^{jw} - z_m) - \sum_{k=1}^N \angle (e^{jw} - p_k) \quad (14)$$

The “pole-zero” form of $H(z)$ is of great help for analyzing the stability of the filter and for evaluating the frequency response characteristics. Stability is verified when all the poles lie inside the unit circle. In addition, the frequency response of a filter can be easily evaluated by noting that $|e^{jw} - z_m|$ is a vector in the z -plane joining the m th zero to the point of the unit circle identified by w . Thus, to obtain an estimate of $H(w)$, we move around the unit circle: When we are close to a zero, $|H(w)|$ will approach zero; conversely, when we are close to a pole, $|H(w)|$ will tend to a peak (the

closer the pole to the unit circle, the sharper the peak).^[9,11]

As previously said, a LTI filter may be completely described by its IR. For finite IR (FIR) filters, the IR is time limited (i.e., it is composed by a limited number of nonzero samples). In a FIR filter, all a_k 's are zeros, and the filter output is a combination of the input sequence only. The FIR filters are always stable (all poles are in the origin) and usually implemented in a nonrecursive form. In addition, the requirement of linear phase can be easily obtained by putting some constraints on the IR coefficients. These have to be symmetrical around their midpoint

$$b_m = \pm b_{M-m} \quad (15)$$

The sign + or - stays in accordance with the symmetry (even or odd) and M value (even or odd). On the contrary, in infinity IR (IIR) filters, the IR oscillates up to infinity with nonzeros values. To support a response of infinite length with a single impulse in input, the IIR filter must contain a feedback path, which feeds the filter when the input has vanished (i.e., at least one a_k must be different from zero). This type of filter is therefore recursive. Finally, in IIR filters, the linear phase response is not guaranteed, and particular attention has to be paid to filter stability.

A filter is designed to satisfy a set of requirements, usually in the frequency response. Those requirements depend on the application, but they usually involve the width of the pass-band (and stop-band), the maximum extent of the transition band, as well as the largest ripple amplitude allowed in the pass-band and stop-band. The aim is to design a filter that mimics the ideal filter response. Different techniques can be used. An IIR filter may be projected using the impulse invariance method, a bilinear transformation or Butterworth, Chebyshev, and elliptic approximations. Window techniques, equiripple approximation, or frequency-sampling methods can be applied for FIR filter design.^[3-5,9]

An example of filter application for the analysis of an EEG signal is depicted in Fig. 2. A filter bank is used to enhance the patterns of rhythmic activity in different frequency bands; from top to bottom: the delta (0–4 Hz), theta (4–8 Hz), alpha (8–13 Hz), and beta (13–30 Hz) rhythms. Rhythm separation was obtained by using band-pass FIR filters. Fig. 2B shows the frequency and phase response of the band-pass filter used to enhance activity in the alpha band. The corresponding zero-pole diagram of the filter is shown in Fig. 2C. Quantitative analysis of the different rhythms of the EEG is important for detecting and quantifying a great number of processes and diseases involving disturbances in brain activity.^[12]

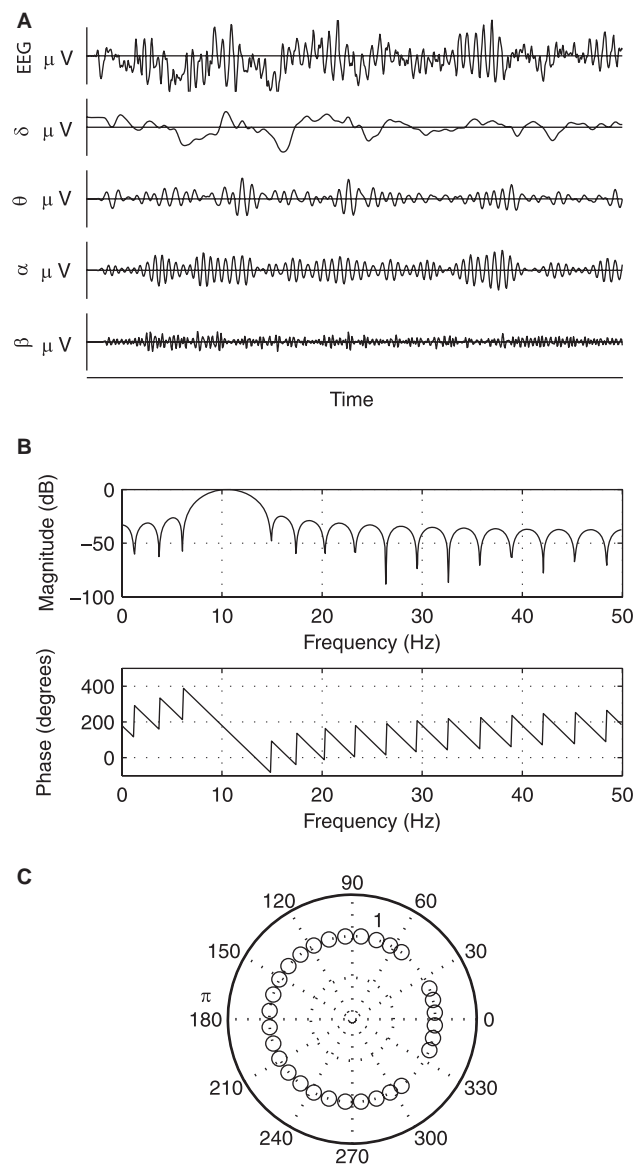

Fig. 2 Separation of EEG rhythms using a bank of band-pass FIR filters: (A) c3 channel of the EEG recorded for the scalp of a subject and its components in δ , θ , α , and β bands; (B) modulus and phase diagrams of the frequency response of the band-pass FIR filter (8–13 Hz) used to separate the α rhythm in the EEG; and (C) zero-poles diagram of the filter. Note the one-to-one correspondence between the position of the zeros on the unit circle and the damping in the modulus of the frequency response as well as the absence of zeros in the slice corresponding to the pulse frequency of the band-pass zone.

Signal Averaging

In many BSP applications, we are faced with the problem of detecting small signal components embedded in wide band noise. A typical example is the enhancement of the EP, i.e., brain potentials evoked by

sensory stimulations of different nature (visual, acoustic, and somatosensory). Usually of lower amplitude than the background EEG, EP (signal) and EEG (noise) have components in the same frequency range, and the problem to separate them cannot be approached by traditional filtering.^[9,12]

When the signal waveform repeats identically at known time instants (i.e., the evoked response occurring after each sensory stimulus) and the noise samples are not correlated (also to the signal), the “signal averaging” technique can be applied to separate signal components from background noise. Let us consider N repetitions (epochs) of a deterministic signal and indicate each repetition as $x_i(n)$ $\{i=1, 2, \dots, N\}$. The signal is embedded in noise $w_i(n)$. We assume that

1. $x_i(n)$ is repetitive and it does not vary epoch-by-epoch [$x_i(n) = x_j(n)$],
2. the noise is a broadband stationary process with zero mean and variance σ^2 , and
3. signal and noise are uncorrelated and additive.

$$y_i[n] = x_i[n] + w_i[n] \quad (16)$$

The averaging technique consists of summing up the signals of the different epochs (after having these properly aligned using efficient trigger points). We have

$$y_e[n] = \frac{1}{N} \sum_{i=1}^N y_i = x[n] + \frac{1}{N} \sum_{i=1}^N w_i[n] \quad (17)$$

where N is the number of epochs, $x[n]$ represents the deterministic signal to be determined, and the second term in Eq. (17) is an estimator of the mean of process $w_i[n]$. This term tends to the true mean of the process (zero, according to our assumptions) when N tends to infinity, while the variance of the estimate decreases with N being equal to σ^2/N . Therefore, after averaging, the original signal components are unaffected, while the variance of noise is decreased to σ^2/N . The net increment in terms of SNR depends on the number of repetitions included in the averaging process. The resulting SNR can be demonstrated as

$$\text{SNR}_e = \sqrt{N} \text{SNR}_i \quad (18)$$

Thus, the original SNR_i is improved by a factor \sqrt{N} . Finally, it may be useful, from a theoretical point of view, to interpret a signal averaging process as a digital filter. For each fixed time sample, the averaging process is analogous to a low-pass moving average

filter whose transfer function is

$$\begin{aligned} H(z) &= \frac{1 + z^{-1} + z^{-2} + \dots + z^{-(N-1)}}{N} \\ &= \frac{1 - z^{-N}}{1 - z} \end{aligned} \quad (19)$$

It is worth noting that this filter does not operate on the time sequence (n is fixed), but on the sequence of aligned samples taken from successive sweeps. The modulus of the frequency response of Eq. (19) presents a main lobe with the first zero located at around $f=1/N$ and secondary lobes spaced by a factor $1/N$ (we are assuming that the repetition frequency of the epoch is 1, without loss of generality). On increasing N , the width of the main (and the secondary) lobe is reduced as well as the amplitude of the secondary lobes. Therefore, as the noise is a broadband process, the larger the value of N , the bigger the noise attenuation. Conversely, the desired signal component (which is constant among sweeps) will not be attenuated by the filter. In fact, the amplitude of the main lobe (located at zero frequency) does not change with N .

An averaging technique is widely used for the analysis of biological signals. In addition to the above-mentioned EP application, other examples can be found in the detection of VLPs,^[6] in the separation between mother and fetal QRS complexes, as well as in the removal of ventricular activity from ECG signal during atrial fibrillation (AF).^[13] An application of this technique to the analysis of VLP is presented in Fig. 3. The VLPs are high-frequency micropotentials, which may occur at the end of QRS complex. The VLPs are signatures of abnormal conduction regions in the ventricles, associated with the substrate responsible for life-threatening arrhythmias. Their amplitude is lower

Fig. 3 Detection of the VLP. (A) Orthogonal X, Y, Z ECG leads; (B) averaged leads obtained by applying the signal averaging technique; and (C) plot of the magnitude vector.

than the QRS amplitude and other noise superimposed onto the ECG. To detect the VLP, orthogonal X, Y, Z leads are recorded (Fig. 3A). As the QRS complex and its VLPs should not vary beat-by-beat, a “signal averaging technique” may reduce the superimposed random noise and enhance the repetitive, low-amplitude VLPs. Normal QRS are detected, aligned (cross-correlation), and averaged to build noiseless templates (Fig. 3B). Then a bidirectional filter (high-pass >40 Hz, Butterworth filter) is applied at each averaged lead to eliminate the low frequencies contained in the QRS and ST segment and to enhance VLP. The filtered signals are combined into a vector magnitude, $\sqrt{X^2 + Y^2 + Z^2}$ (Fig. 3C). The black area represents the last 40 msec of the QRS complex, which is the key window for detecting the VLP.^[6]

SPECTRAL ANALYSIS

The power spectral density (PSD) of a given signal describes how the signal power is distributed in frequency. This representation of signal energy shows information that is not directly perceptible in the time domain. However, the PSD cannot be calculated in practice, as it requires infinite integration time. Only an estimate of the true PSD can be obtained by a number of approaches, basically divided into two classes: nonparametric and parametric.

Nonparametric Approaches

The traditional approach to PSD computation is based on FT. The easy handling and fast computation of FT-based estimators make the nonparametric approach widely used. The PSD may be obtained directly for the time series, using the periodogram approach:^[14,15]

$$P(f) = \frac{1}{NT_s} \left| \sum_{n=0}^{N-1} x[n] e^{-j2\pi f n T_s} \right|^2 \equiv \frac{1}{NT_s} X(f)^2 \quad (20)$$

where N represents the number of samples, T_s is the sampling period, and $X(f)$ corresponds to the FT of the time series $x[n]$. As an alternative, on the basis of the Wiener–Khinchin theorem, the PSD estimate can be obtained from the estimate of the autocorrelation function (ACF) of the signal. We have

$$\phi_{xx}[m] = \frac{1}{N} \sum_{n=0}^{N-|m|-1} x[n] x^*[n+m] \quad (21)$$

$$X(f) = T_s \sum_{m=-N+1}^{N-1} \phi_{xx}[m] e^{-j2\pi f m T_s} \quad (22)$$

where $\phi_{xx}[m]$ is the ACF, m represents the time-lag, and $*$ denotes the complex conjugate.

The FT is defined theoretically for an infinite sequence of data. In practice, only finite data sequences are available, and it is necessary to make some hypothesis, sometimes unrealistic, on the samples outside the observed window: they are commonly assumed to be zeros. This assumption is an implicit rectangular windowing of the data (which drastically truncates the sequence), and produces error or discrepancy in the estimated spectrum called “leakage error.” To handle this problem, different windows, which smoothly connect the side sample to zeros, are often used. The cost to pay is a reduction in the frequency resolution. In addition, the estimators, Eq. (20) and Eq. (22), are not statistically consistent (the variance of the estimate does not tend to zero, as the length of the data window goes to infinity). To improve the statistical performance, various methods have been developed, such as Bartlett, Welch, or Daniell methods.^[4,5,15,16] Even in this case, the application of these procedures is paid in terms of frequency resolution.

Parametric Approaches

Parametric approaches assume the signal to be the output of a mathematical model, and the PSD is estimated as a function of model parameters and its inputs. Special classes of models, driven by white noise and characterized by rational transfer functions, include the autoregressive model (AR), the moving average model (MA), and the autoregressive–moving average model (ARMA). These models are appropriate to fit many deterministic and stochastic stationary processes. They provide a general framework for the description of the input–output relationships of the analyzed process/system, independently from the physical, physiological, or anatomical characteristics of the system itself: it is the so-called black-box approach. An ARMA model is described by the following linear difference equation:

$$y[n] = - \sum_{k=1}^p a[k] y[n-k] + \sum_{m=1}^q b[m] x[n-m] + w[n] \quad (23)$$

where $y[n]$ is the output of the causal filter, which models the observed data, and $w[n]$ is a white noise input with zero average and variance λ^2 . The $a[k]$'s and $b[m]$'s are the model coefficients. As evidenced by Eq. (23), an ARMA process model is built

up by an AR model of order p and an MA model of order q . Because an AR model of appropriate order is able to represent any ARMA or MA processes of finite variance (Wold decomposition theorem) and the AR parameters are easier to estimate than the ARMA ones (estimation of AR parameters needs only solving a set of linear equations), the AR model is usually selected to fit the data. In this case, the AR PSD becomes

$$P(f) = \frac{T_s \lambda^2}{\left| 1 + \sum_{k=1}^p a[k] z^{-k} \right|_{z=e^{j2\pi f T_s}}^2} = \frac{T_s \lambda^2}{\left| \prod_{k=1}^p (1 - z_k z^{-1}) \right|_{z=e^{j2\pi f T_s}}^2} \quad (24)$$

which shows that the PSD is completely described by the properties of the noise feeding the model (i.e., its variance) and by the model parameters. In the right hand part of Eq. (24), we put into evidence the poles of the transfer function.

An attractive and special feature of parametric models is the possibility to decompose the spectrum into several components (i.e., bell-shaped curves in Fig. 4C) and to obtain a direct computation of power and frequency associated with each component. We firstly observe that ACF of the signal and its spectrum are related, in the z -domain, by the following expression:

$$R(k) = \frac{1}{2\pi j} \int_{|z|=1} P(z) z^{k-1} dz \quad (25)$$

If the residual integration method is used to compute the above integral, the ACF is decomposed into a sum of both damped sinusoids, originated by a pair of complex conjugated poles, and damped exponential functions related to real poles.^[17] The FT of the k th ACF component provides the pattern of the spectral component. The frequency and power of each component can be estimated from the poles: The argument of the pole gives the central frequency of the component, while the residual γ_k is used to compute the power [the component power is γ_k for real poles or $2\text{Re}(\gamma_k)$ for conjugate pole pairs]. The residuals γ_k are calculated as

$$\gamma_k = z(z - z_k)P(z) \Big|_{z=z_k} \quad (26)$$

If properly applied, either parametric or nonparametric approaches provide reliable estimates. However, it is worth making a comparative discussion of the two approaches. Advantages of the parametric

approach can be summarized as follows:

- It is statistically consistent on short segments of data, and, under general assumptions, the AR PSD is a maximum entropy spectrum (MES).
- Spectral resolution does not depend on the signal length.
- There is no need to window the data.
- A spectral decomposition method is available, which facilitates the postprocessing of the spectrum and the extraction of the relevant spectral parameters.

Conversely, an AR PSD estimate is more complex and more heavy from a computational point of view; it requires some a priori assumptions as to the kind of model (AR, ARMA, or others) and its complexity (i.e., the model order). Regarding the last point, it is worth mentioning that a battery of criteria does exist, which may help in the identification of the optimal model order. They include the Akaike, the final prediction error, and the minimum description length (MDL) criterion. In addition, some a posteriori tests could be applied to verify the assumptions; for example, a test of whiteness may be performed on the model errors to check if the model was able to capture all the information contained in the data.

As a final remark, the selection of the most appropriate PSD estimator depends on the particular application and the peculiar signal characteristics. One method may be suitable for processes with sharp spectral peaks, while others will perform better with broad, smoothed spectra. The use of a priori knowledge should guide the choice of the proper method.

Fig. 4A shows the R–R interval series (tachogram) of a normal subject. The R–R intervals are not constant, but oscillate under the control of the autonomic nervous system (ANS) controlling heart rate. The power spectrum of this signal evidences two main rhythms (Fig. 4B and C) related to the activity of sympathetic and parasympathetic branches of ANS. A high-frequency (HF) component, (in a range between 0.15 and 0.45 Hz), which is synchronous with respiration and modulated by vagal tone. Conversely, a low-frequency (LF) component (centered around 0.1 Hz) is mainly modulated by sympathetic activity. Thus the PSD of the RR series is a noninvasive tool for assessing ANS status.^[18] In Figs. 4B and C, the PSD is computed using a nonparametric approach (Welch method and Hamming window) and by parametric method (AR model of order 12), respectively. The parametric estimate presents a higher frequency resolution and a lower spectral leakage than those obtained by nonparametric method.

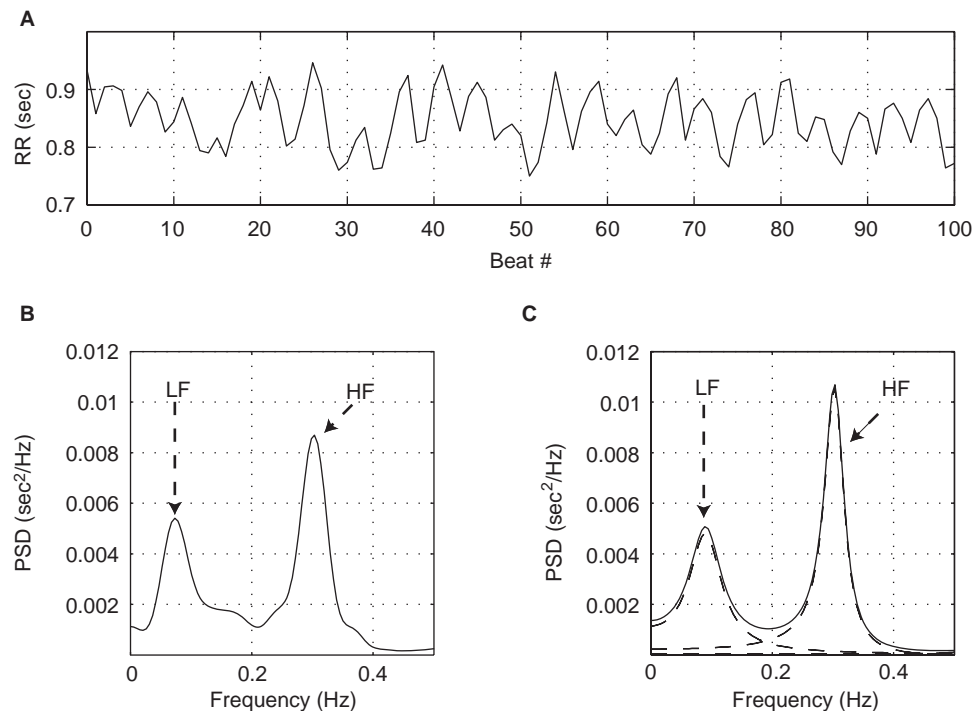

Fig. 4 Example of the spectral analysis of R–R intervals series: (A) the tachogram; PSD obtained; (B) by nonparametric approach; and (C) by parametric approach based on AR modeling. Spectral decomposition is also plotted.

The capability to separate signal power in the frequency domain makes spectral estimation widely used for BSP. The analysis of EEG rhythms (during sleep, anesthesia, or epilepsy), the characterization of heart sounds,^[8] and the quantitative analysis of the free induction decay signal in magnetic resonance spectroscopy (for metabolite quantification)^[19] are only a few representative examples.

EVENT DETECTION

Biomedical signals are characterized by peculiar waveforms, markers of physiopathological events. Detection and classification of such waveforms are of primary importance for a better understanding of physiological processes and to define the degree of pathology in routine clinical practice. In this regard, different techniques and procedures have been developed, which use information on the event (such as morphology, amplitude, or frequency content) to locate it in the signal.^[8]

A well-known example of event detection in BSP is the QRS detector.^[7,8] Location of QRS complexes is usually the fundamental step for subsequent analysis of an ECG signal, such as heart rate computation, beat classification, VLP extraction, and heart rate variability analysis. Detection may be obtained by

observing that QRS complexes have the largest slope with respect to P and T waves. To enhance this, a derivative (or second derivative) filter may be applied. Owing to the inner noisy nature of a derivative filter (which enhances HF components of the signal), the output of derivative steps is usually smoothed (MA filters) prior to other computations. A very popular QRS detection algorithm, reported in several textbooks,^[7,8] is the Pan-Tompkins algorithm. It consists of a few signal-processing steps: 1) a band-pass filter is used to isolate the QRS frequencies (removing the lower frequency related to baseline wandering and higher frequency containing muscle noise); 2) a derivative filter is used to enhance QRS waves; 3) the result is squared to account for different ECG polarity; and 4) the output is low pass filtered. The resulting signal is composed by a set of local maxima, which identify the location of the QRS complex (Fig. 5).

Sometimes the morphology of a certain event is available. In this case, a special filter can be designed to “match” the characteristic of the event. Let us suppose that the reference waveform $x[n]$ is merged in some noise $n[t]$. The resulting signal is passed through a LTI filter whose IR is indicated by $h[t]$. The output signal will be $y[n] = (x[n] + n[n]) * h[t] = x_0[n] + n[n] * h[t]$. Now, among all the possible choice of $h[n]$, we will select the one which maximizes at a certain time instant t_0 , the SNR at the filter output, i.e., the SNR between

Fig. 5 Processing steps in a QRS detector algorithm: (A) Raw ECG signal; (B) output of the band-pass filter; (C) differentiation; (D) squaring process; and (E) final output after the moving average filter. The signals are realigned, taking into account the filter's delay.

$x_0[n]$ (signal) and $n[n] * h[t]$ (noise). It can be demonstrated^[16] that, when the noise is a white process, the optimal IR is

$$h[n] = \frac{1}{\sigma_n^2} x[t_0 - t] \quad (27)$$

where σ_n^2 is the noise power. Thus, the IR is simply a reversed version of the reference waveforms, scaled and shifted. The resulting filter is known as the “matched filter” (MF). The MF has been applied to detect particular patterns in EEG signals such as spike-and-wave patterns and cyclic alternating pattern in sleep, or to detect components of event-related brain potentials.^[20]

In other situations, the template is unknown, but the occurrence of a similar event is searched in two signals. The “cross-correlation function” (CCF) provides a second order statistical comparison of two, zero-mean sequences as a function of the time shift between them. The CCF is evaluated as

$$\phi_{x,y}(\tau) = \frac{1}{N-1} \sum_{n=1}^N x[n]y[n-\tau] \quad (28)$$

where N is the sequence length, and τ is the lag index ($\tau=0, 1, 2, \dots, N$). See the analogy with Eq. (21). A normalized version of CCF (NCCF) is obtained by dividing it by the product of the standard deviation of the two signals

$$\gamma_{x,y}(\tau) = \frac{\sum_{n=1}^N x[n]y[n-\tau]}{\sqrt{\sum_{n=1}^N x[n]^2 \sum_{n=1}^N y[n]^2}} \quad (29)$$

The NCCF ranges from 0 to 1 and reaches its maximum when similar patterns are present in the two signals. In addition, the lag of the maximum indicates the time delay at which the event occurs in the two signals. The CCF is used to align, temporally, two waveforms (see VLP example), to locate events with known templates (P-wave detection), or to detect common patterns in two signals. For example, NCCF can be used to evaluate the degree of organization of atrial activity during AF.

The frequency-domain counterpart of CCF is the “cross-spectral density” or simply “cross-spectrum” (P_{xy}). It provides both amplitude and phase information about the frequencies held in common between two sequences. Formally, the cross-spectrum and CCF are related as a FT pair. Thus

$$P_{xy}(f) = FT(\phi_{xy}[\tau]) = X(f)Y^*(f) \quad (30)$$

and the squared coherence spectrum (SCS) is defined as

$$\gamma_{xy}(f) = \frac{|P_{xy}(f)|^2}{P_{xx}(f)P_{yy}(f)} \quad (31)$$

where $P_{xx}(f)$ and $P_{yy}(f)$ are the auto-spectrums of the sequences.

A value of SCS close to 1 indicates that same rhythms in two signals have a constant phase relationship, thus they may have a common origin or they can be linearly synchronized. The SCS has been applied to detect the occurrence and the extent of synchronized activity in multisite recordings of neuronal activity (during epilepsy, sleep stages, or during preparation and execution of hand movements) and cardiac electrical activity (during different atrial rhythms). In

addition, it has been used to assess the coupling between cardiovascular variability series.^[18]

Finally, it is worth mentioning that some biomedical signals, such as the electromyogram and phonocardiogram (PCG), do not present clear fingerprints. Nevertheless, these signals are affected by changes in their level of activity or in their energy, which may carry useful information. In these cases, very simple metrics can be used to detect these changes. A useful technique is the “zero-crossing rate” (ZCR). The ZCR measures the complexity of a signal in relation to the number of times it crosses the zero activity line or another reference line. As the ZCR is affected by the offset and LF artifacts, it is advisable first to obtain the derivative of the signal. A typical example of ZCR application is the detection of speech and silence epochs in the voice signal.

The “root mean-square value” (RMS) of a signal gives a global indication of its average power. If RMS is evaluated over windows of M samples, it is possible to detect alterations or variations in a process. This technique was used to identify systolic and diastolic segments in the PCG,^[8] to quantify EMG activity, or to evaluate the energy content of EEG in different bands.

CONCLUSIONS

The fundamental and widely used signal-processing techniques for biomedical signal analyses have been introduced in this article. These classical methods are intended as the basic, powerful tools for enhancing important information from biological signals and as fundamental bricks for building more sophisticated algorithms. A few examples of applications, including feature extraction, noise reduction, event detection, and spectral analysis, have been presented. These examples were selected to demonstrate how traditional techniques of digital signal processing may impact on the problem of extracting informative parameters from biological signals.

Digital Biomedical Signal Processing: Advanced Topics

Luca T. Mainardi

Department of Biomedical Engineering, Polytechnic University, Milan, Italy

INTRODUCTION

Biomedical Signal Processing (BSP) deals with extraction and processing of information contained in vital signals recorded from living systems. In the pioneer age, BSP was restricted merely to application of traditional signal processing algorithms for signal-to-noise ratio enhancement and spectral analysis. A review of these basic approaches is provided in another entry of this encyclopedia.^[1] A major breakthrough occurred in the past two decades. Since the 1990s, we have witnessed the explosion of new theoretical tools for signal analysis in an attempt to overcome the limitations of former approaches and to exploit signal features in nonstationarity and nonlinearity contexts. New methodologies became available, ranging from time-scale to time-frequency methods,^[2] higher-order statistics and independent component analysis,^[3] up to nonlinear dynamic approaches.^[4] These tools found their natural application to BSP due to the inner nature of biomedical signals and systems, which are characterized by nonstationarity and may exhibit nonlinear behavior.

The aim of this entry is to provide an introductory review of these modern techniques, putting some emphasis on both methodological aspects and potential application to BSP. The entry is organized as follows: “Wavelet Analysis” introduces wavelet transform as a new tool for signal decomposition and synthesis, and “Spectral Analysis of Nonstationary Signals” describes time-frequency and time-variant approaches as an extension of traditional spectral analysis to nonstationary epochs. The successive section addresses basic concepts of higher-order spectra. Finally, the section “Nonlinear Biomedical Signal Processing” is dedicated to a short overview of popular nonlinear methods. Each section starts by describing basic methodological concepts and ends with explicative examples of possible applications to BSP.

WAVELET ANALYSIS

Signal decomposition and reconstruction have been historically approached using Fourier analysis, which has become ubiquitous for both the analytic and numerical solution of differential equations and for the analysis and treatment of communication signals.

A signal is seen as the sum (possibly infinite) of complex exponentials, and the well-known Fourier Transform (FT) may be written as

$$X(\omega) = \int x(t)e^{-j\omega t} dt = \langle x(t), e^{-j\omega t} \rangle \quad (1)$$

where we put into evidence that FT is obtained as inner product $\langle \cdot \rangle$ between the signal and sinewaves functions of infinite duration. The signal can be reconstructed by the inverse FT

$$x(t) = \int X(\omega)e^{j\omega t} d\omega \quad (2)$$

FT is appropriate when dealing with stationary signals composed by few sinewaves components. However, it is a nonparsimonious transform when signals are nonstationary or characterized by abrupt changes. In the latter case, frequency contents are spread out over the frequency axis, and an infinite number of sinusoidal components is needed. The reason is that complex sinusoids have frequency localization but no time localization. This means that although we may be able to determine all the frequencies present in a signal, we cannot define when they occur.

Theory

To circumvent the previous limitation, we introduce the Continuous Wavelet Transform (CWT)^[5]

$$\begin{aligned} \gamma(\tau, a) &= \int x(t)\psi_{\tau,a}^*(t)dt = \langle x(t), \psi_{\tau,a}^*(t) \rangle \\ &= x(t)^* \psi_{\tau,a}^*(t) \\ \tau, a &\in \Re; \quad a \neq 0 \quad x, \psi \in L^2(\Re) \end{aligned} \quad (3)$$

which measures the similarity between the signal $x(t)$ and a family of functions called wavelets:

$$\psi_{\tau,a}(t) = \frac{1}{\sqrt{a}} \psi\left(\frac{t-\tau}{a}\right) \quad (4)$$

The wavelets are generated from a prototype $\psi(t)$, the mother-wavelet, by scaling (contracting or dilating) and translation. The parameter τ determines the time

shift, while a is the scaling factor that controls the dilation of the wave (coefficient $1/\sqrt{a}$ is used for energy normalization). We would expect that, using an appropriate selection of $\psi(t)$, any general signal can be represented by its decomposition into wavelets, and the signal synthesis may be obtained by summing projections of signal onto wavelets. In particular, if the admissibility condition is satisfied,

$$C_\psi = \int \frac{|\Psi(\omega)|^2}{|\omega|} d\omega < +\infty \quad (5)$$

where $\Psi(\omega)$ if the FT of $\psi(t)$, $x(t)$ can be reconstructed by

$$x(t) = C_\psi^{-1} \int_a \frac{da}{a^2} \int_\tau \gamma(\tau, a) \psi_{\tau, a}(t) d\tau \quad (6)$$

without losing any information.^[6] In Eq. 6, $\gamma(\tau, a)$ represents the weight of every wavelet in the synthesis of $x(t)$. The admissibility condition implies

$$|\psi(\omega)|_{\omega=0}^2 = 0 \quad (7)$$

and for practical application,

$$\int |\psi(t)|^2 dt < +\infty \quad (8) \quad \psi_{j,k}(t) = a_0^{-j/2} \psi(a_0^{-j} t - kT) \quad (9)$$

Therefore, continuous wavelets $\psi(t)$ have zero-mean and finite energy. In practice, they are oscillating around the t axis and vanishing with time (see Fig. 1a). In general, as $|\Psi(\omega)| \rightarrow 0$ when $\omega \rightarrow \infty$ wavelets have a band pass-like spectrum. Other important properties include regularity, null vanishing moments, orthogonality, and finite support.^[5]

Some analogies between FT and CWT exist: they are linear operators, and both transforms can be viewed as a projection of a function into a different domain. For the FT, this new domain contains basis functions that are sines and cosines. For the wavelet transform, this new domain contains more complicated basis functions called wavelets. The main difference lies in the fact that wavelets are usually localized in time, whereas complex exponentials are not (see Fig. 1a).

The CWT is highly redundant, being obtained by continuously translated and dilated functions. Reduction of redundancy may be obtained by discretization of the time-scale parameters ($a-\tau$) according to some sampling grid.^[5] In general $a = a_0^j$, and the translation is discretized with respect to each scale by using $\tau = ka_0^j T$, where j and k are integers, and T is the sampling interval. In this case, the wavelet basis functions are obtained by

Fig. 1 (A) Partitioning of the time–frequency (t – f) plane using STFT (left) and WT (right). The corresponding basis functions are also reported. Note that time localization of wavelets varies in the t – f plane, preferring time localization for higher-frequency components and frequency localization for lower-frequency ones. (B) Calculation of wavelets coefficients, using an iterative filter bank structure. (C) Partitioning of frequency axis, using wavelets and scaling functions. The scaling function substitutes a infinite numbers of wavelets, and at a certain level (J), it covers the frequency spectrum uncovered by wavelets details at that scale.

Discretization acts like a microscope in which the term a_0^{-j} controls the magnification and $a_0^{-j}T$ controls the movement steps. If one is interested in small details, magnification will be large (j is negative and large), and coherently $a_0^j T$ describes small steps to center the details.^[5] In the most common formulation, $a_0=2$ and $T=1$ are used.

The Discrete Wavelet Transform (DWT) may now be introduced, and the resulting wavelet coefficients are

$$c_{j,k} = \int x(t)\psi_{j,k}^*(t)dt = \langle x(t), \psi_{j,k}^*(t) \rangle \quad (10)$$

Obviously, discretization of time-scale parameters makes sense if we are still able to reconstruct the original signal using the wavelets coefficients according to

$$x(t) = K \sum_j \sum_k c_{j,k} \psi_{j,k}^*(t) \quad (11)$$

where K is a constant playing the same role as C_ψ^{-1} in Eq. 6. In contrast with the nonrestrictive constraints imposed on wavelets in the continuous case (see Eq. 5), only very special choices of $\psi_{j,k}$ are now allowed. In general, the larger the redundancy, the milder the restrictions on the basis function.^[5]

Redundancy may be also reduced by designing the wavelets to be orthogonal. In mathematical terms, the family of wavelets can be selected in such a way that

$$\begin{aligned} \langle \psi_{j,k}, \psi_{j',k'} \rangle &= 1 \quad \text{if } k = k', j = j' \\ \langle \psi_{j,k}, \psi_{j',k'} \rangle &= 0 \quad \text{otherwise} \end{aligned} \quad (12)$$

Eq. 12 means that each wavelet coefficient $\psi_{j,k}$ stores information that is not correlated, and all the wavelets are necessary to reconstruct a general signal. They form an orthonormal basis.

Computation of wavelets coefficients can be obtained by using an iterative filter bank structure.^[6] To explain it, the scaling function $\varphi(t)$ has to be introduced. It is the companion of $\psi(t)$ and the two functions are linked through the following relations^[6]:

$$\begin{aligned} \varphi(t) &= \sqrt{2} \sum_{k=0}^{L-1} h_k \varphi(2t - k) \\ \psi(t) &= \sqrt{2} \sum_{k=0}^{L-1} g_k \varphi(2t - k) \end{aligned} \quad (13)$$

where

$$g_k = (-1)^k h_{L-k-1} \quad (14)$$

Different from the wavelet function, the scaling function has a low-pass properties

$$\int \varphi(t)dt = 1 \quad (15)$$

Because our signal $x(t)$ could be expressed in terms of dilated and translated wavelets (Eq. 11), and taking into account Eq. 13, it turns out that $x(t)$ can also be expressed in terms of scaling functions. In particular, at scale $J=0$, we have

$$x(t) = \sum_k \lambda_k \varphi(t - k) \quad (16)$$

where λ_k 's are the scaling coefficients. Let us suppose to proceed one step head along scale ($j=-1$). At this new scale, the scaling function can be still used to approximate the signal, but we have to add wavelets to preserve the same level of detail:

$$x(t) = \sum_k \lambda_{1,k} \varphi(t - 2^1 k) + \sum_k \gamma_{1,k} \psi(t - 2^1 k) \quad (17)$$

Iterating the procedure through the scales

$$\begin{aligned} x(t) &= \sum_k \lambda_{1,k} \varphi(t - 2^1 k) + \sum_k \gamma_{1,k} \psi(t - 2^1 k) x(t) \\ x(t) &= \sum_k \lambda_{2,k} \varphi(t - 2^2 k) + \sum_k \gamma_{2,k} \psi(t - 2^2 k) \\ &\quad + \sum_k \gamma_{1,k} \psi(t - 2^1 k) \\ &\quad \vdots \end{aligned} \quad (18)$$

we finally obtain

$$x(t) = \sum_k \lambda_{J,k} \varphi(t - 2^J k) + \sum_{j=1}^J \sum_k \gamma_{j,k} \psi(t - 2^j k) \quad (19)$$

which is the multiresolution decomposition of $x(t)$ obtained through wavelets.^[6] In addition, as $\psi(t)$ and $\varphi(t)$ are orthonormal bases, wavelet and scaling coefficients are found through inner product (Eq. 3). Substituting Eq. 13 in Eq. 3, after a few rearrangements we obtain the fundamental relationships

$$\begin{aligned} \lambda_{j-1,k} &= \sum_m h(m - 2k) \lambda_{j,m} \\ \gamma_{j-1,k} &= \sum_m g(m - 2k) \lambda_{j,m} \end{aligned} \quad (20)$$

which shows that wavelets and scaling coefficients at each scale can be computed from those of the previous scales. Eq. 20 describes a filter bank structure whose scheme is reported in Fig. 1b.

Applications

Wavelet analysis found wide fields of application in the analysis of biological signals.^[7] Three main objectives

have been pursued: (1) wave detection, (2) data compression, and (3) time–frequency representation of the signal. In addition, statistical properties of wavelets coefficients can be used to evaluate fractal-like properties and scaling exponents.^[8]

Among the earlier applications of Wavelet Transform (WT) to BSP, we found the analysis of heart sounds and murmurs^[7] generated by the beating heart and the resultant flow of blood through valves. WT was documented to characterize primary heart sounds, resolving some frequency components to which other methods were blind. WT was also used to investigate turbulent sounds and to provide a simple, noninvasive approach for detection of coronary-artery disease or stenosis.

In the analysis of electrocardiograms (ECG),^[9] the use of WT has been proposed both for the detection of main signal waves (QRS, T, and P)^[10,11] and for feature extraction and classification of cardiac patterns.^[12] WT seems particularly suitable for this task because ECG waves are transient events well localized in time (i.e., they resemble wavelets). Wave detection can be performed searching for singularity and discontinuity in the ECG. In this regard, the modulus maxima criterion has largely been employed to locate ECG waves and their fiducial points (onset, offset, and deflections). The idea behind the criterion was first elucidated by Mallat and Zhong.^[13] Let's consider a wavelet obtained as the first derivative of a smoothing (scaling) function:

$$\psi_a(t) = \frac{\partial \theta_a(t)}{\partial t} \quad (21)$$

The wavelets transform of $x(t)$ becomes

$$\gamma(\tau, a) = x(t) * \psi_a(t) = \tau \frac{d}{dt}(x(t) * \theta_a(t)) \quad (22)$$

showing that the maximum of $|\gamma(a, \tau)|$ is located on the sharp variation points (positive or negative) of a smoothed version of the signal. In the presence of important discontinuity, the term $x(t) * \varphi_\tau(t)$ will not vanish among scales (as it does in the presence of high-frequency amplitude fluctuations). Thus, local maxima in $|\gamma(a, \tau)|$ that spread among scales are the hallmark of the discontinuity. An example is presented in Fig. 2, where an ECG signal during normal sinus rhythm is analyzed.

WT was also employed to detect Ventricular Late Potentials (VLP),^[14] which are transient, low-amplitude, high-frequency waves occurring at the end part of QRS complex and signature of abnormal conduction regions in the ventricles. With respect to other time–frequency methods (described in the following paragraph), WT was suggested to have superior accuracy in detection of VLPs.^[15] Finally, ECG compression for storing and transmission has largely been performed using WT.^[16,17] WT is particularly appealing for this task because signals become sparser when projected in the wavelets domain than in the Fourier domain (in other words, significant information is contained in only a few of the wavelet coefficients).

In electroencephalography (EEG),^[7] use of WT has been proposed for seizure detection^[18] and for locating transient waveforms (spikes and sharp waves). Wavelet

Fig. 2 (A) ECG signal during normal sinus rhythm. (B) Absolute value of CWT using Morlet wavelet. ECG waves (P–QRS–T) are indicated on the CWT. These waves can be detected by searching for CWT maxima spreading over scales.

has also proved to be effective in enhancing Evoked Potentials (EP) from background EEG activity.^[19,20] This can be pursued either through the selection of significant wavelets coefficients^[20] or through the improvement of the convergence rate of synchronous grand-averaging techniques.^[21]

SPECTRAL ANALYSIS OF NONSTATIONARY SIGNALS

Traditional power spectral analysis (employing either parametric or nonparametric approaches) implies the signal to be stationary, at least in the observation windows. Biomedical signals are intrinsically nonstationary, however, and characterized by transient waveforms of various natures and patterns. As a result, the spectral features of these signals evolve with time, and the capability to track these changes is relevant for the characterization of the dynamics of biological systems during both physiological and pathological conditions.

In this regard, signal processing tools are needed to describe how signal power is simultaneously distributed in the time-and-frequency domain. We look for a joint time–frequency (t – f) representation satisfying the marginal properties^[2]

$$\begin{aligned} \int P(t, \omega) dt &= |X(\omega)|^2 \\ \int P(t, \omega) d\omega &= |x(t)|^2 \end{aligned} \quad (23)$$

and where

$$\begin{aligned} E_x &= \int |x(t)|^2 dt = \int |X(\omega)|^2 d\omega \\ &= \iint |P(t, \omega)|^2 dt \quad d\omega \end{aligned} \quad (24)$$

is the signal energy. The most intuitive way to build such distribution is obtained by the Short Time Fourier Transform (STFT)

$$P_{\text{STFT}}(t, \omega) = \left| \int x(\tau) g(t - \tau) e^{-j\omega\tau} d\tau \right|^2 \quad (25)$$

where $g(t)$ is a time-window shifting along the signal. The STFT divides a signal into segments and takes the FT of each resulting section. Selection of the window defines the property of the distribution, and in general, a trade-off exists between time and frequency resolution. In fact, to locate short-time, high-frequency behavior temporarily, narrow time windows are needed. Conversely, to resolve the low-frequency behavior, a wider time window must be employed. This results

from a more general rule that prohibits simultaneously determining time localization, Δt , and frequency resolution, $\Delta\omega$, at arbitrary precision. A lower bound is defined by the Heisenberg inequality^[2]:

$$\Delta\omega \Delta t \geq \frac{1}{2} \quad (26)$$

Another time–frequency representation (TFR) can be obtained by WT: it can be shown that WT preserves energy. We have

$$E_x = C_\psi^{-1} \int_a \frac{da}{a^2} \int_\tau |\gamma(\tau, a)|^2 dt \quad (27)$$

evidencing that the squared modulus of wavelet coefficients can be interpreted in terms of energy t – f distribution. In this case, the parameter a can be used to tune different resolutions by using a larger window for low-frequency components (in favor of frequency resolution) and shorter windows for higher frequency (best location of high-frequency details is pursued) without violating the constraint of Eq. 26.

STFT and WT are also known as linear t – f distributions. In the following, some examples of quadratic t – f distribution will be revised, and finally, the parametric approach to time-variant spectral estimation will be presented.

Quadratic Time–Frequency Representations

An energy distribution can be obtained^[2] from the marginals by inverting Eq. 23

$$P(t, \omega) = \frac{\partial}{\partial t} |X_t(\omega)|^2 \quad (28)$$

where

$$|X_t(\omega)|^2 = \int E[x(t)x^*(t - \tau)] e^{-j\omega\tau} dt \quad (29)$$

is the spectrum of $x(t)$ and where the subscript t means that this spectrum evolves with time. Substituting Eq. 29 into Eq. 28 leads to the Wigner-Ville distribution (WD)

$$\begin{aligned} P_{\text{WD}}(t, \omega) &= \int x\left(t - \frac{\tau}{2}\right) x^*\left(t + \frac{\tau}{2}\right) e^{-j\omega\tau} d\tau \\ &= \int R(t, \tau) e^{-j\omega\tau} d\tau \end{aligned} \quad (30)$$

where the quantity $R(t, \tau) = x(t - \tau/2)x^*(t + \tau/2)$ is known as an instantaneous autocorrelation function (ACF). WD satisfies several desirable properties for a quadratic TFR. It is real-valued; it satisfies time and

frequency marginals; and it preserves time- and frequency-shifts, the instantaneous frequency, and groups delay properties.^[22] Finally, for linear-chirp (i.e., sinusoids whose instantaneous frequency varies linearly with time $f_x(t) = f_0 + \alpha t$), we have

$$P_{\text{WD}}(t, \omega) = \delta(t, t - f_x(t)) \quad (31)$$

Thus, the WD is a line on the t - f plane located on the instantaneous frequency of the signal. The WD, however, is affected by interference terms (IT) when more than one signal component is present. In fact, as any quadratic TRF, WD satisfies the quadratic superposition principle,^[23] which states that for a N -component signal

$$x(t) = \sum_{k=1}^N c_k x_k(t) \quad (32)$$

the corresponding quadratic TRF is

$$P_x(t, \omega) = \sum_{k=1}^N |c_k|^2 P_{x_k}(t, \omega) + \sum_{j=1}^N \sum_{i=j+1}^N c_i c_j^* P_{x_i, x_j}(t, \omega) + c_j c_i^* P_{x_j, x_i}(t, \omega) \quad (33)$$

where $P_{x_k}(t, \omega)$'s are the N signal terms and the $P_{x_i, x_j}(t, \omega)$'s (for $i \neq j$) represent $\binom{N}{2} = N(N-1)/2$ interference terms—one for each pair of signal components. Note that the number of cross-term grows quadratically with the number of signal terms. The presence of cross-terms prohibits the interpretation of the WD as a pointwise time–frequency energy density and widely limits the readability of the TFR. In fact, cross-terms may appear in TFR as intensities in time and frequency locations, where no true components of the signal are present. ITs have precise geometry in the t - f plane, oscillating as a function of the distance between true signal terms; see Hlawatsch and Boudreaux-Bartels^[22] for details. The oscillatory nature of IT suggests performing a 2-D smoothing of the t - f plane to reduce them. If the properties of this smoothing filter do not vary on the t - f plane, the class of quadratic, shift-invariant, time–frequency distribution, known as *Cohen's Class*,^[2] is obtained.

$$P_C(t, \omega) = \int \psi(\tau - t, v - \omega) P_{\text{WD}}(\tau, v) d\tau dv \quad (34)$$

Each member of the class is derived by convolution between P_{WD} and a *kernel* ψ . Thus, every member of Cohen's Class may be interpreted as a 2-D, filtered version of WD^[22] and is unequivocally defined by ψ . This has practical implications. In fact, by placing constraints on the kernel, one obtains a subset of distributions that satisfies a particular property.^[2]

Introducing the ambiguity function,

$$A(\theta, \tau) = \int x\left(t - \frac{\tau}{2}\right) x^*\left(t + \frac{\tau}{2}\right) e^{j\omega t} dt \quad (35)$$

Cohen's Class can be rewritten as

$$C(\theta, \tau) = \phi(\theta, \tau) A(\theta, \tau) \quad (36)$$

where $\phi(\theta, \tau)$ is the 2-D FT of ψ , and the θ - τ plane is known as the correlative plane. In this plane, signal terms will be located around the origin, whereas the oscillating IT will tend to concentrate far from the origin. As evident from Eq. 36, the kernel merely weights the points of the correlative plane. Thus, to reduce the cross-terms effectively, the kernel must vanish when leaving the origin of the plane, and $\phi(\theta, \tau)$ must be the 2-D FT of a low-pass filter. In the analysis of biomedical signals,^[24,25] the Exponential Distribution (ED), the Reduced Interference Distribution (RID), and the Smoothed Pseudo Wigner-Ville (SPWD) are the most frequently used TFR. In particular, the SPWD expression

$$P_{\text{SPWD}}(t, \omega) = \int_{\tau} g(t - \tau) \int_v H(f - v) P_{\text{WD}}(\tau, v) d\tau dv \quad (37)$$

is characterized by an independent smoothing in frequency (obtained by $H(f)$ window) and time (obtained by $g(t)$ domain). The independent smoothing yields practical advantages, resulting in great flexibility in the choice of smoothing criteria, application, and efficient computation.

Autoregressive Time-Variant Models

A different approach to the analysis of time–frequency properties of a nonstationary signal is based on a recursive identification of AutoRegressive (AR) model parameters.^[25] Let us consider an AR process

$$x(t) = \sum_{k=1}^p a_k x(t - k) + w(t) = \varphi(t)^T \theta + w(t) \quad (38)$$

where the a_k are the model coefficients, p is the order, and $w(t)$ is a white-noise process ($w(t) \approx \text{WN}(0, \sigma^2)$). In Eq. 38, $\varphi(t) = [x(t-1), x(t-2), \dots, x(t-p)]^T$ is the observation vector, and $\theta(t) = [a_1, a_2, \dots, a_p]^T$ is the parameter vector. The model coefficients can be estimated by the least-squares (LS) approach, minimizing the following figure of merit:

$$J = \sum_{t=1}^N e(t)^2 \quad (39)$$

where N is the signal length and

$$e(t) = y(t) - \hat{y}(t) = y(t) - \varphi(t)^T \theta \quad (40)$$

is the prediction error—i.e., the difference between the current sample $y(t)$ and the model predicted one, $\hat{y}(t)$. The minimization of J leads to the solution^[26]

$$\begin{aligned} \hat{\theta}(t) &= \left[\sum_{k=1}^N \varphi(k)\varphi(k)^T \right]^{-1} \sum_{k=1}^N \varphi(k)x(k) \\ &= \mathbf{S}(N)^{-1} \mathbf{Q}(N) \end{aligned} \quad (41)$$

When using the LS method, the model is identified on a batch of data. If a new sample is added to sequence, the whole procedure has to be restarted. In addition, in many practical problems, the estimation needs to be performed in real time, sample by sample. Thus, it is necessary to employ recursive identification algorithms, where the estimation at time t is obtained by updating the estimation at time $t-1$ with the new information contained in the sample at time t . The LS method can be easily expressed in a recursive form, which is called recursive least squares (RLS). We have

$$\begin{aligned} \hat{\theta}(t) &= \hat{\theta}(t-1) + \mathbf{K}(t)e(t) \\ \mathbf{K}(t) &= \frac{\mathbf{P}(t-1)\varphi(t)}{1 + \varphi(t)^T \mathbf{P}(t-1)\varphi(t)} \\ e(t) &= y(t) - \varphi(t)^T \hat{\theta}(t) \\ \mathbf{P}(t) &= \left[\mathbf{P}(t-1) - \frac{\mathbf{P}(t-1)\varphi(t)\varphi(t)^T \mathbf{P}(t-1)}{1 + \varphi(t)^T \mathbf{P}(t-1)\varphi(t)} \right] \end{aligned} \quad (42)$$

where $\mathbf{P}(t) = \mathbf{S}^{-1}(t)$. We may observe that the parameter vector $\hat{\theta}(t)$ is updated by a factor that is proportional to the estimation error $e(t)$ through the gain vector $\mathbf{K}(t)$. This gain, which is also updated step by step, defines the property of the algorithm and modulates the extent to which the model errors are reflected in the estimation of $\hat{\theta}(t)$. If the data samples are coming from a nonstationary process, the estimated model suffers from the same problems as the batch estimation: in fact, the updating is based on the whole dataset, and after a while, the algorithm becomes unable to track changes. If we want the model to track the process modification, a forgetting factor has to be introduced to make the updating dependent mainly on the more recent data. The most popular forgetting function is based on the selection of an exponentially decreasing weight to the sequence of prediction error. A new figure of merit can be defined:

$$J = \frac{1}{t} \sum_{i=1}^t \mu^{t-i} e(i)^2 \quad (43)$$

The parameter μ ($0 < \mu < 1$) is the forgetting factor,^[25] and the quantity $1/(1-\mu)$ can roughly be seen as the

memory length of the algorithm, because it indicates approximately how many data samples are taken into account at time t to produce the estimate. The algorithm becomes

$$\begin{aligned} \hat{\theta}(t) &= \hat{\theta}(t-1) + \mathbf{K}(t)e(t) \\ \mathbf{K}(t) &= \frac{\mathbf{P}(t-1)\varphi(t)}{\mu + \varphi(t)^T \mathbf{P}(t-1)\varphi(t)} \\ e(t) &= y(t) - \varphi(t)^T \hat{\theta}(t) \\ \mathbf{P}(t) &= \frac{1}{\mu} \left[\mathbf{P}(t-1) - \frac{\mathbf{P}(t-1)\varphi(t)\varphi(t)^T \mathbf{P}(t-1)}{\mu + \varphi(t)^T \mathbf{P}(t-1)\varphi(t)} \right] \end{aligned} \quad (44)$$

The forgetting factor can be seen as the “tuning knob” of the algorithm. Low values for μ lead to estimates based on a small number of samples, and correspondingly, the algorithm results are quite reactive to changes in the true parameter vector. On the other hand, the averaging property necessary to effectively reduce the effect of the noise cannot be obtained if a short memory length is employed. Therefore, even if the true parameter vector stays constant, the estimates may be characterized by high variability using small values of μ .

The sequence of evolutionary spectra can be estimated from the time-varying parameter vectors as

$$P_{\text{AR}}(t, \omega) = \frac{\sigma^2(t)}{[1 + z^T \theta(t)]_{z=e^{j\omega}}^2} \quad (45)$$

where $z = [z^{-1}, z^{-2}, \dots, z^{-p}]^T$ and where $\sigma^2(t)$ is the variance of the prediction error, which also has to be estimated from the data and updated step by step.

Applications

In EEG processing, quadratic TFRs have been applied to analyze evoked or event-related potentials, as well as to characterize surface and cortical EEG recordings.^[24] The WD of EPs have been demonstrated to be useful for characterizing EP patterns, thanks to the excellent time–frequency resolution of the method.^[27] In addition, if associated with appropriate postprocessing, the RID was able to enhance subtle changes in EP’s response to physiological and psychological stimuli.^[28] At the level of cortical EEG recordings, the RID was used to characterize the recordings during epilepsy of the temporal lobe.^[29] Finally, WD was documented to be helpful in detecting rapid frequency changes related to changes in the level of consciousness of patients during anesthesia—changes that could not be captured by traditional spectral analysis.^[30]

In the analysis of the ECG, the frequency contents of the main waves (P–QRS–T) have been explored. Aims were the detection of P-wave, the analysis of

Fig. 3 (A) HRV signal during a rest-to-stand maneuver. Time–frequency representation of the signal obtained by SPWD. (B) Time-smoothing rectangular window $M=25$; frequency-smoothing Gaussian window ($\alpha=1.2$) and AR time-variant model (C), (model order 8, $\omega=0.98$). Both methods provide similar results, which is relevant information to describe the dynamical changes in LF and HF rhythms during the test. A dominant, quite stable, HF component is present during rest, but it decreases during stand. Conversely, LF components become predominant during stand, and their amplitude oscillates in time.

VLP,^[31] or the characterization of normal and pathological complexes.^[32] In particular, higher-frequency (>90 Hz) contents of the QRS, when exploited by SPWD, were augmented in patients after myocardial infarction than in normal subjects, and these components were present for the whole QRS complexes.^[31] In addition, TFR of the QRS and ST–T tracts were used to evaluate the efficiency of thrombolytic treatments.^[32] Finally, the time–frequency resolution properties of SPWD may be used to detect ventricular fibrillation events^[33] or to characterize the dynamic variation of the frequency of atrial activity during atrial fibrillation.^[34]

The beat-to-beat fluctuations of the RR interval (the so-called Heart Rate Variability [HRV]) were also investigated by quadratic TFR.^[25] The power spectrum of this signal evidences two main rhythms: (1) a high-frequency (HF) component, synchronous with respiration (in a range between 0.2 and 0.45 Hz) and modulated by vagal tone, and (2) a low-frequency (LF) component (centered around 0.1 Hz) mainly modulated by sympathetic activity. The dynamical changes of these rhythms were quantified through SPWD during a provocative test (i.e., tilt test) evidencing different responses of LF and HF rhythms: a fast reduction of HF component is followed by a more gradual increase of LF. In addition, LF was less stable in patients undergoing a tilt-induced syncopal event. These patients also experienced higher very-low-frequency (<0.03 Hz) components in the early phase of tilt.^[35] An example of SPWD

of RR series during a rest-to-tilt maneuver is shown in Fig. 3.

Other applications deal with the analysis of electromyograms (EMG) for the evaluation of fatigue in muscle during slow dynamic contractions^[36] or the analysis of electrogastrograms (EGG) for detecting gastric contractions and stomach motility.^[37]

Time-variant estimators have been used mainly in the presence of pseudo-stochastic signals or when noise is predominant. Typical applications deal with the analysis of HRV signals during pharmacologically induced ischemia,^[38] autonomic tests, or syncope events.^[39] In these situations, the evolutionary spectra of Eq. 45 have been documented to track the spectral changes associated with the dynamic variation of ANS control mechanisms.^[25]

In neurophysiology, only a few applications have been suggested to assess the dynamic variation of EEG signals using adaptive AR identification.^[40] Other applications include the analysis of the EGG^[41] and uterine EMG.^[42] In the latter work, several TFR methods were compared. The one based on an adaptive AR model provides the best tracking of main EMG spectral peaks, even if quadratic TFR may provide a more accurate quantification of spectral parameters.

HIGHER-ORDER SPECTRA

The Power Spectrum Density (PSD) of a signal may be obtained as the FT of the autocorrelation function

$(R_x(\tau))$ of the signal^[1]

$$S_x(\omega_1) = \sum_{\tau_1=-\infty}^{\infty} R_x(\tau_1) \exp^{-j\omega_1 \tau_1} \quad (46)$$

and the information carried by PSD is essentially contained in R_x . Being a second-order statistic, R_x provides complete statistical description of Gaussian processes. There are situations, however, in which it could be useful to look beyond PSD introducing higher-order spectra based on higher-order statistic (HOS) of the signal. The key advantage over traditional second-order techniques is that phase information is preserved. PSD is blind to phase, and as a consequence, second-order techniques cannot be used to identify nonminimum phase signals or to check certain types of phase coupling (associated with nonlinearities).^[43] In addition, using the fact that for Gaussian processes, all cumulants of order greater than two are identical to zero, HOS can be used to assess deviation from Gaussianity or to filter out Gaussian noise.

Moments and Cumulants

Let's consider a stochastic variable x with known probability density function $p(x)$. The characteristic function is defined as

$$\begin{aligned} \phi(\gamma) &= \int_{-\infty}^{\infty} p(x) e^{j\gamma x} dx \\ &= 1 + j\gamma \int_{-\infty}^{\infty} xp(x) dx \\ &\quad + \frac{(j\gamma)^2}{2} \int_{-\infty}^{\infty} x^2 p(x) dx + \dots \end{aligned} \quad (47)$$

or

$$\phi(\gamma) = \sum_{k=0}^{+\infty} \frac{(j\gamma)^k}{k!} \int_{-\infty}^{\infty} x^k p(x) dx = \sum_{k=0}^{+\infty} \frac{(j\gamma)^k}{k!} M_x^k \quad (48)$$

where the M_x^k are the k th-order central moment. The characteristic function uniquely defines the statistical distribution and can be used to generate both the n -order moments

$$M_x^k = (-j)^k \frac{\partial^k \phi(\gamma)}{\partial \gamma^k} \Big|_{\gamma=0} \quad (49)$$

and the cumulants

$$C_x^k = (-j)^k \frac{\partial \ln \phi(\gamma)}{\partial \gamma^k} \Big|_{\gamma=0} \quad (50)$$

Intuitively, moments and cumulants are closely related, and a formula exists to compute the latter from the former, and vice versa.^[3]

Let's consider a zero-mean, stationary random process $x(n)$, $\{n=0,1,2,3,\dots\}$. Similarly to Eqs. 49 and 50, we may define the joint k -order moments (cumulant) of the process

$$\begin{aligned} M_x^k &= (-j)^k \frac{\partial^k \phi(\gamma_1, \gamma_2, \dots, \gamma_k)}{\partial \gamma_1 \partial \gamma_2 \dots \partial \gamma_k} \Big|_{\gamma_1=\gamma_2=\dots=\gamma_k=0} \\ C_x^k &= (-j)^k \frac{\partial^k \ln \phi(\gamma_1, \gamma_2, \dots, \gamma_k)}{\partial \gamma_1 \partial \gamma_2 \dots \partial \gamma_k} \Big|_{\gamma_1=\gamma_2=\dots=\gamma_k=0} \end{aligned} \quad (51)$$

In particular

$$\begin{aligned} M_x^k(\tau_1, \tau_2, \dots, \tau_{k-1}) \\ = E[x(k)x(k+\tau_1)x(k+\tau_2)\dots(k+\tau_{k-1})] \end{aligned} \quad (52)$$

represents the k th-order moment, and it depends on time difference τ_i due to the assumption of stationarity. We may observe that M_x^1 and M_x^2 are the mean and the variance of the process. The cumulant functions become^[44]

$$\begin{aligned} n=2 \quad C_x^2(\tau_1) &= M_x^2(\tau_1) \\ n=3,4 \quad C_x^k(\tau_1, \tau_2, \dots, \tau_{k-1}) &= M_x^k(\tau_1, \tau_2, \dots, \tau_{k-1}) \\ &\quad - M_G^k(\tau_1, \tau_2, \dots, \tau_{k-1}) \end{aligned} \quad (53)$$

where $M_G^k(\tau_1, \dots, \tau_{k-1})$ is the k th-order moment of an equivalent Gaussian signal with the same mean and autocorrelation function of $x(n)$. It turns out that $C_x^n(\tau_1, \dots, \tau_{n-1}) = 0$ for Gaussian processes for orders $n=3$ and $n=4$. Thus, cumulants provide a measure of the distance of a random process from Gaussianity.

The C_k^n 's have several interesting properties^[44]: They are scaled quantities, symmetric and additive in their arguments, and blind to additive constants. In addition, the cumulant of the sum of statistical independent variables is the sum of cumulants of the individual quantities. Thus, if a certain process x is corrupted by Gaussian noise w , we have $C_{x+w}^k = C_x^k + C_w^k = C_x^k$, and the resulting cumulants are blind to the superimposed Gaussian noise. It is worth noting that the additive property does not hold for higher-order moments. Therefore, it usually is easier to use cumulants than moments as operators. A more detailed description of cumulants and moments can be found in Nikias and Petropulu.^[3]

Practically speaking, the estimation of higher-order cumulants from sampled data becomes harder when the order is increased, because longer datasets are required to reduce the variance associated with the estimate of joint probabilities. Therefore, computation usually is restricted to third- and fourth-order cumulants.

Higher-Order Spectra

The higher-order spectra (or polyspectra) are defined as^[44]

$$S_x^k(\omega_1, \omega_2, \dots, \omega_{k-1}) = \sum_{\tau_1=-\infty}^{\infty} \dots \sum_{\tau_{k-1}=-\infty}^{\infty} C_x^k(\tau_1, \tau_2, \dots, \tau_{k-1}) \exp(-j \sum_{i=1}^{k-1} \omega_i \tau_i) \quad (54)$$

where

$$|\omega_1| < \pi, |\omega_2| < \pi, \dots, |\omega_{k-1}| < \pi,$$

$$|\omega_1 + \omega_2 + \dots + \omega_{k-1}| < \pi.$$

Polyspectra, therefore, are the $(k-1)$ -dimensional FT of the k th-order cumulant, and the power spectrum (Eq. 46) is in fact a member of the class because $R_x = C_x^2$. Even if polyspectra can be defined in terms of either moments or cumulants, the latter are preferable when dealing with stochastic process. Reasons are contained in the properties of cumulants described above.

In particular, the FT of third-order cumulants is known as bispectrum.^[43]

$$S_x^3(\omega_1, \omega_2) = \sum_{\tau_1=-\infty}^{\infty} \sum_{\tau_2=-\infty}^{\infty} C_x^3(\tau_1, \tau_2) \exp(-j(\omega_1 \tau_1 + \omega_2 \tau_2)) = |S_x^3(\omega_1, \omega_2)| \exp(j\psi(\omega_1, \omega_2)) \quad (55)$$

Bispectrum generally is a complex function; it carries information on both amplitude and phase (conversely, the PSD is a real quantity, blind to phase). Taking into account the properties of symmetry of cumulant, the bispectrum is highly symmetric in the ω_1 - ω_2 plane. In particular, 12 regions of symmetry can be evidenced, and the knowledge of S_x^3 in the triangular region (known as the principal region) $\omega_2 \geq 0$, $\omega_1 \geq \omega_2$, $\omega_1 + \omega_2 \leq \pi$ is enough for a complete description of the bispectrum.^[43]

The bicoherence is a normalized bispectrum

$$K_x^3(\omega_1, \omega_2) = \frac{C_x^3(\omega_1, \omega_2)}{\sqrt{S_x^2(\omega_1) S_x^2(\omega_2) S_x^2(\omega_1 + \omega_2)}} \quad (56)$$

that combines the third-order cumulant spectrum and the power spectrum (S_x^2) of a signal. Bicoherence is useful for detection and characterization of nonlinearities in the time series and to discriminate between linear and nonlinear processes. Consider

$$z(n) = \sum_{i=1}^3 \cos(\omega_i n + \varphi_i) \quad (57)$$

where, $\omega_2 > \omega_1 > 0$, $\omega_3 = \omega_1 + \omega_2$, φ_1, φ_2 are independent and uniformly distributed on $0-2\pi$. Let's consider

two situations: (1) φ_3 is uniformly distributed on $0-2\pi$ and independent from, φ_1, φ_2 and (2) the relation $\varphi_3 = \varphi_1 + \varphi_2$ links phases—i.e., a Quadratic Phase Coupling (QPC) does exist between ω_1 and ω_2 harmonics. QPC results in phase relations that are the same as the frequency relations. QPC can arise only among harmonically related components. In the first case, observing that the harmonics are phase independent and that third-order cumulant of complex harmonic is zero, the resulting magnitude bispectrum (evaluated in the principal region) is zero everywhere. Conversely, in case (2), the bispectrum is zero everywhere, but in the point, ω_1, ω_2 indicating that this pair of frequencies are phase coupled. Because only phase-coupled components contribute to the bispectrum, the latter is a useful tool for discriminating quadratic phase-coupling components.^[43]

Applications

The use of polyspectra has attracted much attention for the processing of many biological signals, including EEG analysis, EMG studies, and interaction among rhythms. In most of the cases, interest has been limited to computing bispectrum, assessing the nature of the frequencies contained in the signal, and studying QPC. For the analysis of EEG, the bispectrum has some remarkable properties: it enhances the signal-to-noise ratio for nonGaussian EEG; it identifies nonlinearities and detects phase coupling (which is a common phenomenon in signals generated from the central nervous system); and it quantifies both power and phase information. In particular, HOS analysis of EEG is the basis of the well-known Bispectral Index (BIS), developed by Aspect Medical System (Newton, Massachusetts). BIS is a composite index of parameters^[45] used to assess the depth of anesthesia and the level of unconsciousness. It includes time domain, frequency domain indexes, and a bispectral metric (the SynchFastSlow ratio) computed as the logarithm of the ratio of cumulative values of the bispectrum over two ranges (0.5–47 Hz and 40–47 Hz). Even if the BIS does not work properly in all situations, the method is popular as a result of strong empirical evidence of high probability to predict the absence of consciousness correctly.^[46] Other EEG applications include the possibility of assessing the place and the extent of focal ischemic cerebral injury^[47] or characterizing sleep spindles.^[48]

Higher-order statistics have been also applied for diagnostic assessment and characterization of lung sounds. Harmonic analyses of lung sounds have been combined with the bicoherence index to provide reliable evaluation of pulmonary dysfunctions. Especially in noisy environments, the use of HOS was proved to be advantageous.^[49]

Even if some promising applications have been suggested, HOS analysis of BSP is limited by the difficulty of estimating high-order statistics accurately when short data sequences are available (which is often the case).

NONLINEAR BIOMEDICAL SIGNAL PROCESSING

Chaotic systems are characterized by complex dynamics, determinism, and sensitivity to initial conditions, making long-term forecasting impossible. Several signals and series of biological origin exhibit patterns typical of complex dynamics. The topic is certainly too

wide to be covered fully by this entry. Textbooks^[4] are available to the interested reader. Here, we mention only a few popular signal processing methodologies largely used to investigate biological time series. They are (1) Detrended Fluctuation Analysis (DFA) for exploring scaling behavior and (2) entropy-based metrics for assessing series regularity.

Detrended Fluctuation Analysis

Several signals and series of biological origin display scaling (self-similar) behavior. The concept is evidenced in Fig. 4, where the HRV signal is observed at various time windows (scales): the signal has an irregular

Fig. 4 (A) Evidence of self-similar fluctuations in the dynamic of HRV signal. On different time scales, the static properties of the signal are self-similar (i.e., the signal resembles itself when observed with different time lenses). (B) Examples of scaling properties in the HRV fluctuations and their changes in health (triangle), ageing (circle), and chronic heart failure disease (star).

appearance, which is statistically similar among scales. It is not possible to distinguish a scale from the others, and there is a lack of a characteristic (single) scale for this process. A scale invariance is observed, and the process is self-similar. Far from being just a fancy manifestation, the existence of scaling properties is an useful probe for understanding the inner nature of biological phenomena and their modifications with age and pathologies.^[50] Among the numerous tools developed to assess scaling behavior,^[8] DFA is likely to be the method most used, as its implementation is straightforward, and it is robust and blind to superimposed linear trends.^[51] DFA permits the detection of long-range correlations embedded in a seemingly non-stationary time series, and it also averts the spurious detection of apparent long-range correlations that are artifacts of nonstationarity.^[51]

Let us consider a discrete-time series $x(n)$ $n = \{1, 2, \dots, N\}$ and integrate it:

$$y(k) = \sum_{i=1}^k x(i) - E[x] \quad (58)$$

Next, the integrated time series is divided into boxes of equal length n . In each box of length n , an LS line is fit to the data, representing the trend in that box. Finally, the integrated time series is detrended by subtracting the local trend $y_n(k)$ in each box, and the root mean-square fluctuation of this integrated and detrended time series is calculated by

$$F(n) = \sqrt{E[(y(k) - y_n(k))^2]} \quad (59)$$

The computation is repeated over all time scales (box size) to provide a relationship among $F(n)$, the average fluctuation as a function of box size, and the box size n .

If this relationship is linear on a log–log plot, it indicates the presence of power law scaling—that is,

$$F(n) \sim n^\alpha \quad (60)$$

where α is the scaling exponent. Taking the logarithm, we get a linear relationship

$$\log[F(n)] \sim \alpha \log(n) \quad (61)$$

and the scaling exponent can be evaluated by the slope of a fitting curve.

This exponent provides a measure of the “roughness” of the original time series: the larger the value of α , the smoother the time series.^[50] A value of $\alpha = 0.5$ indicates a white-noise process (complete unpredictability), whereas $\alpha = 1.5$ is characteristic of Brownian noise. Finally, a value of $\alpha = 1$ indicates $1/f^2$ -like noise behavior.

Approximate Entropy

Approximate entropy (ApEn) is a regularity statistic quantifying the unpredictability of fluctuations in a time series. Intuitively, the presence of repetitive patterns of fluctuation in a time series makes it more predictable than a time series in which such patterns are absent. ApEn reflects the likelihood that “similar” patterns of observations will not be followed by additional “similar” observations. A time series containing many repetitive patterns (i.e., a regular and predictable series) has a relatively small ApEn; a less predictable (i.e., more complex) process has a higher ApEn.

Given a sequence S_N consisting of N samples $x(n)$ $n = \{1, 2, \dots, N\}$, we define the pattern of length m $p_m(i) = \{x(i), x(i+1), \dots, x(i+m-1)\}$ as the sequence of m samples that begins at interval i . We now define criterion of similarity r , and two patterns, $p_m(i)$ and $p_m(j)$, are considered similar if the difference between any pair of corresponding measurements in the patterns is less than r —i.e., if for $|x(i+k) - x(j+k)|$.

Now consider the set P_m of all patterns of length m within S_N . We may now define

$$C_{im}(r) = \frac{n_{im}(r)}{N - m + 1} \quad (62)$$

where $n_{im}(r)$ is the number of patterns in P_m that are similar to $p_m(i)$. The quantity $C_{im}(r)$ is the fraction of patterns of length m that resemble the pattern of the same length that begins at interval i . $C_{im}(r)$ is calculated for each pattern in P_m and $C_m(r) = E[C_{im}(r)]$ is defined as the mean of these $C_{im}(r)$ values. The quantity $C_m(r)$ expresses the prevalence of repetitive patterns of length m in S_N . Finally, the approximate entropy of S_N , for patterns of length m and similarity criterion r is defined as^[52]:

$$\text{ApEn}(S_N, M, r) = \ln \left[\frac{C_m(r)}{C_{m+1}(r)} \right] \quad (63)$$

i.e., as the natural logarithm of the relative prevalence of repetitive patterns of length m compared with those of length $m+1$.

Regularity Index

The regularity of a signal may be quantified by using its Conditional Entropy (CE)—the amount of information carried by the signal when its past samples are known.^[53] From a given process $x = \{x(n), n = 1, \dots, N\}$, let's label $x_L(n)$ the $N-L+1$ patterns of length L that may be extracted from x and p_L its probability. In terms of the Shannon entropy $E(x)$, the CE may be

defined as

$$CE(L) = E(x_m) - E(x_{m-1}) \quad (64)$$

which emphasizes the amount of information carried out when the pattern is enlarged from $m-1$ to m . Eq. 64 has several computational advantages, but its major drawback is that estimation of $CE(L)$ is no longer statistically consistent when L increases.^[53] Therefore, when a limited amount of samples is available, the Corrected Conditional Entropy (CCE) must be used,

$$CCE(L) = CE(L) + \text{perc}(L)E(x) \quad (65)$$

where $\text{perc}(L)$ is the percentage of single points in the L -dimensional phase space and $E(1,12)$ is the Shannon Entropy for $L=1$. As $\text{perc}(L)$ increases with L , the corrective term tends to compensate the decrease in $CE(L)$ due to the increasing number of single ($L-1$) patterns giving a null contribution to $CE(L)$. CCE is the sum of two contributions: the first one decreasing and the second one increasing with L . The best estimate of CE is the minimum of $CCE(L)$. An index of regularity may be defined as follows,^[53]

$$R = 1 - \min\left(\frac{CCE(L)}{E(x)}\right) = 1 - \min(\text{NCCE}(L)) \quad (66)$$

where NCCE is the CCE value normalized by $E(x)$, to derive an index that is independent of the different probability distribution of the processes. R tends to be 1 when the process x is periodic (i.e., it is perfectly

predictable), falls to zero in the presence of high complexity (i.e., completely unpredictable) signals, and remains in between the two positions for intermediate processes.

Applications

DFA is a widely used technique for the assessment of long-range correlations in nonstationary time series. The most straightforward and studied examples can be found in the analysis of both beat-to-beat fluctuation of the HRV^[50] and DNA sequences,^[54] but other evidences may be found in the analysis of human walking^[55] or neuron spiking.^[56] An example of DFA applied to the analysis of long-term fluctuations in the heartbeat series is shown in Fig. 4b. Two regions with different slopes are evidenced, suggesting that there are both short-range ($0 < n < 16$) and a long-range scaling exponents. Differences in scaling properties induced by age and pathology have been also reported.^[50] In particular, the low scaling exponents were powerful predictors of mortality among patients surviving myocardial infarction^[57] or congestive heart failure.^[58] In addition, DFA indexes were superior to spectral analysis in the classification of sleep stages and in separation of apnea severity.^[59] In the analysis of DNA sequences, DFA was used to assess long-range correlations in coding and noncoding regions of the gene.^[54]

ApEn has gained much attention as an indicator of in-depth anesthesia monitoring, differentiating between awake and asleep states,^[60] classifying the burst suppression patterns,^[61] or monitoring the transitions

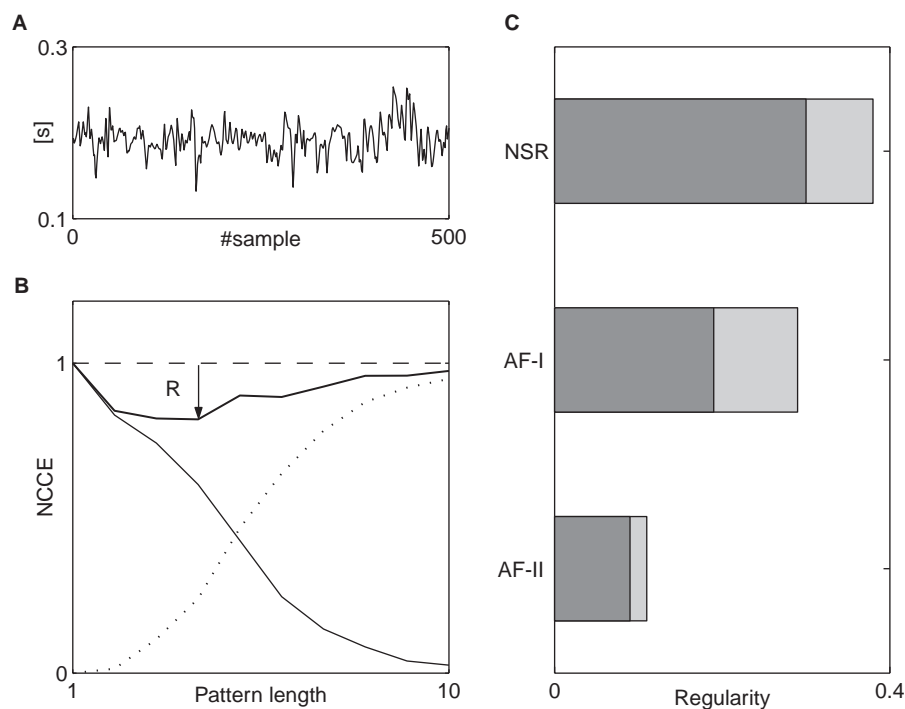

Fig. 5 (A) Local Atrial Period (LAP) series recorded during AF-I episode. (B) The estimated normalized corrected conditional entropy functions (bold line) is obtained as the sum of the conditional entropy term (thin line) and the corrective term (dotted line). The regularity index (R) is obtained as the distance between the minimum of the resulting curve and the unity line (dotted). (C) Mean (\pm std) value of R estimated during Normal Sinus Rhythm (NSR), AF-I, and AF-II. It is interesting to note the decreasing of R passing from NSR to organized (AF-I) and not organized (AF-II) fibrillatory rhythms.

between awareness and unresponsiveness.^[62] In the analysis of HR series, changes of ApEn have been correlated with the aging process^[63] or with the phases of fetal growth.^[64] In an interesting application, entropy-based indexes have been proposed as indicators of the early diagnosis of sepsis in premature newborns in intensive care units.^[65] In addition, altered RR dynamics have been assessed before the spontaneous onset of paroxysmal atrial fibrillation (AF) episodes.^[66] Other applications deal with the evaluation of intracranial pressure^[67] or the analysis of respiratory patterns.^[68]

The Regularity index (R) has mainly been applied to evaluate complexity in cardiovascular beat-to-beat variability signals or in sympathetic nerve discharge^[53] during various stimulations induced by head-up tilt, controlled respiration, or peripheral muscarinic blockade.^[69] In general, systolic arterial pressure (SAP) series is more regular than RR series; regularity of RR, however, is influenced by the above stimulus, whereas regularity of SAP is not.

In addition, R was used to characterize the dynamic of the Local Atrial Period (LAP) series (i.e., the sequences of time intervals computed among successive atrial activations) during Well's types of Atrial Fibrillation (namely, AF-I and AF-II type). An example of LAP series during AF is shown in Fig. 5: LAP series (a) and corresponding NCCE (b) were obtained during a Wells AF-II type episode. When comparing NSR and AF rhythms, it has been documented that $R^{[70]}$ is able to detect the atrial rhythms (see Fig. 5c): regularity is significantly reduced by passing from NSR to AF-I to AF-II. Such a reduction measures the reduced atrial organization in wavefront propagation characteristic of AF-I and AF-II events, and demonstrates a more fragmented atrial activation.

CONCLUSION

We have introduced some advanced signal processing methods that have been used to extract new quantitative information from biological signals. The methods include wavelets transform, time-frequency analysis, and higher-order spectra, as well as some known tools from nonlinear analysis of biological series. The advent of these tools in BSP makes it possible to quantify new signal features and considerably enlarge the number of parameters that can be extracted from recorded vital signals, opening new perspectives for a deeper comprehension of biological phenomena and pathologies. The few examples were selected to emphasize the new available information from the analysis of widely analyzed signals, such as ECG, EEG, and EP. Finally, it is important to point out that a larger number of parameters does not necessarily mean more information on the biological process if we are not able to correctly

handle and integrate information coming from modern and traditional approaches. In fact, the abundance of parameters opens new questions and problems, such as those related to the appropriate fusion of the information for a better understanding of physiological systems or for a better definition of patient status.

Distal Protection Devices

Thomas Tu
Roger Laham

Cardiovascular Division, Beth Israel Deaconess Medical Center and Harvard Medical School, Boston, Massachusetts, U.S.A.

INTRODUCTION

Angioplasty of atherosclerotic lesions can result in the liberation of microscopic and macroscopic debris. Recent evidence suggests this embolization occurs more frequently than was previously thought. The particulate matter is comprised of plaque components, platelets, thrombus, and vasoconstrictors. Large emboli may obstruct the epicardial vessel and can generally be treated by traditional angioplasty techniques. Smaller material that is too large to pass through the capillary network of the distal bed (15–100 micron) becomes lodged in the microvasculature. Embolization leads to microvascular dysfunction by a variety of mechanisms, including occlusion, vasoconstriction, and platelet aggregation. The angiographic appearance of this phenomenon is described as no reflow, which is defined as reduced coronary flow despite the lack of epicardial stenosis.

Embolization and no reflow can result in periprocedural ischemia and microvascular infarction, which is detectable by cardiac enzyme elevation, impaired wall motion, and abnormalities on MRI. Percutaneous interventions associated with impaired flow and periprocedural enzyme elevation are associated with longer hospital stay and increased mortality.

OVERVIEW

Recent advances in percutaneous coronary and peripheral revascularization have focused on the problem of distal embolization during interventions, a process which often results in the phenomenon of no-reflow during coronary intervention with resultant microvascular dysfunction and major adverse cardiac events and cerebral and peripheral ischemia during peripheral and carotid interventions.^[1–7] The use of glycoprotein IIb/IIIa antagonists has been shown to reduce periprocedural infarcts and also improves long-term outcomes.^[10–12] This is thought to be due in part to a reduction in ischemic complications. However, in the subset of degenerated vein grafts, the benefit is not evident, perhaps because the magnitude of

embolization is too great to be mitigated by antiplatelet therapy.^[13]

Angioplasty technique has also been modified in response to concern about microembolization. The use of high pressure inflation to maximally expand stents has been widely adopted and is effective at reducing subsequent restenosis. It is also associated with a higher incidence of embolization, which is likely due to increased vessel trauma. When approaching lesions at high risk of embolization, many operators choose to use less traumatic self-expanding stents and/or foregoing high-pressure postdilation.

Despite these advances, there is still a significant incidence of periprocedural infarction after percutaneous intervention. A number of devices have been developed in order to prevent the distal embolization associated with angioplasty. Together, they are known as distal protection devices.

Currently, the principal applications of distal protection include saphenous vein graft and carotid artery angioplasty.

Saphenous Vein Grafts (SVG)

Saphenous vein grafts are the most common conduits used for aorto-coronary bypass surgery. They exhibit accelerated intimal hyperplasia and atherosclerosis when compared to native coronary arteries and arterial conduits.^[14] Ten years after surgery, 40% of SVGs are occluded and even more have developed severe stenosis.^[15] The plaque is typically diffuse and complex with large amounts of friable atheroma and intraluminal thrombus. Traditional percutaneous intervention on these lesions was often complicated by distal embolization, no reflow, and decreased procedural success.^[8,9] Factors that have been associated with worsened acute success include grafts older than three to four years, multiple lesions or diffuse disease, small graft diameter, and presence of intraluminal thrombus.^[14]

Carotids

Percutaneous carotid artery intervention for carotid stenosis has been performed successfully and is

Supported in part by NIH grants MO1-RR01032 and HL 63609 (RJL).

currently being investigated as a possible alternative for carotid endarterectomy. The major complication of the procedure is stroke, which occurs in 1–3% of the cases, presumably from embolization.^[16] Transcranial Doppler studies have demonstrated a high incidence of microembolization during percutaneous intervention.^[17–19] The clinical significance of this phenomenon is not clear. However, it is likely that substantial reduction of embolization may reduce the incidence of periprocedural stroke as well as more subtle late neurological deficits. There is significant interest in distal protection as the complication rates of carotid artery stenting become similar to surgical endarterectomy.

DEVICES TO REDUCE DISTAL EMBOLIZATION

There are three major categories of devices that have been developed to address the problem of distal embolization: balloon occlusion devices, filter devices, and flow reversal devices (Table 1).

Balloon occlusion devices utilize a compliant balloon mounted on a coronary guidewire. The wire is directed across the target lesion, and the balloon is inflated until coronary blood flow has stopped. The intervention is performed over the balloon wire, and the liberated particles are unable to migrate into the distal vascular bed. These particles are then removed by various aspiration techniques.

Filter devices employ a porous, expandable filter mounted on a coronary guidewire. The collapsed filter is directed across the target lesion. The filter is then deployed, and the coronary intervention can then be performed over the filter wire. Anterograde perfusion is maintained while any debris larger than the filter pore size is trapped. At the completion of the procedure, the filter is retracted into a recovery sheath. The filter with its captured debris is then removed from the body.

Table 1 Types of distal protection devices

Balloon occlusion devices

- Guardwire (Medtronic)
- Triactiv (Kensey-Nash)

Filter devices

- Angioguard (Cordis)
- Filterwire EX (Boston Scientific)
- Mednova Neuroshield (MedNova)
- AccUNET (Guidant)

Flow reversal devices

- Parodi Anti-Emboli System (PAES) (Arteria Medical Science)

Flow reversal devices have been developed particularly for percutaneous intervention on the carotid artery. They occlude anterograde flow proximal to the lesion, which results in a reversal of flow in the target vessel. Liberated particles migrate away from the distal vascular bed and are aspirated by the device.

PERCUSURGE GUARDWIRE (MEDTRONIC)

Device Description

The PercuSurge Guardwire Temporary Occlusion and Aspiration System consists of four principal components: The Guardwire, the Microseal Adapter, the Export Catheter, and the EZ-Flator Inflation Device. The Guardwire design utilizes a 0.014-inch hollow-core wire that is connected to an elastomeric balloon near the distal end. The wire has a radiopaque, shapeable distal tip that facilitates lesion crossing. The Microseal Adapter allows access to the hypotube inside the wire. The EZ-Flator Inflation Device is connected to the Guardwire via the Microseal adapter (Fig. 1A). The balloon can be inflated to a diameter of 3–6 mm using the graded inflation device (Fig. 1B). The Export Catheter consists of a 5 French monorail system with a 1 mm internal diameter central lumen. The catheter is used to aspirate debris from the static blood column formed by the occlusion balloon.

Procedure

A 7 French or larger guiding catheter is used to cannulate the SVG ostium. The Guardwire is prepared by inflating and deflating the balloon with the Inflation Device. The wire is then directed across the target stenosis in a similar fashion as a standard coronary guidewire. The occlusive balloon is positioned 2 to 10 cm distal to the lesion. The proximal end of the Guardwire is placed into the Microseal Adapter. Dilute radiographic contrast is infused until anterograde perfusion has ceased. It is possible to trap a column of contrast in the vessel to allow easy visualization of the lesion during occlusion. The lumen of the Guardwire is then sealed, which allows removal of the Microseal Adapter and Inflation Device. Treatment of the lesion can then proceed in standard fashion by using the Guardwire to direct angioplasty and stenting. Any liberated plaque or thrombus tends to remain in the static column of blood in the occluded vessel. The Guardwire is then used to direct the Export Catheter up to the occlusion balloon. A syringe is used to aspirate 20–40 cc of blood through the export catheter lumen, which removes the trapped debris. The Guardwire is reattached to the Inflation Device using

Fig. 1 The Percutaneous Distal Protection system is the only FDA-approved device in the United States. It consists of an Inflation Device with a Microseal Adapter (A) that connects to the Guardwire (B). The balloon can be inflated to a diameter of 3–6 mm using the graded inflation device.

the Microseal Adapter, and the balloon is deflated and thereby restores antegrade flow.

In the hands of skilled operators, the entire procedure can be completed with an occlusion time of three to four minutes. Depending on the size and importance of the vascular territory involved, the patient may have severe ischemia during occlusion, as evidenced by angina, ST-segment changes, hypotension, or arrhythmias. Occlusion time can be reduced by planning the procedure well and performing the intervention quickly. If several balloon/stent treatments are required, the procedure can be performed in stepwise fashion with multiple occlusion and aspiration cycles. Occasionally, the patient cannot tolerate even a short period of balloon occlusion, and a filter device should be substituted.

Clinical Trials

The Guardwire system is the only distal protection device approved by the U.S. Food and Drug Administration (FDA) for treatment of saphenous vein graft stenoses. The initial clinical results were published in the SAFE registry (Saphenous Vein Graft Angioplasty Free of Emboli).^[20] One hundred three patients underwent percutaneous vein graft intervention using the Guardwire balloon occlusion system. Macroscopically visible red and/or yellow debris was extracted in 91% of patients. By core lab analysis, normal coronary flow was present in 98.9% of grafts postintervention versus 83.5% before intervention. No patient developed angiographic evidence of no reflow or distal embolization. Postprocedural infarcts, defined by creatine phosphokinase MB isozyme levels elevated to $>3\times$ normal, were seen in only five patients (5%), and 97 patients (94%) were free of major adverse events at 30 days.

The pivotal SAFER (Saphenous Vein Graft Free of Emboli Randomized) trial^[21] was the first multicenter randomized trial to evaluate use of a distal embolic protection device during stenting of saphenous vein graft lesions. Four hundred six patients were randomly

assigned to stent placement over the shaft of the distal protection device, and 395 were assigned to stent placement over a conventional 0.014-inch angioplasty guidewire (control group). The primary end point—a composite of death, myocardial infarction, emergency bypass, or target lesion revascularization by 30 days—was observed in 65 patients (16.5%) assigned to the control group and 39 patients (9.6%) assigned to the embolic protection device ($P=0.004$). This 42% relative reduction in major adverse cardiac events was driven by myocardial infarction (8.6% versus 14.7%, $P=0.008$) and no-reflow phenomenon (3% versus 9%, $P=0.02$). Clinical benefit was seen even when platelet glycoprotein IIb/IIIa receptor blockers were administered (61% of patients) with composite end points occurring in 10.7% of protection device patients versus 19.4% of control patients ($P=0.008$).

These two studies demonstrated that use of this distal protection device during stenting of venous graft lesions was associated with a highly significant reduction in major adverse events compared with stenting over a conventional angioplasty guidewire. The SAFER study highlighted the importance of distal embolization in causing major adverse cardiac events and the value of embolic protection devices in preventing such complications.

There are several ongoing clinical studies that are evaluating the use of the Guardwire system for carotid angioplasty. The CAFÈ (Carotid Angioplasty Free of Emboli) registry will look at the 30-day success rate of 100 patients who undergo carotid stenting with Guardwire distal protection. MAVERIC (Medtronic AVE Self-Expanding Carotid Stent System with Distal Protection in the Treatment of Carotid Stenosis) is a multicenter registry of 50 patients at high risk of carotid endarterectomy who will undergo carotid stenting with a new stent system and Guardwire distal protection. SHELTER (Carotid Stenting of High-Risk Patients: Extracranial Lesion Trial with Emboli Removal) is a registry of 630 patients with one-year follow-up after carotid stenting with a Monorail Carotid Wall-stent and Guardwire distal protection.

TRIACTIV (KENSEY NASH)

Device Description

The Triactiv device is a balloon occlusion-type distal protection device that acquired its CE Mark in January 2002, which gives approval for use in Europe. It consists of a hollow 0.014-inch stainless steel guidewire with a distal elastomeric balloon. The wire is used to cross the lesion in a similar fashion to a coronary guidewire. A calibrated syringe filled with CO₂ is attached to the proximal end of the wire and is used to inflate the balloon to a diameter of 3.0–5.0 mm. Once vessel occlusion is achieved, the wire is used to guide the stent to the target lesion. After vessel treatment, a 3 French sump catheter is attached to the side of the guidewire using a spiral groove monorail. The sump catheter is advanced to the distal occlusion balloon (Fig. 2). A peristaltic pump is used to infuse saline into the vessel while aspiration of debris is performed through the coronary guide catheter. The active infusion/sumping of clean saline may provide enhanced clearance of embolic debris. The balloon is then deflated, and anterograde perfusion is restored. If postdilation or additional stenting is required, the balloon can be reinflated, and the procedure can be repeated.

Clinical Trials

The Triactiv device is currently being evaluated in a clinical trial called PRIDE (Protection During Saphenous Vein Graft Intervention to Prevent Distal

Embolization). In this U.S. trial, up to 800 patients at up to 50 sites who undergo vein graft intervention will be randomized to standard-of-care versus intervention with Triactiv distal protection. Early results of the trial suggest a low major adverse cardiac event rate and led to approval of its CE Mark.^[22] The trial is expected to be completed sometime in the spring of 2004.

ANGIOGUARD (CORDIS)

Device Description

The Angioguard device utilizes a polyurethane filter mounted on a nitinol skeleton. The filter is attached distally to a floppy wire tip and proximally to a 300 cm, 0.014-inch, medium-support guidewire (Fig. 3). The closed filter, contained in a delivery sheath with a diameter of 0.061 to 0.065 inch and a maximum profile of 4 F to 4.5 F, is advanced through the lesion. A second-generation device (Angioguard XP) has crossing profiles of 3.2–4.1 F. The filter is opened in the target vessel distal to the lesion by removal of the delivery sheath. A filter 0.5 to 1.0 mm larger than the visually estimated distal vessel diameter is chosen to ensure complete apposition of the filter to the vessel wall. Sizes range from 4–8 mm. The filter has numerous, laser-drilled 100 micron holes that allow anterograde passage of red blood cells while the filter is deployed. Liberated debris is trapped by the filter, which is then collapsed by advancement of a retrieval sheath and removed from the artery.

Fig. 2 The Triactive system is currently in clinical trials in the United States and Europe. (A) It consists of a hollow 0.014-inch stainless steel guidewire with a distal elastomeric balloon. A calibrated syringe filled with CO₂ is attached to the proximal end of the wire and is used to inflate the balloon to a diameter of 3.0–5.0 mm. Once vessel occlusion is achieved, the wire is used to guide the stent to the target lesion. After vessel treatment, a 3 French sump catheter is attached to the side of the guidewire using a spiral groove monorail. The sump catheter is advanced to the distal occlusion balloon. A peristaltic pump is used to infuse saline into the vessel while aspiration of debris is performed through the coronary guide catheter. (B) Atherosclerotic debris retrieved with the Triactive system underscores the need for distal protection.

Fig. 3 The Angioguard device utilizes a polyurethane filter mounted on a nitinol skeleton. The filter is attached distally to a floppy wire tip and proximally to a 300 cm, 0.014-inch, medium-support guidewire. The closed filter, contained in a delivery sheath with a diameter of 0.061 to 0.065 inch and a maximum profile of 4 F to 4.5 F, is advanced through the lesion. A second-generation device (Angioguard XP) has crossing profiles of 3.2–4.1 F. The filter is opened in the target vessel distal to the lesion by removal of the delivery sheath. Liberated debris is trapped by the filter, which is then collapsed by advancement of a retrieval sheath and removed from the artery.

Clinical Trials

Initial feasibility and safety data demonstrated a high rate of technical success using the Angioguard device in saphenous vein grafts.^[23] SAPPHERE (Stenting and Angioplasty with Protection in Patients at High Risk for Endarterectomy) was a pivotal study comparing stenting with distal protection to traditional surgical carotid endarterectomy for high-risk patients. The results of this combination registry and randomized control trial were presented at the November 2002 American Heart Association meeting. There were 307 patients in the randomized trial and 416 patients followed in the registry arm enrolled from 29 centers. The Nitinol Precise Stent and Angioguard distal protection device (both from Cordis) were used for the intervention. Entry criteria included symptomatic patients with more than 70% stenosis or asymptomatic patients with over 80% stenosis. In general, high-risk characteristics that allowed enrollment included severe heart failure, unstable angina or recent myocardial infarction, severe lung disease, concomitant coronary and carotid disease, open heart surgery planned within six weeks, or technically difficult surgical anatomy.

Results of the trial showed a significant reduction in major clinical events at 30 days favoring stenting over surgery. Stroke, myocardial infarction, or death occurred in 5.8% of the stent patients versus 12.6% of the surgical patients ($p=0.047$). Thirty-day

complication rates were equivalent between the two groups for transient ischemic attack and bleeding. The surgical group had a 5.3% incidence of cranial nerve injury, which is compared to 0% with stenting. There were 409 patients in the stent registry compared to seven in the surgical registry, which indicates a strong preference for the less invasive intervention.

GUARD (Saphenous Vein Graft Intervention Using Angioguard for Reduction of Distal Embolization) is a randomized safety and efficacy trial for vein graft interventions. Between 300–700 patients will be randomized to percutaneous intervention with or without use of the Angioguard device. The primary outcome will be major adverse clinical events at 30 days.

NEUROSHIELD (MEDNOVA)

Device Description

The MedNova NeuroShield is a filter that is mounted on the distal tip of a 0.014-inch guidewire. The filter contains a preshaped nitinol expansion system that facilitates fluoroscopic visualization, accurate deployment, and wall apposition. The filter guidewire is placed within the delivery catheter and is passed through the target lesion. The delivery catheter is then withdrawn, and the filter is deployed. After the vascular intervention, a retrieval catheter is advanced to envelop the filter. The entire device, including the trapped embolic contents, is then withdrawn.

Clinical Trials

Preliminary clinical experience with Neuroshield device for use in carotid stenting has been published.^[24] Between September 1999 and July 2001, a total of 162 patients (164 hemispheres) underwent carotid stenting with filter protection according to prospective protocols evaluating the filter system at three institutions. Angiographic success was achieved in 162 of the procedures (99%), and filter placement was successful in 154 (94%) procedures. Carotid access was unsuccessful in two cases (1%) and filter placement in eight cases (5%). Of the latter, five procedures were completed with no protection, and three were completed using alternative protection devices. On an intention-to-treat basis, the overall combined 30-day rate of all stroke and death victims was 2% (four events: two minor strokes and two deaths). This includes one minor stroke in a patient with failed filter placement, and stenting was completed without protection. There was one cardiac arrhythmic death and one death from hyperperfusion-related intracerebral hemorrhage. There were no major embolic strokes. From these studies, it appears that carotid artery stenting with Mednova filter

protection is technically feasible and safe. Larger comparative studies are now underway.

Mednova has developed a similar device for use in vein graft interventions called the Cardioshield. It is currently being evaluated in the CAPTIVE study (CardioShield Application Protects during Transluminal Intervention of Vein Grafts by reducing Emboli), which is a randomized trial of 800 patients undergoing vein graft intervention. The primary end point will be major adverse clinical events at 30 days.

FILTERWIRE EX (BOSTON SCIENTIFIC)

Device Description

The Filterwire EX (Boston Scientific Corporation) is another filter-type device currently undergoing clinical investigation. It consists of a nitinol filter loop mounted on a 0.014-inch guidewire. The filter material is made of polyurethane and has 80-micron pores to permit anterograde perfusion during deployment (Fig. 4). The filter rotates freely on the end of the guidewire. The device is housed within a 1.3 mm (0.052 inch) delivery sheath. The loop has an off-center, fish-mouth design that facilitates complete apposition for vessels 3.5–5.5 mm in diameter. After the intervention, the device is retracted into the delivery sheath. The trapdoor action of the filter loop allows retention of the embolic debris during retrieval.

Clinical Trials

Early clinical work has demonstrated feasibility and safety in using the device.^[25] From May 16, 2000, to October 26, 2000, a total of 36 lesions in 35 patients were protected using the Filterwire EX system. Of the 36 lesions, 22 (61%) were located in native coronaries, and 14

(39%) were located in SVG. The Filterwire EX device was delivered, deployed, and removed successfully in 33 procedures. In two procedures, the device could not easily cross extraordinarily angled and tight lesions, and, in one other procedure, the device could not be deployed because of abnormal distal anatomy of the vessel. In every procedure in which the Filterwire EX was deployed, retrieval was successful. Embolic material was obtained in 71% of these cases, and only 2 of 31 patients (6%) meeting eligibility criteria experienced major adverse cardiac events. This appears to be an improved rate in comparison to that expected without protection.

The FIRE (Filterwire During Transluminal Intervention of Saphenous Vein Grafts) trial is enrolling up to 800 patients at 70 sites. It is a safety and efficacy trial of treatment with the Filterwire during percutaneous intervention of saphenous vein grafts.

The BEACH (Boston Scientific/EPI: A Carotid Stenting Trial for High-Risk Surgical Patients) Investigation began in February 2002 and is enrolling up to 776 patients in 40 sites. It is investigating the use of the Carotid Wallstent Monorail Endoprosthesis and Filterwire EX embolic protection in carotid stenting. The primary end point is 30-day combined major adverse clinical events.

The CABERNET (Carotid Artery Revascularization Using the Boston Scientific EPI Filterwire EX and the EndoTex Nexstent) is an international, multicenter study of the safety and efficacy of the self-expanding NexStent used in conjunction with the Filterwire for high-risk carotid angioplasty.

ACCUNET (GUIDANT)

Device Description

The AccUNET device consists of a polyurethane filter supported by a nitinol basket frame. The pore size is

Fig. 4 The Filterwire EX of a nitinol filter loop mounted on a 0.014-inch guidewire. The filter material is made of polyurethane and has 80-micron pores to permit anterograde perfusion during deployment. The filter rotates freely on the end of the guidewire. The device is housed within a 1.3 mm (0.052 inch) delivery sheath. The loop has an off-center, fish-mouth design that facilitates complete apposition for vessels 3.5–5.5 mm in diameter. After the intervention, the device is retracted into the delivery sheath. The trapdoor action of the filter loop allows retention of the embolic debris during retrieval.

Fig. 5 The Accunet device consists of a polyurethane filter supported by a nitinol basket frame. The pore size is ≤ 120 microns. It is available in sizes ranging from 4–8 mm in diameter. The filter is mounted on an ACS Hi-Torque Balance Heavyweight coronary wire platform, which is 300 cm in length and 0.014 inch in diameter. The sheathed filter is directed beyond a target vascular lesion and is deployed by withdrawal of the delivery sheath. The filter is then collapsed and retracted into the sheath for removal.

≤ 120 microns (Fig. 5). It is available in sizes ranging from 4–8 mm in diameter. The filter is mounted on an ACS Hi-Torque Balance Heavyweight coronary wire platform, which is 300 cm in length and 0.014 inches in diameter. The sheathed filter is directed beyond a target vascular lesion and is deployed by withdrawal of the delivery sheath. The intervention is then performed over the 0.014-inch wire. The filter is then collapsed and retracted into the sheath for removal.

Clinical Trials

The ACCUNET Trial is a 50-patient registry designed to evaluate the safety and efficacy of the Acculink carotid stent used in conjunction with the Accunet distal protection device. Outcomes will be the acute success of the device as well as a 30-day combined outcome of stroke, death, and myocardial infarction.

The device is also being evaluated in CREST (Carotid Revascularization Endarterectomy versus Stenting Trial), which is an NIH-funded prospective, randomized, multicenter clinical trial of carotid endarterectomy (CEA) versus carotid artery stenting (CAS). CREST includes a lead-in phase for credentialing of interventionalists who have previously been trained and evaluated in CAS. Patients with transient ischemic attack, amaurosis fugax, or non-disabling stroke within 180 days of randomization and ipsilateral carotid stenosis $\geq 50\%$ (defined as $\geq 70\%$ by ultrasound or $\geq 50\%$ by angiography) are eligible for randomization. Follow-up includes clinic visits at 1, 6, and 12 months and then every 6 months and phone contact every 3 months for study duration. Primary

end points are a composite of stroke, myocardial infarction, or death within 30 days and stroke ipsilateral to the study artery after 30 days. A total of 2500 patients will be randomized. After review of early device data, the CREST Executive Committee approved the addition of an embolic protection device in the trial. The CREST Embolic Protection Subcommittee analyzed the clinical data from the study of the ACCUNET Embolic Protection System, and the committee's recommendation to the Executive Committee was approved. In the fall of 2001, a protocol revision to include the ACCUNET Embolic Protection Device was approved by the NIH and the FDA. To date, 52 centers have been selected to participate in CREST, and 21 centers are approved to enroll participants. As of the end of November 2001, 79 participants have been enrolled.

PARODI ANTI-EMBOLI SYSTEM

Device Description

The Parodi Anti-Emboli System (PAES) is an 80-cm guiding catheter with a distal occlusion balloon. The balloon is 7 mm long and can be inflated up to 10 mm. It is placed proximal to the lesion and inflated, which thereby reverses flow in the target vessel. In the carotid artery, the balloon is used to occlude the common carotid, which reverses blood flow in the internal carotid artery. A second occlusion balloon is placed in the external carotid artery, which prevents flow of embolic material from the internal to external carotid artery. This system establishes distal protection without having to cross the target lesion and thereby avoids potential embolization caused by disruption of the plaque during device deployment.

Clinical Trials

To investigate the safety and efficacy of the Parodi antiembolism system (PAES), seven centers participated in a nonrandomized, prospective trial of carotid angioplasty and stenting.^[26,27] PAES protection was used in 30 patients with 15 symptomatic ($>70\%$) and 15 asymptomatic ($>80\%$) stenotic carotid arteries. Safety was defined as achieving sufficient brain oxygenation during flow reversal as determined by level of awareness and motor control. The presence of new or enhanced neurological deficits and death were end points. Performance was based on angiographic evidence of successful retrograde flow. The PAES was positioned in all 30 patients, but technical error and access-related difficulties prevented establishment of reversed flow in two. Among the 28 (93%) patients

treated under PAES protection, one patient developed aphasia after flow reversal, which necessitated balloon deflation between subsequent stages of the procedure. Three other adverse events included one case of bradycardia and two cases of hypotension with dysarthria and facial paresis in one and temporary loss of consciousness in the other. All events resolved with appropriate therapy, and there was no change from baseline in the neurological status or brain scans at 24 hours. There were no strokes or neurological deficits at 30 days. From this early experience, it appears that the PAES can be a safe and effective means of providing protection from embolic complications during carotid stenting. This finding needs to be confirmed with larger randomized clinical trials.

ADVANTAGES AND DISADVANTAGES OF EACH DEVICE

Balloon occlusion devices have been used longer than the other distal protection systems. The most experience has been with the Medtronic Guardwire system. There are many advantages of this type of protection device. The balloons typically allow easy and complete occlusion of a vessel. Particles of any size are trapped in the static column of blood. The balloon devices have smaller crossing profiles and greater flexibility than filters and therefore are generally easier to deliver and withdraw.

Disadvantages of the balloon occlusion technique are related to ischemia due to complete occlusion of blood flow. For most interventions, the procedure time is short enough that the ischemia is well-tolerated. In a large-territory vessel or in one without collateral circulation, the occlusion may not be tolerated. Because aspiration of the debris is required, the procedure has multiple steps and is technically challenging. These procedures are best performed with two experienced operators. Occlusion prevents angiographic visualization during the intervention. Typically, operators will either use noncontrast landmarks or attempt to trap a column of contrast with the occlusion balloon. Balloon and stent lengths tend to be longer to ensure lesion coverage given the time and visualization constraints. In internal carotid artery intervention, there is a risk of embolization to the external carotid, which is not protected by the balloon.

Filter devices are advantageous because they maintain antegrade perfusion during the intervention. The procedure requires fewer steps because aspiration is not required. Preservation of antegrade flow also allows continual angiographic visualization. The bulkiness of the current designs limits their ability to be delivered easily, especially in tortuous vessels. The larger crossing profile may be associated with embolization during delivery of the protection device.

The filters trap the largest particles but allow smaller particles to pass through the pores. It is unclear whether the smaller emboli are clinically significant. Large amounts of liberated plaque can overwhelm a filter, which converts it to an occlusion device.

The flow reversal devices are advantageous because the distal protection is established prior to placing equipment across the target lesion. Transcranial Doppler studies have demonstrated evidence of microemboli just with passage of the distal protection filter or balloon. Difficult and tortuous anatomy does not affect the device as it does not have to be placed across the lesion. The flow reversal can remove particles of any size. The intervention can be performed over any choice of guidewire rather than being limited to the characteristics of the distal occlusion platform.

The chief disadvantage of the Parodi device is that it requires an 11 French arterial sheath. Its initial use was associated with a higher incidence of arterial access site complication. Some patients may not tolerate reversal of flow, particularly if they have contralateral carotid disease. The device is somewhat complicated, and use in the carotid requires a second occlusion balloon for the external carotid branch.

MECHANISMS OF FAILED DISTAL PROTECTION

Distal protection devices can fail by a number of different mechanisms. Device-related vessel injury can be caused by the occlusion balloon or filter, which results in vasospasm, dissection, or thrombosis. The bulkier devices, particularly filters, can become entrapped in the freshly placed stent. Balloon occlusion and flow reversal devices can be limited by prolonged ischemia. Filter devices that become occluded with debris are also at risk for this complication. Distal protection can be lost for a number of reasons. The occlusion balloon may rupture or move during wire exchange, which leads to a loss of protective effect. The export catheter may not clear the embolic material completely, which results in embolization when the occlusion balloon is deflated. Filters may incompletely occlude to the vessel wall, which allows emboli to travel through an unfiltered channel. The pore size may allow passage of small but clinically important particles. Incompletely trapped debris may be liberated from the filter during retrieval.

EVOLUTION OF CURRENT DISTAL PROTECTION TECHNOLOGY

Current distal protection technology can be improved to handle an ever-increasing range of clinical situations. All devices can be improved by reducing their crossing

profile and improving steerability. This will improve their deliverability in severely stenotic or tortuous vessels. It may also mitigate embolization prior to device deployment. The devices can also be improved to reduce the local injury related to balloon/filter deployment. Protection of vessels with complex anatomy including bifurcations, large proximal sidebranches, ostial, and distal lesions is particularly challenging. Device-sizing in totally occluded vessels is also difficult. The problem of prolonged ischemic time can be addressed by simplifying the procedure to allow more rapid intervention. Additional research with filter devices can help determine the optimal pore size to maintain antegrade perfusion without sacrificing protective effect. Finally, debris retrieval can be improved with better aspiration techniques and filter retrieval systems.

FUTURE APPLICATIONS OF DISTAL PROTECTION

It is becoming apparent that distal embolization occurs more frequently than was previously realized. As the field of percutaneous vascular interventions grows, so do the potential applications for distal protection devices.

Acute Myocardial Infarction

Acute myocardial infarction is generally caused by rupture of an atherosclerotic plaque with subsequent platelet deposition and thrombus formation. Lesions are at high risk of embolization during intervention. Use of distal protection devices in native coronary arteries is somewhat problematic due to the inability to protect major sidebranches. The use of distal protection is currently being evaluated in the EMERALD trial in which acute myocardial infarction patients are randomized to conventional angioplasty versus use of the Guardwire distal protection system.

Renal Artery Intervention

Percutaneous intervention of the renal arteries is rapidly supplanting surgery for the treatment of renal artery stenosis. The procedure is associated with a substantial risk of postprocedural decline in renal function. Many postulate that this is due to distal embolization. While the scope of this phenomenon is not yet known, some operators are using distal protection devices in an attempt to minimize this complication.

Superficial Femoral Artery Intervention

Revascularization of the superficial femoral artery (SFA) for lower extremity claudication has many

similarities to vein graft intervention. The vessel is long with generally diffuse disease and is without major sidebranches. Distal embolization is uncommon, but it is likely an underrecognized phenomenon. For this reason, some operators propose the use of distal protection devices during SFA angioplasty.

CONCLUSION

Distal protection devices have been successful in reducing the embolic complications associated with angioplasty of high-risk lesions. The three types of devices being developed have differing properties that can be tailored to individual clinical situations. The majority of clinical experience thus far has been with the balloon occlusion type of devices. The filter and flow-reversal devices are not yet approved in the United States, but they are actively being investigated. Distal protection is rapidly becoming standard-of-care for vein graft and carotid interventions. As the devices continue to evolve and improve, they will be useful for an ever-expanding array of percutaneous procedures.

Drug Delivery, Controlled

M.N.V. Ravi Kumar

Department of Pharmaceutics, National Institute of Pharmaceutical Education and Research (NIPER), Mohali, India

A.J. Domb

Department of Medicinal Chemistry and Natural Products, The Hebrew University of Jerusalem, Jerusalem, Israel

INTRODUCTION

Most drugs, whether taken orally or via injection, are delivered to the body systemically. The medication is expected to circulate through the whole body affecting the cells and the organs that are dysfunctional as well as those that are healthy. Systemic drug delivery floods the body with medication and can cause serious side effects. Conventional drug formulations typically provide a prompt release of drug in a bolus form. For drugs that get cleared rapidly from the body, achieving and maintaining the drug concentration within the therapeutic window requires a multiple dosing regimen, often more than once a day. Such an inconvenient dosing regimen can lead to a lack of patient compliance as well as a significant fluctuation in drug levels in the plasma. Recently, several technical advancements have resulted in the development of new technologies capable of controlling the administration of a drug at a targeted site in the body in an optimal concentration-versus-time profile. The term “drug delivery” covers a very broad range of techniques used to get therapeutic agents into the human body. Polymer-based devices are gaining importance due to their capabilities of controlling the rate of drug delivery, sustaining the duration of therapeutic activity, and/or targeting the delivery of drug to a tissue or organ. Controlled drug delivery using polymers can be achieved via various forms depending upon the end use specification, e.g., hydrogels, nanoparticles, microparticles, transdermal, etc. The advancement in this fascinating area of science, which requires interdisciplinary scientific approach, is enormous. Thus, we restrict ourselves to discussing important issues on polymer-based delivery systems and their mechanism of action with representative applications.

WHY DO WE NEED CONTROLLED-RELEASE SYSTEMS?

The ways in which drugs or new biological products are administered have gained increasing attention in the past few decades. Controlled-release systems

provide numerous benefits over the conventional dosage forms. Conventional dosage forms, which are still predominant in pharmaceutical products, are not able to control either the rate of drug delivery or the target area of drug administration or provide an immediate or rapid drug release. This necessitates frequent administration in order to maintain a therapeutic level. As a result, drug concentrations in the blood and tissues fluctuate widely. In conventional dosage forms, the concentration of an administered drug is initially high, which can cause toxic and/or harmful side effects, and then quickly falls down below the minimum therapeutic level with time elapsed. The duration of therapeutic efficacy is dependent upon the frequency of administration, the half-life of the drug, and the release rate of the dosage form. In contrast, controlled-release dosage forms are not only able to maintain therapeutic levels of drug with narrow fluctuations but they also make it possible to reduce the frequency of drug administration, which in turn can minimize side effects.^[1–12] Drug concentration profile in serum depends on the preparation technology, which may generate different release kinetics resulting in different pharmacological and pharmacokinetic responses in the blood or tissues.

Controlled drug-release formulations (CDRFs) offer several advantages over conventional dosage forms. Some of the salient features of controlled-release formulations are described below.

- The drug is released in a controlled fashion that is suitable for the application.
- The frequency of doses could be reduced thereby enhancing patient compliance.
- The drug could be released in a targeted region. This could be achieved either by tailoring the formulation to release the drug in that particular environment or by timed release of the drug. By targeting drugs, the drug efficacy could be maximized.
- The drug could be protected from the physiological environment for a longer duration of time. Thus the effective residence time of the drug could be extended.

However, controlled-release products do not always provide positive effects for every type of formulation design. Negative effects outweigh benefits in the following circumstances.^[13,14]

- Dose dumping
- Less accurate dose adjustment
- Increased potential for first-pass metabolism
- Dependence on residence time in GI tract
- Delayed onset

The limitations of CDRF technology making some drugs unsuitable for formulations are as follows:^[15]

- There is a risk of drug accumulation in the body if the administered drug has a long half-life, causing the drug to be eliminated at a slower rate than it is absorbed.
- Some drugs have a narrow therapeutic index, and thus, need to be administered repeatedly to maintain the serum drug level within a narrow range. Such drugs may not be feasible for CDRF.
- If the GI tract limits the absorption rate of the drug, the effectiveness of the CDRF is limited (for oral controlled release).
- If a drug undergoes extensive first-pass clearance, its controlled release formulation may suffer from lower bioavailability.
- The cost of CDRF may be substantially higher than the conventional form.

POLYMERS IN CONTROLLED DRUG-RELEASE FORMULATIONS

Polymers have been widely used as excipients that adjust the consistency of creams and liquid formulations, as plasma expanders, and as tablet coatings. Generally, pharmaceutical research is focused on the synthesis and testing of new drug molecules, while less effort is made on the final dosage form. Drugs are almost exclusively administered orally or injected, often at a site remote from the target tissue. However, conventional therapeutic systems suffer from various disadvantages while using the recently developed more potent drugs. The disadvantages include adverse side effects, strongly fluctuating drug levels in the body, poor drug efficacy, and poor patient compliance. The concentration, duration, and bioavailability of the pharmaceutical agents cannot be controlled. Controlled-release technology was anticipated to circumvent these problems.^[15] The ambition was to maintain a therapeutic concentration of a drug in the body for a sustained period of time by releasing the agent in a predictable and controllable fashion. Various natural, semisynthetic and synthetic polymers are in use as the

structural backbone for both controlled-release and conventional drug delivery systems^[6,7,15] (various articles in this encyclopedia describe a variety of polymers used for biomedical applications). Polymers selected in the preparation of the dosage form must comply with the following requirements.

- **Safety:** Harmful/toxic impurities must be removed from polymers before their use in CDRFs. The residual monomers, initiators, and other chemicals used in the polymer synthesis/modification must be removed after the polymerization/modification. The chemicals employed in the polymer fabrication processes (i.e., additives, stabilizers, plasticizers, and catalyst residues) are carefully selected to meet regulatory requirements.
- **Physical and mechanical properties:** The polymers must possess the necessary mechanical properties required for the dosage form design, such as elasticity, compatibility, resistance to tensile, swelling, and shear stresses, and resistance to tear and fatigue.
- **Biocompatibility:** The polymer should not cause significant local irritation to the surrounding tissues. If biodegradable, then the polymer degradation by-products must be nontoxic and non-immunogenic and noncarcinogenic.

There are many ways to synthesize new polymers and modify existing polymers. Different monomers (for addition polymerization or condensation polymerization) may be used or existing polymers may be modified. However, only a handful of polymers are used in pharmaceutical drug delivery systems due to their commercial availability, established biocompatibility, and government registration. Most polymers used in pharmaceutical dosage forms were not originally designed for this purpose. However, the production of new, life-saving, genetically engineered drugs (peptides and proteins), that have characteristically short half-lives presents an opportunity for significant research in the area of polymer development in order to prolong their therapeutic effects in the human body.

POLYMER FABRICATION AND DRUG ENCAPSULATION

Encapsulation of the therapeutic agent into a polymer matrix can be brought about by a variety of methods. These methods depend on the desired fabrication of the polymer matrix. Some of the common techniques used for drug encapsulation for different polymer forms are described in this section.

Polymer Films and Rods

Polymer films can be cast by various techniques including dip coating, spin coating, hot-melt casting, and solvent casting. Typical applications for polymer films are in the medical device industry as coatings for controlled-release devices and implants such as stents. These applications require the polymer to be elastomeric to allow flexible films at micron-size thickness. The films can be cast with the drug encapsulated by homogenization/solubilization in the polymer melt/solution. The polymer film could also be extruded using a single or double screw extruder. Screw extrusion is also used to fabricate another form of polymer, i.e., drug encapsulated rods/cylinders. Such extruded rods could be implanted subcutaneously to provide sustained drug delivery. There are several reports describing the preparation techniques and application of polymer films and rods.^[16,17]

Polymer Particulates

For applications in drug delivery, the polymer formulation should be present as an injectable form. From this perspective, the polymer-drug combination could be fabricated as microspheres that can be suspended in an injection vehicle prior to injection. Subcutaneous or intramuscular injections are used for microspheres, whereas smaller particles (in the nano range) can be injected intravenously (Fig. 1). Although, a number of microencapsulation techniques have been developed and reported to date, the choice of the technique depends on the nature of the polymer, the drug, the intended use, and the duration of the therapy.^[18–20]

Fig. 1 Atomic force microscopic picture of chitosan nanoparticles. (Photo by M. N. V. Ravi Kumar. Unpublished data.)

Microspheres can be fabricated using a variety of techniques, some of which are described below.

- **Spray drying:** The polymer and drug are dissolved in a common solvent and spray atomized to create microspheres. This technique is useful to create particles in the size range of up to 50 microns, wherein the polymer has a sufficiently high glass transition temperature to allow formation of discrete microparticles during atomization. The size and morphology of microparticles created using the spray drying technique depends on the nature of the polymer as well as the spray dryer operating parameters, including chamber volume, flow rate, and nozzle design.^[21]
- **Emulsion technique:** The drug is emulsified/dispersed in the polymer solution. This emulsion/dispersion is further emulsified in a surfactant bath to allow formation of solid microparticles consisting of the drug encapsulated within the polymer matrix. Variations of this technique include single emulsion and double emulsion microencapsulation. Since microparticles are created during the slow evaporation of the solvent, this technique is also termed as solvent evaporation technique. Solvent evaporation/emulsification techniques are useful when the desired particle size is higher and/or when the drug is not soluble in the organic solvent. A schematic representation of routine emulsion technique to make nano- and microparticles is shown in Fig. 2.
- **Freeze spray atomization:** A suspension of drug in an organic polymer solution is atomized into a liquid nitrogen bath. Absolute ethanol is added to extract the organic solvent from the bath. This process is particularly feasible for proteins since the protein is in a solid, less reactive form, making it less susceptible to damage during processing. Furthermore, the low temperature maintained throughout the process prevents thermal denaturation of the protein.^[22] This process has been utilized in the production of the first commercially available polymer-based, sustained-release protein formulation, Nutropin Depot, marketed by Genentech.

Polymer Gels

Drug encapsulation for injectable gels could be carried out by simply mixing the drug into the polymer gel. To obtain sustained release, the polymer gel should acquire some viscosity upon injection into the body. Such in situ gelation characteristics could be achieved by various mechanisms as:

- **Temperature-induced gelation:** Thermoreversible gelation could be obtained for ABA-type

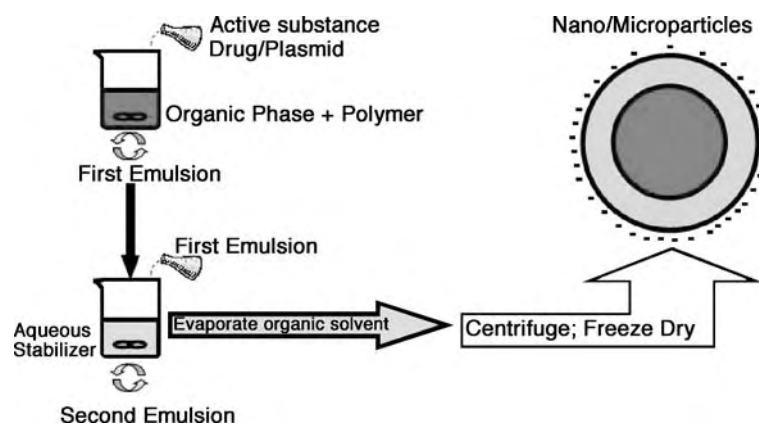

Fig. 2 Routine emulsion technique to make nano- and microparticles.

block copolymers wherein A denotes a hydrophilic segment and B denotes a hydrophobic segment. Because of the alternating block structure, such polymers undergo micellization driven by increasing temperature. The formation of micelles is thermodynamically favorable in ABA block structures, especially when the hydrophobic-hydrophilic balance is appropriately achieved. Examples of such thermoreversible polymers include PEG-PLGA-PEG^[23] and Pluronics, which are ABA-type block copolymers of PEG and PPG. In each of the examples, the polymers could be engineered to be solutions at room temperature and convert into semisolid gels at body temperature. Recently, this concept has also been applied to chitosan gels, which are intact for 7 days when injected subcutaneously in rats (Fig. 3).^[24–26]

- pH-induced gelation: If the polymer is soluble at a certain pH and is insoluble at pH 7.4, then it would undergo pH-induced gelation on injection into the body. Examples of such polymers include synthetic polymers such as polyacrylic acid and natural polymers such as chitosan.
- Solvent-induced gelation: Solvent-induced gelation could be obtained for a water-insoluble polymer dissolved in a biocompatible solvent to create an injectable solution. When the solution is injected, the solvent diffuses out and water from the physiological environment diffuses in. This diffusion process leads to a phase transition for the polymer as it goes from the solvent phase to a nonsolvent phase and forms a semisolid gel.^[27] Several factors such as polymer crystallinity, hydrophilicity, and water uptake govern the sol-gel transition and subsequently the drug release characteristics.

CLASSIFICATION OF CONTROLLED DRUG-RELEASE FORMULATIONS

Drug delivery systems have been classified on the basis of route administration, for example, parenteral, enteral, respiratory, transdermal, etc. (Fig. 4). Controlled-release systems are based on the release mechanisms of erosion, diffusion, or chemical control. For example, under enteral drug delivery systems, release of a drug can be controlled by various mechanisms such as diffusion, osmosis, or a chemically controlled mechanism. In a broad sense, these devices fall into two types: reservoir devices and matrix devices. The former involve the encapsulation of a drug within the polymeric shell, while the latter describes a system in which a drug is well dispersed throughout the polymer matrix.

Fig. 3 Subcutaneous gel-implants had bean-like shapes and remained quite morphologically intact when excised at 3, 6, 12, 24, 48, and 72 hr and 7 days. All implants were intimately integrated within the subdermal fibrous membranes. (Adapted from Ref. [24].)

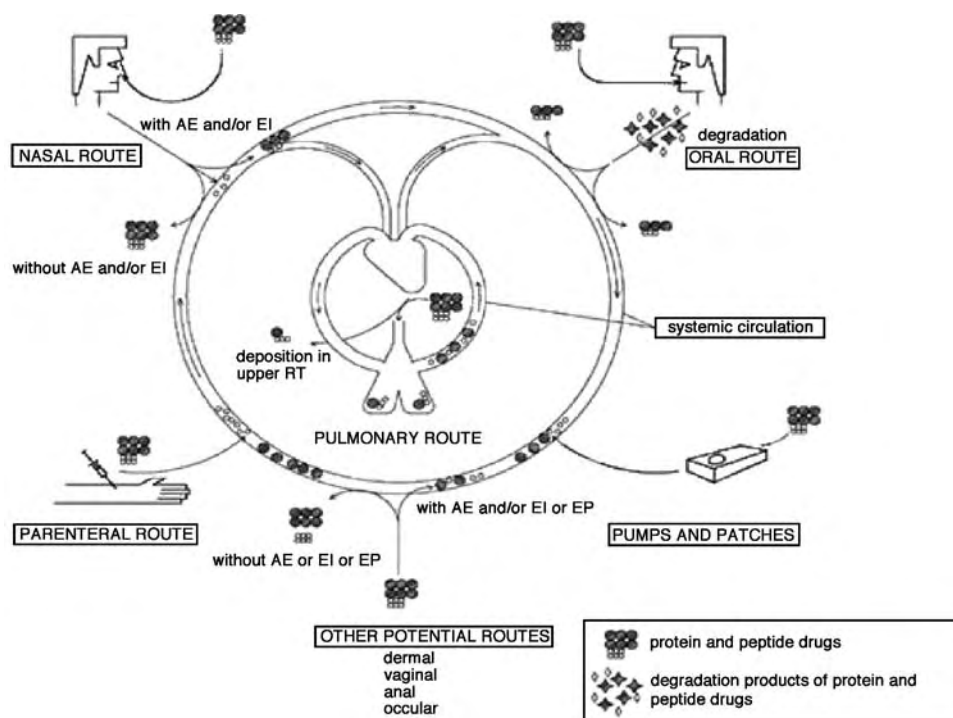

Fig. 4 Clinical and potential routes of administration for therapeutic proteins and peptides. Note that small peptides may be absorbed in limited amounts without absorption enhancers (AE) and/or enzyme inhibitors (EI) via some routes (e.g., nasal). EP, electroporation/iontophoresis (specific for dermal delivery); RT, respiratory tract. (Adapted from Ref. [28].)

Some examples of controlled-release systems are described briefly here.

Diffusion-Controlled

Two types of diffusion-controlled systems have been used including reservoir systems (drug coated by a polymer membrane) and matrix systems (drug dispersed in a polymer matrix). In the reservoir systems, the drug is encapsulated by a polymeric membrane through which the drug is released by diffusion. This polymeric membrane is known as the solution diffusion membrane (implying the mechanism of drug transport) and can be microporous or nonporous. In a nonporous membrane, drug release is governed by the diffusion through the polymer and, thus, release can be controlled by selecting a polymer showing desirable drug solubility and diffusivity in the polymer matrix. In microporous membranes, pores with the size range 1.0 nm to several hundred nm are filled with a drug-permeable liquid or gel medium. Thus, diffusion of the drug through the medium in the pore will dominate the drug-release process. These systems are very useful in the delivery of high-molecular-weight drugs such as protein and peptide drugs. Singh et al.^[29] reported the theoretical considerations of designing and engineering a “barrier coated-reservoir” type of a delivery system for theophylline using poly (vinyl alcohol) (PVA) as

the coating material. After getting the desired theoretical in-vitro release profile, in-vivo studies were carried out on a dog model.

In monolithic systems, the drug is dissolved or dispersed homogeneously throughout the water-insoluble polymer matrix, which may be microporous or nonporous.^[30] Monolithic systems are not suitable for zero-order release; however, it can be achieved by adjusting the physical shape of the device.^[31]

Dissolution-Controlled

Dissolution-controlled systems can also be classified as either reservoir or matrix devices. Polymers used for these devices are generally water-soluble but water-insoluble polymers can also be used as long as they absorb water and disintegrate the drug. In reservoir devices, drug particles are coated with water-soluble polymeric membranes. The solubility kinetics of the membrane depend on the thickness of the membrane and the type of polymer used. Thus, drug release can be achieved and controlled by preparing devices with alternating layers of drug and polymeric coats or by preparing a mixture of particles that have different coating characteristics. Matrix dissolution devices are generally prepared by compressing a powder mix of drug and a water-soluble or water swellable polymer. They can also be made by casting and drying a

polymer solution containing a suitable amount of dissolved or dispersed drug. A variety of other excipients may optionally be included to aid formulation properties. The influence of excipients and formulation factors on the dissolution behavior of methyl hydroxyethyl cellulose (MHEC)-tablets is investigated in Ref. [32]. The use of drugs with higher solubility leads to a slight acceleration of the release due to the contribution of diffusion to the release process (caused by channels formed due to drug solubilization). Furthermore, alterations of the composition of the dissolution medium affect drug release.

Degradation/Erosion-Based Systems

Though early research on polymer-based controlled-release systems involved both degradable and non-degradable polymers, degradable polymers are preferred for parenteral drug delivery applications.^[33] Degradation of the polymer eliminates the need for surgery to recover the spent polymer after the entire drug is released. It also reduces issues related to the long-term safety of the polymer. For biodegradable polymers, release of the drug is often intricately tied up with the polymer degradation profile. The drug can be either physically entrapped in the polymer matrix, wherein it will be released by diffusion and/or erosion of the polymer mass, or chemically attached to the polymer backbone. In such a situation, the drug is released by the enzymatic/hydrolytic cleavage of the chemical bond between the polymer and the drug. A further classification of polymer degradation is established based on the polymer mass erosion patterns. If the polymer is hydrophobic, then it restricts the diffusion of water into its matrix and hence polymer erosion may be restricted to the surface. A more conventional case for the majority of polymers including PLA and PLGA is when erosion occurs throughout the bulk of the polymer matrix (termed bulk erosion). Bulk erosion is associated with a drop in pH within the interior of the matrix. Though such a pH drop is detrimental to pH-labile drugs, it could be utilized to stabilize certain type of basic drugs such as camptothecin.^[34]

Various diffusion models have been proposed for different scenarios and embodiments.^[35] Ritger and Peppas^[36] proposed an empirical equation that has been successful in modeling the drug release for several formulations. This equation correlates the fraction of drug released to the time as:

$$M_t/M_o = kt^n$$

M_t and M_o denote the drug release at time t and total amount of drug in the formulation, respectively. The empirical coefficients k and n are related to the kinetics and diffusion mechanism, respectively. When $n=0.5$,

this equation obeys Fick's law of diffusion. On the other hand, $n=1$ denotes case II diffusion to play a prominent role. The key feature of this model is its simplicity as well as its ability to offer insights into the diffusion mechanisms based on the value of k .

Mathematical models have also been proposed to incorporate polymer degradation kinetics as an integral part of the theoretical framework explaining drug release characteristics.^[37] Similarly, kinetic models have been used to explain degradation profiles of the polymer.

Osmotic Delivery Systems

Osmotic controlled devices compose a core reservoir of drugs, with or without osmotically active salt, coated with a semipermeable membrane. The presence of salt or drug molecules creates an osmotic pressure gradient across the membrane and the diffusion of water into the device gradually forces the drug molecules out through an orifice made in the device. For a durable device, the mechanical strength of semipermeable membrane should be strong enough to resist the stress building inside the device. The drug release rate from the osmotic devices, which is directly dependent on the rate of external water diffusion, can be controlled by the type, thickness, and area of the semipermeable membrane. Alza developed osmotic devices such as an elementary osmotic pump system for oral administration and Alzet an osmotic pump for implant. Singh et al.^[38] discussed osmosis as a phenomenon for controlled drug delivery, along with the device concepts Rose Nelson pump, Higuchi osmotic pump, and Higuchi Theeuwes osmotic pumps.

Ion-Exchange Systems

Polyelectrolytes have been used as cross-linkers to form water-insoluble ion-exchange resins. The drug is bound to the ionic groups by salt formation during absorption and released after being replaced by appropriately charged ions in the surrounding media. For cationic drug delivery, poly(styrene sulfonic acid) and poly(acrylic acid) can be used as anionic ion-exchange resin, where sulfonic and carboxylic group make the complexes with cationic drugs and hydrogen ions and/or other cation such as sodium or potassium ions activate the release of cationic drugs by replacing them from the drug-resin complex. Though cationic ion-exchange resinlike poly(dimethylamino ethyl methacrylate) has been used for the delivery of anionic drug, in which basic groups, namely amino or quaternary amino groups, make a complex with anionic drugs. The interaction of a series of *o-n*-acyl propranolol prodrugs (I, R=C1-9 alkyl or Me3C) with strong cation exchange resins is reported and various variables

that control loading and release profiles were investigated.^[39] The effect of *o-n*-acyl chain length on the loading and release profiles was detected by molecular size; for example, the loading was inhibited for the groups with increased size and release rates were reduced. Again, this enables some control of release profiles but the approach was found to be most suitable for drugs that were active at low doses, which allows full use of these variations without the necessity of large amounts of resin in the delivery system. Sometimes, the ion-exchange resins are additionally coated with a polymer film, such as acrylic acid and methacrylate copolymer or ethylcellulose, to regulate the swelling of the resin and to further control the drug release. The Penkinetic system is an example of the devices based on these mechanisms to deliver dextromethorphan from the ethylcellulose-coated poly(styrene sulfonate).

Polymeric Prodrugs

Many water-soluble polymers possess a functional group to which drug molecules can be covalently attached, and thus these polymers that have no therapeutic effect serve as drug carriers. The drug molecules are gradually released from the polymer by hydrolytic or enzymatic cleavage. If the cleavage occurs by chemical hydrolysis, the drug release depends on the nature of the covalent bonds and pH of the environment, but this release is very slow in the body. If the drug molecule is released by enzymatic hydrolysis, the release is mainly dependent on the concentration of enzymes. Thus, the exact release profile depends on the in-vivo condition, not on the delivery system itself. To be a useful carrier, a polymer should possess certain features:

- The polymer should remain water-soluble even after drug loading.
- The molecular weight of the polymer should be large enough to permit glomerular filtration but small enough to reach all cell types.
- Drug-carrier linkages should be stable in body fluid and yet degradable after capturing in target cells.

This can be achieved by making the linkage degradable by lysosomal enzymes, in which the polymer is nontoxic, non-immunogenic, biocompatible, and degradable by lysosomal enzymes to be eliminated from the body after releasing drugs. Starch derivatives, dextran, poly(aminoacids), PVP, poly(hydroxypropyl methacrylamide), and arabinogalactan have been used as polymeric drug carriers.^[6,7,11,40,41]

Magnetically stimulated systems

The two principal parameters controlling the release rates in these systems are magnetic field characteristics

and mechanical properties of the polymer matrix. It was found that when the frequency of the applied field was increased from 5 to 11 Hz, the release rate of the bovine serum albumin (BSA) from EVAc copolymer matrices increases in linear fashion.^[42] The mechanical properties of the polymeric matrix also affect the extent of magnetic enhancement.^[42] For example, the modulus of elasticity of the EVAc copolymer can be easily altered by changing the vinyl acetate content of the copolymer. The release rate enhancement induced by the magnetic field increases as the modulus of elasticity of EVAc decreases. A similar phenomenon was observed for cross-linked alginate matrices: higher release-rate enhancement for less rigid matrices.^[43] Edelman et al.^[44] also showed that enhanced release rates observed in response to an electromagnetic field (50 G, 60 Hz) applied for 4 min were independent of duration of the interval between repeated pulses.

Photostimulated systems

Photoresponsive gels reversibly change their physical or chemical properties upon photoradiation. A photoresponsive polymer consists of a photoreceptor, usually a photochromic chromophore, and a functional part. The optical signal is captured by the photochromic molecules and then the isomerization of the chromophores in the photoreceptor converts it to a chemical signal. Suzuki and Tanaka^[45] reported a phase transition in polymer gels induced by visible light, where the transition mechanism is due to the direct heating of the network polymer by light.

Ultrasonically stimulated systems

Kost et al.^[46] proposed that cavitation and acoustic streaming are responsible for the augmented degradation and release of biodegradable polymers. Miyazaki et al.^[47] speculate that the ultrasound caused increased temperature in their delivery system, which may facilitate diffusion.

Electrically stimulated systems

In late 1980s Grimshaw et al.^[48] reported four different mechanisms for the transport of proteins and neutral solutes across hydrogel membranes:

- Electrically and chemically induced swelling of a membrane to alter the effective pore size and permeability
- Electrophoretic augmentation of solute flux within a membrane
- Electroosmotic augmentation of solute flux within a membrane

- Electrostatic partitioning of charged solutes into charged membranes

Kwon et al.^[49] studied drug release from electric current-sensitive polymers. Edrophonium chloride, a positively charged solute, was released in an on-off pattern from a matrix device by an electric field. The mechanism was explained as an ion exchange between positive solute and hydroxonium ion, followed by fast release of the charged solute from the hydrogel. The fast release was attributed to the electrostatic force, the squeezing effect, and the electroosmosis of the gel. However, the release of neutral solute was controlled by diffusion affected by swelling and deswelling of the gel.

REPRESENTATIVE APPLICATIONS

Controlled Release of Peptides and Proteins

Sustained-release applications are especially useful for proteins/peptides due to their short half-lives which require frequent injections.^[50] This concept was first utilized commercially in Lupron Depot, which was introduced as a sustained release formulation of a luteinizing hormone-releasing hormone (LHRH) using leuprolide acetate, with poly(lactic acid) as the polymer.^[51] Following the success of Lupron Depot, other sustained release formulations of LHRH analogs have also been commercialized including Zoladex, wherein the LHRH peptide is encapsulated in PLA extruded rods, and Trelstar depot, wherein the peptide is encapsulated in PLGA polymer matrices.

Recently, a once-in-4-weeks formulation of a cyclic peptide Octreotide, encapsulated in biodegradable PLGA-glucose polymer matrix, has also been commercialized under the trade name Sandostatin LAR (Novartis Pharmaceuticals Corporation).^[52] In 2000, a human growth hormone sustained-release formulation (Nutropin Depot) became the first polymer-based sustained release formulation of a therapeutic protein to receive marketing approval from the U.S. Food and Drug Administration. This commercialized formulation encapsulates a zinc-complexed form of recombinant human growth hormone in a PLGA matrix.^[21] Other therapeutic proteins that are being tested for encapsulation in polymer matrices include bone morphogenic protein,^[53] erythropoietin,^[54] and nerve growth factor.^[55]

Controlled Release of Antirestenotic Agents from Stent Coatings

Stents are tiny wire scaffoldlike devices that have become the most successful and widely used innovation

in interventional cardiology of the last decade. These devices are inserted inside blocked sections of coronary arteries and expanded into place using a balloon catheter in a procedure called an angioplasty. In as many as 40 percent of patients receiving angioplasty, a new blockage develops at the site due to scar tissue growth and inflammation, a condition referred to as restenosis. More than 500,000 Americans are treated for restenosis annually. Stents coated with a biocompatible polymer encapsulating an antirestenotic agent have proven to be a successful therapy to reduce or eliminate restenosis. Several drugs including cytostatic agents (such as Rapamune), antiproliferative agents (such as Paclitaxel), and anti-inflammatory agents have been encapsulated in micron-thick films that coat the metallic stent.^[56] The polymers used for this application are required to be elastic, biocompatible, and hemocompatible. Lewis and coworkers^[57] demonstrated the use of phosphorylcholine-based polymers for this application. Various other polymers have also been tested for this purpose.^[58,59]

Controlled-Release Systems for Cancer Treatment

By providing sustained release at the desired site, high doses of toxic drugs can be delivered to the site without introducing the drug into systemic circulation. This results in a major advantage for the administration of chemotherapeutic drugs, wherein the drugs can be encapsulated into polymer matrices and administered directly into the tumor area. Gliadel[®] (Guilford Pharmaceuticals) implant is a product based on the aforementioned concept, encapsulating a chemotherapeutic agent carmustine into a biodegradable polymer, fabricated as a dime-sized wafer. Several wafers are implanted by the surgeon into the brain cavity during a tumor resection surgery. By direct release of the drug in the tumor region in the brain, the problem of overcoming the blood-brain barrier is resolved. Also, high doses of the chemotherapeutic agent are delivered at the tumor site, thus making the therapy significantly more effective than systemic administration. Other chemotherapeutic agents that are also being developed as sustained-release formulations include paclitaxel and cisplatin.^[60]

The biggest success of polymer-controlled release systems in cancer therapy, however, has been in the area of prostate cancer treatment. This therapy is unique because it uses a hormone suppressant rather than a chemotherapeutic agent to minimize cancer cell growth in the prostate. Several products currently in use include Lupron Depot (TAP Pharmaceuticals), Zoladex (Astra-Zeneca), and Trelstar Depot (Debio RP, Pharmacia). Lupron Depot involves PLA

Table 1 Controlled-release products in market

Technology	Product/drug	Application	Organization
Liposome-based formulations	Evacet (Doxorubicin)	Breast cancer and other cancers	Elan with acquisition of Liposome Inc.
One-yearly drug implant	Leuprolide (Viadur)	Prostate cancer	ALZA
Intradose injectable gel	Cisplatin/ epinephrine	Recurrent or refractory head and neck cancer	Matrix Pharmaceuticals Inc.
Biodegradable microsphere for sustained release	Medisorb	Delivery of peptides and small molecules	Alkermes Inc.
Sustained-release injections	ProLease	Delivery of fragile proteins and small bioactive molecules	Alkermes Inc.
Time release oral drug release	Pulsincap	Drug release at predetermined time or location in the GI-tract	RP scherer corporation
Oral controlled-release system to control the release of a specific drug	Geomatrix	Predetermined therapeutic objective for a drug	SkyePharma

microspheres and Zoladex formulation is an extruded rod, whereas Trelstar depot consists of PLGA microspheres. All of these drugs incorporate LHRH analogs.

Sustained Release of Drugs for CNS-Related Disorders

Another area of application for polymer-based controlled-release technologies is for the sustained delivery of drugs for central nervous system (CNS)-related disorders. CNS-related drugs include a wide range of therapeutics including pain management agents, drugs to prevent substance abuse, and drugs for conditions such as schizophrenia, Parkinson's disease, and Alzheimer's disease. Drugs such as lidocaine and bupivacaine have been studied for sustained local anesthesia at the site of surgery.^[61] For this application, the anesthetic agent is encapsulated in a biodegradable polymer and injected in the proximity of the site of pain. The drug is released facilitating high concentrations at the local site without reaching the threshold levels of systemic toxicity. In other cases such as schizophrenia, Parkinson's disease, and Alzheimer's disease, sustained release of the medication may reduce the chance of missed doses and aid in an effective dose regimen.

COMMERCIALY AVAILABLE CONTROLLED-RELEASE SYSTEMS

Controlled release has had a good impact among the various drug delivery technologies due to patient compliances, safety of the drug, and minimum side

effects. It had been estimated that the world's pharmaceuticals sales reached nearly \$400 billion during the year 2000, and that about 12.5%, or \$50 billion, went toward drugs involving special drug-delivery technology. Sales of drug-delivery products are expected to more than double to \$104 billion in 2005. More than 20% of the world's drug-delivery products sold in 2005 are estimated to involve controlled drug-release technologies. Examples of controlled-release technologies available in the market place are given in Table 1.

INTRODUCTION

Elastomeric proteins are widely distributed among a diverse range of animal species and tissues in which they have evolved precise structures to perform specific biological functions. These proteins, which include abductin,^[1] tropoelastin,^[2,3] bysuss,^[4] silk,^[5,6] and titin all possess rubberlike elasticity. This flexibility enables them to undergo high deformation without rupture, store energy involved in deformation, and then recover to their original state when the stress is removed. Significantly, the resilience of these bioelastomeric proteins dominates low-strain mechanical responses, which minimizes fatigue and failure due to repetitive loads by preventing the dissipation of transmitted energy into heat. In man, elastin is an important component of tissues subjected to repetitive strain, such as the arterial wall, aortic and mitral valves, plus skin and pulmonary alveoli. In certain circumstances, elastin also serves an important physiologic role by facilitating tissue shape recovery upon deformation. A case in point is respiration, which is dependent upon effective air exchange that is linked to rapid alveolar recoil during expiration.

Although elastin fibers are structurally complex and may contain glycoproteins and glycosaminoglycans, the physical properties of the network have been attributed primarily to the elastin protein component produced from the soluble precursor tropoelastin. The ability of this protein to exhibit rubberlike elasticity relates both to its primary and secondary structure as well as to those features such as protein self-assembly and other intermolecular interactions that dictate the formation of true or virtual networks. The objective of this article is to provide an overview of the structure and properties of elastin and elastin-related proteins as well as provide a brief description of their potential applications as novel biomaterials.

STRUCTURE OF THE ELASTIN GENE

While the primary focus of this section is the description of structure-function relationships that

underlie the unique potential of elastin and elastin-related polymers as biomaterials, it should be recognized that recent efforts in tissue engineering have also been directed at manipulating the expression of elastin through metabolic or genetic approaches in order to enhance the functional performance of cell-based tissue engineering constructs. Thus, it is important to note that the elastin gene exists as a single copy localized on chromosome 7q11.1-21.1 where it is characterized by small exons (27–265 bp) that are interspersed between large introns.^[6] Tropoelastin, the soluble noncross-linked precursor of elastin, expression is primarily under pre-translational control with potential control regions in untranslated regions, intronic regions, and promoter regions. But, posttranslational mechanisms that control protein expression have also been described.^[7] For example, decreased tropoelastin synthesis due to mRNA destabilization has been observed in aortic smooth muscle cells isolated from elderly animals.^[8] Furthermore, growth factors such as transforming growth factor- β , insulin-like growth factor I, vitamin D, and interleukin-1 α have all been shown to modulate tropoelastin expression.^[7]

ELASTIN PROTEIN STRUCTURE

Determination of the Primary Structure of Elastin

Defining the primary sequence of elastin was initially difficult due to its unusual physiochemical properties, including its remarkable resistance to enzymatic, chemical, and physical degradation. These properties have been attributed to both its intrinsic molecular structure and its highly cross-linked state. In 1969, Partridge^[9] provided insight into the complex and varied nature of the elastin cross-links by determining that four lysine residues—two from each elastin chain—could combine to form desmosine and isodesmosine crosslinks while two lysine residues were capable of forming an individual cross-link that is termed lysinonorleucine. With insight into cross-link

formation, the soluble precursor, tropoelastin, could be produced through an inhibition of these processes. This was accomplished by raising pigs on a copper-free diet, which limited the activity of lysyl oxidase,^[10,11] the critical copper-dependent enzyme responsible for oxidizing lysine residues. With a soluble precursor protein in hand, elastin's primary structure was determined.

By the early 1970s, Gray and Sandberg^[12] began to elucidate elastin's amino acid sequence with the identification of alanine-lysine rich sites that were presumed to be important for cross-linking and glycine-proline-valine rich sequences. Repeat sequences of Val-Pro-Gly-Val-Gly and Val-Pro-Gly-Gly were frequently identified between potential cross-linking regions, and it was postulated that these sequences were responsible for elastin's unusual extensibility and fatigue resistance. In the process, Gray and Sandberg established that elastin was a fibular protein composed of alternating segments of cross-linked and loosely coiled regions, which they referred to as oiled coils. Thus, while Hoeve and Flory^[13] demonstrated in 1974 that the driving force for the spontaneous recoil of stretched elastin is entropic in origin, which is consistent with classical theory of rubber elasticity, an apparent paradox to this conceptual picture of elastin were these and other experimental results that confirmed that, at a supra-molecular level, the conformation of elastin was not that of a random coil that is typical of polyisoprene or other classic nonprotein based elastomers.

Further molecular insight into elastin's structure was subsequently provided by a comparative analysis of human^[6] and bovine^[14] elastins and their gene structure. Human elastin,^[6] which consists of 786 amino acids and has a molecular weight of approximately 70 kDa, exhibits significant homology with both DNA and amino acid sequences of elastins isolated from chick,^[15] bovine,^[14] and rat^[16] tissue. In all cases, the amino acid composition is remarkable for a high content of Gly, Ala, Val, and Pro; a scarcity of Arg relative to lysine; absence of His, Cys, Met, and Trp; and a very low frequency (<5%) of polar amino acids. The C-terminus of tropoelastin is highly conserved among all species tested. The highly basic terminus region contains the only two Cys residues in elastin and ends with a positively charged RKRK sequence.^[7] The loss of lysine through the formation of cross-links is the main difference between soluble tropoelastin and insoluble elastin.^[12] Indik et al.^[6] was the first to isolate the human elastin cDNA clone and confirmed the presence of coding regions for both hydrophobic domains as well as hydrophilic regions rich in lysine residues, as suggested by protein sequencing studies. Of significance, they demonstrated that these regions were coded by separate exons of the 17.8 kb elastin gene. Although alterations in mature elastin mRNA produced by alternative splicing has been noted, the functional significance of these splicing events currently remains unknown (Fig. 1).

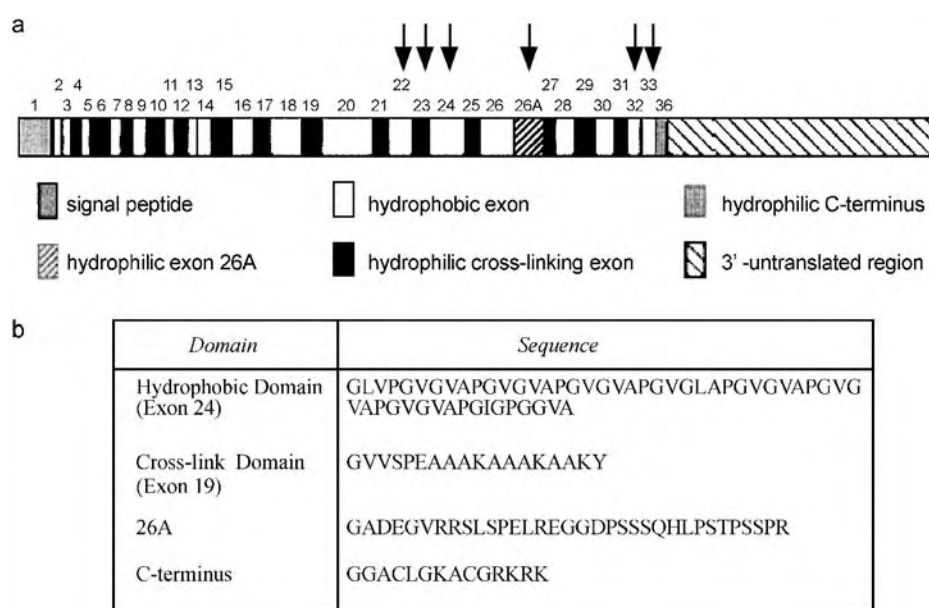

Fig. 1 Structure of human tropoelastin: a) cDNA structure; and b) amino acid sequences of selected domains. Most of the gene consists of exons encoding hydrophobic and cross-linking regions which alternate. Typical sequences are shown in (b). Exon 26A is an unusual hydrophobic exon of unknown function that does not encode any lysine residues. Thus, it is not involved in lysyl oxidase mediated cross-linking. Exon 36 encodes a hydrophilic C-terminus as well as a large three-foot-untranslated region. Exons subject to alternate removal by splicing are marked with an arrow. (Used with permission from Vrhovski and Weiss. From Ref. [7].)

Secondary and Tertiary Structure of Elastin

In applying their knowledge of the primary sequence of elastin, Gray and Sandberg were the first to propose a molecular model for elastin's secondary structure, the β -spiral. Moreover, additional spectroscopic studies confirmed the presence of α -helical and β -turn conformations and a twisted-rope organization imaged by electron microscopy. In an effort to relate a growing understanding of elastin's molecular structure to its mechanical properties, liquid drop and oiled coil models were proposed as an alternative to the random coil model following the identification of both hydrophobic and hydrophilic elastin protein domains. The liquid drop model assumed that, when hydrated, elastin could be viewed as a two-phase system such that hydrophobic globular domains (oil droplets) were connected by hydrophilic cross-links. When subjected to strain, additional hydrophobic regions containing Val and Pro residues would be exposed to surrounding water, which causes a decrease in entropy with a predilection for recoil due to an entropic driving force.^[17,18] In an extension of the liquid drop model, the oiled coil model considered elastin to be composed of globular units composed of broad, coiled hydrophobic regions separated by cross-linked α -helical regions.^[12] Although high-resolution NMR and X-ray crystallography structures have yet to be obtained, subsequent investigations by Urry, Tamburro, et al.^[13,19-24] have elaborated more refined models in order to reconcile the entropic origins for elastin's tensile characteristics and its known molecular structure.

The Tamburro model is largely derived from studies of the GXGGX repeat sequence in which G represents glycine and X is a hydrophobic amino acid.^[25,26] The model suggests that there are two major families of folded or quasifolded structures (type I and type II β -turns, γ -turns, and half-turns) and extended or quasiextended structures (β -sheets, polyproline II conformation) that are dynamically interchanging among themselves and, in the case of β -turns, sliding along the chain.^[25-29] In the stretched chain, a reduction of phase-space volume and the development of hydrophobic interactions allow only high-frequency, low-amplitude motion. In structural terms this would be consistent with less flexible β -pleated sheets. On relaxation, larger amplitude motions are characterized by high dynamic entropy.^[30]

The Urry model is based upon studies with synthetic polymers derived from the pentapeptide unit (VPGVG)_n.^[31] This sequence occurs frequently along the elastin chain, albeit in a different region than that containing the GXGGX sequences. Urry noted by NMR and circular dichroism spectroscopy that proline, due to its rigid imino acid structure, induces a type II β -turn when associated with glycine. As a

consequence, hydrogen bond formation between the valine residues located in the 1st and 4th positions of pentapeptide repeat sequence is facilitated and gives rise to helical β -spiral. One type II β -turn is present per pentameric unit and, as a group, acts as spacers between dipeptide VG segments, which can undergo large-amplitude, low-frequency rocking motions. On chain extension, a decrease in amplitude of the rocking motion causes a large decrease in the entropy of the segment. In turn, this provides the driving force for a return to the relaxed state.

Further insight into elastin's tertiary structure has also been obtained by a consideration of its propensity to coacervate or aggregate in aqueous solution upon heating. The temperature above which coacervation occurs, which is referred to as an inverse transition temperature (T_i), or the lower critical solution temperature (LCST) in the synthetic polymer literature, appears to be associated with folding and assembly of elastin molecules that are individually organized as loose β -spiral chains.^[32] This phenomenon can be explained by the interaction of water molecules with the hydrophobic regions of the β -spiral. In brief, water forms an ordered arrangement around the hydrophobic regions of tropoelastin at low temperature, which maintains the protein in an unfolded state. Upon increasing temperature, the surrounding water becomes more disordered and allows the hydrophobic segments to form a more ordered β -spiral.^[32] This structure is inherently in an equilibrium state since the positive entropy change from the disordering of surrounding water is greater than the negative entropy arising from the formation of the β -spiral.^[33] Since the interactions of water with the elastin chain are dependent upon the polarity of the substituent residues, the inverse transition temperature (T_i) provides a measure of the relative hydrophobicity of the substituent residue.^[31]

TROPOELASTIN ASSEMBLY AND ELASTIN ULTRASTRUCTURE

Insight into the formation of higher order elastin structures in vivo, such as fibers and fiber networks, have been provided by in-vitro studies, which have demonstrated, that, with an increase in temperature to 37°C, tropoelastin exhibits an increasing rate of aggregation or coacervation. It is noteworthy that tropoelastin assembly in aqueous solution at temperatures of up to 50°C is characterized by the formation of fibers with diameters in the 5 nm range and lateral attachments similar to native elastin fibers. As the temperature is increased above 50°C, additional organization of elastin filaments is noted by the appearance of banded fibers with a staggered periodicity of

50 nm.^[34] Since these processes are thermodynamically controlled, they can be reversed by cooling in aqueous solution. All told, coacervation is believed to be a physiologically relevant step in elastin fiber formation since it both concentrates and aligns elastin to enable cross-linking. Moreover, this aggregation behavior has also been demonstrated for synthetic peptides composed of hydrophobic elastin consensus sequences.^[35] Thus, the presence of an inverse temperature transition and associated protein coacervation is also an important consideration in the processing of elastin-based materials and the development of novel applications in the areas of actuator, sensor design, and drug delivery.

Although freeze fracture electron microscopy of purified tropoelastin monomers reveals a globular protein structure with a diameter range of 5–7 nm,^[36] within tissues, elastin is organized as a network of interwoven fibers. The arrangement of which varies within organ systems and amongst various phyla and species. For example, mammalian aorta contains dense elastin fibers while lower vertebrates tend to have loose fiber arrangements.^[37] In general, elastin is most abundant in tissues that are subjected to repetitive strain, such as skin, alveoli, arterial wall, and cartilage, with an organizational pattern that varies in relationship to the applied stress field.^[38] For example, detailed examination of the mammalian arterial wall has demonstrated networks of fenestrated elastin lamellae arranged in concentric layers that are separated by spindle-shaped smooth muscle cells, loose collagen bundles, and proteoglycans.^[39] In the dermis, elastin forms a loose network parallel to the skin surface in which the volume fraction is between 1.0 and 2.5%. Mean fiber diameters range between 0.5 and 3.0 μm .^[40] In ligamentum nuchae, elastin fibers tend to be much thicker (10–20 μm) in which they run parallel to and are separated by collagen fibers.^[41] All of this emphasizes that both the molecular structure of elastin and its organization into higher order assemblies are critical determinants of functional properties.

APPLICATIONS IN BIOENGINEERING

Elastin's capacity for shape and energy recovery as well as its capacity to aggregate or coacervate in aqueous solution with changes in temperature, pH, pressure, salt, organic solutes, and oxidation state of a side chain or functional group provide opportunities for the design of novel materials for drug delivery, biosensors, or tissue engineering.^[42–45] Other potential advantages of elastin-based polymers are their inherent biostability and biocompatibility. For example, the extraordinary metabolic stability of native elastin has been confirmed by ¹⁴C prevalence data and quantitative

autoradiography that suggest very slow elastin turnover with an associated half life of 70 years.^[46] Furthermore, implant studies of radiation cross-linked poly(VPGVG)-related materials have been associated with minimal or no inflammatory response and without evident material degradation.^[47]

Tissue-derived elastin has had relatively limited impact as a biomaterial primarily due to difficulty in generating a pure product that is free of contaminating globular proteins. As a result, model polymers based upon the elastin pentapeptide sequence have been synthesized by solution chemistry and solid-phase approaches and recently by more efficient recombinant genetic engineering methodologies.^[48,49] As materials, these protein polymers have been processed into elastomeric hydrogels of various forms including sheets and tubular constructs by chemical, enzymatic, and γ -irradiation mediated cross-linking of protein solutions.^[32] Recently, the successful generation of fibers from elastin-mimetic peptide polymers has established a unique opportunity for the creation of fiber-reinforced composites and network structures that may lead to the engineering of improved human tissue constructs as well as completely synthetic artificial organs with enhanced clinical performance capabilities.^[50,51] In addition, the incorporation of cell binding sites into elastin-mimetic protein polymers further extends the functionality of these materials. For example, both Panitch et al.^[52] and Nicol et al.^[53] have demonstrated promotion of cell adhesion and growth when such polymers are cast from solution onto otherwise nonadhesive substrates.

The use of these elastin mimetic polymers as drug delivery devices is also under active investigation. By introduction of specific cross-links and amino acid sequences, the rate of degradation and thus drug release can be controlled. In addition, these materials are easily processable and compliant, and can be designed to swell and contract by manipulation of the polymer's inverse temperature transition (T_i).^[32] Motifs may be incorporated that allow for gel-formation, stimuli-responsive characteristics, biodegradation, and biorecognition.^[54] Recently, protein polymers derived from elastin-mimetic protein sequences have been expressed using such recombinant techniques as formation of diblock and triblock copolymers. Blocks that display different phase separation behavior facilitate the generation of a thermally reversible, self-assembled gel.^[55] The capacity of these materials to sense alterations in their chemical microenvironment and release a drug or elicit a mechanical response may enhance the effectiveness of controlled drug delivery.

Finally, elastin and elastin mimetic polymers also can be viewed as molecular machines that are able to convert energy from one form or location to another. Through the manipulation of the inverse temperature

transition (T_i) by either altering relative protein hydrophobicity, chemical-electromagnetic potential, or mechanical force, free energy transduction can be facilitated and controlled.^[33] For example, films of elastin-mimetic proteins have been used to create proton-driven machines by the addition of a glutamic acid residue (VPGE_G).^[33] As mechanochemical engines, elastin protein polymers are only constrained by the specific chemical energy selected to drive the coacervation phenomenon.

INTRODUCTION

The attraction of biodegradable elastomers for applications in tissue engineering and drug delivery is the latitude that they provide to the biomaterials engineers in achieving mechanical properties that can approximate soft tissue behavior. To achieve these properties, a variety of synthetic biodegradable elastomers have been developed. Two major groups are discussed, polyesters and polyurethanes, although the majority of examples of the latter contain polyester segments. The synthesis, mechanical properties, and biodegradation are generally addressed for these polymers, and, when appropriate, biocompatibility, processing, and applications are also discussed.

The mechanical properties of elastomers include high breaking strains, low stiffness, and high resilience, which is defined as the ability of a material to quickly return to its original shape after being deformed. Synthetic polymers that possess elastic properties are applicable to a variety of biomaterials applications, including drug delivery vehicles and scaffolds for the engineering of tissues with elastic properties. Many of the shortcomings faced with natural materials are of less concern with synthetic molecules. Immunogenicity of the molecular segments is likely absent, degradation is generally designed to occur through hydrolysis and may be less susceptible to enzymatic environment, and processing of thermoplastic elastomers can achieve varied three-dimensional architectures. Further, the options for molecular design are many and varied to achieve desired mechanical and chemical properties. Among the limitations and concerns with synthetic materials are the potential toxicity of degradation products or remnant synthetic by-products, material stimulation of inflammatory processes, and extra

processing or manipulation that is necessary to impart bioactivity.

POLYESTER BIODEGRADABLE ELASTOMERS

Polyesters have been the most commonly utilized biodegradable synthetic polymers for biomedical applications. The hydrolytically labile ester bond imparts degradability in vivo with the relative accessibility of water to this bond being dependent upon the molecular architecture, in addition to the micro- and macrostructure of the material. Polyglycolide (PGA), polylactide (PLA), polycaprolactone (PCL), and poly[(R)-hydroxy butyrate] (R-PHB) are aliphatic polyesters that have found use in a variety of settings. These polymers are usually crystalline or have high glass transition temperatures (T_g) leading to high tensile strength and low elongation at break (Table 1). Mechanical properties can be softened by copolymerization with other ester monomers to alter the crystalline behaviour of the bulk polymers. Examples are poly(lactide-co-glycolide) (PLGA),^[1] poly(glycolide-co- ϵ -caprolactone) (50/50),^[2] poly(glycolide-co-lactide-co- ϵ -caprolactone),^[3] and PLGA-b-PEG-b-PLGA in which PEG is poly(ethylene glycol).^[4] Most of these copolymers have attractive tensile strengths and high elongation at break, but they exhibit plastic deformation due to their amorphous linear molecular structure. For use as elastomers, cross-linking is necessary to impart resilience. However, the cross-linking of aliphatic polyesters is not readily achieved under ordinary chemical or radiation conditions because of the risk of decomposition.^[5] Chemically cross-linked polyesters can be achieved by employing multifunctional monomers and polycondensation

techniques. Another method is to introduce physical cross-links into the polymer by microphase separation of the backbone into hard and soft segments.

Chemistry

Synthesis of cross-linked polyesters

Cross-linked polyesters can be prepared by polycondensation of trifunctional alcohol and bifunctional acid monomers of low molecular weight as demonstrated recently by Wang et al. with glycerol and sebacic acid.^[6] Here, it was suggested that the presence of hydroxyl groups on at least one monomer could lead to hydrogen bonding interactions that influenced mechanical properties. Cross-linked polyester can also be prepared by polycondensation of multifunctional hydroxyl-telechelic polyester oligomer and multifunctional isocyanate.^[7] Usually, difunctional hydroxyl-telechelic polyester oligomers react with triisocyanate, and trifunctional hydroxyl-telechelic polyester oligomers react

Table 2 Tensile properties of poly(ε-caprolactone-co-δ-valerolactone) networks

Oligomer molecular weight (MPa)	Modulus (MPa)	Tensile strength (%)	Elongation at break
900	2.59	1.96	193

with diisocyanate. Multifunctional polyesters are prepared by ring-opening polymerization (ROP) of cyclic monomers initiated by multifunctional alcohol. The monomers used are ε-caprolactone, δ-valerolactone, lactide, and glycolide. Storey et al. described the use of 1,6-hexanediol to initiate the copolymerization of ε-caprolactone with δ-valerolactone to form difunctional hydroxy-terminated poly(ε-caprolactone-co-δ-valerolactone). The polyester oligomers were cross-linked by triphenylmethane triisocyanate (TTI). Trifunctional hydroxyl-telechelic polyester oligomers were synthesized by copolymerization of monomers initiated by trimethylolpropane (Table 2). The networks of polyesters were formed by reacting with toluene-2,6-diisocyanate (TDI). The resulting cross-linked polyesters were amorphous with glass transition temperatures ranging from 21°C to –45°C.^[7,8]

Synthesis of linear polyester elastomers

Linear polyester elastomers have microphase separated structures with crystalline hard segments and amorphous soft segments. In this structure, hard segments act as cross-linkers whereas soft segments provide the flexibility. The properties of the polyester elastomer are controlled by the ratio of hard and soft segments.^[5] In general, linear polyester elastomers are prepared by random or block copolymerization of monomers. The ratio of crystalline and amorphous segments can be controlled by the feed ratio of monomers. Polyester elastomers are usually synthesized by ring-opening polymerization (ROP) instead of condensation polymerization as the former yields high molecular weight polymers under relatively mild conditions. ROP can be carried out with no or very

Fig. 1 Structures of various monomers used in biodegradable polyesters.

limited side reactions, which makes it possible to control properties like molecular weight and polydispersity. ROP can be divided into free radical polymerization, anionic polymerization, carbocationic polymerization, and coordinative ring-opening polymerization.^[9] Among them, coordinative ring-opening polymerization is the most popular method because the polymerization conditions are easy to control. Coordinative ring-opening polymerization can be conducted with or without alcohol as an initiator.^[9] Tin(II) or tin(IV) compounds such as stannous octanoate ($\text{Sn}(\text{oct})_2$) and dibutyltin oxide have been used as catalysts.^[9] Lactones (ϵ -caprolactone, [R,S]- β -butyrolactone) and cyclic diesters (lactides, glycolide, trimethylene carbonate) are used as monomers (Fig. 1).

PHA and copolymers

Polyhydroxyalkanoate (PHA) elastomers can be synthesized by bacterial fermentation, transgenic microorganisms, and plants.^[10] By incorporating various functional monomers in the polymer sequence during

the biosynthesis, one can obtain different PHAs with various physical properties ranging from crystalline polymers to elastomers. PHAs can also be obtained by chemical synthesis. Polymerization of the racemic monomer [R,S]- β -butyrolactone with distannoxanes as initiators can obtain an atactic or syndiotactic-rich poly(3-[R,S]-hydroxybutyrate) ([R,S]-PHB) with different stereoregularities.^[11]

For [R,S]-PHB, introduction of a biodegradable hard segment can give a wholly biodegradable creep-resistant elastomer. Hiki et al. prepared ABA block copolymers with [R,S]-PHB as the soft segment (B) and poly(L-lactide) (PLLA) as the hard segment (A).^[5] The polymerization was carried out by a two-step method. In the first step, hydroxy-terminated poly([R,S]- β -butyrolactone) was prepared by the reaction of (R,S)- β -butyrolactone with 1,4-butanediol. In the second step, L-lactide was initiated by hydroxyl groups of [R,S]-PHB to form PLLA blocks (Fig. 2). Two different catalysts were used to prepare [R,S]-PHB and PLLA blocks. Distannoxane was used for [R,S]-hydroxybutyrate polymerization as it is a high transesterification catalyst whereas $\text{Sn}(\text{oct})_2$ was used for polymerization of L-lactide for the chain transfer reaction to occur.^[5]

Polyglycolide, polylactide, poly(ϵ -caprolactone), and copolymers

As mentioned previously, PLA, PGA, and PCL are high-strength materials with low distensibility. Modification of these polymers by incorporating other monomer(s) can alter the mechanical properties from rigid materials to thermoplastic elastomers, which can be used in mechanically challenging environments. Elastomers containing microphase separation can be prepared by random or block copolymerization. Microphase separated poly(glycolide-co- ϵ -caprolactone) has

Fig. 2 Ring-opening polymerization of [RS]-beta-butyrolactone and copolymerization with L-lactide. Reproduced from Ref. [5].

been prepared by random polymerization of glycolide and ϵ -caprolactone with zirconium(IV) acetylacetonate or zirconium(IV) chloride as initiators.^[12] Poly(lactide-co- ϵ -caprolactone) elastomers have been prepared by random copolymerization of lactide and ϵ -caprolactone with tin(II) as initiator.^[13] The microphase separated chain structure was dependent on both composition of monomers and reaction temperature.

1,5-dioxepan-2-one (DXO) has been used as a versatile component in biodegradable polymers. Poly (DXO) is amorphous, but introduction of a crystalline segment such as PCL and PLLA can lead to microphase separated elastomers. PCL-b-PDXO-b-PCL block copolymers have been prepared by the sequential addition of different monomers to a living polymerization system initiated with aluminum isopropoxide in tetrahydrofuran (THF) or toluene solution.^[14] PLLA-b-PDXO-b-PLLA block copolymers were prepared by using controlled ROP in a two-step method. In the first step, polymerization of DXO using 1,1,6,6-tetra-*n*-butyl-1,6-distanna-2,5,7,10-tetraoxacyclodecane was processed to obtain PDXO. In a second step, lactide was added and polymerization was conducted at 60°C in chloroform.^[15]

Similar to PDXO, poly(1,3-dioxan-2-one) (PTMC) is amorphous. Random copolymerization of trimethylcarbonate (TMC) and ϵ -caprolactone can obtain a blocklike copolymer since the reactivity of ϵ -caprolactone is higher than TMC.^[16] When the ϵ -caprolactone content is higher than 70%, the copolymer exhibits elastomeric characteristics. Microphase separated block copolymers based on PTMC and PLLA were prepared by Kim et al.^[17] The hydroxy-terminated PLLA-b-PTMC-b-PLLA was prepared by polymerization of *L*-lactide with the PTMC diol chain using Sn(oct)₂ as catalyst. Next, the polymer was chain extended by hexamethylene diisocyanate (HMDI).

Mechanical Properties

Mechanical properties of polyester elastomers depend on several factors, such as the molecular composition, crystallinity, and molecular weight. For cross-linked polyesters, the mechanical properties depend on the cross-linking density and molecular weight between cross-links as demonstrated in the polyester synthesized from glycerol and sebacic acid by Wang et al.^[6] For cross-linked elastomers synthesized from difunctional hydroxy-terminated poly(caprolactone-co-valerolactone) oligomers, it was found that the tensile strength decreased and elongation at break increased with increased oligomer length (Table 2). This trend resulted from increased interactions between molecular chains as the molecular weight between

Table 3 Mechanical properties of poly(trimethylene carbonate-co- ϵ -caprolactone)

ϵ -caprolactone (%)	Young's modulus (MPa)	Tensile strength (MPa)	Elongation at break (%)
75	4.6	0.1	236
86	123	46	1008
90	252	40	906

Data adapted from Pego et al. 2001. Ref. [16].

cross-links increased from decreasing molecular weight of oligomer.^[8]

For random copolymerized linear polyester elastomers of caprolactone, glycolide, or lactide, the feed ratio and reaction temperature can affect the microstructure of resulting polymers and thus their mechanical properties. The microphase separated elastomers can be prepared only at certain monomer ratios^[18] and reaction temperatures.^[5] For example, a copolymer made from 85 wt% of *DL*-lactide and 15 wt% ϵ -caprolactone is a thermoplastic elastomer; whereas a copolymer prepared from 90 wt% of *DL*-lactide and 10 wt% ϵ -caprolactone is a rigid thermoplastic. The poly(glycolide-co- ϵ -caprolactone) copolyesters are elastomers when the reaction temperature is 100°C; whereas more randomized structures are formed when the temperature is 150°C. For copolymers of ϵ -caprolactone and TMC, the microphase-separated structure can be formed at a wide feed ratio range. When the ϵ -caprolactone ratio is higher than 70 wt%, the copolymers are semicrystalline and have microphase separated structures. The increase in ϵ -caprolactone content increased the crystallinity and thus increased the Young's modulus (Table 3).

Block copolyester elastomers possess combined properties of both homopolymers. The elastomeric mechanical properties are enhanced by microphase separation. Because the soft segment provides flexibility and the hard segment provides mechanical strength, tensile strength generally increases with an increased length of hard-segment block and crystallinity, while the strain increases with the length of soft-segment block as shown by Lofgren et al., who synthesized the well-defined PCL-b-PDXO-b-PCL triblock copolyesters.^[14]

Biodegradation

The biodegradation rate of cross-linked polyester elastomers depends on both the nature of monomers and the cross-linking density. The previously discussed cross-linked polyester based on glycerol and sebacic acid possessed low cross-linking density and

crystallinity. This polymer has approximately a 17% weight loss after 60 days and could be totally absorbed in 60 days *in vivo*.^[6] Storey et al. prepared a series of cross-linked amorphous polyesters from triol polyester oligomers and TDI. The triol polyesters were poly(glycolide-co-TMC) (PGTMC), poly(lactide-co-TMC) (PLTMC), and poly(ϵ -caprolactone-co-TMC) (PCTMC). It was found that the degradation rates, in order of fastest to slowest, were PGTMC > PLTMC > PCTMC, which follows the hydrophilicity order of glycolide > lactide > caprolactone.^[7]

For linear polyester elastomers, the degradation rate depends on the chemical composition, the nature of monomers as well as the individual microphases. The degradation rate is mainly influenced by the amorphous phase because of reduced water access to the crystalline phase. Increases in the amorphous content can increase the degradation rate.^[11] As the rate of hydrolytic degradation of the ester linkage is higher than the carbonate linkage,^[9] incorporation of carbonate functionalities can decrease the degradation rate.

BIODEGRADABLE POLYURETHANES

Polyurethanes are the most economically important elastomers for a variety of commercial applications. Thus, it is not surprising that this class of polymers has been the focus of many groups seeking to develop biodegradable elastomers for medical applications. Polyurethane and poly(urethane urea) thermoplastic elastomers derive their attractive mechanical properties from microphase separation between hard and soft segments. The selection of hard and soft segments and the complexity possible within these segments offers polymer chemists a myriad of options in achieving material design objectives. Although urethane and urea linkages are susceptible to degradation *in vivo*, efforts to make biodegradable polyurethanes have incorporated more labile bonds into the polymer backbone, usually by introducing polyester segments.

Polyurethane Synthesis

Polyurethanes are commonly synthesized by one of two methods. The first involves the reaction of bis-chloroformates with diamines. The second—and most important method—is the reaction of diisocyanates with dihydroxy compounds, which has the advantage of no by-products. Diisocyanates can also react with diamines to form polyureas, with carboxylic acids to form polyamides, and with water to form polyurea foam. Side reactions in polyurethane synthesis can occur when unreacted isocyanate groups react with the growing urethane or urea chains to yield allophanate and biuret groups, respectively. These reactions yield polymers with unwanted cross-linking and generally less attractive mechanical properties. Biodegradable polyurethane elastomers can also consist of a network of chemically cross-linked chains. These elastomers can be synthesized by using monomers that are trifunctional or of higher functionalities compared with the difunctional monomers used in synthesizing linear (thermoplastic) polyurethanes.^[20–22] Cross-linked polyurethanes have the disadvantage of not being amenable to processing by thermal or solvent-based techniques.

Polyurethane elastomers are usually constructed from long-chain polyester or polyether diols and diisocyanates with short-chain diols or diamines utilized as chain extenders. The reaction is commonly carried out in two steps with the initial formation of a prepolymer of the polyester and diisocyanate that is subsequently chain-extended to a high molecular weight (Fig. 3).

Alternatively, the reaction can occur in one step (one-shot polymerization) when all of the monomers are mixed together at once. The longer-chain polyester or polyether in the resulting polyurethane is referred to as the soft segment, and the diisocyanate and chain extender are referred to as the hard segment. Common polyester soft segments used in biodegradable polyurethanes include PCL,^[23–25] PLA,^[26] PGA,^[27] and

Fig. 4 Chemical structures of diisocyanates used as monomers in biodegradable polyurethanes.

PHB.^[27,28] Common diisocyanates used in constructing biodegradable polyurethanes are 1,6-hexamethylene diisocyanate (HDI),^[29,30] 1,4-diisocyanate (BDI),^[23–25] lysine diisocyanate (LDI),^[31] isophorone diisocyanate, and 2,2,4-trimethyl-1,6-diisocyanate (TMDI).^[27] The chemical structures of these diisocyanates are shown in Fig. 4 along with the chemical structures of 4,4'-methylenediphenyl diisocyanate (MDI) and toluene diisocyanate (TDI), which are commonly employed industrial diisocyanates. However, there is speculation that MDI and TDI degradation products—4,4'-methylene aniline (MDA) and toluene diamine (TDA)—are carcinogenic.^[32–34]

The chemical and physical properties of polyurethanes can be varied by choice of appropriate hard and soft segments. Table 4 summarizes the different biodegradable polyurethanes that have been reported in the literature based on their soft and hard segment composition. The majority of these polymers contain PCL in the soft segment. Gorna et al. bulk-polymerized PCL with aliphatic HDI and 1,4-butanediol (BDO) as a chain extender.^[29] Other studies have introduced PEG along with PCL into the soft segment with or without BDO chain extenders.^[30,35] High-molecular weight polyurethanes based on PCL soft segments with BDI were chain-extended with BDO, BDO-b-BDI-b-BDO blocks, or BDI-b-BDO-b-BDI-b-BDO-b-BDI blocks.^[24,25] The larger-chain extenders were used to prevent transesterification reactions from creating a large size distribution of hard segments. de

Groot et al. synthesized a series of linear polyurethane ureas based on a PCL soft segment and hard segments consisting of either LDI, HDI, or BDI that were chain-extended with putrescine.^[36] Similar poly(ester-urethane ureas) were synthesized by Guan et al. using putrescine and lysine ethyl ester as chain extenders.^[23]

Bioerodible polyurethanes have also been synthesized with L-lactide in the soft segment. Kylma and Seppala investigated comonomers of lactic acid and caprolactone in poly(ester-urethanes) based on HDI.^[26] Condensation copolymerization of lactide and ϵ -caprolactone at different feed ratios took place with stannous octoate as a catalyst. High molecular weight polyurethanes were produced by chain extending with HDI. Polyurethanes based on a 50/50 poly(L-lactide-co- ϵ -caprolactone) prepolymer with BDI were synthesized.^[36] Because the lactide bond is susceptible to aminolysis, chain extension was not possible with putrescine. Furthermore, the use of BDO as a chain extender resulted in transesterification that led to poor mechanical properties. For these reasons, an isocyanate-terminated chain extender, BDO-b-BDI-b-BDO, was used.

Several research groups have constructed biodegradable polyurethanes and poly(urethane ureas) by introducing biodegradable functionalities into the hard segment as well as the soft segment to facilitate hydrolytic degradation. Poly(ester-urethanes) consisting of crystallizable poly(3-R-hydroxybutyrate)-co-(3-R-hydroxyvalerate) (PHB-co-PHV) hard segments

Table 4 Composition and physical properties of linear biodegradable polyurethanes and polyurethane ureas

Soft segment composition	Hard segment composition		Soft segment Tg/C	Tensile strength, MPa	Modulus (MPa)	Ultimate elongation (%)	Reference
	Diisocyanate	Chain extender or other					
PCL ^a	HDI	BDO	− 54.4 to − 40.6	12–63	13–107	460–760	[29]
PCL	LDI	putrescine	− 45	17	40	800	[31]
PCL	BDI	putrescine	− 45	29	52	1042	[31]
PCL	BDI	BDO	− 54	23.1	23.2	843	[25]
PCL	BDI	BDO.BDI.BDO	− 54	44	70	560	[24]
PCL	BDI	BDI.BDO.BDI.BDO.BDI	− 60.4	35	105	650	[24]
(50/50) L-lactide/PCL	BDI	BDO.BDI.BDO	− 5	45	60	560	[36]
PCL ^a	BDI	putrescine	− 53.2 to − 36.5	25–29	54–78	660–686	[23]
PCL ^a	BDI	lysine ethyl ester	− 54.3 to − 39.7	9.2–13	14–38	841–895	[23]
PCL ^a	LDI	p-alanine based diamine ^a	− 51.9 to − 6.2	12.5–30.8	6.6–81.9	618–676	[42]
PCL-PEG ^a	HDI	BDO	− 115.7 to − 101.5	4–48.6	7.3–58.8	120–866	[30]
PCL, PGA, PEG ^a	TMDI	PHB-co-PHV ^a	− 44 to 2	2.6–15.9	50–500	50–1250	[27]
PCL ^a	TMDI	poly(p-dioxanone)diol ^a	− 51 to − 39	17–25	34–90	540–1100	[40]

^aIndicates series of polymers synthesized with different feed concentrations or monomer molecular weights.

and amorphous segments from ϵ -caprolactone, diglycolide, and ethylene glycol homopolymers or copolymers have been reported.^[27,28] Aliphatic TMDI was the diisocyanate employed in the polymerization. Elastomeric polyurethanes have also been synthesized from poly(ϵ -caprolactone)diols and poly(*p*-dioxanone)diols (PDX) reacted with TMDI.^[27] The crystalline PDX was used as a biodegradable hard segment. Skarja and Woodhouse synthesized novel poly-(urethane ureas) based on either PCL or PEG soft segments, HDI or LDI, and with an amino acid-based chain extender based on L-phenylalanine.^[37,38]

Mechanical Properties

The soft segments impart polyurethanes with softness, flexibility, and low temperature properties whereas the hard segments reinforce or strengthen the soft segment to increase the hardness, modulus, tear strength, and high temperature properties of polyurethanes. The hard segments possess a high affinity for hydrogen bonding due to the large number of polar groups present. Urea groups provide even more opportunities

for hydrogen bonding relative to urethane groups. The combination of crystallinity and hydrogen bonding in the phase separation of polyurethanes ties together the polymer chains in physical cross-links. These physical cross-links result in a network of polymer chains that display rubberlike elasticity.

Similar to multiphase polyesters, the factors that affect mechanical properties of biodegradable polyurethanes include hard- and soft-segment composition, degree of crystallization of the hard segment and amount of microphase separation, and molecular weight of the polymer. A summary of mechanical properties for different monomer composition of biodegradable polyurethanes and poly(urethane ureas) is provided in Table 4. Gorna et al. showed that the mechanical properties of polyurethanes with similar molecular weights were dependent on the hard-segment content.^[29] Tensile strength and modulus increased with increasing hard-segment molecular weight or with shorter soft segment while the breaking strain decreased. In an extensive study, the mechanical properties of polyurethanes based on L-lactide and ϵ -caprolactone copolymers were found to be highly dependent on the initial feed ratio of the monomers.

Poly(ester-urethanes) containing a high ratio L-lactide and ϵ -caprolactone were found to be rigid with tensile modulus of 1700–2100 MPa, tensile strength of 36–47 MPa, and breaking strains of 4–7%.^[26] Polymers with low L-lactide to ϵ -caprolactone ratios were found to be highly elastomeric with a maximum tensile strength of 9 MPa and breaking strain greater than 1000%. These properties were found to be direct functions of the glass transition temperatures of the polymers. When the glass transition temperatures were above room temperature, the soft segment would be amorphous and mostly immobile, which would contribute to higher tensile strengths and lower elongation.^[26]

The polyurethanes and poly(urethane ureas) synthesized by de Groot et al. and Spaans et al. showed high flexibility and tensile strength, which results from high molecular weights and phase-separated morphology.^[24,25,31] Poly(ester-urethanes) containing lysine ethyl esters as a chain extender compared to those with putrescine as a chain extender were found to have lower mechanical properties than the latter.^[23] These properties may have been caused by the lower molecular weight of the lysine-extended polymers or because the bulky, lysine-based chain extender may have reduced the chain packing and physical cross-linking of the polymer chains.

Biodegradation

Biodegradation products and rates for polyurethanes can be controlled by the choice of the soft and hard segment. Controlling or predicting degradation rates can be very complicated and is influenced by factors similar to mechanical properties such as crystallinity and polymer molecular weight. The degradation of the common soft-segment PCL usually occurs first by hydrolytic chain scission and then by bulk mass loss of subsequently lower chain lengths.^[39] PCL alone has demonstrated some long degradation times that can extend to the order of years due to its hydrophobicity and tendency to crystallize at higher molecular weights. The in-vitro degradation of PCL-based polyurethanes in aqueous buffers have also demonstrated slow degradation times. Because most studies are conducted over limited time periods, the time scales for complete resorption of most PCL-based degradable polyurethanes both in vitro and in vivo are mostly unknown. Degradation of PCL-based polyurethanes by Gorna et al. exhibited slow degradation times with a 1–2% mass loss at 48 weeks and a 1.1–3.8% mass loss at 76 weeks.^[30] However, poly(ester ether urethanes) composed of PCL-PEG diols exhibited levels of weight loss from 1.6–76% at 48 weeks and 1.6–96% at 76 weeks. The weight loss was found to increase with

higher levels of the more hydrophilic PEG.^[30] A similar in-vitro degradation trend was observed for amino acid chain-extended, PCL-based polymers that exhibited little mass loss after 56 days compared with the PEG-based polymers that exhibited high mass loss in this period.^[37]

The in-vitro degradation of L-lactide/ ϵ -caprolactone copolymer-based polyurethanes was found to be highly dependent on the comonomer ratio. Polymers synthesized from high ratios of L-lactide to ϵ -caprolactone exhibited mass losses of more than 80% after 50 days compared with higher ϵ -caprolactone content polymers exhibiting less than 10% weight loss after 50 days.^[26] These degradation weights were related to the hydrophilicity of the monomers with lactic acid being more hydrophilic than PCL.

A very thorough investigation of the hydrolytic degradation of copoly(ester urethanes) with PHB-co-PHB hard blocks synthesized by Lendlein et al. has shown the degradation rate to be dependent on the amount and distribution of the glycolate ester bonds in the soft segments of the urethane.^[39] Here, the polymer degradation began hydrolytically, which decreased the molecular weight and lowered the breaking strain. Next, weight loss decreased the sample size and left the poly(PHB-PHV) hard segment as the principal remaining material.^[39] Due to the nature of the amorphous segment and crystalline segment of physically cross-linked polyurethanes, it is common for the soft segment to degrade at a much faster rate than the hard segment, which resulted in a nonlinear degradation rate. However, Lendlein and Langer demonstrated a linear weight loss in vitro of their polyurethane based on PCL/PDX due to the high crystallinity of the polyesters.^[40]
